V. parahaemolyticus occurs in estuarine environments throughout the world. It also occurs occasionally in fresh-water sites, especially in brackish water during the summer, but only in small numbers. The halophilic nature of the vibrios is related to their ability to survive in the aquatic environment. They survive in estuarine water for more than 1 week at 15–20 °C, whereas they rapidly become extinct in fresh water under the same conditions as those of estuarine waters. The fate of the vibrios in fresh water is also partly concerned with osmotic pressure which causes autolysis of the cells. In brackish water, however, they may survive as long as in estuarine water in the summer. They are not found in the estuarine water in winter, although the vibrio can usually be isolated from sediment even when the water temperature is less than 10 °C. Indeed, it is likely that it survives in sediment in estuarine areas during the winter. The vibrio produces chitinase and the action of this enzyme enables it to adhere to the chitin of marine life. It thus colonizes zoo-plankton and the surface of shellfish. It therefore occurs in the digestive tracts of shellfish as a result of their ingestion of zooplankton. *V. parahaemolyticus* probably survives in a viable but nonculturable state in a cold environment, as reported for *V. cholerae* and *V. vulnificus*.

Reservoirs

Gastroenteritis due to *V. parahaemolyticus* is usually associated with seafoods. Coastal fish and shellfish are usually contaminated with *V. parahaemolyticus* in the summer. On the surface of market marine fish, the vibrios do not proliferate if kept below 10 °C, but at 20 °C their numbers increase rapidly. About 10–100 cells of *V. parahaemolyticus* have been found on the surface of coastal fish just after landing. If the fish were kept at atmospheric temperature, especially in summer, the number of vibrios increases to more than 10^6 cells within a few hours. It has not been found on market fish in winter.

Seafoods responsible for illness vary with local eating habits in different countries. In Japan, the high incidence of infection is undoubtedly due to the national custom of eating the meat of raw fish, shellfish, and other fish products. Any kind of seafish served as sushi and sashimi can act as the vehicle for the transmission of gastroenteritis. Although the vibrio may be killed within several minutes in 0.5% acetic acid, raw fish or shellfish with vinegar, which are widely eaten in Japan, nevertheless often transmit this infection. Also, infection is sometimes associated with consumption of cured vegetables cross-contaminated with the vibrio in the kitchen. The incidence of *V. parahaemolyticus* infection may be less in other countries where fish are not usually consumed uncooked. Nevertheless, cases of gastroenteritis caused by this organism have been reported in East European countries, the UK, Africa, and the USA. In the USA, for example, 40 outbreaks of infection were reported to the Centers for Disease Control and Prevention between 1973 and 1998. In countries other than Japan, although fish are usually cooked shortly before consumption, crab meat and shrimp, which are the seafoods most often implicated with this infection, are usually extracted either by hand or

mechanically after cooking, becoming contaminated from other sources. Oysters and clams which are consumed raw are also significantly associated with gastroenteritis caused by this vibrio. It is possible that *V. parahaemolyticus* may cause diarrheal diseases in developing countries more often than is currently recognized. In such countries, waterborne infection with this vibrio should also be considered.

Clinical Infection with *V. parahaemolyticus*

Although *V. parahaemolyticus* is associated with occasional skin and soft-tissue infections as well as with otitis media in fish handlers and bathers, gastroenteritis is the essential clinical manifestation of foodborne infection. Symptoms usually occur about 12 h after consumption of contaminated food. The outstanding features are severe abdominal cramps and diarrhea, together with nausea, vomiting, and fever. These symptoms range from mild with a few loose stools to very severe. In addition, dysentery-like stools with blood and mucus may occur in some cases. Recovery of patients and disappearance of the vibrio from stools are usually complete within a few days. The mortality rate is very low. Person-to-person transmission has not been recognized.

Although the size of the infectious dose necessary to produce clinical symptoms may vary with the strain and individual, according to the data from human volunteer experiments it, probably lies between about 10^5 and 10^8 viable cells. However, based on the low numbers of Kanagawa-positive cells usually found in samples of the food implicated or in waterborne infections encountered in developing countries, it appears that the numbers of viable vibrios needed to cause illness may be much smaller.

Virulence Factors

It has been found that strains of *V. parahaemolyticus* isolated from patients with gastroenteritis were hemolytic, on a modified brain–heart infusion agar containing human blood, whereas those from sea fish and the marine environment were nonhemolytic. This hemolysis is referred to as the Kanagawa reaction. It was found that 96% of 2720 strains from patients with gastroenteritis were Kanagawa-positive compared with only 1% of 650 environmental strains. Feeding tests with Kanagawa-negative strains in 15 adult volunteers failed to induce any clinical signs of illness. The hemolysin responsible for the Kanagawa reaction is known as TDH. Although *V. parahaemolyrticus* is known to produce at least four hemolytic substances – TDH, a thermolabile hemolysin, phospholipase A, and lysophospholipase – it is probable that only TDH plays a significant role in the pathogenesis of gastroenteritis.

Occasional outbreaks of gastroenteritis may be associated with Kanagawa-negative vibrios. These strains produce a thermolabile TRH but not the thermostable TDH.

TDH is a 21-kDa protein not affected by heating at 100 °C for 15 min at pH 6.0. It is a pore-forming toxin which expresses hemolytic activity, cytotoxicity, and cardiotoxicity. In hemolytic tests, TDH is strongly active against erythrocytes of dogs, rats, mice, and humans, weakly active against those of rabbits and sheep, and inactive against horse erythrocytes. Although it is clear that TDH is associated with the pathogenesis of infection, it is not clear how this toxin causes diarrhea. TDH, when inoculated at doses of 100 μg into ligated ileal loops in rabbits, failed to produce fluid accumulation but caused erosive lesions and necrosis of the intestinal mucosa. Such histological changes do not occur when whole bacteria are tested in ileal loops.

It has been reported that a TDH-positive parent vibrio strain caused fluid accumulation in ligated ileal loops in rabbits, whereas a TDH-negative mutant did not cause fluid accumulation. Similar results were obtained with culture supernatants of TDH-positive strains tested on rabbit ileal tissues mounted in an Ussing chamber, which represents a more sensitive measure of secretory activity. In these assays, the ability of TDH to alter iron transport in the intestinal tract was demonstrated at nanogram levels, with no histological changes. TDH induces intestinal chloride ion secretion and trisialoganglioside G_{T1b} appears to be the cellular receptor. However, recent work suggests that other unknown receptor(s) may be present. TDH uses Ca^{2+} as an intracellular second messenger, and is thus the first bacterial enterotoxin for which a linkage between changes in intracellular calcium and secretory activity has been established.

TDH is encoded by two copies, *tdh1* and *tdh2*, of the *tdh* gene in *V. parahaemolyticus*. The two gene copies are not identical and the predicted protein products differ in seven amino acid residues, although the proteins themselves are immunologically indistinguishable. The level of TDH production may be under the control of a regulator similar to that of ToxR in *V. cholerae*.

Although TRH and TDH are similar in their biological, immunological, and physicochemical properties, TRH is thermolabile and differs from TDH in its activity on erythrocytes. TRH is encoded by the *trh* gene which shares 69% identitiy with the *tdh2* gene. TRH is linked epidemiologically to gastroenteritis, but the secretory mechanism of this toxin is still uncertain.

Several adhesive factors, including fimbriae, peritrichous flagella, outer membrane proteins, and a mannose-resistant, cell-associated hemagglutinin, have also been proposed, but no substantial studies have yet implicated any of the candidate adhesins in the pathogenicity of the organism.

Isolation and Identification

Several selective agar media have been devised, but thiosulfate citrate bile salts sucrose (TCBS) agar is recommended for the isolation of *V. parahaemolyticus*. In clinical microbiology laboratories, MacConkey agar containing 0.5% additional NaCl is also convenient for routine culture of diarrheal stools.

Enrichment culture is used for the detection of the vibrio from food and marine samples. Polymyxin salt broth, containing 2% NaCl and 50 $\mu g\,ml^{-1}$ of polymyxin B (pH 7.6) may be used for the selective growth of *V. parahaemolyticus*. It should be noted that some factor(s) in shellfish may inhibit the growth of vibrios. It is therefore recommended that shellfish are cut into small pieces, but not homogenized. After shaking the enrichment broth vigorously, the pieces of shellfish are removed with forceps. However, enrichment culture of seafoods incriminated in outbreaks of infection may be unrewarding, because most yield Kanagawa-negative isolates, in contrast to those from patients.

The colonial appearance of *V. parahaemolyticus* on TCBS agar is so typical that provisional identification of the isolates from stool specimens may be made directly from the plates. However, isolates from marine sources must be further examined in order to differentiate them from related organisms. The addition of 1% NaCl to medium for biochemical tests is essential to obtain valid reactions.

The Kanagawa reaction is a reliable test for the recognition of virulent strains. For determination, isolates should if possible be tested using Wagatsuma agar, which contains 0.5% yeast extract, 1% peptone, 0.5% mannitol, 0.05% K_2HPO_4, 7% NaCl, 0.0001% crystal violet, 1.5% agar, and washed human red blood cells. However, as adequate sources of human blood, or of blood from other suitable animals, are not always readily available, other suitable media may be considered. Thus, an enzyme-linked immunosorbent assay has been described for the detection of TDH-producing vibrios.

Several molecular approaches for the detection of Kanagawa-positive vibrios have also been developed. DNA and oligonucleotide probes specific for the genes *tdh* and *trh* have been described. However, the probes also hybridize with *tdh* genes in some strains of non-O1 *V. cholerae*, *V. hollisae*, and *V. mimicus*. A polymerase chain reaction technique has been reported using oligonucleotide primers derived from the nucleotide sequence of the *tdh* gene.

Serotyping of isolates of *V. parahaemolyticus* may be performed by slide agglutination tests using O and K antisera. In outbreaks of *V. parahaemolyticus* infection, however, the same serovar as that identified in patients is seldom detected in incriminated seafoods. Serotyping of isolates from seafoods and marine sources is thus not usually significant unless they are Kanagawa-positive.

Vibrio vulnificus

A C Wright, University of Florida, Gainesville, FL, USA
J G Morris, Jr., University of Maryland School of Medicine, Baltimore, MD, USA

Background

Vibrio vulnificus, first recognized as a distinct species in the late 1970s, is a Gram-negative bacterium that is indigenous to the estuarine environment. Virtually all oysters harvested in the USA during warmer, summer months harbor this organism, and it has been reported in association with shellfish and fish in a number of locations in South America, Asia, and Europe. For persons in 'high risk' groups (i.e., persons with liver disease, iron overload states, or immunosuppression), ingestion of *V. vulnificus* in raw or undercooked seafood can result in a syndrome of 'primary septicemia,' characterized by intractable shock and a mortality rate of greater than 50%. These infections are the leading cause of death associated with consumption of shellfish in the USA. The microorganism can also cause serious wound infections and may be a cause of gastroenteritis. In population-based studies in US coastal areas, the incidence of *V. vulnificus* infections is approximately 0.5/100 000 persons per year. Case series from Korea and Taiwan suggest that *V. vulnificus* infections are even more common in these latter areas.

Virulence of *V. vulnificus* is most closely linked with the presence of a polysaccharide capsule and is greatly influenced by availability of iron in the host during infection. *V. vulnificus* is also known to produce a variety of extracellular factors, including a cytolysin, siderophores, pili, lipopolysaccharide, proteases, and other exoenzymes; however, the role of these factors in virulence remains unclear. Animal studies of the lethality of this organism have indicated that mutants deficient in cytolysin and protease do not exhibit reduced virulence. Mutants deficient in siderophores or pili expression are somewhat less virulent than wild-type strains, but these results are complicated by the pleiotropic nature of these mutations. However, excess iron in the host and expression of capsular polysaccharide (CPS) by *V. vulnificus* clearly increase the lethality of this disease. For mice with normal iron status, the LD50 ranges from 10^5 to 10^7, depending on the strain and the ability to produce CPS. The LD50 for unencapsulated mutants in iron-overloaded mice is also about 10^5; however, encapsulated strains in iron-overloaded mice may be lethal at a dose of one bacterium.

There is tremendous diversity in capsular types among strains, and no one type (or group of types) predominates among clinical or environmental isolates. Three biotypes (or two biotypes and one distinct serovar) of *V. vulnificus* are currently recognized. The majority of clinical and environmental *V. vulnificus* isolates reported to date are in biotype 1. Strains initially classified as biotype 2 are responsible for sepsis in eels; they do not cause human disease. More recently, it has been recognized that the biotyping characteristics described for these strains lacked specificity; however, the eel pathogens are homogeneous in their lipopolysaccharide-based serogroup, leading to their reclassification as serovar E. Biotype 3 strains have been described in association with wound infections related to handling of live fish (tilapia) from fish farms in Israel.

Occurrence in the Environment

As noted above, *V. vulnificus* is commonly isolated from water and organisms, particularly shellfish, collected from estuarine environments. The highest numbers are found in areas with intermediate salinities (5–25 p.p.t.) and warmer temperatures (optimally, $>20\,^{\circ}C$). Isolation has been reported from the US Atlantic, Gulf, and Pacific coasts, as well as the Atlantic coast of Europe, the Mediterranean, the Indian Ocean, Malaysia, and the Pacific Coast of Asia. It is likely that the organism is present in

virtually all estuarine areas with appropriate salinity and temperature ranges. Using a DNA probe, *V. vulnificus* has been identified in 80% of Chesapeake Bay water samples collected during months in which water temperatures exceeded 8°C: concentrations ranged from 3.0×10^1 to 2.1×10^2 CFU^{-1} ml^{-1}, representing approximately 8% of the total culturable heterotrophic bacteria. However, none of the samples collected during February and March, when temperatures were less than 8°C, were positive for this organism.

V. vulnificus is generally not recovered from the environment during colder months, and several lines of evidence suggest that it may enter a viable but nonculturable state, where recovery on typical solid media is not possible. Other studies have suggested that the majority of *V. vulnificus* cells die off with the stress of cold temperature or starvation, and only a small resistant subpopulation remains viable. However, both experimental and epidemiological data strongly indicate that nonrecoverable forms probably are not virulent, as little or no disease is observed in colder months. Thus, the relevance of this issue to the seafood industry may be negligible. However, further study may shed light on how the species is maintained in the environment and help elucidate survival mechanisms that could be targets for control measures.

Entry to the Food Chain

Epidemiologically, there is a very strong association between *V. vulnificus* infection and eating raw oysters, particularly those harvested from warmer waters. It should be noted that most, if not all, serious disease is associated with the raw, freshly shucked product; proper cooking eliminates the disease risk. In Chesapeake Bay studies, *V. vulnificus* was found in virtually all oysters collected during warmer months (water temperature 7.6°C or above), with the numbers of this species approximately two orders of magnitude above those found in the surrounding water. In studies conducted by the US Food and Drug Administration, *V. vulnificus* was detected in virtually all oysters from the US Gulf Coast. The numbers varied based on temperature and salinity; representative data from this study are shown in Figure 1. The prevalence of this organism in the environment correlates well with disease incidence, as approximately 90% of the infections occur between April and October.

Unlike other pathogens associated with seafood consumption, several studies have shown no correlation between the presence of *V. vulnificus* and fecal coliforms. *V. vulnificus* is clearly an indigenous estuarine species with an environmental reservoir;

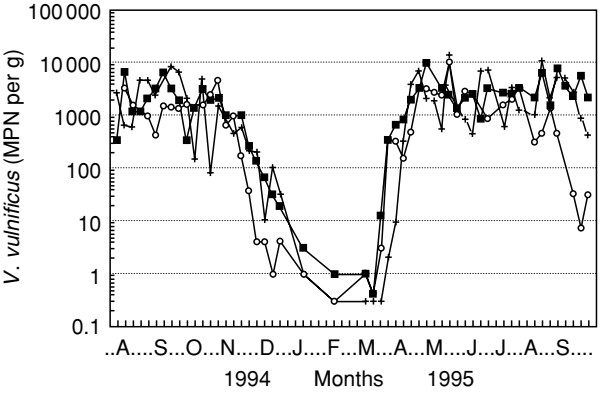

Figure 1 Weekly densities of *V. vulnificus* in oysters from Gulf Coast sites in Alabama (+), Florida (○), and Louisiana (■) during a 14-month period. Each point represents the geometric mean ($n = 2$) of the MPN of bacteria per gram of oyster meat. From Motes ML, DePaola A, Cook DW *et al*. (1998) Influence of water temperature and salinity on *Vibrio vulnificus* in northern Gulf and Atlantic Coast oysters. *Applied and Environmental Microbiology* 64: 1459–1465, with permission.

however, many aspects of this reservoir are still unclear. For example, does this organism exist and replicate as a free-living species or in association with algae, shellfish, or fish? While it may be assumed that concentrations of *V. vulnificus* in shellfish, in part, reflect filtering of the organism from surrounding water, there are data suggesting that *V. vulnificus* can assume a symbiotic relationship with oysters. At a practical level, this relationship implies specific attachment or internalization, which may account for the difficulties in clearing the organism from oysters by using traditional depuration techniques.

The condition and overall health of the oyster may also influence the numbers of *V. vulnificus* in oyster tissue. Numerous variables such as heavy metal concentrations, water turbidity, availability and types of food sources, spawning status, etc. may influence the ability of oysters to clear or control endogenous bacterial populations. Bacterial growth also may be enhanced by coinfection with parasites such as *Perkinsus marinus*, the presence of which may depress innate defense mechanisms.

Fate on Processing/Storage and Control Measures

V. vulnificus can persist in oyster shellstock for extended periods of time. In oysters held at 18°C for 30 h, or at ambient temperatures for 12 h, there are significant increases in *V. vulnificus* counts, highlighting the importance of refrigeration after harvest and during storage and transport. Currently in the USA, Hazard Analysis Critical Control Point

recommendations are being implemented that provide more rapid postharvest refrigeration of shellfish to limit increases in the numbers of *V. vulnificus* resulting from temperature abuse.

A variety of approaches have been proposed to reduce or eliminate *V. vulnificus* from oyster shellstock. Traditionally, depuration or the incubation of oysters in recirculating, sanitized fresh water has been used to reduce bacterial contamination of fecal origin in shellstock; however, several studies found this treatment to be ineffective for *V. vulnificus* control. In one study, *V. vulnificus* was cleared from the digestive organs but persisted in other tissues following depuration treatment. Recently, alternative treatments such as freezing, cold or hot water immersion, relaying to high salinity waters, high pressure, and irradiation have shown promising results for the reduction and possible elimination of this species from oysters. Unfortunately, many of these treatments are lethal to oysters as well, and their application to the 'oyster on the half shell' market may be limited. Some suppliers are currently using these methods to produce a product that greatly resembles a freshly shucked oyster but will not be sold as live product.

Detection in Food, Water, and Physiological Samples

V. vulnificus has traditionally been evaluated in food and water samples using most probable number (MPN) calculations and standard microbiologic techniques. In this procedure, oysters are homogenized in buffer and serially diluted to MPN enrichment tubes, which are subsequently screened for vibrios by growth on selective/differential media. Unfortunately, owing to the diversity and abundance of vibrios in the environment, this method lacks reliability, and further confirmatory methods such as species-specific monoclonal antibody are generally required for identification.

More recently, there has been increasing use of molecular approaches, including DNA probes and PCR techniques. Several of the probes and PCR primers are based upon the DNA sequence for the *V. vulnificus* cytolysin gene, *vvh*. This gene appears to be common to most, if not all, strains and is highly species-specific. Applications include a colony hybridization protocol that can be combined with total viable counts on nonselective medium to provide more direct enumeration. Multiplex PCR analyses have also been described that simultaneously detect *V. vulnificus* and other *Vibrio* spp. Unfortunately, these probes, as well as the standard MPN methods described, do not discriminate between potentially virulent and avirulent strains.

For patient samples, *V. vulnificus* will grow without difficulty in standard blood culture media or on nonselective media (such as blood agar) routinely used for wound cultures; identification and speciation of the organism are possible through any of the standard, commercially available microbiology identification systems. As with all *Vibrio* species, isolation of the organism from stool generally requires the use of a specific selective culture media (thiosulfate citrate bile-salts sucrose).

Symptoms and Characteristics

V. vulnificus has been linked with three different clinical syndromes: (1) 'primary septicemia' (presence of the organism in the blood, without an obvious source such as a wound infection), (2) wound infections, and, possibly, (3) gastroenteritis. Serious *V. vulnificus* infections occur almost exclusively in persons who have underlying liver disease (including alcoholic liver disease), are immunosuppressed, or have chronic diseases such as diabetes or renal failure. Risk of infection is also substantively increased in persons with increased iron stores, as found in patients with hemochromatosis.

Primary Septicemia

Approximately one-third of patients with primary *V. vulnificus* septicemia present in shock or become hypotensive within 12 h of hospital admission. Three-fourths of patients have distinctive bullous skin lesions. Thrombocytopenia is common, and there is often evidence of disseminated intravascular coagulation. Complications such as gastrointestinal bleeding are not infrequent. The mortality rate for persons with primary *V. vulnificus* septicemia is more than 50% overall and more than 90% in persons who are hypotensive. Although the actual infection may be cleared rapidly, patients often require prolonged hospitalization in intensive care units because of the associated shock syndrome and resultant multiorgan system failure.

Wound Infections

V. vulnificus may contaminate wounds exposed to estuarine waters or shellfish. In persons in the risk groups noted above, the infection may spread rapidly, producing severe myositis and fasciitis reminiscent of gas gangrene and requiring amputation in extreme cases.

Gastroenteritis

V. vulnificus has also been associated with gastroenteritis. However, an etiologic role is difficult to

establish, as isolation from stool samples is of uncertain significance, given the ubiquitous presence of the organism in both water and shellfish.

Treatment and Prevention

In *V. vulnificus* septicemia, the sooner antibiotic therapy is initiated, the greater the chance that the patient will survive. Based upon clinical observations and *in vitro* susceptibilities, tetracycline and quinolone antibiotics have been recommended for management of *V. vulnificus* infections. Recent *in vitro* and animal studies from Taiwan indicate that there is synergism between minocycline and cefotaxime in treatment of serious *V. vulnificus* infections, leading to the recommendation that these latter two drugs be used as 'first line' therapy. Patients with serious infections need to be aggressively managed in an intensive care unit setting to minimize the possible consequences of hypotension, septic shock, and multiorgan system failure.

Given the high mortality associated with *V. vulnificus* infections, persons in the high-risk groups noted above should avoid eating raw or undercooked shellfish, particularly oysters. By law, restaurants in many states are now required to post warnings about this risk. Persons at high risk for infection should also avoid situations in which estuarine-associated wounds are likely to occur.

VINEGAR

M Plessi, Dipartimento di Scienze Farmaceutiche, Università degli Studi di Modena, Modena, Italy

Summary and Background

Vinegar is traditionally the product of the acetous fermentation of dilute alcoholic solutions. At the present time it is produced microbiologically from natural alcoholic solutions or by dilution of acetic acid. Vinegar and its characterization are presented in this article.

Vinegar has been known since ancient times, for more than 10 000 years, and has been used for its typically acid flavor. It uses were many and various for centuries, not only for food but also for medicinal and ritual uses. It is traditionally the product of the acetic fermentation of dilute alcoholic liquors and it was wine that was the first alcoholic liquid used, thus the derivation of its name (from the French *vin aigre* = sour wine).

History

During Babylonian times vinegar was used as a condiment and for food preservation. Hippocrates recognized its medicinal properties and it is also mentioned in the Bible as a remedy on account of its sedative and curative properties. Pliny reported that vinegar, diluted with water (known as posca), was given to the Roman legionnaires during their long marches.

The medicinal use of vinegar was widespread during the Middle Ages and the Renaissance, for both internal and topical use. It was in fact used as a digestive, a prophylactic against liver disorders, an anthelmintic, for sore throats, and to rub on the wrists against fever, but also against hair loss and tinea.

Vinegar production as an industry began during the period of the Communes; those who swore not to reveal the secret of its fabrication were admitted to the corporation of manufacturers. Although widely used, little was known about the real nature of vinegar and its fermentation until the eighteenth century. In 1723, Stahl obtained acetic acid from vinegar, but nothing was known of the causes which determined the formation of acetic acid. The first breakthrough came with Berzelius, who, at the beginning of the nineteenth century, explained how acetic acid was formed from alcohol by a process of oxidation. Persoon (1822) and Kùtzing (1837) were the first to suggest the presence of microorganisms in the process. Finally, in 1864, Pasteur brilliantly demonstrated the biological origin of the acetic fermentation, indicating *Mycoderma aceti* as the fermentation agent. Later studies clarified the nature of the microorganisms, which turned out to belong to several species.

Vinegar is now used above all to give foodstuffs a pleasant acidic flavor; it is also used as a preserver of foodstuffs and is recognized to have certain pharmacological qualities.

Production

At the present time, vinegar is still produced microbiologically from a mostly natural alcoholic solution, but can also be produced by dilution of acetic acid.

Microbiological Production

Vinegar is the product of the acetic fermentation of slightly alcoholic liquids (less than 10–12% by volume of ethyl alcohol); transformation of alcoholic liquids into vinegar is not really fermentation, but oxidation.

Raw materials may be wine, cider, beer, and other liquors deriving from the alcoholic fermentation of cereals, fruit and potatoes, sugar solutions, such as molasses, honey, and whey, and also diluted pure ethanol with the addition of nutrients. These are the so-called brewed vinegars, derived from the oxidation activity of aerobic microorganisms. The microorganisms belong to the genus *Acetobacter* (initially called *Mycoderma*), and the most widespread species are *A. aceti*, *A. pasteurianus*, and *A. hansenii*. These are the ones that oxidize ethyl alcohol into acetic acid. The oxygen used for the bioxidation is that of air.

These microorganisms, in the shape of asporigenous rods or cocci, form membranes of different consistencies (vinegar mother). The optimum temperature for their multiplication is between 18 and 34 °C, depending on the species.

Ethanol is dehydrogenated to acetic acid and the reduced cosubstrates are oxidized via the respiratory chain (**Figure 1**). Similarly, but less abundantly and in an anaerobic atmosphere, acetic acid is formed by dismutation of 2 molecules of acetaldehyde (derived in their turn from alcohol by oxidation). In theory, 1 g of alcohol yields 1.3 g of acetic acid; in practice, however, the yield is 15–20%, lower mainly because alcohol, acetaldehyde, and acetic acid tend to volatilize. The theoretical amount of air required for 1 l of vinegar containing 6% of acetic acid is about 120 l,

whereas, in practice, given the slow rate of liquid–gas exchange, the amount required is much greater.

Acetous fermentation is accompanied by secondary fermentation which combines to produce the flavor and typical aroma; small quantities of volatile substances are formed (e.g., ethane, acetaldehyde, ethyl formate, ethyl acetate, isopentyl acetate, butanol, methylbutanol, 3-hydroxi-2 butanone or acetylmethylcarbinol), which vary from vinegar to vinegar depending on the starting material and which, because of their individual characteristics, produce vinegars with a variety of odor, taste, color, and other properties. The fermentation is usually stopped at a minimum residual ethanol level to avoid overoxidation, as oxidation of acetic acid to water and CO_2. (*See* **Fermented Foods: Origins and Applications.**)

Methods of manufacture The manufacture of vinegar is an ancient craft, known and practiced all over the world from time immemorial. A certain amount of vinegar is still manufactured following the centuries-old empirical methods of the small producer, but since the last century a flourishing vinegar-manufacturing industry has developed.

Industrial vinegar-manufacturing processes fall into three main categories. The slow processes, which are the oldest commercial procedure and resemble home-brewing techniques, are no longer used. The Orleans process is still in use for the production of high-quality vinegar; the procedure has remained unchanged through the years but is very slow and requires a great deal of space (Figure 2). The starting liquor is placed in a large cask, containing wood shavings or grape stalks, where the acetification process gets underway. After about 8 days, the liquid is withdrawn and transferred into barrels, which are left only one-half or two-thirds full and where the liquid remains until acidity reaches its peak (about 3 months). From now on, two-thirds or three-quarters of the vinegar is withdrawn from the bottom of the barrel every week and an equal volume of liquid from the generator cask is added from the top. (*See* **Barrels: Wines, Spirits, and Other Beverages.**)

The processes of the second and third categories aim at a closer contact, with maximum possible

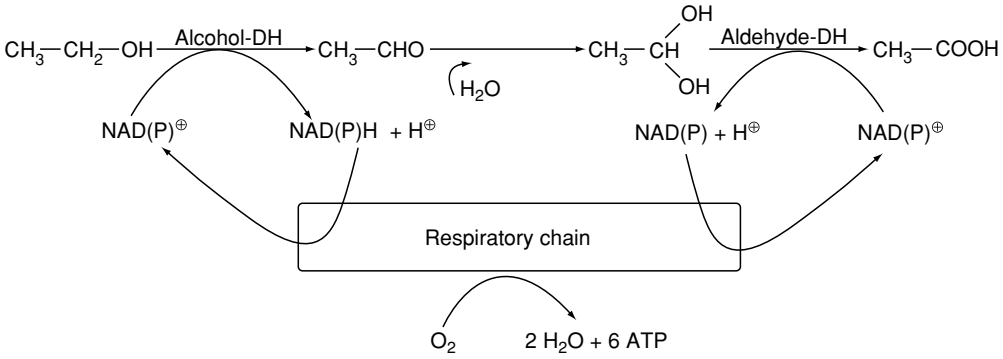

Figure 1 Ethanol oxidation to acetic acid by *Acetobacter* spp.

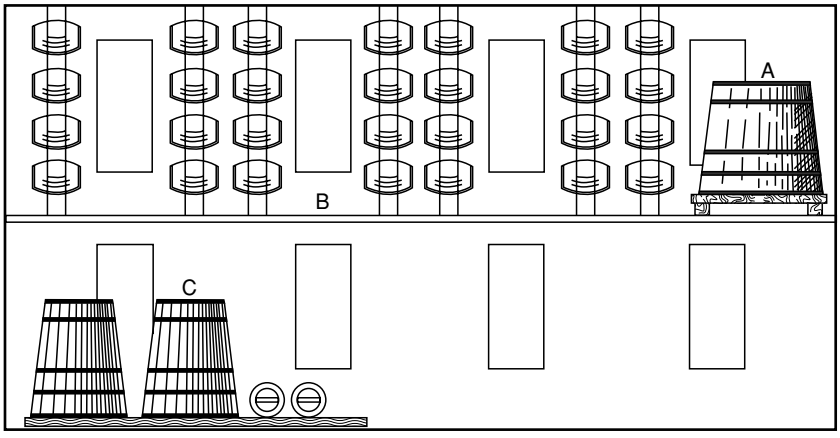

Figure 2 Vinegar making Orleans method: A, starting vat; B, acetifier casks; C, vats of clarification.

surface exposure, between the alcoholic liquid undergoing acetification and the ambient air. The passage of oxygen from the gaseous to the liquid phase is thereby accelerated and intensified and the acetification time, which with traditional methods is rather long, is reduced.

Generator processes, first introduced in Germany, have been in general use for more than 100 years. The generator tanks are generally made of wood or sometimes steel, are equipped with cooling coils, and are vented to allow the air to circulate; they have a perforated false bottom which serves to support the wood shavings (preferably beech) or grape stalks with which the tanks are filled. A spray mechanism distributes the alcoholic liquid over the surface of the packing (Figure 3). The liquid trickles over the wood shavings covered with *Acetobacters* and then is pumped back to the sprinkler header-tank and the cycle is repeated. The process continues until acetification is complete, which generally takes about a week providing the temperature is kept in the optimal range of 27–30 °C. A measured volume of vinegar is then withdrawn from the bottom of the tank and is replaced with an equal volume of fresh liquid. The generator process is a continuous process which gives a fairly clear vinegar with good sensory characteristics. However, it is slow and about 20% of yield is lost through evaporation. Also, the wood shavings have to be replaced at least once a year.

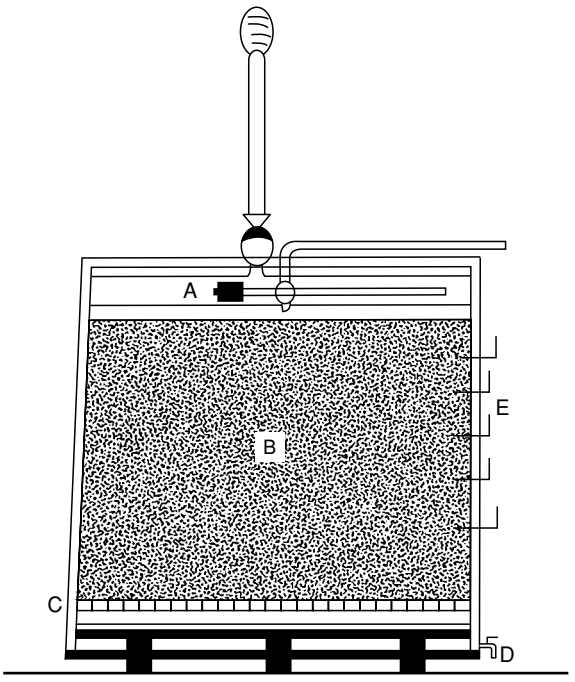

Figure 3 Circulating generator: A, sprinkler for dispersal of the liquid over the wood shavings; B, beechwood shaving; C, perforated false bottom; D, tap for withdrawal of the liquid; E, thermometers.

The third category involves the submerged processes. These are the most up-to-date, benefitting as they do from industrial experience with submerged culture techniques employed in the field of antibiotics. These processes do not use wood shavings, but air forced into the liquid, and the mother of vinegar is often replaced with selected cultures of *Acetobacters*. The generator tank is made of stainless steel, or polypropylene reinforced with fiberglass; it is equipped with devices to insure an adequate and continuous flow of air, with cooling coils which maintain a steady temperature of about 30 °C in the fermenting body of liquor, with thermometers for monitoring temperature and, sometimes, with an automatic gage for measuring the alcohol content of the fermenting liquid. Oxidation of the alcohol is started slowly by means of aeration, and fermentation is apparent after about 24 h. Air is then introduced at regular hourly intervals; it permeates the body of liquor in a uniform manner, causing rapid and lively fermentation. Acetification is deemed complete when the residual alcohol is around 0.2–1.5% w/v (depending on the type of vinegar required). The process is extremely rapid. About half of the resultant vinegar is then withdrawn; the remaining vinegar acts as mother for the next batch.

This method was first developed in the USA and Germany. It spread rapidly throughout the world and displaced the older, slower processes. The yield is very high (90–95%), since there is little loss through evaporation. However, the product is rather cloudy and less aromatic than vinegars obtained by slower fermentation processes. This is due to the fact that, given the brief period of contact, the esterases do not have time to perform their function adequately and the characteristic volatile substance content is low as a result.

The product is therefore filtered and, in some cases, put into wooden casks to age; the result is a vinegar of superior quality which is rich in biological principles, generated by bacterial-cell autolysis, and perfectly clear.

Malt vinegar Malt vinegar, which is the most common variety in UK, is produced without intermediate distillation from the double fermentation (alcoholic and acetous) of malted barley with or without the addition of other cereals, the starch of which has been converted into fermentable sugars from α-amylase of malted barley.

Malt vinegar manufacture involves mashing, fermentation, and acetification. During mashing, the malted barley, sometimes mixed with other cereals such as maize and rice, is milled and mixed with hot water in mash tuns, where the starch is converted by α-amylase into maltose, dextrose, and dextrins. The sweet liquor drains off the mash through the

perforated false bottom of the tun and is collected in vessels where it is fermented by the addition of yeasts, which convert the fermentable sugars to ethanol and carbon dioxide. When fermentation is practically complete, the alcoholic liquor is separated from the yeasts and acetified by inoculation with *Acetobacter* cultures. The resultant alcohol is thus oxidized to acetic acid in the presence of atmospheric oxygen. The process lends itself to the different systems in current use. The vinegars will be more or less aromatic, the superior varieties will be those produced by the old and slow Orleans process.

Malt vinegar is straw-colored and must in any case contain 4% w/v of acetic acid. Distilled malt vinegar is prepared by distilling malt vinegar. This product contains only the volatile constituents of the original vinegar and is colorless; it is generally used for the preparation of pickled silverskin onions. (*See* **Malt**: Chemistry of Malting.)

Wine vinegar Wine vinegar, which is obtained from acetous fermentation of wine, is largely produced in continental Europe.

The wines used for acetification are those with too low an alcohol content (7–9% v/v) or those in which volatile acidity is too high. Spoilt wines cannot be used. If wines with a high alcohol content are to be used, they need to be appropriately diluted with water, since a high concentration of alcohol will inhibit the development of the *Acetobacters*. For the same reason, the wine must be free of sulfur dioxide and dregs.

Both white and red or rosé wines can be used to produce white or red vinegar, respectively. In the domestic or small-scale production of wine vinegar, the wine is poured into small wooden barrels, together with the vinegar mother, which consists of colonies of *Acetobacters* taken from barrels in which vinegar has already been produced. The barrel must contain air, so for this reason it is not filled completely. Acetification is slow and stops spontaneously when acidity reaches 7–8%. The slow transformation of wine into vinegar leads to the formation of many substances which impart excellent organoleptic qualities to the end product. The most important of these are acetaldehyde and ethyl acetate – which in top-grade vinegars are present in quantities far greater than those of wine – volatile alcohols, particularly 3-methyl-1-butanol, and 3-hydroxy-2 butanone (or acetylmethylcarbinol).

The vinegar is then partly withdrawn for use and replaced with fresh wine to be acetified. Vinegar produced in this way is bound to vary in composition and character: it may be more or less cloudy and its acidity may vary according to the degree of alcohol in the wine and the nature of the fermentation.

However, most wine vinegar is produced by industrial processes and, as such, is a standardized industrial product; according to EC regulations, its total acidity must not be less than 6 g of acetic acid per 100 ml and residual ethanol may be present in quantities not exceeding 1.5% v/v. The color varies from pale yellow to red, depending on the wine used; the clear vinegars made from white wine are in great demand for pickling. (*See* **Wines**: Types of Table Wine.)

Cider vinegar Cider vinegar is prepared from apple wine that has undergone acetous fermentation and is widely used as a table vinegar, above all in the USA and UK. It is yellowish in color and may be darkened with caramel. Its acidity is not very high and its acidic, astringent flavor recalls the fruit of origin. (*See* **Cider (Cyder; Hard Cider)**: The Product and its Manufacture; Chemistry and Microbiology of Cidermaking.)

Fruit vinegars Fermented juices from other fruits such as peaches and berries are also used to produce vinegar. Since these alcoholic liquids are not distilled, they maintain the subtle flavors and aromas of the raw ingredients; this confers on the vinegars much-appreciated characteristics.

Rice vinegar In the Far East, where rice is the staple cereal, vinegar is prepared from rice as such, from sake (its fermentation product), or from the by-products of sake manufacture. Traditional methods, similar to the Orleans process, are still in use but have been largely superseded by modern submersion techniques. This vinegar has a fairly low acidity and a high amino acid content. It is light in color and has a clean, delicate flavor. It is therefore highly prized in oriental cooking since it does not significantly alter the taste of the food; it is excellent for flavoring with herbs, spices, and fruits because of its mild flavor.

Molasses vinegar This vinegar is prepared from sugar syrup or molasses by double fermentation, alcoholic fermentation of sugars, and the subsequent acetic bioxidation. It serves to make use of the by-products of the sugar industry, but is not widely used.

Honey vinegar This vinegar is obtained from honey which is added to the right quantity of water, subjected to alcoholic fermentation so as to obtain a drink containing ethanol (mead), which, at the right temperature and in the presence of oxygen is subject to the action of acetic bacteria so as to obtain acetic acid. The vinegar is then clarified by bland filtration or by decanting, so that all the qualities of honey remain unaltered.

Spirit vinegar Spirit vinegar, sometimes referred to as white, distilled, or alcohol vinegar, is prepared by acetous fermentation of an alcoholic distillate obtained from the products of alcoholic fermentation of natural sugar solutions. In countries where it is permitted by law, wide use is made of synthetic ethanol, diluted to 10–14% v/v. Spirit vinegar is colorless and is often colored with caramel; it is strongly acid but not aromatic; the distillation of the alcoholic liquids increases the concentration of ethanol, but reduces flavor. This vinegar is less expensive and is the most widespread in the world. When diluted to 4–5% acidity it is used for pickling.

Balsamic vinegar A particular type of highly prized vinegar has been produced for centuries in the provinces of Modena and Reggio Emilia in Northern Italy.

The raw material is grape must, preferably Trebbiano. When alcoholic fermentation has just started, about 24 h after pressing, the must is boiled gently until it has reduced to about one-half or one-third of its starting volume. The result is a liquor with a high sugar concentration (about 30%) in which alcoholic and acetous fermentation take place together extremely slowly; yeasts (*Saccharomyces* and *Zygosaccharomyces*) and acetic bacteria (*Acetobacter* and *Gluconobacter*) are needed for the formation of this vinegar.

Traditional balsamic vinegar takes many years to produce. During the process of fermentation, maturing, and aging, the product becomes highly concentrated and the sugars, alcohols, aldehydes, and organic acids undergo extremely gradual chemical transformation. The vinegar battery consists of a variable number of barrels (between five and 12 or even more) of different woods and decreasing in size. They are set up in well-ventilated areas which are hot and dry in summer and cold in winter. According to the traditional method, part of the contents of the smallest barrel is withdrawn annually for consumption, and is replaced with an equal volume from the next largest barrel in the battery. This is in turn replenished from its neighbor, and so on up the line. Finally, the largest barrel is topped up with the season's boiled must (**Figure 4**).

The process takes at least 12 years, though it is not uncommon to find vinegars that are 50 or more years old, and the yield is very low (no more than 1 l of vinegar from 100 kg of fresh must). The end product, however, is of exceptionally high quality, dark brown in color, of a syrupy consistency, sweet and sour to the taste, and with a characteristically pleasant aromatic smell. In traditional balsamic vinegar the total solids are very high (20–70%), acidity varies between 6 and 18% w/v acetic acid and there are large amounts of sugars, essentially glucose and fructose, as well as numerous aromatic substances that have gradually been formed over the years.

Chemical Synthesis

Acetic acid is usually synthesized by catalytic oxidation from acetaldehyde. Acetaldehyde is in turn obtained by catalytic hydration of acetylene or by catalytic dehydrogenation of ethanol (**Figure 5**). Formic acid and formaldehyde, byproducts of acetic acid synthesis, are removed by distillation.

The acetic acid is subsequently purified and diluted with water to 60–80% by volume to obtain the

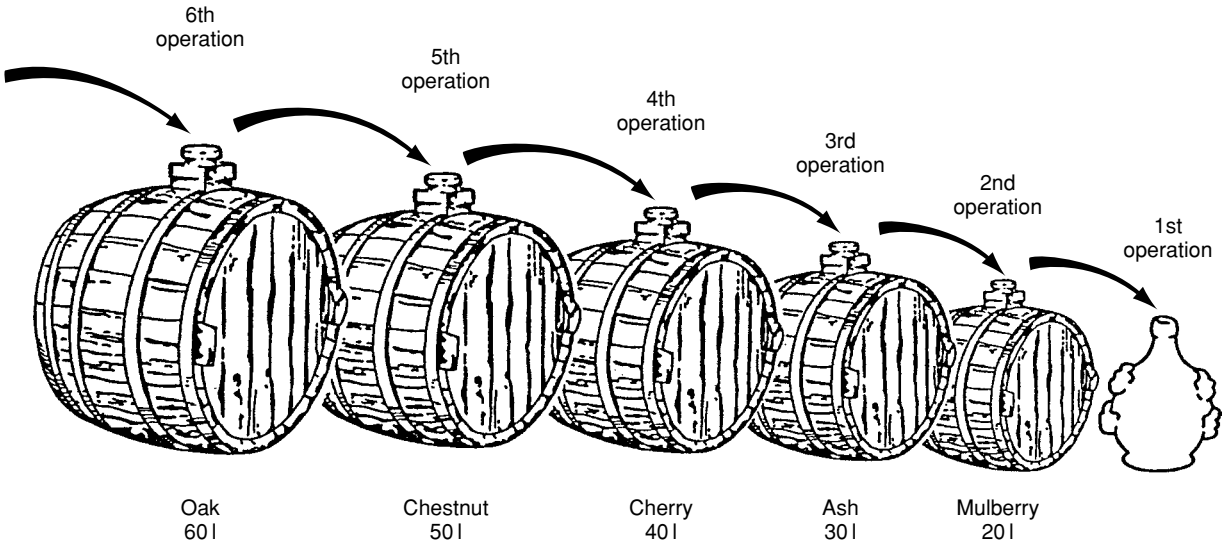

Figure 4 Battery of barrels for manufacture of the 'traditional balsamic vinegar of Modern'.

'vinegar essence.' In order to produce a food-grade vinegar, this 'vinegar essence,' which is a concentrated solution of acetic acid and highly corrosive, is further diluted until it contains 4–5% w/v of acetic acid. This liquid is used in the preparation of synthetic vinegar.

Synthetic Vinegar A number of countries allow a nonfermented vinegar to be used for alimentary purposes which may be produced using synthetic acetic acid that is diluted, aromatized, and colored. The synthetic vinegar thus obtained needs to be colored artificially, and for this purpose caramel is commonly used. It is then aromatized with the addition of sugars, chemical seasoning, and salt or with the addition of natural vinegar. The end product must contain at least 4% w/v of acetic acid, as in the case of fermented vinegars. However, the name 'vinegar' is not always accepted for this product; in the UK for example, it must be labeled 'nonbrewed condiment.'

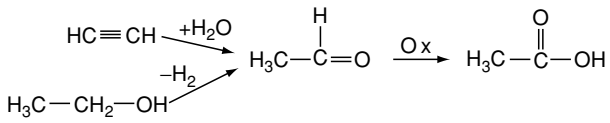

Figure 5 Chemical syntheses of acetic acid.

Characterization and Analysis of Vinegars

The relative density of vinegars ranges from 1.007 for synthetic vinegars to 1.360 for balsamic vinegars. Total solids and ash vary according to type. They are very high in the 'traditional balsamic vinegar of Modena.' They are more abundant in malt, wine, and cider vinegars than they are in spirit vinegars and synthetic vinegars.

Brewed vinegars, being a natural product, contain a large number of components that may derive from the raw materials, be the result of primary or secondary fermentation, or derive from the interaction of components from these two sources (Table 1).

The most abundant volatile constituent is acetic acid, which is largely responsible for the acidity of the vinegar. It ranges from 4–5% for rice vinegars to 10–12.5% for distilled vinegars.

The presence of acetaldehyde, a byproduct of acetous fermentation, is typical. Numerous esters, major contributors to aroma, are present, notably ethyl acetate, the major portion of which was formed during storage, and also methyl and isopentyl acetate; various isomeric butanols and pentanols, present in the raw material, occur in vinegars.

The formation of 3-hydroxy-2-butanone and 2,3-butanedione are typical, deriving from 2,3-butandiol,

Table 1 A comparison of some typical figures for the chemical composition of various vinegars

a product of the condensation of acetaldehyde by microorganisms, which are always, and only, found in brewed vinegars, albeit in variable quantities (Table 2).

Organic acids, other than acetic acid, are also present: tartaric and citric are largely found in wine vinegars, while formic and malic acid are those most commonly found in cider vinegars. During the fermentation process small quantities of other acids, such as succinic acid, lactic acid, and fumaric acid, are formed.

Of the many analyses that vinegars lend themselves to, the most useful from the point of view of general characterization are the following:

- *Sensory examination*: The sensory characteristics to be taken into account are color, odor, and taste, which must conform to those attributed to the type of vinegar being analyzed. If the vinegar is cloudy, it must be examined under strong magnification for vinegar eels (*Anguillula aceti*), a nematode that is a typical parasite of vinegar.
- *Relative density*: This is determined at 20 °C using a Westphal balance or pyknometer.
- *Total acidity*: This is determined by titrating the diluted product with a standard alkaline solution. It is expressed as grams of acetic acid per 100 ml of vinegar.
- *Fixed acidity*: A 10-ml aliquot of vinegar is evaporated to dryness and reconstituted with water, the process being repeated in order to eliminate acetic acid. The final residue is dissolved in water and titrated with an alkaline solution. It is expressed as grams of tartaric acid per 100 ml of vinegar.
- *Volatile acidity*: This is calculated from the difference between total and fixed acidity, both expressed as grams of acetic acid per 100 ml of vinegar.
- *Total solids*: A 50-ml aliquot of vinegar is evaporated in a platinum capsule with water in order to eliminate the acetic acid. It is then dried to constant weight in an oven at 100 °C.
- *Ash*: The total solids are ignited at 500–550 °C. If a high ash figure is obtained, salt should also be determined.
- *Ash alkalinity*: This is chiefly due to potassium carbonate formed during calcination and is determined by dissolving the ash in an exact quantity of standard sulfuric acid, of which the excess is titrated with alkali. It is expressed in mmol of alkali per liter.
- *Ethanol*: A 100-ml aliquot of vinegar is neutralized with sodium hydroxide and double-distilled. The density of the solution is measured and, consequently, the quantity of ethanol is calculated from tables.
- *Total nitrogen*: This is determined by the Kjeldahl method on 25 ml of vinegar.

Methods of Differentiating Between Various Types of Vinegar

Apart from color and odor, the nitrogen, phosphates, ash, and their alkalinity also serve to differentiate between the various types of vinegar. In a malt vinegar, nitrogen and phosphate figures are low, while in a rice vinegar the nitrogen figure is higher and distilled vinegar has a very low ash content.

However, useful methods of routine differentiation are based on those values that depend on the volatile substances present, namely:

- *Oxidation value*: The number of ml of 0.002 mol l^{-1} $KMnO_4$ discolored by 100 ml of sample in 30 min under standard conditions. Alcohol and

acetylmethylcarbinol are mostly responsible for the oxidation value.

- *Iodine value*: The number of ml of 0.01 mol l^{-1} iodine absorbed by 100 ml of sample under standard conditions. This value is mostly influenced by acetylmethylcarbinol and diacetyl.
- *Ester value*: The number of ml of 0.01 mol l^{-1} KOH required to saponify the esters contained in 100 ml of sample under standard conditions.

Brewed vinegars give comparatively high values, but those for artificial products are low as the latter are almost devoid of volatile reducing substances.

Vinegars can be more specifically identified by means of gas chromatography. This technique can distinguish brewed vinegar from synthetic vinegar and also brewed vinegars from different origins by analyzing the accompanying compounds (metabolic byproducts of *Acetobacter* strains and substances derived from the raw material).

In addition, the blending or adulteration of brewed vinegar with synthetic acid can be detected by mass spectrometric determination of the $^{13}C/^{12}C$-isotope ratio; brewed vinegar has 5% more ^{13}C isotope than acetic acid synthesized petrochemically.

Food Uses

Vinegar has long been used worldwide as a basic seasoning in the preparation and cooking of certain foods, because its sharp taste makes it so useful and versatile.

A considerable quantity of vinegar is marketed as such for domestic use. In the UK and USA the table vinegar most widely used is cider vinegar, while in Ireland it is malt vinegar and, in grape-growing countries, such as Italy, France, and Spain, wine vinegar. In the Far East, in addition to the traditional rice vinegar, synthetic vinegar is very common.

Vinegar adds flavor to vegetable and meat products. It is one of the ingredients of salad dressings, sauces, such as tabasco, and tomato products, such as ketchups, mustard, and aspics. Mixed with oil and salt it makes the classic vinaigrette, and it can be used as a condiment for salad and as a sauce for cold, cooked vegetables, meat, and fish.

For condiment uses, vinegar can be aromatized with herbs and spices like tarragon, basil, garlic, shallot, and elder. They are steeped in the vinegar when acetification is complete; in certain types of vinegar sugars are added as well. These vinegars add special and unusual tastes to food.

The aroma and sweet and sour flavor which balsamic vinegar confers on foods to which it has been added is decidedly particular; it is suitable for all types of food, such as sauces, green salads, and meat and sprinkled on strawberries, peaches, or melon adds a pleasant flavor and aroma.

Finally, because of its acetic acid content and low pH, vinegar is used as a preservative for both domestic use and in the food industry. It is in fact used for the preservation, or pickling, of a wide variety of foods such as vegetables, meat, fish products, and spiced fruits. For this purpose, the food-processing industry uses mainly distilled vinegar and, where the law permits, synthetic vinegar.

VIRUSES

H Appleton, PHLS Central Public Health Laboratory, London, UK

Background

Viruses are usually transmitted directly from person to person, but it is clearly recognized that, on occasions, some viruses may also be transmitted by foods and water. Unlike bacteria, viruses do not multiply or produce toxins in food: food items merely act as vehicles for their passive transfer. Any virus that is infectious via the gastrointestinal tract could be considered a potential foodborne pathogen, but in practice, the most commonly reported foodborne viral infections are gastroenteritis and, less frequently, hepatitis. Although the clinical characteristics of these two illnesses differ, their food-related mode of transmission is essentially the same. Foodborne spread of both these infections has been clearly defined, but the extent of the problem is unknown. For various reasons, the incidence of both is almost certainly under-reported.

Viral Gastroenteritis

Gastroenteritis is the most common foodborne viral infection. Discovery of the viruses responsible for causing gastroenteritis began with the identification of the Norwalk virus in 1972 and then the human rotavirus in 1973. These viruses are usually transmitted directly from person to person via the fecal–oral route. In 1977, however, there was a report that a virus had been responsible for a community-wide outbreak in England associated with shellfish. At least 800 people were affected, and it is now clearly established that food may also play an important role in transmission.

Prior to the discovery of gastroenteritis viruses and recognition of their foodborne mode of transmission, there were many reports of 'food poisoning outbreaks of unknown etiology,' which were assumed to be bacterial but in retrospect have the characteristics of viral gastroenteritis. Such reports still occur when appropriate viral investigations are not undertaken. Viral gastroenteritis tends to mimic bacterial food poisoning, and invariably, outbreaks are initially investigated for traditional food poisoning bacteria. However, there are characteristic features that should alert investigators to the possibility of a viral cause. The incubation period is somewhat longer and more variable than for most bacteria, with a peak of around 30–36 h (range 12–60 h, which may be dose-dependent). Symptoms are variable and may include both vomiting and diarrhea as well as the usual range of associated complaints such as abdominal pain, general malaise, and nausea.

Secondary person-to-person spread is a characteristic feature. Illness is usually regarded as mild and self-limiting with recovery within 24–48 h. However, people commonly feel debilitated for 2–3 weeks, and this can have considerable impact socially and economically in impaired performance. Outbreaks may be very disruptive and have led to closure of hospitals and schools. Some outbreaks have been very large, involving several hundred people. Treatment is not normally required unless people are severely affected and become dangerously dehydrated. This is a more common problem in children suffering diarrheal diseases in underdeveloped countries. Oral rehydration therapy with simple balanced salt solutions is an effective treatment.

The overall incidence viral gastroenteritis is unknown. A community-based study of infectious intestinal disease, from all causes in England from 1993 to 1996, confirmed that the vast majority of cases go unreported. The study found that viruses were responsible for a far greater proportion of gastrointestinal illness than national surveillance figures had previously indicated. The study also concluded that infections resulting from viruses are less likely to be

reported than bacterial infections. It was estimated that only one in 35 infections with rotavirus and one in 1562 infections caused by Norwalk-like viruses occurring in the community are reported to national surveillance, compared with one in three cases of salmonellosis.

The proportion of these viral gastrointestinal infections that is foodborne is similarly unknown. Viruses account for 6% of foodborne outbreaks and 5% of waterborne outbreaks occurring in England and Wales and reported to national surveillance, but this is likely to be a gross underestimate of the true incidence. The mild nature of the illness means that persons do not tend to consult a medical practitioner. However, the short incubation period means that when an illness is investigated, possible association with a food source is more likely to be recognized than for hepatitis A, for which there is a long incubation period. The highly infectious nature of the viruses and the frequent occurrence of secondary person-to-person spread also add to the difficulties of identifying a food- or waterborne outbreak.

The Gastroenteritis Viruses

Several different viruses cause gastroenteritis (Table 1), but it is the viruses of the Norwalk group that have been particularly linked to foodborne transmission. They form a complex group, and the nomenclature is confusing. The viruses have been known variously as Norwalk-like viruses (NLV), and as small round structured viruses (SRSV) because of their appearance when viewed in the electron microscope (Figure 1). The virus particle measures 30–35 nm in diameter and has an amorphous surface and a ragged outline. They are classified as members of the Caliciviridae family and hence are sometimes referred to as human caliciviruses.

Norwalk-like Viruses The Norwalk virus, which originated from a school outbreak of nonbacterial gastroenteritis at Norwalk, Ohio, in the USA, was the first virus of the group to be discovered. Viruses of this group are frequently the cause of both community and institutional outbreaks of nonbacterial gastroenteritis, whether resulting from person-to-person spread or a food or water source. Outbreaks in hospitals, residential homes, schools, hotels, restaurants, and cruise ships have been reported frequently. The rapid spread of infection can cause major disruption, leading to closure of schools and hospital wards. There are also considerable economic costs in terms of working days lost. They are probably the most important cause of sporadic gastroenteritis in the community, although because of the relatively minor nature of illness, such incidents are not usually investigated. In the UK, NLVs have been implicated in more than 90% of foodborne outbreaks where a virus has been detected, and it is clear that this virus group is the main cause of foodborne viral gastroenteritis in developed countries.

Several different serotypes have been identified. Immunity to NLVs is poorly understood and may be short-lived. Volunteer studies have shown that some

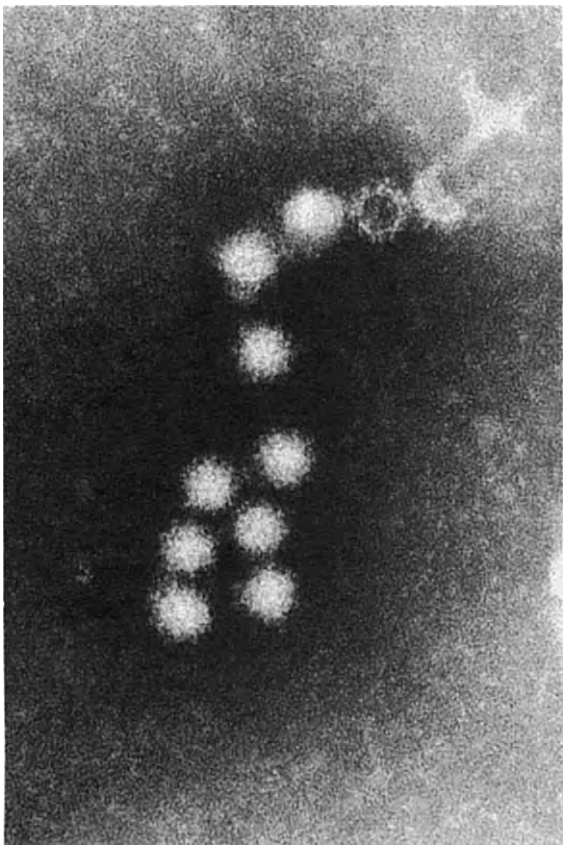

Figure 1 Electron micrograph of a group of Norwalk-like viruses. The virus particles have an amorphous surface and ragged outline. Most particles are complete, but an empty stain-penetrated particle can be seen at the top of the group. Virus particles negatively stained with phosphotungstic acid. Magnification: ×200 000.

Table 1 Viruses commonly causing gastroenteritis

Virus	*Person-to-person spread*	*Food- or waterborne spread*
Norwalk-like virus[a]	Yes	Yes
Rotavirus	Yes	Infrequent[b]
Astrovirus	Yes	Infrequent
Adenovirus (types 40 and 41)	Yes	Not reported

[a]Also known as small round structured viruses.
[b]Food- and waterborne transmission is probably more significant in underdeveloped countries.

people may be infected on more than one occasion by the same virus. Thus, people who experience several incidents of illness may not only be infected with different antigenic types of NLV, but may also develop illness on more than one occasion from the same virus.

The development of polymerase chain-reaction (PCR) assays has allowed the molecular characterization of virus strains from many outbreaks. The human gastroenteritis viruses in the Caliciviridae family form three broad genogroups. Two groups have the morphology of NLVs (Figure 1) and broadly similar genomic features. Members of the third group are known as Sapporo-like viruses (SLVs). The genomic arrangement of this third group is distinct from the other two groups. In addition, SLVs have the classical morphology more usually associated with the calicivirus group, with hollow cup-like depressions on the surface, which are not usually seen in NLVs. (The name calicivirus derives from the Latin *calix* meaning cup.) The different serotypes of the human caliciviruses broadly correspond with the genotypic groups. The majority of reported infections caused by viruses with classical calicivirus morphology have occurred in young children. Outbreaks in nursery groups involving person-to-person transmission have been recorded. The virus has also observed in older persons, and some reported foodborne outbreaks have been attributed to calicivirus.

Rotavirus Rotaviruses mainly infect young children and are the most frequently reported of the gastroenteritis viruses. It is estimated that they may cause a million deaths a year in children under 5 years of age, mostly in developing countries. In developed countries, deaths are relatively rare, but rotavirus gastroenteritis is the most frequent reason for admission of young children to hospital. Foodborne and particularly waterborne spread are probably significant modes of transmission in developing countries, but in developed countries, reports are rare. Although rotavirus has been detected in shellfish, so far, there have been no reports of illness from this source.

Astrovirus Astroviruses form a morphologically distinct group of viruses, and are named from the five- or six-point star seen by electron microscopy on the surface of some particles. Astroviruses are normally associated with gastroenteritis in young children, often under 1 year of age. There have been occasional reports of astrovirus infection in some adults following consumption of shellfish or contaminated water, but these incidents appear comparatively rare.

Adenovirus Adenovirus serotypes 40 and 41 have been specifically linked to gastroenteritis, and infections in young children are frequently reported. Reports in older patients are rare. There have been no reports of food- or water-associated adenovirus infection.

Parvovirus Parvoviruses are small DNA-containing viruses. Their role as causative agents of gastroenteritis in humans is uncertain, since, unlike other gastroenteritis viruses, there is a prolonged carrier state in some persons. However, parvoviruses are an important cause of gastroenteritis in some animal species. Parvoviruses have been observed in school outbreaks of winter vomiting disease and in a number of shellfish associated outbreaks of gastroenteritis. Parvovirus-like particles have been detected occasionally in shellfish that have been implicated in illness and where a similar virus has been found in patients.

Hepatitis

Hepatitis is an inflammation of the liver and is usually recognized by the occurrence of jaundice. Descriptions of hepatitis can be traced back to the time of Hippocrates, but it was not until the eighth century that the infectious nature of the disease was first mentioned in letters from Pope Zacharias to Saint Boniface, Archbishop of Mainz. The viral etiology was first postulated by MacDonald in 1918 and was later confirmed by volunteer studies in the 1940s. It is now known that several different viruses may cause hepatitis, but it is the enterically transmitted viruses, hepatitis A and hepatitis E, that are of importance in foodborne and waterborne transmission.

Types of Hepatitis

Hepatitis A Hepatitis A is transmitted by the fecal–oral route and is prevalent in conditions of overcrowding and poor hygiene. Although it has long been recognized that hepatitis A may be transmitted by food and water, the incubation period of 3–6 weeks makes it difficult to link infection to a food source. Hence, reports of foodborne hepatitis are infrequent and are unlikely to indicate the true extent of the problem. Symptoms in addition to, or instead of, jaundice are nausea and general malaise. Patients may feel unwell for several weeks, but recovery is complete; fatalities are rare. There is no specific treatment, but a vaccine is available. Illness tends to be less severe in children, and in some, infection is symptomless. Once infected, a person is immune from further infection. As hygienic conditions improve, infection becomes less common in children, and a larger proportion of the adult population becomes susceptible.

Serological surveys in the UK indicate that only 10–15% of young adults have antibody to hepatitis A virus (HAV).

HAV is a small, compact icosohedral virus measuring 25–30 nm in diameter. It is classified as a picornavirus (from the Latin *pico* (small) + rna as it has an RNA genome). Within the Picornaviridae family, it is assigned to the hepatovirus genus. There is only one serotype.

Hepatitis E More recently, another enterically transmitted form of hepatitis (designated hepatitis E) has been described. This virus has been associated with large waterborne outbreaks in some developing countries, notably in Asia, Africa, and Central America. Illness appears more severe than hepatitis A, particularly in pregnant women for whom a mortality rate of 17–34% has been reported. Secondary person-to-person transmission is estimated at only 0.7–8%. The primary source of infection appears to be contaminated water rather than person-to-person spread. Cases in the UK are reported infrequently and are mainly imported from endemic areas.

Hepatitis E is classified as a calicivirus but is serologically unrelated to the viruses that cause gastroenteritis. Like all caliciviruses, the virus particles have a diameter of 30–35 nm. When viewed in the electron microscope, the characteristic cup-like depressions of members of the calicivirus group can be seen on the surface of the virus particles.

Other Hepatitis Viruses There are other hepatitis viruses that are not transmitted by the fecal–oral route. Hence, they are not considered to be associated with foodborne transmission. The commonest, hepatitis B and hepatitis C, are usually transmitted parenterally, e.g., by blood transfusions, from injections of contaminated blood products such as factor VIII, or from contaminated needles used by drug addicts. They may also be transmitted by sexual contact.

Other Viruses

Enteroviruses

Enteroviruses form a distinct genus within the Picornaviridae family and include the polioviruses, echoviruses, and Coxsackie viruses. Most infections are asymptomatic, but enteroviruses can cause a variety of symptoms, including paralysis, meningitis, cardiomyopathy, and less severe conditions such as colds and fever. Most enteroviruses grow readily in cell cultures of human and primate origin. An outbreak of poliomyelitis associated with raw milk in 1914 is believed to be the first recorded foodborne outbreak of viral illness. Raw milk was implicated in a further 10 outbreaks in the UK and USA by 1949. Milkborne outbreaks of poliomyelitis then appeared to cease in developed countries, even before the introduction of polio vaccine. This could largely be attributed to the widespread use of pasteurization. Various enteroviruses have been isolated from foods such as meat and shellfish, but there is no clear epidemiological evidence to suggest that foodborne infection is occurring.

Tick-borne Encephalitis

A further mode of foodborne transmission of viruses is by zoonotic infection. Cases of tick-borne encephalitis arising from consumption of raw milk from infected goats, sheep, and cattle or products made from unpasteurized milk have occurred in Eastern Europe. The incidence is fortunately rare, owing to the limited distribution of the appropriate species of ticks.

Entry of Viruses to the Food Chain

Foods may become contaminated with viruses in two main ways. Food may be contaminated at source, usually by coming into contact with sewage-polluted water: this is known as primary contamination. Additionally, food may be contaminated during preparation and serving by infected food handlers, in just the same way as some types of foodborne bacterial contamination can arise. This is known as secondary contamination.

Contamination at Source

Shellfish The most clearly implicated foods in the transmission of viruses are bivalve molluscs (oysters, clams, cockles, and mussels). Indeed, most illness associated with this type of shellfish is viral. These shellfish are harvested from shallow estuarine and coastal waters, which are frequently polluted with sewage. They feed by filtering particulate matter from the large volumes of water passing over their gills, and this can include potentially pathogenic microorganisms. Although human viruses do not replicate in shellfish, they can be concentrated within molluscs to higher concentrations than occur within the surrounding water up to 100-fold. Bivalve molluscs are not usually thoroughly cooked before being eaten, and oysters are frequently consumed raw.

Fruit and Vegetables There is the potential for fruits, vegetables, and salad items to become contaminated during irrigation with polluted water and by fertilization with untreated or inadequately treated sewage sludge. Many vegetables are cooked before

consumption, and there is no evidence that if such food is primarily contaminated, illness ensues. However uncooked soft fruits such as strawberries and raspberries have been implicated in a number of outbreaks when contamination is assumed to have occurred at the growing site. Salad items are commonly implicated in outbreaks, although in many of these incidents, contamination is believed to have originated from infected food handlers at the time of preparation.

Secondary Contamination: Food Handlers

Viruses causing gastroenteritis and hepatitis A are infectious in very low doses, and thus are spread very readily from infected persons. It is now recognized that outbreaks arising from infected food handlers are common occurrences. The foods that pose the greatest risk to the consumer are cold items, such as sandwiches and salads, that require much handling during preparation. Without meticulous attention to personal hygiene and thorough and frequent hand washing, fecally contaminated fingers can contaminate foods and work surfaces. Viral gastroenteritis can be very sudden in onset and commence with projectile vomiting. The virus can be disseminated over a wide area in aerosol droplets so that, in food preparation areas, exposed foods, working surfaces, and door handles are likely to be contaminated.

Virus Survival

Gastroenteritis viruses and hepatitis viruses are robust viruses and survive extremely well in the environment. It is the NLVs and HAV that are the most resistant to inactivation. There is little precise information on the stability of NLVs, since they cannot be cultured in the laboratory. Most information on survival and inactivation has come from epidemiological observations in outbreaks and limited studies of infectivity in volunteers. Some strains of HAV and rotavirus can be cultured, and there have been a small number of experimental studies on their stability. Gastroenteritis and hepatitis viruses have been detected in food, water, and other environmental samples by PCR assays, but such assays only detect the viral genome and do not necessarily correlate with infectivity.

Viruses that infect via the gastrointestinal tract are acid-stable. Both NLVs and HAV retain infectivity after exposure to acidity levels below pH 3. Hence, they are often able to survive the food-processing and preservation conditions used to inhibit bacterial and fungal spoilage of foods, such as pickling in vinegar and fermentation processes to produce foods such as yogurt. Alcohol and high sugar concentrations are unlikely to have any adverse effect on survival. Refrigeration and freezing are routinely used to preserve viruses and have no effect on viability. Frozen foods that are not subsequently cooked, such as soft fruits, have been implicated in a number of incidents of both viral gastroenteritis and hepatitis A.

The viruses are destroyed by normal cooking processes. For foods that only undergo partial cooking in special heat processes, such as the treatment of shellfish and other pasteurization procedures, care must be taken to ensure that inactivation of virus is achieved. Both NLVs and HAV retain infectivity after heating to 60 °C for 30 min.

Gastroenteritis viruses and hepatitis viruses appear to survive in the environment for long periods. They survive on inanimate surfaces, on hands and in dried fecal suspensions. Lingering outbreaks have occurred in hospitals, residential homes and on cruise ships, probably as a result of environmental contamination. NLVs have been detected by PCR in swabs from hospital lockers and hotel carpets supposedly cleaned after incidents of vomiting.

There is conflicting evidence on the efficacy of disinfectants. Chlorine-based disinfectants are usually considered the most effective against enteric viruses and the most suitable in food preparation areas. However, NLVs and HAV are resistant to a level of 0.5–1 mg per liter of free residual chlorine, which is consistent with that present in drinking water. NLVs are inactivated by 10 mg per liter of chlorine. In the USA, a level of 5 mg per liter of chlorine with a contact time of 1 min is recommended for inactivation of HAV. Infectivity of HAV is reduced by sodium hypochlorite, 2% glutaraldehyde, and quarternary ammonium compounds, but there are no comparative data for NLVs.

Virus Detection

In Food

It is not feasible to examine food samples routinely for the presence of viruses. Although it has been possible to culture HAV since 1980, primary isolation is a lengthy and unreliable procedure, and there have been very few isolations of virus from food or water samples. Virus was isolated from a drinking water supply responsible for a large outbreak in the USA, but this involved culture of highly concentrated water samples for up to 21 weeks. There have been several studies involving recovery of virus from artificially contaminated foods, particularly shellfish, but these have used highly adapted laboratory strains of virus. Viruses stick avidly to shellfish meat, and complex extraction techniques are required. Even with the best

of these methods, virus recovery rates are poor. NLVs cannot be cultured in the laboratory. Culture of rotaviruses and astroviruses is complex and unreliable, and the problems of avidity similarly apply. Rapid solid-phase immunoassays are available for the detection of hepatitis and gastroenteritis viruses. These are not sufficiently sensitive, however, to detect the very small numbers of virus particles likely to be present in contaminated foods. Similarly, electron microscopy is insufficiently sensitive for the detection of virus in food samples.

There is considerable interest in the application of PCR assays to the detection of viruses in food and water samples. PCR is an extremely sensitive technique. However, extraction of viral RNA from samples and removal of PCR inhibitors is a fairly complex and time-consuming procedure. Hence, such assays cannot be used for routinely screening food samples. Furthermore, unlike culture, a positive PCR result only indicates the presence of viral nucleic acid and does not necessarily confirm the presence of viable infectious virus. These tests do have an important role in the epidemiological investigation of outbreaks and assessing the efficacy of treatment procedures.

In Patients

HAV is excreted in feces, but it is not usually appropriate to examine fecal specimens for virus as the main excretion period precedes illness. The usual diagnostic test is detection of anti-HAV specific immunoglobulin M (IgM) antibody in serum, for which there are a number of commercially available solid-phase immunoassays. The presence of IgM antibody is indicative of recent infection. If the fecal specimens are collected at the appropriate time, it is quite feasible to detect viral antigen by various techniques, the most rapid and straightforward being the solid-phase immunoassays and PCR tests.

All the gastroenteritis viruses were discovered by electron microscopy, and this has continued to play an important role in diagnosis. Viruses from different groups look different, and it is this characteristic morphology that is the basis for their identification. However, electron microscopy is a time-consuming technique that demands considerable skill and experience on the part of the operator, and it is not a technique that lends itself to examining large numbers of specimens. PCR assays are being used increasingly for the detection of NLVs, but their use is mainly confined to specialist virology laboratories. Although of far greater sensitivity than electron microscopy, current primers will not detect all strains of NLVs. Recombinant capsid antigens have been made from a small number of NLV strains and have been used to develop ELISA tests. So far, only a very few NLV types can be detected, and the tests are not yet widely available. Commercial ELISA and latex agglutination test kits are readily available for the detection of rotaviruses. Astroviruses are usually detected by electron microscopy. Some laboratories use in-house PCR assays or culture combined with immunofluorescence.

Prevention and Control

Elimination of viral contamination at source is an ideal that is unlikely to be attained in the near future. In practice, it would be necessary to prevent the discharge of sewage into rivers and coastal waters, which not only pollutes water supplies that may be used for irrigation but also results in the contamination of shellfish. Sewage sludge provides beneficial nutrients and is applied to agricultural land as fertilizer. In developed countries, increasingly stringent regulations for the use of untreated or partially treated sewage are being introduced. Since the end of 1999, application of all untreated sewage sludge on agricultural land has been prohibited in the UK. Where treated sewage is applied to land for growing salad and vegetable crops, permitted time intervals, between applying the sewage and harvesting the crops, are specified. Hepatitis A is endemic in underdeveloped areas of the world and viral gastroenteritis more prevalent. Viruses commonly occur in polluted coastal waters in these areas, and contamination of shellfish is likely. Standards for the use of sewage in agriculture are also less satisfactory. Imports of fruits, salads, vegetables and shellfish could potentially pose a risk to consumers.

It is usual practice to treat shellfish in some way to remove microbial contamination before they are sold to the public. In the European Union, conditions for bivalve molluscs are laid down in the European Council Directive on Shellfish Hygiene (91/492/ECC), and there are similar regulations in the USA. Shellfish, such as oysters and mussels, may be cleansed, either by relaying in cleaner coastal or estuarine waters or by transfer to land-based depuration facilities. Harmful microorganisms should be washed out during the natural feeding process. These procedures are remarkably successful in removing bacterial contamination but do not completely eliminate viruses. These may remain for several weeks in molluscs held in depuration tanks. Even though molluscs may appear entirely satisfactory in bacteriological tests, incidents of viral illness may follow their consumption.

Up to the middle of the 1980s, many outbreaks of viral illness were recorded, related to the

consumption of inadequately cooked shellfish such as cockles. Prolonged cooking results in a tough unpalatable product, and thus the aim of treatment must be to apply the minimum heat necessary to render shellfish safe. Studies on the inactivation of hepatitis A virus in shellfish led to recommendations that the internal temperature of shellfish meat should be raised to 90 °C and maintained for 1.5 min. These recommendations were adopted by the UK shellfish industry and subsequently accepted as a valid method of treatment by the European Commission. Later studies, using feline calicivirus as a model, indicated that these conditions were also adequate for inactivation of the NLVs. Epidemiological evidence strongly supports the view that this treatment is effective for the inactivation of gastroenteritis viruses. Since early 1988, there have been no further reports in England and Wales of any viral illness, either hepatitis A or gastroenteritis, from shellfish heat-treated according to the recommendations.

Foods may be contaminated during preparation and serving by infected food handlers. Both the gastroenteritis viruses and hepatitis A virus are extremely infectious in low doses and thus are spread easily from infected persons. Persons with symptoms should be excluded from handling food. However, food handlers with very minimal symptoms have been implicated in the transmission of NLVs. There is a little circumstantial evidence that asymptomatic excretion of virus occurs, but in the absence of more definitive data, it is generally recommended that people should be allowed to resume work 48 h after symptoms have ceased. That recommendation was based on the rapid decline in virus shedding observed by electron microscopy and in practice appears to work satisfactorily. However, NLVs often can be detected by PCR for a longer period than by electron microscopy and, in some instances, for up to a week after the onset of symptoms. It is not clear if persons shedding virus detectable by PCR are infectious after symptoms have ceased. Recommendations on how long to exclude people from work need to be kept under review.

Excretion of hepatitis A virus precedes symptoms, and hence, early exclusion of infectious food handlers is not usually possible. An effective vaccine is available. Currently, in the UK, hepatitis A vaccine is used selectively for persons at high risk, such as travelers. It is not generally used for food handlers except in outbreak situations. If exposure is known to have occurred, the use of normal human immunoglobulin might be considered in persons at risk of developing illness.

In the kitchen, prevention of transmission of viruses through foods largely depends on rigorous application of normal good hygiene practices, including frequent hand washing and thorough washing of fruit and vegetables. Shellfish must be regarded as a potential source of infection, and uncooked shellfish should be kept separate from other food items that are not to be cooked. If vomiting occurs, virus may be spread over a wide area. Uncovered food should be discarded. Even food that is to be cooked is a potential source of cross-contamination. Work surfaces, door handles, and toilet areas should be cleaned thoroughly. Chlorine-based disinfectants are considered the most effective. Handling of food should be kept to a minimum. Wearing gloves may prevent fecally contaminated fingers coming into contact with food but will not prevent transfer of organisms from contaminated work surfaces.

Vitamin B_6: Properties and Analysis

Vitamin B_6 is a B-complex vitamin. Vitamin B_6 is the generic descriptor for all 3-hydroxy-2-methylpyridine derivatives possessing the biological activity of pyridoxine.

Gyürgy, in 1934, identified vitamin B_6 as a curative factor for a characteristic dermatatis in the laboratory rat. The first naturally occurring form of the vitamin was isolated in 1938; its structure was confirmed by chemical synthesis as 3-hydroxy-4,5-bis(hydroxymethyl)-2-methylpyridine in 1939. 'Pyridoxine' was the trivial name of this compound, and 'pyridoxine' and 'vitamin B_6' were synonyms. Other compounds having vitamin B_6 activity were detected and isolated. In the 1960 IUPAC Definitive Rules for the Nomenclature of Vitamins, 'pyridoxine' was recommended as the generic descriptor of the B_6 vitamers and 'pyridoxol' as the trivial name of the alcohol form of the vitamin. In the 1966 IUPAC-IUB Tentative Rules, the suggestion was made that 'pyridoxol' should be designated as 'pyridoxine.' In 1968, the IUPAC-IUB Commission on Biochemical Nomenclature decided to publish a special document regarding vitamin B_6 nomenclature, which clearly stated that 'pyridoxine should not be used as a generic name synonymous with vitamin B_6'; this document, published in 1973, also designated the composition of the six forms of the vitamin and oxidized metabolites, 4-pyridoxic acid and 4-pyridoxolactone. However, confusion still exists in the literature regarding usage of the term 'pyridoxine.'

	R_1	R_2
PN	CH_2OH	H
PL	CHO	H
PM	CH_2NH_2	H
4-PA	COOH	H
PNP		PO_3^-

*When $-CH_2O{\cdot}PO_3^=$, then is PNP, PLP, or PMP.

Figure 1 Stuctural formulae of vitamin B_6 compounds.

The chemical structures of the vitamin B_6 compounds and the accepted ring numbering system are shown in Figure 1. The vitamin B_6 congeners are pyridoxine (PN), pyridoxal (PL), and pyridoxamine (PM) – alcohol, aldehyde, or amine groups are at the #4 position of the pyridine ring. Each of these three forms also has a corresponding 5′-phosphate (P), i.e., pyridoxine 5′-phosphate (PNP), pyridoxal 5′-phosphate (PLP), and pyridoxamine 5′-phosphate (PMP). The various forms of the vitamin are biochemically interconvertible, as shown in Figure 2. They can also be chemically interconverted. The major excretory form of the vitamin is 4-pyridoxic acid (4-PA), which is eliminated in the urine.

Physical and Chemical Properties

In general, the various vitamin B_6 compounds are white crystals that are very soluble in water, slightly soluble in alcohol, and often insoluble in ether. They melt, usually with decomposition. Aqueous solutions of the various vitamin B_6 compounds are relatively sensitive to light and often are destroyed by heating. The light sensitivity of the vitamers is affected by pH. The nonphosphorylated vitamers are relatively stable to heat at an acidic pH but not at an alkaline pH. According to Ang, stability values of PN·HCl, PL·HCl, and PM·2HCl at pH 4.5 to white light for 8 h are 97, 97, and 81%, respectively, which decreases with increasing pH. For example PN·HCl stability is 88% pH 7; at PL·HCl, 81% at pH 6; and PM·2HCl, 74% at pH 8. Overall, PN is the most stable, followed by PL and then PM. Greater

decomposition of the vitamin B_6 compounds is observed with ultraviolet and near-ultraviolet radiation. Researchers working with this nutrient generally perform their analyses in darkened laboratories (red or yellow lights may be used); in addition, media containing the vitamin are kept at temperatures of 5 °C or less.

The physical properties of the vitamin B_6 compounds are summarized in Table 1. The ultraviolet absorption spectra of these compounds are dependent upon the pH because of changes to the electronic structure. The pyridine ring of the vitamin B_6 compounds is zwitterionic at neutral pH with ionized phenolate and pyridinium groups. The physical properties of the B_6 compounds are useful with regard to detection and quantitation of the vitamin.

As mentioned previously, the various forms of vitamin B_6 are interconvertible. The various B_6 vitamers

can change from one form to another during food processing and food preparation, and in the body.

Occurrence and Forms in Foods

Information regarding the vitamin B_6 content of foods has been obtained primarily via microbiological assay, although some values are available which were obtained by high-performance liquid chromatography (HPLC) methodologies, which can differentiate between the vitamers. In the microbiological assay techniques, acid (generally hydrochloric acid) is used in extracting the vitamin from the food; the acid hydrolyzes phosphates. Hence, vitamer values obtained using microbiological methods represent the sum of the phosphorylated and nonphosphorylated forms of the vitamin. Frequently, total vitamin B_6 concentration values are obtained rather than values for the individual vitamers.

Food composition values are available for the three forms of the vitamin (PL + PLP, PN + PNP, and PM + PMP) in various foods. These can be found in the USDA's publication *Pantothenic Acid. Vitamin B_6 and Vitamin B_{12} in Foods*. In some reports, the individual phosphate and free-base forms are also available.

A high proportion of the B_6 vitamers in plant-derived foods is glycosylated PN, primarily as 5′-β-D-glucoside. PL, primarily as the phosphorylated form, is generally the predominant B_6 vitamer in animal-derived foods. Different foods vary somewhat as to which form of the vitamin is predominant.

Vitamin B_6 found in unprocessed foods is mainly bound to proteins. Table 2 gives the vitamin B_6 content of selected foods. This information can be obtained by accessing the USDA food composition website or from a variety of printed formats such as McCance and Widdowson. Meats, whole-grain products, and nuts are good sources of vitamin B_6. Cultured cheeses and other fermented products are also good sources of the vitamin. Fruits and vegetables are generally rather poor sources. PN, PM, and PL have been reported to have equal potencies in the rat. In humans, dietary PM and PL are about 10% less effective than PN, as indicated by effects on plasma PLP and urinary 4-PA levels according to a previous report. In the human body, the nonphosphorylated forms of vitamin B_6 can be converted to their respective phosphorylated forms and vice versa by pyridoxal kinase and pyridoxamine (pyridoxine) phosphate oxidase (see Figure 2). Recently, these kinase and oxidase enzymes have been identified as potential targets for pharmacologic agents.

Glycosylated vitamin B_6 is found in all plant-type foods. The glycosylated vitamin B_6 contents of selected foods can be found in various publications. Gregory indicated that a mixed diet contains about 15% of glycosylated vitamin B_6, which is about 50% as available as the other B_6 vitamers. This is often excluded from food composition data. Bioavailability is of importance in that it reflects the quantity of a consumed nutrient that becomes available to the cells of the body.

Effects of Food Processing and Preparation Methods upon Vitamin B_6 Content of Foods

Vitamin B_6 is one of the more labile nutrients. The vitamin is stable to dry heat; its stability in moist heat is largely dependent upon the pH of the media, being relatively stable to heat in an acidic media but not in alkaline media. The vitamin is unstable to light, both visible and ultraviolet. The vitamin undergoes rapid destruction or loss during cooking procedures.

Food processing and subsequent storage may also have an effect upon the vitamin B_6 content of various foods. The retention of the vitamin is quite high following the processing of dry foods. Thirty to 50% of the vitamin B_6 present in whole milk and infant formulas is retained following liquid processing including sterilization treatments, whereas the spray drying of these products results in minor loss. Storage of canned dairy products shows no degradation over 2–3 years. The same is true with regard to commercial canning and irradiation of boned chicken, although the retention is better for the irradiated than the canned product. Heat processing by retorting results in vitamin B_6 losses in several products. The stability of the vitamin in dehydrated foods is affected by moisture content, water activity, and storage conditions. Food-processing techniques generally result in losses of 0–50% of the vitamin.

Vitamin B_6 aldehydes can bind to food proteins as ε-pyridoxyllysine complexes during thermal processing and low-moisture storage. Gregory has shown that the protein-bound ε-pyridoxyllysine has antivitamin B_6 effects in rats. This pyridoxyllysine complex may also affect vitamin B_6 availability to humans, particularly with regard to the vitamin in unfortified infant formulas.

Much of the vitamin loss is due to cooking and holding practices of consumers and food service personnel. The retention of the vitamin in oven-braised beef rounds prepared in food service establishments has been reported to range from 45 to 62%; values for green beans are slightly higher, whereas those for baking potatoes prepared in the skins are around 80%. The vitamin B_6 content of meats and vegetables has been shown to decrease following various

Table 2 Vitamin B_6 content of selected foods

Food	Edible portion (mg per 100 g)	Food	Edible portion (mg per 100 g)

Data from US Department of Agriculture, Agricultural Research Service (1999) *USDA Nutrient Database for Standard Reference, Release 13*.

household cooking procedures, even when foods were cooked according to standard recipes or manufacturer's instructions. The retention of vitamin B_6 in selected vegetables has been found to be highest for those steamed in plastic bags, followed by those boiled in plastic bags, those steamed, and lastly, for those boiled. Boiling results in degradation and leaching but the retention of the vitamin in vegetables following microwave steaming or regular microwave cooking techniques is around 90%. It has been found that more vitamin B_6 is retained when beef and pork strips are cooked by stir-frying ($\sim$67%) than

by microwaving (~60%) or by broiling (~58%). More vitamin B_6 is retained when pork roasts are cooked to an internal temperature of 71 °C (62%) than 82 °C (54%) and this retention is greatest when pork is cooked in a bag than roasted or braised. Vitamin B_6 retention has been found to be similar (68%) in bison patties cooked by grilling and by broiling. In summary, loss of some vitamin B_6 is inevitable during all household/food service preparation, to a greater or lesser extent.

Fortification of Foods with Vitamin B_6

PN·HCl is listed on the generally recognized as safe (GRAS) list of the US Food and Drug Administration and is used in the fortification of foods, particularly various cereal and dairy products. This form of the vitamin is also used in dietary supplements and pharmaceutical products. PN·HCl is resistant to destruction by heat as well as by other factors but should be protected from light and moisture. Pharmaceutical products containing this vitamin have been reported to have less than 10% loss in vitamin activity after storage at room temperature for 1 year.

Methods of Analysis

There are two basic stages in procedural methods dealing with quantitation of vitamin B_6 components – preparative or extraction techniques and determinative methods. Several excellent reviews have been published on methods of vitamin B_6 analysis including chromatographic techniques. Many methods have been utilized in quantitating the vitamin B_6 components in foods. These include animal and microbiological growth, enzymatic, fluorometric, immunologic, gas chromatographic (GC), and HPLC assays.

Extraction Techniques

The major problem encountered in quantitating vitamin B_6 in plant or animal products is extraction. Vitamin B_6 compounds must be extracted from food products before being analyzed by microbiological, chromatographic, and other methods. Vitamin B_6 frequently occurs in biological materials in association with proteins. The most common bond for PLP is the Schiff base linkage with the ε-amino group of lysine. The Schiff base linkage is easily hydrolyzed by deproteinizating agents.

Great care must be taken during sample handling and extraction and with relation to the stability of the different vitamers as well as their interconversions. The samples must be homogenous and representative of the bulk product.

Conventional methods for extracting vitamin B_6 compounds from foods entail the use of high temperature and acidic media to denature the protein and disrupt the sample matrix. The phosphate esters of PNP, PLP, and PMP are hydrolyzed by autoclaving in acidic media. The microorganisms used in microbiological assays lack response to the phosphates. Efficient extraction of vitamin B_6 compounds is obtained using a sample size containing 2–4 μg of the vitamin and hydrolyzing in 180 ml of 0.055 N H_2SO_4 for 1 h at 128 °C (20 psi, 138 kPa); 0.44 N sulfuric acid under the same conditions is essential for all plant products. Thermal extractions of pH 1.7–1.8 have been found to be optimally effective for most samples; this pH range corresponds closely to the 0.055 N sulfuric acid, which was recommended earlier. Hydrochloric acid is also used in thermal extractions of the vitamin. Complete hydrolysis of PLP is achieved after autoclaving the sample in 0.055 N hydrochloric acid at 121 °C (15 psi, 103 kPa) for 1 h; however, 5 h are required for extraction of the vitamin from dried yeast and liver powder. Complete hydrolysis of PMP requires 3 h at 125 °C in 0.055 N hydrochloric acid, whereas PLP is hydrolyzed completely in 30 min. The B_6 vitamers in rice bran are best hydrolyzed using 2 N hydrochloric acid. The AOAC method of thermal hydrolysis for B_6 vitamers is as follows: use 1–2 g of dry product; add 200 ml of 0.44 N hydrochloric acid for plant products followed by autoclaving at 121 °C for 2 h and for animal products, add 200 ml of 0.055 N hydrochloric acid, and autoclave at 121 °C for 5 h; after the solution has cooled to room temperature, adjust the pH to 4.5 with 6 N or saturated potassium hydroxide; then dilute to 250 ml with water and filter, using Whatman No. 40 paper. Complete release of both protein-bound and phosphorylated forms of the vitamin is essential for quantitative assay using microorganisms.

Perchloric acid, trichloroacetic acid, and sulfosalicylic acid may be used as deproteinating agents. These acids are particularly useful when one desires to quantitate phosphorylated, nonphosphorylated, and glycosylated forms of the vitamin individually, as use of these agents does not result in dephosphorylation or deconjugation. If so desired, trichloroacetic acid may be removed from the extract by extraction with diethyl ether or freon amine. Perchloric acid can also be removed from the extract by precipitation with potassium hydroxide; and sulfosalicylic acid can be removed via ion-exchange chromatographic techniques. Metaphosphoric acid has been used in extraction of the vitamin from brain tissue. This acid does not need removal from the extract prior to many of the HPLC techniques for vitamin B_6 assay.

Extraction procedures must solubilize the vitamers for subsequent quantitation. The effectiveness of the extraction procedures may be determined by evaluation of recoveries of B_6 vitamers added during sample homogenization or, even better, by incorporation of radiolabeled forms of the vitamin into the sample, called intrinsic labeling.

Animal Growth Assays

Bioassays are based on the growth response of animals, usually rats or chicks, to purified diets containing graded levels of a standard vitamin to the sample being tested. An advantage of the method is that the vitamin in the sample does not have to be extracted. Animal assays are not used very frequently because of their lack of specificity as well as their expense and time requirement. The intestinal microflora of these animals may affect the data; efforts to prevent coprophagy or the use of antibiotics are not completely effective.

Microbiological Assays

The vitamin B_6 composition of plant and animal products is generally determined using microbiological assays. These assays are tedious, and none are without problems. The most widely used microbiological assay is a growth assay using the yeast *Saccharomyces uvarum* (ATCC 9080; formerly *S. carlsbergenesis*). Growth is measured via turbidity using a spectrophotometer. Unfortunately, the response of many cultures of the yeast to PM is frequently 60–80% of that to PN and PL. It is advisable to evaluate the magnitude of the response differences under the conditions of each assay. PL, PN, and PM can be separated by subjecting the acid extractant to cation-exchange chromatography on Dowex AG 50W-X8 resin using KOAc solutions of three different pHs; each form of the vitamin is then analyzed, utilizing its respective calibration curve. Care must be taken to assure proper separation of the vitamers and avoid cross-contamination of the three fractions.

The yeast *Kloeckera brevis* (ATCC 9774; formerly *K. apiculata*) may be used in quantitating total vitamin B_6. Some researchers indicate that *K. brevis* has an equal growth response to PL, PN, and PM, whereas others indicate that it has an even lower relative response to PM than *S. uvarum*. The *K. brevis* assay has been adapted to radiometric quantitation.

The total, as well as the three nonphosphorylated vitamers, may also be determined by a differential microbiological technique. *S. uvarum* responds to PL, PN, and PM, whereas *Streptococcus faecalis* R (ATCC 8043) responds to PL and PM, and *Lactobacillus casei* (ATCC 7469) responds to only PL. *Tetrahymena pyriformis*, a protozoan, has also been used as an assay organism.

Saccharomyces uvarum is the microorganism used in the AOAC method. The concentrations of the three nonphosphorylated B_6 vitamers are quantitated in this method.

Assays for glycosylated vitamin B_6 compounds in foods have been developed utilizing *S. uvarum* and differential hydrolytic procedures. This method does have a tendency to underestimate the quantity of the glycosylated vitamin in raw plant foods having *p*-glycosidase activity.

Values given in food composition tables have been derived primarily using *S. uvarum* as the test organism. These tables generally list total vitamin B_6 concentrations but may list PL, PN, and PM concentrations. The Center for Nutrient Analysis of the US Food and Drug Administration uses *S. uvarum* for quantitating vitamin B_6 in foods. Data obtained microbiologically using *S. uvarum* do not always agree with those obtained by animal growth assays.

Enzymatic Assays

Several enzymatic methods are available that quantitate PLP, the main circulating form of vitamin B_6. These methods are frequently utilized as parameters for the assessment of vitamin B_6 status of animals, including humans but are not utilized in the analysis of food samples. The enzymatic methods that have been more commonly used include the following: the cleavage of tryptophan using apotryptophanase (EC 4.1.99.1), the measurement of aspartate aminotransferase (EC 2.6.1.1; formerly referred to as glutamic-oxaloacetic transaminase), and alanine aminotransferase (EC 2.6.1.2; formerly referred to as glutamic-pyruvic transaminase) activities, and the radiomonitored decarboxylation of [^{14}C]tyrosine using the apoenzyme of tyrosine decarboxylase (EC 4.1.1.25). Currently, the most acceptable enzymatic method of quantitating PLP is the tyrosine apodecarboxylase technique.

Fluorometric Assays

Direct fluorometric analysis of vitamin B_6 in extracts of plant and animal products is generally unsatisfactory. This is due to the presence of many potentially interfering compounds that fluoresce, as well as the varying spectral characteristics of the B_6 vitamers. As a result, the total vitamin B_6 content of selected foods is higher when measured by fluorometry following open-column chromatography than published values based on microbiological assay.

Immunologic Assays

Antibodies specific for (phospho)pyridoxyl groups have been utilized in immunoassays for certain B_6 vitamers. However, there is a marked variation in the affinity of the antibodies for the B_6 vitamers, so these methods are not widely used.

Gas Chromatographic Assays

Unless B_6 vitamers are nonphosphorylated and their polar functional groups derivatized, these compounds are not well suited for GC analysis. Nonvolatile components and water are not easily removed from sample extracts. Methods involving the formation of acetyl, isopropylidene, trimethylsilyl, trifluoroacetyl, and heptafluorobutyryl derivatives of the nonphosphorylated B_6 vitamers have been developed, but other chromatographic methods are preferred.

HPLC Assays

The physiochemical properties of the B_6 vitamers facilitate their assay by HPLC assay. HPLC has the potential for high resolution and high sensitivity with regard to the B_6 vitamers found in biological materials, without the necessity of complex extraction and derivatization techniques. If desired, the phosphate esters of the phosphorylated B_6 vitamers can be hydrolyzed using phosphatase yielding nonphosphorylated vitamers. Otherwise, the phosphorylated vitamers can be preserved during extraction and quantitated as such. All six B_6 vitamers and 4-PA can be quantitated at nanogram levels using HPLC techniques. Alternatively, all forms of the vitamer can also be converted to PN, followed by HPLC quantitation of total vitamin B_6 as PN techniques. This method is rapidly becoming the preferred way of determining total vitamin B_6. Ion-exchange (anion or cation) and reversed-phase (with or without paired-ion) HPLC methods for assay of B_6 vitamers have been published. Most of the methods utilize fluorescence detectors, although some methods, particularly the earlier methods, do utilize ultraviolet (UV) detectors; the fluorescence detector is far more sensitive and specific. The use of an internal standard, most frequently 4-deoxypyridoxine, increases the accuracy and precision of HPLC analysis of B_6 vitamers, providing that it is not naturally present in the samples. External standards (spiking) are also utilized in proving identities of the peaks. The identities of the peaks should be confirmed by other means such as mass spectrometry and fluorescence spectra.

Ion-exchange chromatography is accomplished using packing material that possesses charge-bearing functional groups. Many of the HPLC separations reported in the 1970s were cation- or anion-exchange methodologies, which generally involved determinations of nonphosphorylated B_6 vitamers in acid hydrolysates. An HPLC method has been developed for the separation of all of the B_6 vitamers using Aminex A-25 anion-exchange resin, isocratic elution, and a pH 10 glycine buffer. This anionic method was successfully applied to the determination of vitamin B_6 components in milk, animal tissues, meats, and fortified cereals. Unfortunately, the manufacturer altered the composition of the resin in such a manner that the method no longer provided satisfactory separation of the vitamers. Also, a cation-exchange HPLC method, fluorometric detection, has been developed, which successfully quantitated all B_6 vitamers in plasma and other animal tissues.

Reversed-phase chromatography is the term given to chromatographic conditions in which a nonpolar stationary phase is used in conjunction with a polar mobile phase. Gregory and Kirk were the first to separate nonphosphorylated B_6 vitamers using reversed-phase HPLC methods, with fluorescence detection, which successfully measured PN in fortified cereals.

Paired-ion (also called ion-pair) chromatography was developed to deal with separating compounds that are either very polar, multiply ionized, or strongly basic. Several paired-ion, reversed-phase HPLC methods, both gradient and isocratic, have been developed for determining vitamin B_6 components in biological materials and foods. These methods have also been utilized successfully in quantitating the six B_6 vitamers and 4-PA in plasma. This type of methodology may also be utilized in quantitating glycosylated and other forms of the vitamin.

Several researchers have reported comparable results when specific foods were analyzed for total vitamin B_6 vitamer content using microbiological (*S. uvarum*) and HPLC techniques. Most researchers in the vitamin B_6 area believe that HPLC is the preferred method for determining the vitamin B_6 content of food because individual vitamers can be determined. However, as indicated earlier, vitamin B_6 content data for food composition tables are obtained primarily using microbiological (*S. uvarum*) methods. As discussed earlier, the potencies of the B_6 vitamers in the human body appear to be rather similar, so one questions the importance of routinely determining each of the six B_6 vitamers in foods. However it does have academic interest and is of clinical significance where drugs or diseases/conditions influence the metabolism of the B_6 vitamers. Information as to the form of the vitamin in food may be of importance therapeutically.

Summary

The quantitation of vitamin B_6 components in biological materials is difficult. The vitamin must be extracted, generally using acidic media, from plant and animal products before being analyzed by one of the many chemical, biochemical or biological methods. The official AOAC method for determination of the vitamin B_6 content of foods involves the use of the microorganism *Saccharomyces uvarum*. Although researchers have developed HPLC methods that quantitate all six forms of the vitamin, these methods are rarely utilized in determining the vitamin B_6 content of food. Little difference appears to exist in bioavailability of the different B_6 vitamers in humans so total vitamin B_6 composition is determined by conversion to pyridoxine. Researchers are continuing to seek improved methodologies for the analysis of vitamin B_6 involving use of the latest technology such as mass spectrometry. Additional research is also needed to determine the importance of specific forms of the vitamin in humans.

Physiology

D A Bender, University College London, London, UK

Introduction

Vitamin B_6 has a central role in amino acid metabolism, as the coenzyme for a variety of reactions, including transamination and decarboxylation. It is also the coenzyme of glycogen phosphorylase, and acts to modulate the activity of steroid and other hormones (including retinoids and vitamin D) which act by regulation of gene expression.

Dietary Forms, Biological Availability, and Metabolism

The main form of vitamin B_6 in foods is pyridoxal phosphate, bound to enzymes. There is also a small amount of pyridoxamine phosphate. In plant foods a significant amount of the vitamin is present as pyridoxine.

A number of plants contain relatively large amounts of pyridoxine glycosides, which are not biologically available, since they are not substrates for mammalian glycosidases. They are absorbed (passively) from the intestinal lumen and are excreted more or less quantitatively in the urine. Between 5% and 50% of the total vitamin B_6 in some foods may be present as pyridoxine glycosides.

A proportion of the vitamin B_6 in foods may be biologically unavailable, especially after heating, as a result of the formation of (phospho)pyridoxyllysine by reduction of the aldimine (Schiff base), by which pyridoxal phosphate is bound to the ε-amino groups of lysine residues in proteins. While some of this pyridoxyllysine may be useable, since it is a substrate for pyridoxine phosphate oxidase, it is also a vitamin B_6 antimetabolite, and even at relatively low concentrations can accelerate the development of deficiency in experimental animals maintained on deficient diets. In the 1950s there was an outbreak of vitamin B_6 deficiency among infants fed on formula that had been overheated in manufacture, resulting in the formation of relatively large amounts of pyridoxyllysine.

Digestion and Absorption

Pyridoxal phosphate bound as a Schiff base to lysine in dietary proteins is released on digestion of the protein. The phosphorylated vitamers are dephosphorylated by membrane-bound alkaline phosphatase in the intestinal mucosa; pyridoxal, pyridoxamine, and pyridoxine are all absorbed rapidly by passive diffusion. Intestinal mucosal cells have pyridoxine kinase, and pyridoxine phosphate oxidase so that there is net accumulation by metabolic trapping. Much of the ingested pyridoxine is released into the portal circulation as pyridoxal, after dephosphorylation at the serosal surface.

Metabolism and Transport

Most of the absorbed vitamin is taken up by the liver, although other tissues can also take up the unphosphorylated vitamers from the circulation. Uptake is by carrier-mediated diffusion, followed by metabolic trapping as phosphate esters. Pyridoxine and pyridoxamine phosphates are oxidized to pyridoxal phosphate. All tissues have pyridoxine kinase activity, but pyridoxine phosphate oxidase is only found in liver, kidney, and brain (**Figure 1**).

Pyridoxine phosphate oxidase is a flavoprotein, and its activity falls markedly in riboflavin deficiency. Despite this central role of riboflavin in vitamin B_6 metabolism, blood and tissue concentrations of pyridoxal phosphate are not affected by riboflavin deficiency, and riboflavin nutrition appears to have no effect on vitamin B_6 nutritional status.

Pyridoxine phosphate oxidase is inhibited by its product, pyridoxal phosphate. This is not simple product inhibition, but involves binding at a specific inhibitor site on the enzyme. The normal intracellular concentration of free pyridoxal phosphate gives significant inhibition, which indicates that this is a physiologically important mechanism in the control of tissue pyridoxal phosphate.

Pyridoxine is phosphorylated rapidly in liver and other tissues. Pyridoxal phosphate does not cross cell membranes, and uptake and efflux of the vitamin in most tissues are as pyridoxal. Pyridoxal phosphate is exported from the liver bound to albumin. Much of the free pyridoxal phosphate in the liver is hydrolyzed to pyridoxal, which is also exported, and circulates bound both to albumin and to hemoglobin in erythrocytes. Free pyridoxal remaining in the liver is rapidly oxidized to 4-pyridoxic acid, which is the main excretory product of the vitamin.

Extrahepatic tissues take up pyridoxal from the plasma. Pyridoxal phosphate is hydrolyzed to pyridoxal, which can cross cell membranes, by

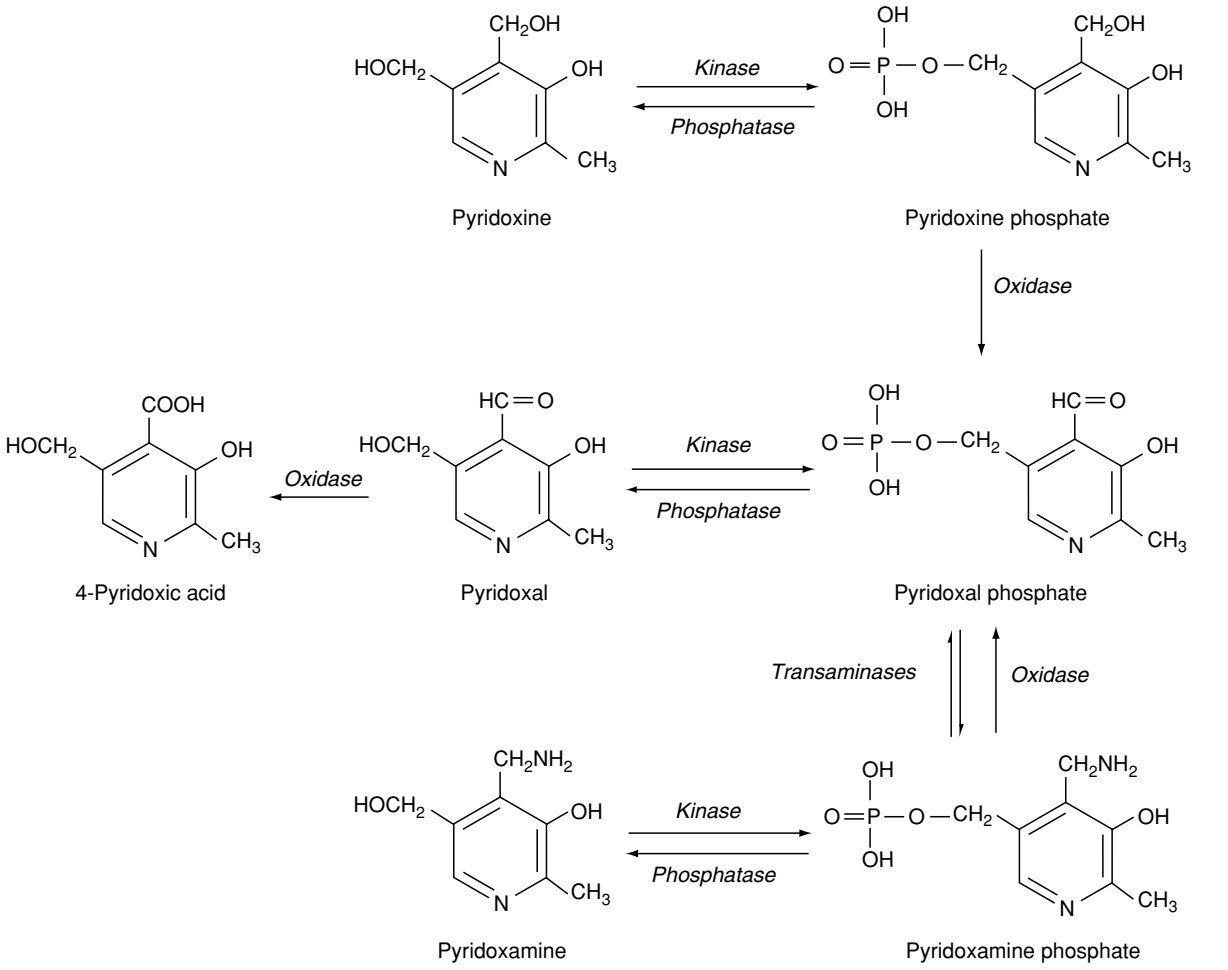

Figure 1 Metabolism of vitamin B_6.

extracellular alkaline phosphatase, then trapped intracellularly by phosphorylation.

Tissue concentrations of pyridoxal phosphate are controlled by the balance between phosphorylation and dephosphorylation. The activity of phosphatases acting on pyridoxal phosphate is greater than that of the kinase in most tissues. This means that pyridoxal phosphate that is not bound to enzymes will be dephosphorylated and hence leave the cell by diffusion. Thus there is little accumulation of pyridoxal phosphate in tissues, other than that which is bound to enzymes and other proteins (e.g., hormone receptors).

Free pyridoxal either leaves the cell or is oxidized to 4-pyridoxic acid by aldehyde dehydrogenase, which is present in all tissues, and also by hepatic and renal aldehyde oxidase. 4-Pyridoxic acid is the main excretory product of vitamin B_6, and its excretion reflects recent intake more than the state of underlying tissue reserves of the vitamin. Small amounts of pyridoxal and pyridoxamine are also excreted in the urine, although much of the active vitamin B_6 which is filtered at the glomerulus is resorbed in the kidney tubules.

Storage and Body Reserves

There is no specific storage of vitamin B_6 in the body; as discussed above, pyridoxal phosphate that is not bound to enzymes is rapidly dephosphorylated, oxidized to 4-pyridoxic acid, and excreted.

The total body pool of vitamin B_6 is of the order of 60 μmol (250 mg); 15 μmol (3.7 mg) per kg body weight. About 80% of this is in muscle, associated with glycogen phosphorylase. This does not seem to function as a true reserve of the vitamin and is not released from muscle in times of deficiency.

Muscle pyridoxal phosphate is released into the circulation (as pyridoxal) in starvation, as muscle glycogen reserves are exhausted, and there is less requirement for glycogen phosphorylase activity. Under these conditions it is available for redistribution to other tissues, especially liver and kidney, to

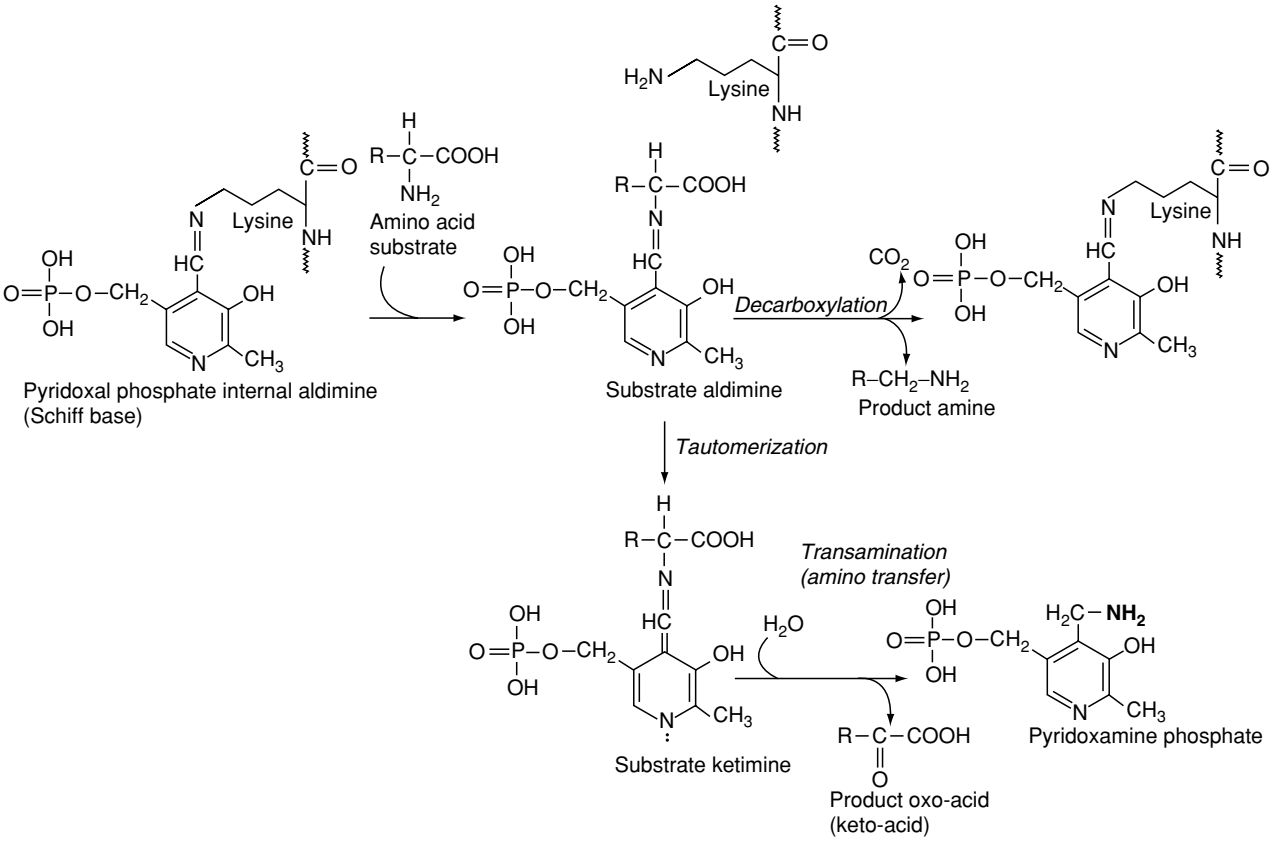

Figure 2 Roles of vitamin B_6 in amino acid metabolism.

meet the increased requirement of transamination of amino acids for gluconeogenesis.

Metabolic Functions of Vitamin B_6

The metabolically active vitamer is pyridoxal phosphate, which is involved in many reactions of amino acid metabolism, where the carbonyl group is the reactive moiety, in glycogen phosphorylase, where it is the phosphate group that is important in catalysis, and in the release of hormone receptors from tight nuclear binding, where again it is the carbonyl group that is important.

The Role of Pyridoxal Phosphate in Amino Acid Metabolism

The various reactions of pyridoxal phosphate in amino acid metabolism (Figure 2) all depend on the same chemical principle – the ability to stabilize amino acid carbanions, and hence to weaken bonds about the α-carbon of the substrate. This is achieved by reaction of the α-amino group with the carbonyl group of the coenzyme to form a Schiff base (aldimine).

Pyridoxal phosphate is bound to enzymes, in the absence of the substrate, by the formation of an internal Schiff base to the ε-amino group of a lysine residue at the active site. Thus the first reaction between the substrate and the coenzyme is transfer of the aldimine linkage from this ε-amino group to the α-amino group of the substrate.

The ring nitrogen of pyridoxal phosphate exerts a strong electron-withdrawing effect on the aldimine, and this leads to weakening of all three bonds about the α-carbon of the substrate. In nonenzymic model systems, all the possible pyridoxal-catalyzed reactions are observed: α-decarboxylation, aminotransfer, racemization, and relevant side-chain elimination and replacement reactions. By contrast, enzymes show specificity for the reaction pathway followed; which bond is cleaved will depend on the orientation of the Schiff base relative to reactive groups of the catalytic site. However, a number of decarboxylases and enzymes that catalyze side-chain elimination reactions of amino acids undergo gradual inactivation as a result of catalyzing the half-reaction of transamination, leaving (catalytically inactive) pyridoxamine phosphate at the catalytic site.

α-Decarboxylation If the electron-withdrawing effect of the ring nitrogen is primarily centered on

the α-carbon-carboxyl bond, the result is decarboxylation of the amino acid with the release of carbon dioxide. The resultant carbanion is then protonated, and the primary amine corresponding to the amino acid is displaced by the lysine residue at the active site, with reformation of the internal Schiff base.

A number of the products of the decarboxylation of amino acids are important as neurotransmitters and hormones: 5-hydroxytryptamine, the catecholamines dopamine, norepinephrine (noradrenaline), and epinephrine (adrenaline), histamine and γ-aminobutyrate (GABA), and as the diamines and polyamines involved in the regulation of DNA metabolism. The decarboxylation of phosphatidylserine to phosphatidylethanolamine is important in phospholipid metabolism.

Racemization of Amino Acids Deprotonation of the α-carbon of the amino acid leads to tautomerization of the Schiff base to yield a quinonoid ketimine. The simplest reaction that the ketimine can undergo is reprotonation at the now symmetrical α-carbon. Displacement of the substrate by the reactive lysine residue results in the racemic mixture of D- and L-amino acid.

Amino acid racemases are important in bacterial metabolism, since several D-amino acids are required for the synthesis of cell wall mucopolysaccharides. There is no evidence that there are any mammalian amino acid racemases; such utilization of D-amino acids as occurs is probably due to the action of renal D-amino acids oxidase to form the symmetrical 2-oxo-acid which is then a substrate for transamination.

Transamination Hydrolysis of the α-carbon-amino bond of the ketimine formed by deprotonation of the α-carbon of the amino acid results in the release of the 2-oxo-acid corresponding to the amino acid substrate, and leaves pyridoxamine phosphate at the catalytic site of the enzyme. In this case there is no reformation of the internal Schiff base to the reactive lysine residue. This is the half-reaction of transamination. The process is completed by reaction of pyridoxamine phosphate with a second oxo-acid substrate, forming an intermediate ketimine, followed by the reverse of the reaction sequence shown in Figure 2, releasing the amino acid corresponding to this second substrate after displacement from the aldimine by the reactive lysine residue to reform the internal Schiff base.

Transamination (Figure 3) is of central importance in amino acid metabolism, providing pathways for the catabolism of all of the amino acids except lysine, which does not undergo transamination. Many of these reactions are linked to the amination of 2-oxoglutarate to glutamate or glyoxylate to glycine, which are substrates for oxidative deamination, reforming the oxo-acids. Transamination reactions also provide a pathway for the synthesis of those amino acids for which there is an alternative source of the oxo-acid (the nonessential amino acids). Indeed, the nonessential amino acids can be defined as those whose oxo-acids can be formed other than from the amino acid itself.

Side-chain elimination and replacement reactions The third bond in the Schiff base aldimine that can be labilized by the electron-withdrawing

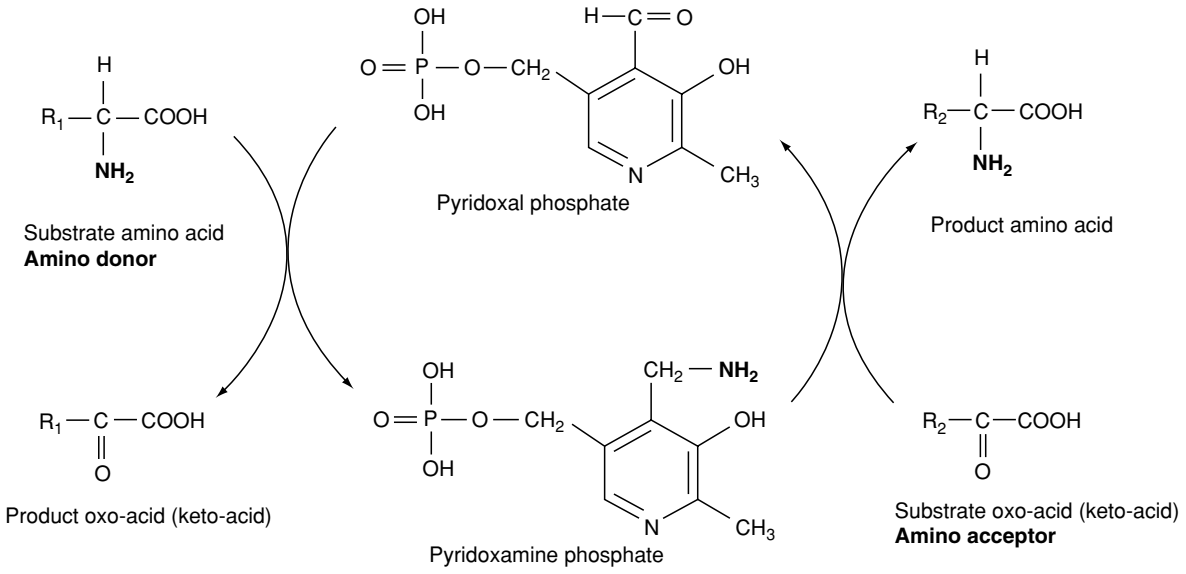

Figure 3 The role of vitamin B_6 in transamination reactions.

effect of the ring nitrogen of pyridoxal phosphate is that between the α-carbon and the side-chain of the amino acids, resulting in a variety of α–β elimination and β–γ replacement reactions.

The Role of Pyridoxal Phosphate in Glycogen Phosphorylase

Glycogen phosphorylase catalyzes the sequential phosphorolysis of glycogen to release glucose 1-phosphate; it is thus the key enzyme in the utilization of muscle and liver reserves of glycogen.

Unlike other pyridoxal phosphate-dependent enzymes, in which the carbonyl group is essential for catalysis, the internal Schiff base between pyridoxal phosphate and lysine in glycogen phosphorylase is not broken during the reaction. The catalytic region of the coenzyme is the 5′-phosphate group. The initial stage in the phosphorolysis of glycogen is protonation of the glycosidic oxygen of the polysaccharide by inorganic phosphate. The resultant oxycarbonium ion is stabilized by the inorganic phosphate. The role of pyridoxal phosphate is as a proton shuttle or buffer to stabilize the oxycarbonium-phosphate ion pair, permitting covalent binding of the phosphate to the oxycarbonium ion, to form glucose 1-phosphate.

The Role of Pyridoxal Phosphate in Steroid Hormone Action

Pyridoxal phosphate has a role in modulating the action of those hormones which act by binding to a nuclear receptor protein, inducing transcription of DNA, and hence regulating gene expression, leading to new protein synthesis. Such hormones include androgens, estrogens, progesterone, glucocorticoids, calcitriol (the active metabolite of vitamin D), retinoic acid and other retinoids, and thyroid hormone. Target-tissue specificity of hormone action is insured by the presence of characteristic receptor proteins with a zinc finger motif, which are responsible for both nuclear uptake of the hormone and the interaction with DNA and nucleoproteins to initiate gene expression.

Pyridoxal phosphate reacts with a lysine residue in the receptor protein, and displaces the hormone–receptor complex from tight nuclear binding. *In vitro*, reaction with pyridoxal phosphate also inhibits the binding of receptor protein to isolated DNA and chromatin. The effect is specific for the phosphorylated vitamer, suggesting that there may be a specific pyridoxal-phosphate binding site on the receptor proteins, and it occurs at low concentrations of pyridoxal phosphate, of the same order of magnitude as occur in tissues under normal conditions.

This suggests that pyridoxal phosphate acts as a cofactor in the release of hormone–receptor complexes from tight nuclear binding, resulting in release of the receptor from the nucleus, termination of hormone action, and recycling receptor protein for further uptake of hormone.

In experimental animals, vitamin B_6 deficiency results in increased and prolonged nuclear uptake and retention of steroid hormones in target tissues, and there is enhanced sensitivity to hormone action. Deficient animals show greater induction of uterine peroxidase, and considerably greater suppression of the hypothalamic secretion of luteinizing hormone, by estrogens than do vitamin B_6-supplemented controls. In vitamin B_6-deficient male animals there is an increased mitotic response of the prostate to low doses of testosterone. Deficient male animals have a higher activity of ornithine decarboxylase (an androgen-induced enzyme) in the liver, and deficient females have higher renal ornithine transaminase (an estrogen-induced enzyme). The induction of hepatic tyrosine transaminase and tryptophan dioxygenase by glucocorticoids is also enhanced in vitamin B_6-deficient animals.

In a variety of cells in culture that have been transfected with a glucocorticoid, estrogen, or progesterone response element linked to a reporter gene, acute vitamin B_6 depletion (by incubation with 4-deoxypyridoxine) leads to a twofold increase in expression of the reporter gene in response to hormone action. Conversely, incubation of these cells with high concentrations of pyridoxal, leading to a high intracellular concentration of pyridoxal phosphate, results in a halving of the expression of the reporter gene in response to hormone stimulation.

Criteria of Adequacy and Assessment of Nutritional Status

Plasma Concentrations of the Vitamin

The fasting plasma concentration of either total vitamin B_6 or, more specifically, pyridoxal phosphate, is widely used as an index of vitamin B_6 nutritional status. The generally accepted criteria of adequacy are shown in Table 1.

Conditions that involve increased plasma activity of alkaline phosphatase may result in reduced plasma pyridoxal phosphate, without affecting tissue concentrations of pyridoxal phosphate or vitamin B_6 nutritional status, as assessed by other criteria. There is a compensatory increase in the circulating concentration of pyridoxal, which is the main form for tissue uptake of vitamin B_6. Despite the fall in plasma pyridoxal phosphate in pregnancy, which has been

Table 1 Indices of vitamin B_6 nutritional status

	Adequate status
Plasma total vitamin B_6	> 40 nmol (10 μg) l^{-1}
Plasma pyridoxal phosphate	> 30 nmol (7.5 μg) l^{-1}
Erythrocyte alanine aminotransferase activation coefficient	< 1.25
Erythrocyte asparate aminotransferase activation coefficient	< 1.80
Erythrocyte asparate aminotransferase	> 0.13 units (8.4 μkat) l^{-1}
Urine 4-pyridoxic acid	> 3.0 μmol $24\,h^{-1}$ > 1.3 mmol mol^{-1} creatinine
Urine total vitamin B_6	> 0.5 μmol $24\,h^{-1}$ > 0.2 mmol mol^{-1} creatinine
Urine xanthurenic acid after 2 g tryptophan load	< 65 μmol $24\,h^{-1}$ increase
Urine cystathionine after 3 g methionine load	< 350 μmol $24\,h^{-1}$ increase

widely interpreted as indicating vitamin B_6 depletion, the plasma concentration of (pyridoxal phosphate plus pyridoxal) is unchanged. This suggests that determination of plasma pyridoxal phosphate alone may not be a reliable index of vitamin B_6 nutritional status.

Urinary Excretion of 4-Pyridoxic Acid

About half of the normal dietary intake of vitamin B_6 is excreted as 4-pyridoxic acid. Urinary excretion of 4-pyridoxic acid will largely reflect recent intake of the vitamin rather than underlying nutritional status; the criteria for assessment of 4-pyridoxic acid excretion are shown in Table 1.

Coenzyme Saturation of Transaminases

Various pyridoxal phosphate-dependent enzymes compete with each other for the available pool of coenzyme. Thus the extent to which an enzyme is saturated with its coenzyme provides a means of assessing the adequacy of the body pool of coenzyme. This can be determined by measuring the activity of the enzyme before and after the activation of any apoenzyme present in the sample by incubation with pyridoxal phosphate added *in vitro*. Erythrocyte aspartate and alanine transaminases are both commonly used; the results are expressed as either the percentage stimulation of activity by added pyridoxal phosphate, or the activation coefficient – the ratio of activity with added coenzyme to that without added coenzyme.

It seems to be normal for a proportion of pyridoxal phosphate-dependent enzymes to be present as inactive apoenzyme, without coenzyme. This may be a mechanism for metabolic regulation. It is possible that increasing the intake of vitamin B_6, so as to insure complete saturation of pyridoxal phosphate-dependent enzymes, may not be desirable.

Metabolic Loading Tests

A direct test of the adequacy of an individual's intake to meet his or her idiosyncratic metabolic requirement is the ability to metabolize a test dose of a substrate whose metabolism is dependent on the vitamin. For vitamin B_6, two metabolic loading tests can be used, although neither can be considered to be reliable for population studies of vitamin B_6 status.

The Tryptophan Load Test The oxidative pathway of tryptophan metabolism is shown in Figure 4. Kynureninase is a pyridoxal phosphate-dependent enzyme, and in vitamin B_6 deficiency its activity is lower than that of tryptophan dioxygenase. This means that there is a considerable accumulation of both hydroxykynurenine and kynurenine, sufficient to permit greater than usual metabolic flux through kynurenine transaminase, resulting in increased formation of kynurenic and xanthurenic acids. Although kynurenine transaminase is also pyridoxal phosphate-dependent, it is relatively unaffected in vitamin B_6 deficiency. Kynureninase is exquisitely sensitive to vitamin B_6 deficiency because it undergoes a slow inactivation as a result of catalyzing the half-reaction of transamination in addition to its normal reaction. The resultant enzyme with pyridoxamine phosphate at the catalytic site is catalytically inactive, and can only be reactivated if there is an adequate concentration of pyridoxal phosphate to displace the pyridoxamine phosphate.

Xanthurenic and kynurenic acids are easy to measure in urine, so that the ability to metabolize a test dose of 2 or 5 g of tryptophan has been widely adopted as a convenient and sensitive index of vitamin B_6 nutritional status. However, induction of tryptophan dioxygenase by glucocorticoid hormones will result in a greater rate of formation of kynurenine and hydroxykynurenine than the capacity of kynureninase, and will thus lead to increased formation of kynurenic and xanthurenic acids – an effect similar to that seen in vitamin B_6 deficiency. Such results may be erroneously interpreted as indicating vitamin B_6 deficiency in a variety of subjects whose problem is increased glucocorticoid secretion as a result of stress or illness, not vitamin B_6 deficiency.

Inhibition of kynureninase, e.g., by estrogen metabolites, also results in accumulation of kynurenine and hydroxykynurenine, and hence increased formation of kynurenic and xanthurenic acids, again giving results which falsely suggest vitamin B_6 deficiency.

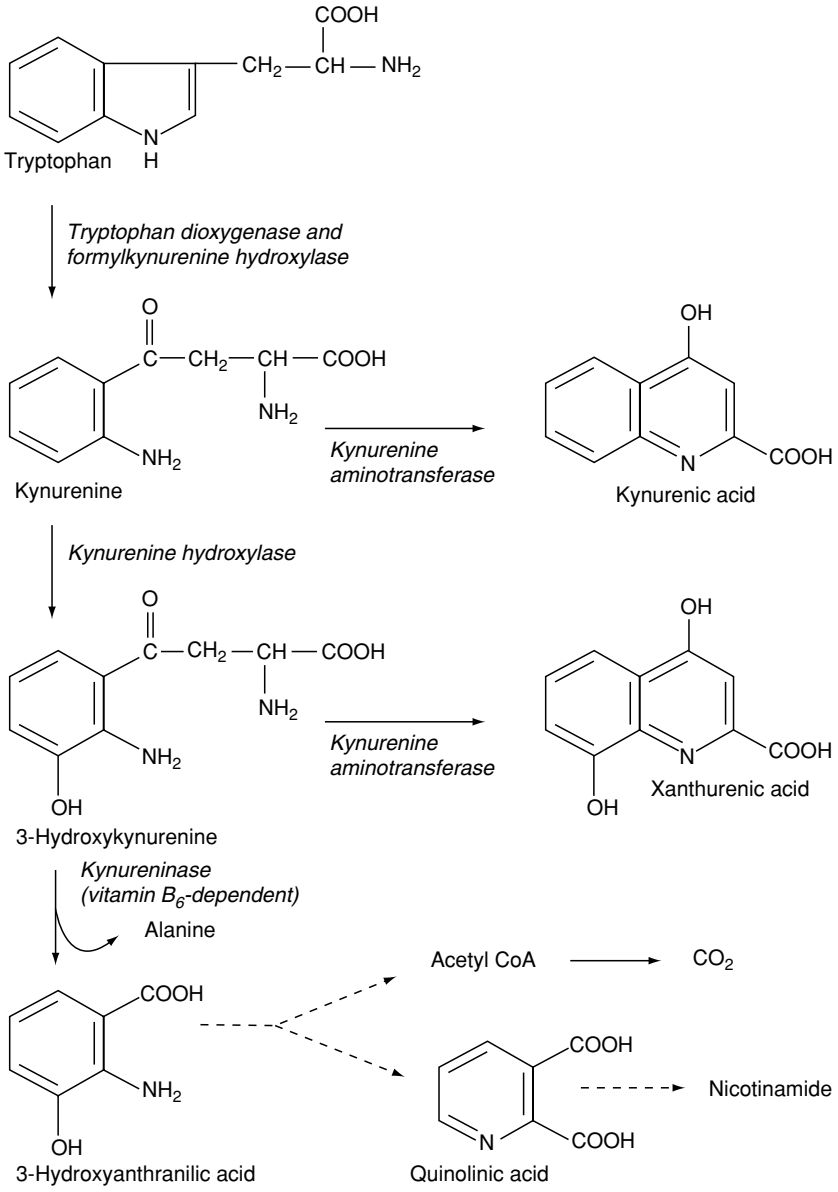

Figure 4 The oxidative pathway of tryptophan metabolism – the basis of the tryptophan load test for vitamin B_6 status.

This has been widely, but incorrectly, interpreted as estrogen-induced vitamin B_6 deficiency – it is in fact simple competitive inhibition by estrogen metabolites of the enzyme that is the basis of the tryptophan load test.

There is normally a considerable excess of either apokynureninase or kynureninase that has undergone transamination, and has pyridoxamine phosphate at the catalytic site, in the liver. This can be activated by (relatively high concentrations of) pyridoxal phosphate. The abnormalities of tryptophan metabolism associated with increased activity of tryptophan dioxygenase, or inhibition of kynureninase by estrogen metabolites, are thus corrected by the administration of high doses of vitamin B_6, although they are not in fact due to deficiency.

This means that, while the tryptophan load test may be an appropriate index of status in controlled depletion/repletion studies to determine vitamin B_6 requirements, it is not an appropriate index of status in population studies.

The methionine loading test The metabolism of methionine, shown in Figure 5, includes two pyridoxal phosphate-dependent steps, catalyzed by cystathionine synthetase and cystathionase. In vitamin B_6 deficiency there is an increase in the plasma concentration of homocysteine, and increased urinary

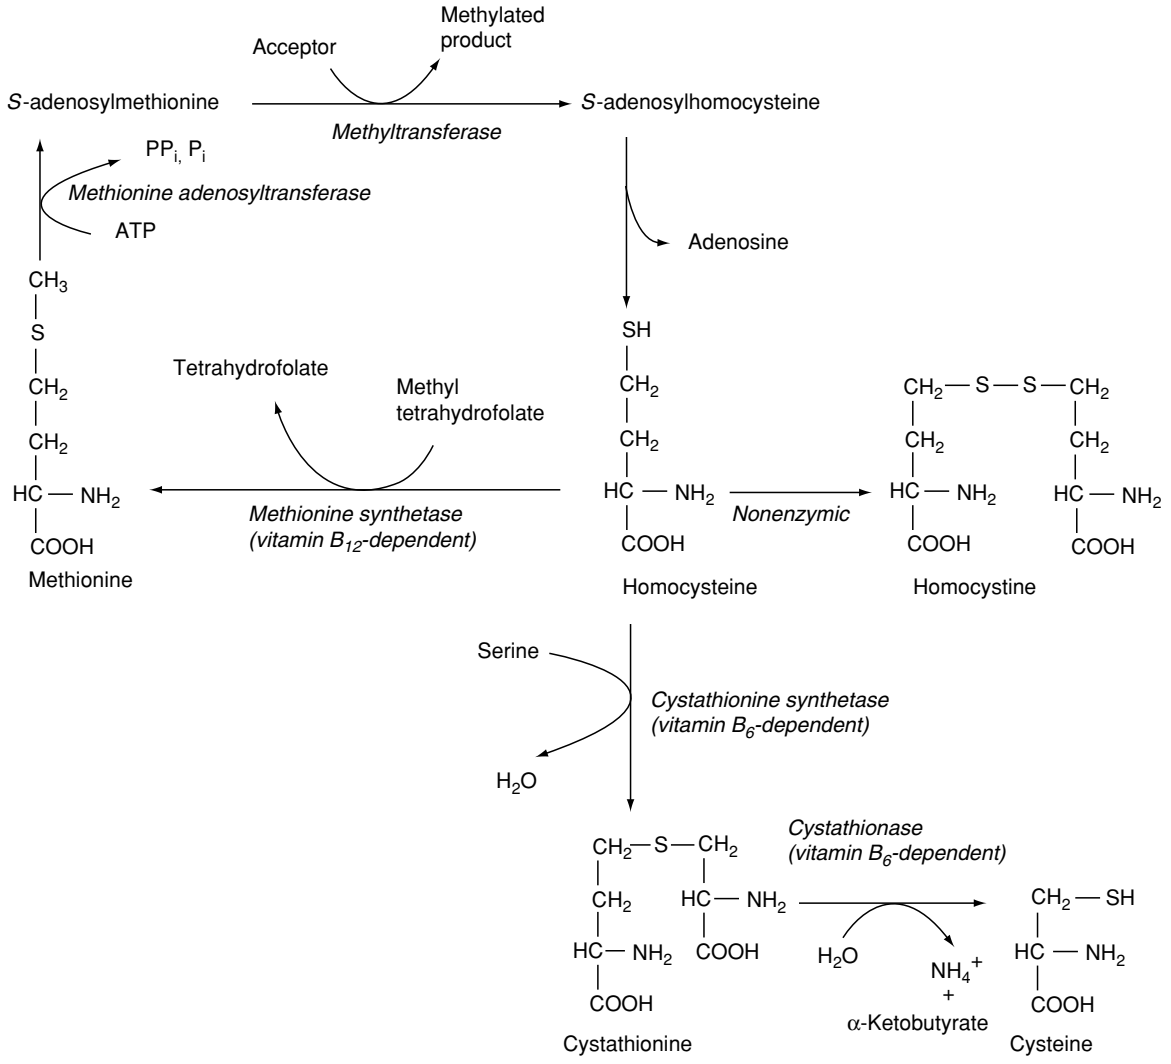

Figure 5 The pathway of methionine metabolism – the basis of the methionine load test for vitamin B_6 status.

excretion of cystathionine and homocysteine, both after a loading dose of methionine and under basal conditions. The ability to metabolize a test dose of methionine therefore provides an index of vitamin B_6 nutritional status. Because measurement of homocysteine and cystathionine is technically less easy than measurement of xanthurenic and kynurenic acids, the methionine load test has been less widely used than the tryptophan load test.

Some 10–25% of the population have a genetic predisposition to hyperhomocysteinemia, which is a risk factor for atherosclerosis and coronary heart disease, as a result of polymorphism in the gene for methylenetetrahydrofolate reductase. As discussed below, there is no evidence that supplements of vitamin B_6 reduce fasting plasma homocysteine in these subjects and, like the tryptophan load test, the methionine load test may be an appropriate index of status in controlled depletion/repletion studies to determine vitamin B_6 requirements, but not in population studies.

Requirements and Recommendations

The total body pool of vitamin B_6 is of the order of 15 μmol (3.7 mg) per kg of body weight. Isotope tracer studies suggest that there is a turnover of about 0.13% per day, and hence a minimum requirement for replacement of 0.02 μmol (5 μg) per kg of body weight – some 350 μg day^{-1} for a 70-kg adult.

Most studies of vitamin B_6 requirements have followed the development of abnormalities of tryptophan (and sometimes also methionine) metabolism during depletion, and normalization during repletion with graded intakes of the vitamin. While the tryptophan and methionine loading tests are unreliable as

indices of vitamin B_6 nutritional status in field studies, under the controlled conditions of depletion/repletion studies they do indeed provide a useful indication of the state of vitamin B_6 nutrition.

Although some 80% of the total body pool of vitamin B_6 is associated with muscle glycogen phosphorylase, this pools turns over relatively slowly. The major metabolic role of the remaining 20% of total body vitamin B_6, which turns over considerably more rapidly, is in amino acid metabolism. Therefore, *a priori*, it seems likely that protein intake will affect vitamin B_6 requirements.

People maintained on (experimental) vitamin B_6-deficient diets develop abnormalities of tryptophan and methionine metabolism faster, and their blood vitamin B_6 falls more rapidly, when their protein intake is high. Similarly, during repletion of deficient subjects, tryptophan and methionine metabolism and blood vitamin B_6 are normalized faster at low than at high levels of protein intake. However, the relevance of these studies to normal nutrition is unclear – they were conducted using extremes of protein intake: 40 g day^{-1} for the low protein intake, which is barely adequate to maintain nitrogen balance, and 150 g day^{-1} for the high intake, which is considerably higher than average western intakes of protein.

These studies suggest a mean requirement of 13 μg of vitamin B_6 per gram of dietary protein; recommended dietary allowances (RDA) are based on 15–16 μg per g of protein. At average intakes of about 100 g of protein per day, this gives an RDA of 1.4–1.6 mg of vitamin B_6.

More recent studies of women's requirements have suggested an RDA of 20 μg g^{-1} protein intake. It is not clear whether this reflects a gender difference (most of the earlier studies were conducted using men) or the use of more sensitive criteria of adequacy than were used previously.

Possible Benefits of Higher Levels of Intake

The identification of hyperhomocysteinemia as an independent risk factor in atherosclerosis and coronary heart disease has led to suggestions that higher intakes of vitamin B_6 than are currently considered adequate to meet requirements may be desirable. As shown in Figure 5, homocysteine is an intermediate in methionine metabolism, and may undergo one of two metabolic fates: remethylation to methionine (a reaction that is dependent on vitamin B_{12} and folic acid), or onward metabolism leading to the synthesis of cysteine (the vitamin B_6-dependent transsulfuration pathway).

Among elderly survivors of the Framingham study cohort (aged 67–96), hyperhomocysteinemia was most significantly correlated with low folate status, but there was also a significant association with low vitamin B_6 status. However, a number of studies have shown that, while folate supplements lower fasting homocysteine in moderately hyperhomocysteinemic subjects, 10 mg day^{-1} vitamin B_6 has no effect.

Vitamin B_6 supplements do, however, reduce the peak plasma concentration of homocysteine following a test dose of methionine. This can probably be explained by the kinetics of the enzymes involved. The K_m of cystathionine synthetase is 10-fold higher than that of methionine synthetase. Under basal conditions, little homocysteine is metabolized by way of the transsulfuration pathway. It is only after a loading dose of methionine, when homocysteine rises to relatively high levels, that the activity of cystathionine synthetase, rather than the availability of its substrate, is limiting or transsulfuration.

It is thus unlikely that intakes of vitamin B_6 above amounts that are adequate to prevent metabolic signs of deficiency will be beneficial in lowering plasma concentrations of homocysteine.

Vitamin B_6 Requirements of Infants

Estimation of the RDA for vitamin B_6 of infants presents a problem, and there is a clear need for further research to achieve a realistic estimate of infants' requirements. Human milk, which must be assumed to be adequate for infant nutrition, provides only some 40–100 μg l^{-1}, or 3–8 μg of vitamin B_6 per gram of protein – very much lower than the apparent requirement for adults. There is no reason why infants should have a lower requirement than adults, and indeed since they must increase their total body pool of the vitamin as they grow, they might be expected to have a proportionally higher requirement than adults.

A first approximation of the vitamin B_6 needs of infants came from studies of those who convulsed as a result of gross deficiency caused by overheated infant milk formula in the 1950s. At intakes of 60 μg day^{-1} there was an incidence of convulsions of 0.3%. Provision of 260 μg day^{-1} prevented or cured convulsions, but 300 μg day^{-1} was required to normalize tryptophan metabolism. This is almost certainly a considerable overestimate of requirements, since pyridoxyllysine, formed by heating the vitamin with proteins, has antivitamin activity, and would therefore result in a higher apparent requirement.

Based on the body content of 15 μmol (3.7 mg) of vitamin B_6 per kg of body weight, and the rate of weight gain, the minimum requirement for infants over the first 6 months of life would appear to be 100 μg (417 nmol) day^{-1} to establish tissue reserves.

Pharmacological Uses and Toxicity of Vitamin B_6 Supplements

Supplements of vitamin B_6 ranging from 25 to 500 mg day^{-1}, and sometimes higher, have been recommended for the treatment of a variety of conditions in which there is an underlying physiological or biochemical mechanism to justify the use of supplements, although in most cases there is little evidence of efficacy. Such conditions include postnatal depression, depression and other side-effects associated with oral contraceptives, hyperemesis of pregnancy, and the premenstrual syndrome.

Supplements have also been used empirically, with little or no rational basis, and little or no evidence of efficacy, in the treatment of a variety of conditions, including acute alcohol intoxication, atopic dermatitis, autism, dental caries, diabetic neuropathy, Down's syndrome, Huntington's chorea, schizophrenia, and steroid-dependent asthma.

Doses of 100 mg day^{-1} have been reported to be beneficial in the treatment of the carpal tunnel syndrome, or what has been called tenosynovitis. However, most of the reports originate from one center, and there appears to be little or no independent confirmation of the usefulness of the vitamin in this condition.

Vitamin B_6 has been reported to be effective in suppression of lactation, although other reports have shown no difference from placebo. Because the vitamin suppresses the increase in prolactin induced by treatment with the dopamine receptor antagonist pimozide, and because lactation is also suppressed by the dopamine agonist bromocriptine, it has been suggested that it acts to stimulate dopaminergic activity in the hypothalamus. However, it is more likely that its action is by reduction in target tissue responsiveness to the steroid hormones that stimulate prolactin secretion.

Doses of 50–200 mg day^{-1} have an antiemetic effect, and the vitamin is widely used, alone or in conjunction with other antiemetics, to minimize the nausea associated with radiotherapy and to treat pregnancy sickness. There is no evidence that vitamin B_6 has any beneficial effect in pregnancy sickness, nor that women who suffer from morning sickness have lower vitamin B_6 nutritional status than other pregnant women. There have been reports of a teratogenic effect of vitamin B_6 used to treat morning sickness, but all of these involved use of the vitamin together with the sedative Debendox, and there is no evidence that vitamin B_6 itself is teratogenic. However, since it downregulates responsiveness to steroid hormones and retinoids, it is possible that high levels of vitamin B_6 intake may affect embryonic or fetal development.

Vitamin B_6 and the Side-Effects of Oral Contraceptives

Although estrogens do not cause vitamin B_6 deficiency, the administration of vitamin B_6 supplements has beneficial effects on some of the side-effects of both administered and endogenous estrogens. The supplements act in two main areas: in normalizing glucose tolerance and as an antidepressant.

Impairment of glucose tolerance is common in pregnancy, and may indeed be severe enough to be classified as gestational diabetes mellitus, which generally resolves at parturition, although in some subjects it may persist, pregnancy having been the trigger for the development of maturity-onset diabetes. High-estrogen oral contraceptives may also cause impaired glucose tolerance. This seems to be the result of increased tissue and blood concentrations of xanthurenic acid, because of the inhibition of kynureninase by estrogen metabolites. Xanthurenic acid forms a complex with insulin which has little or no hormonal activity. Vitamin B_6 supplements may have a beneficial effect on glucose tolerance by activating apokynureninase or kynureninase that has been inactivated by undergoing transamination.

One of the relatively common side-effects of estrogenic oral contraceptives is depression, affecting about 6% of women in some studies. This frequently responds well to the administration of relatively large amounts of vitamin B_6 (generally in excess of 40 mg day^{-1}). Postnatal depression also responds to similar supplements in some studies.

Again, this does not seem to be due to correction of vitamin B_6 deficiency, but rather to a direct effect of pyridoxal phosphate on the metabolism of tryptophan. High concentrations of pyridoxal phosphate attenuate the response to glucocorticoid hormones; tryptophan dioxygenase is a glucocorticoid-induced enzyme, and thus its synthesis and activity will be reduced by high intakes of vitamin B_6. This reduces the oxidative metabolism of tryptophan, and increases the amount available for synthesis of 5-hydroxytryptamine in the brain. Increased brain 5-hydroxytryptamine synthesis has a mood-elevating effect.

Vitamin B_6 in the Premenstrual Syndrome

The studies showing a beneficial action of vitamin B_6 in overcoming depression associated with oral contraceptives have led to the use of the vitamin in depression and other pathology associated with endogenous estrogens, in the premenstrual syndrome. There is no evidence of poorer vitamin B_6 nutritional status in women who suffer from the premenstrual syndrome.

There are few well-controlled studies of the effects of vitamin B_6 in premenstrual syndrome. In general, those that have been properly controlled report little benefit from doses between 50 and 200 mg day^{-1} compared with placebo, although some studies do claim a beneficial effect. Interestingly, meta-analysis of controlled cross-over trials shows that whichever treatment is used second, active vitamin or placebo is (marginally) more effective. There is no obvious explanation for this observation.

Despite the lack of evidence of efficacy, vitamin B_6 is widely prescribed (and self-prescribed) for the treatment of the premenstrual syndrome.

Toxicity of Vitamin B_6

Animal studies have demonstrated the development of signs of peripheral neuropathy, with ataxia, muscle weakness and loss of balance, in dogs given 200 mg pyridoxine HCl per kg of body weight for 40–75 days, and the development of a swaying gait and ataxia within 9 days at a dose of 300 mg per kg of body weight. At a dose of 50 mg per kg of body weight, there are no clinical signs of toxicity, but histologically there is a loss of myelin in dorsal nerve roots. At higher doses there is more widespread neuronal damage, with loss of myelin and degeneration of sensory fibers in peripheral nerves, the dorsal columns of the spinal cord, and the descending spinal tract of the trigeminal nerve. The clinical signs of vitamin B_6 toxicity in animals regress after withdrawal of these massive doses, but sensory nerve conduction velocity, which decreases during the development of the neuropathy, does not recover fully. The mechanism of the neurotoxic action of vitamin B_6 is unknown.

The development of sensory neuropathy has been reported in patients taking 2–7 g of pyridoxine HCl day^{-1}. Although there was residual damage in some patients, withdrawal of these extremely high doses resulted in a considerable recovery of sensory nerve function.

Other reports have suggested that intakes as low as 50 mg day^{-1} are associated with neurological damage, although these have been based on patients reporting symptoms rather than on detailed neurological examination. Nevertheless, this led to a proposal in the UK in 1997 to regulate the sale of vitamin B_6 supplements, with 50 mg day^{-1} being available only on prescription, and between 10 and 50 mg day^{-1} only available from qualified pharmacists. The proposals were put in abeyance in 1998, pending further studies and reexamination of the evidence of toxicity at intakes below 100–200 mg day^{-1}.

Vitamin B_6 Deficiency

Gross clinical deficiency of vitamin B_6 is more or less unknown. The vitamin is widely distributed in foods, and intestinal flora synthesize relatively large amounts, at least some of which is believed to be absorbed and hence available.

In vitamin B_6-deficient experimental animals there are more or less specific skin lesions (e.g., acrodynia in the rat) and fissures or ulceration at the corners of the mouth and over the tongue, as well as a number of endocrine abnormalities, defects in the metabolism of tryptophan, methionine and other amino acids, hypochromic microcytic anemia (the first step of heme biosynthesis is a pyridoxal phosphate-dependent reaction), changes in leukocyte count and activity, a tendency to epileptiform convulsions, and peripheral nervous system damage resulting in ataxia and sensory neuropathy.

Much of our knowledge of human vitamin B_6 deficiency is derived from an outbreak in the early 1950s, which resulted from an infant milk preparation which had undergone severe heating in manufacture. The probable result of this was the formation of pyridoxyllysine by reaction between pyridoxal phosphate and the ε-amino groups of lysine in proteins. In addition to a number of metabolic abnormalities, many of the affected infants convulsed. They responded to the administration of vitamin B_6 supplements.

Investigation of the neurochemical basis of the convulsions in vitamin B_6 deficiency helped to elucidate the role of GABA as a neurotransmitter; GABA is synthesized by the decarboxylation of glutamate. More recent studies have suggested that the accumulation of hydroxykynurenine in the brain may be the critical factor precipitating convulsions in deficiency; GABA is depleted in the brains of deficient adult and neonate animals, while hydroxykynurenine accumulation is considerably more marked in neonates than adults – only neonates convulse in vitamin B_6 deficiency. GABA depletion may be a necessary but not sufficient condition for convulsions in vitamin B_6 deficiency.

Vitamin B_6 Dependency Syndromes

A small number of cases have been reported of patients with genetic defects which result in an abnormally high requirement for vitamin B_6 in order to maintain the activity of the affected enzyme (Table 2). Such vitamin B_6 dependency syndromes have been reported in cases of xanthurenic aciduria, homocystinuria, hypochromic sideroblastic anemia, ornithinemia, and infantile convulsions. The molecular basis of the defects appears to be a severely impaired affinity of the affected enzyme for its

Table 2 Vitamin B_6-responsive inborn errors of metabolism

	Enzyme affected
Convulsions of the newborn	Enzyme defect not known
Cystathioninuria	Cystathionase (**Figure 5**)
Gyrate atrophy with ornithinuria	Ornithine-δ-aminotransferase
Homocystinuria	Cystathionine synthase (**Figure 5**)
Primary hyperoxaluria, type 1	Peroxisomal alanine-glyoxylate transaminase
Sideroblastic anemia	δ-Aminolevulinate synthase (↓ heme synthesis)
Xanthurenic aciduria	Kynureninase (**Figure 4**)

cofactor, and patients respond well to doses of 500–1000 mg of vitamin B_6 per day. Apart from the affected enzyme, other biochemical indices of vitamin B_6 nutritional status are normal in these patients. Interestingly, there are few reports of peripheral neuropathy among such patients treated with high doses of vitamin B_6 for many years.

Groups at Risk of Deficiency

A number of studies have shown that between 10 and 20% of the apparently healthy population have low plasma concentrations of pyridoxal phosphate or abnormal erythrocyte transaminase activation coefficient, suggesting vitamin B_6 inadequacy or deficiency. In most studies, only one of these indices of vitamin B_6 nutritional status has been assessed. Where both have been assessed, while each shows some 10% of the population apparently inadequately provided with vitamin B_6, few of the subjects show inadequacy by both criteria.

There is a decrease in the plasma concentration of vitamin B_6 with increasing age, and some studies have shown a high prevalence of abnormal transaminase activation coefficient in elderly subjects, suggesting that the elderly may be at risk of vitamin B_6 deficiency. It is not known whether this reflects an inadequate intake, a greater requirement, or changes in the tissue distribution and metabolism of the vitamin with increasing age.

Drug-induced vitamin B_6 deficiency A number of drugs which react with carbonyl compounds are capable of causing vitamin B_6 deficiency on prolonged use. These include the antituberculosis drug isoniazid (iso-nicotinic acid hydrazide), penicillamine, and the antiparkinsonian drugs Benserazide and Carbidopa. In general, the main effect is impairment of tryptophan metabolism by inhibition of kynureninase, and hence the development of the niacin deficiency disease pellagra. The condition therefore responds to the administration of either vitamin B_6 or niacin. Isoniazid also causes peripheral neuropathy, which responds to vitamin B_6 supplements, but not to niacin.

Estrogens and vitamin B_6 nutritional status There have been many reports of abnormal tryptophan metabolism in women taking estrogens as oral contraceptives and menopausal hormone replacement therapy. These have been widely interpreted as evidence of estrogen-induced vitamin B_6 deficiency. However, as discussed above, this is the result of inhibition of kynureninase by estrogen metabolites, not estrogen-induced deficiency of the vitamin. Where other indices of vitamin B_6 status have been reported, they have been generally unaffected by contraceptive use, again suggesting an effect on tryptophan metabolism *per se*, rather than on vitamin B_6 nutritional status.

In many cases the metabolism of tryptophan has been normalized by the administration of vitamin B_6 supplements of the order of 20–50 mg day^{-1}, compared with an RDA of 1.4–1.6 mg day^{-1}. It was noted above that there is an apparent excess of apokynureninase in the liver and therefore the administration of vitamin B_6 supplements will increase kynurenine metabolism, even when there is no preexisting deficiency.

Background

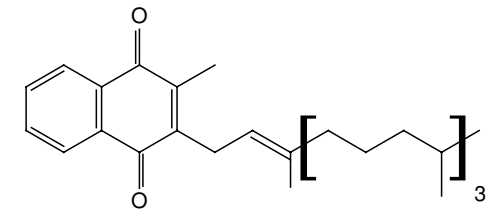
Vitamin K is a fat-soluble vitamin widely distributed in nature and comprising several molecular forms. It was discovered as an essential antihemorrhagic factor in the 1930s by the Danish scientist Henrik Dam, who named it *Koagulationsvitamin*. This article reviews the properties and analysis of vitamin K, with special reference to its measurement in foods. Such measurements have proved difficult, and reliable methods have only become available since the 1980s with the development of physicochemical assays based on high-performance liquid chromatography (HPLC). A subsequent article deals with the physiology of vitamin K, where the introduction of new assay techniques for vitamin K and its dependent proteins has led to a greater understanding of its nutritional role. According to recent evidence, this includes the probability that, in addition to its well-defined role in blood coagulation, vitamin K is needed for a variety of physiological processes related to a number of extrahepatic vitamin K-dependent proteins. (*See* **Vitamins**: Overview.)

Chemical Structures and Nomenclature

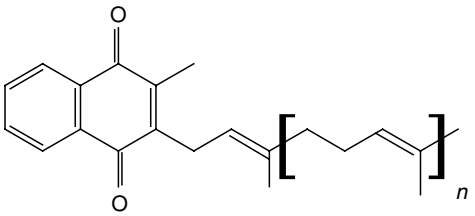
Naturally occurring compounds with vitamin K activity possess a common 2-methyl-1,4-naphthoquinone

nucleus, but differ in the structures of the side-chain at the 3 position (Figure 1).

In traditional nomenclature (Table 1), the vitamin K found in plants (of which there is only one major chemical form) is known as vitamin K_1 and the multiple forms synthesized by bacteria as vitamin K_2, where the number of carbon atoms (n) in the side chain is indicated as vitamin $K_{2(n)}$. This nomenclature was revised by the International Union of Pure and Applied Chemistry – International Union of Biochemistry (IUPAC–IUB) Subcommittee on Nomenclature of Quinones, who recommended that vitamins K_1 and K_2 be called phylloquinone and menaquinones, respectively. Recommended current abbreviations are K_1 for phylloquinone and MK-n for menaquinones. Table 1 also shows a nomenclature that the International Union of Nutritional Sciences (IUNS) recommended should replace the IUPAC system. This new system, however, has not found favor among most workers in this field. Consequently, the IUPAC-IUB nomenclature is still the one most generally accepted at the present time and will be used throughout this article.



(a) Phylloquinone



(b) Menaquinone

Figure 1 Chemical structures of naturally occurring K vitamins: (a) phylloquinone (vitamin K_1) and (b) menaquinones (vitamin K_2).

The parent compound of the vitamin K group of vitamers is 2-methyl-1,4-naphthoquinone. This structure is not found in nature but, because of its historical use as a synthetic derivative, was originally designated vitamin K_3. Under the IUPAC system, this artificial vitamin K is called menadione.

Phylloquinone, which has the same phytyl side-chain as chlorophyl, is found throughout the plant kingdom and in cyanobacteria (blue–green algae). In higher plants, the synthesis of phylloquinone is associated with the chloroplast, while the unusual finding of phylloquinone in cyanobacteria has been cited as supportive evidence for the possible bacterial origin of the chloroplast in evolution.

The menaquinones represent a highly diverse family of compounds all synthesized by bacteria. The side-chain of menaquinones is based on a number of repeating unsaturated five-carbon (prenyl) units. The major forms are designated menaquinone-n (MK-n), with n denoting the number of prenyl units. Some bacteria also synthesize menaquinones in which one or more of the multiprenyl side-chain double bonds are saturated. In such cases, the additional hydrogen atoms are indicated by the prefixes dihydro, tetrahydro, hexahydro, etc., and these may be abbreviated to MK-n(H_2), MK-n(H_4), MK-n(H_6), etc. The division between the plant-form phylloquinone and the bacterial menaquinones is somewhat artificial, since phylloquinone may be regarded as a partially saturated form of menaquinone-4, namely MK-4(H_6), but the distinction serves to emphasize their different origins.

Carbon atoms in the side-chain are designated C1′, etc., and the presence of double bonds at C2′ in phylloquinone and at C2′, 6′, 10′, etc. in menaquinones indicates that *cis–trans* isomerism is possible. Natural forms of phylloquinone and menaquinones exist as *trans* isomers, but synthetic forms contain both *trans* and *cis* isomers.

Biological Activities

The biological activity of different vitamin K compounds has been assessed in whole animal systems (*in vivo*), or as a cofactor to the vitamin K-dependent γ-glutamyl carboxylase in isolated enzyme systems

Table 1 Nomenclature of K vitamins

Chemical name	*Old name*	*IUPAC–IUB (abbreviation)*	*IUNS (abbreviation)*
2-Methyl-1,4-naphthoquinone	Vitamin K_3	Menadione	Menaquinone
2-Methyl-3-phytyl-1,4-naphthoquinone	Vitamin K_1	Phylloquinone (K)	Phytylmenaquinone (PMQ)
2-Methyl-3-multiprenyl-1,4-naphthoquinone (class)	Vitamin K_2	Menaquinone-n (MK-n)	Prenylmenaquinone-n (MQ-n)
2-Methyl-3-farnesylfarnesyl-1,4-naphthoquinone	Vitamin $K_{2(30)}$	Menaquinone-6 (MK-6)	Prenylmenaquinone-6 (MQ-7)

(*in vitro*). γ-Glutamyl carboxylase is an integral membrane glycoprotein that requires vitamin K to activate posttranslational modification of glutamate (Glu) to γ-carboxyl glutamate (Gla) in specific vitamin K-dependent proteins. The *in vivo* systems are normally based on the correction of blood clotting time in chicks induced by vitamin K deficiency, or through measurement of undercarboxylated vitamin K-dependent proteins, and their interpretation needs to take account of the route of administration and other metabolic considerations, such as absorption and interconversion to other chemical forms. (*See* **Coenzymes**.)

It has been established that besides the 1,4-naphthoquinone nucleus, a methyl group at the C2 position is essential for both *in vivo* and *in vitro* activity. The activity of menadione *in vivo* is due to the presence of tissue alkylating enzymes that can transform this compound to MK-4. Recent evidence is accumulating that suggests an alternative *in vivo* route to MK-4 via tissue-mediated conversion of phylloquinone. The essential requirement for *in vitro* activity is for a 2-methyl-3-phytyl (or polyisoprenyl)-1,4-naphthoquinone structure, which can be reduced to the corresponding hydroquinone. The biological activity of K_1 is reduced by saturation of the phytyl double bond (2′,3′-dihydrophylloquinone), whereas the desmethyl or *cis* isomers have no appreciable activity *in vitro*, although some conversion of the *cis* form to the active *trans* form may occur *in vivo*.

Physicochemical Properties

Appearance, Solubility, and Stability

Phylloquinone and menaquinones are golden yellow oils at ambient temperature, though the higher menaquinones may also be obtained as fine, yellow crystals.

All K vitamins are insoluble in water but are soluble in normal lipid solvents such as hexane, chloroform, diethyl ether, and acetone, but are less soluble in ethanol. They are only sparingly soluble in methanol, and the degree of solubility depends on their hydrophobicity (i.e., menaquinones with long side-chains are less soluble than those with short side-chains).

Vitamin K compounds are reasonably stable towards heat, oxygen, and mild acidic conditions, but are degraded by UV light, alkalis, and strong acids.

Spectroscopy

The spectroscopic properties of K vitamins are important for their detection, identification, and quantification in assays. All vitamin K compounds possess the same characteristic ultraviolet spectrum, which is a summation of the benzenoid and 1,4-quinone components. Naturally occurring phylloquinone and menaquinones exhibit typical benzenoid bands with maxima at 242, 248, and 238 nm (shoulder), whereas the quinone contributions appear as distinct bands with absorption maxima at 260 and 269 nm and a higher-wavelength maximum at 326 nm. Ultraviolet spectroscopy is particularly useful for the quantification of standard solutions; the molar absorption coefficient (ε) is the same for both phylloquinone and menaquinones and, at 248 nm (the wavelength of highest absorption), has a value of 18 900. (*See* **Spectroscopy**: Overview.)

Vitamin K compounds, in their stable quinone forms, do not possess native fluorescence, but they can be readily reduced to the corresponding quinols, whose fluorescent properties have been exploited for the assay of K vitamins in foods and other biological tissues. (*See* **Spectroscopy**: Fluorescence.)

The K vitamers also exhibit infrared and nuclear magnetic resonance absorption spectra distinctive of the naphthoquinone nucleus, and may be further characterized by mass spectroscopy. (*See* **Mass Spectrometry**: Principles and Instrumentation; Applications.)

Occurrence and Forms in Foods

Vitamin K is largely found in the membranous fractions of cells. Thus, in plants, phylloquinone is concentrated in the chloroplast lamellae, and in bacteria, menaquinones are located in the plasma membrane. In animals, the vitamin is found in various cellular membranes, especially those of the microsomes and mitochondria.

Recent progress in analytical techniques for this vitamin, as well as increased emphasis on its nutritional significance, is responsible for the current development of a comprehensive database of the vitamin K content of foods. Whereas, before 1980, most published values for the vitamin K content of foods originated from bioassays, contemporary data derive from the highly specific and accurate HPLC methods. These techniques have focused predominantly on phylloquinone ubiquitously distributed in foods, although more recently, increasing amounts of data are becoming available for the menaquinones.

Table 2 lists some values of the phylloquinone content of various foods arranged into four concentration ranges to illustrate the wide distribution of the vitamin in the diet.

In general, the relative values confirm the known association of phylloquinone with photosynthetic tissues, with the highest values (400–600 μg per 100 g) being found in green, leafy vegetables. Nutritionally significant amounts of phylloquinone are, however, present in many nonleafy vegetables,

Table 2 Vitamin K_1 content of common foods determined by HPLC (μg per 100 g)[a]

0.1–1.0	*1–10*	*10–100*	*100–1000*
Bananas	Apples	Avocado	Broccoli tops
Beef, steak	Aubergines	Beans, runner	Brussels sprouts
Bread, white	Baked beans	Beans, French	Cabbage, green
Chicken, thigh	Barley	Beans, broad	Kale
Coconut oil	Beef, minced (1–30)	Cabbage, red	Lettuce
Cod, fillet (0.1–2)	Bilberries	Cauliflower	Margarine
Cornflakes	Bran, wheat	Chick peas	Parsley
Flour, white	Bread, wholemeal	Cucumber	Rapeseed oil
Grapefruit	Butter	Greengages	Soybean oil
Ham, tinned	Carrots	Kiwi fruit	Spinach
Icecream	Celery	Margarine	Water cress
Maize	Cheeses (1–80)	Mustard cress	
Mangoes	Chocolate, plain	Natto (900–1200)	
Melon, yellow	Corn oil	Olive oil, ex. Virgin	
Melon, water	Courgettes	Peas	
Milk, cows	Cranberries		
Mushrooms	Cream, double		
Onion	Dates, fresh		
Oranges	Eggs (10–25)		
Parsnips	Figs, fresh		
Peanuts, roast	Grapes, black		
Pilchards, brine (0.1–2)	Grapes, green		
Pineapple	Infant Formula		
Pork chop, lean	Leeks		
Potatoes	Liver, lamb		
Rice white	Liver, ox (10–20)		
Rice brown	Nectarines		
Salmon, brine	Oats		
Sausages, pork/beef	Palm oil		
Spaghetti	Peaches, fresh		
Trout, Rainbow (0.1–3)	Pears		
Tuna, brine	Peppers, green		
Turnips	Peppers, red		
Yogurt (0.1–0.4)	Plums, red		
	Raisins		
	Rhubarb		

[a]MK-*n* ranges are shown in parentheses.

as well as in fruits, oils, dairy products, eggs, and some meat products. With modern HPLC techniques, naturally occurring phylloquinone can be detected in most foods. Vegetable oils show a high degree of variability, ranging from < 5 μg per 100 g in coconut, corn, groundnut, and safflower oils, to 100–200 μg per 100 g in soya bean and rapeseed oils. This leads to a similar variation in the phylloquinone content of margarines according to the oil base. The phylloquinone content of lean meat and fish is generally low (< 1 μg per 100 g), but higher amounts are found in animal livers; this organ acts as a storage site of the vitamin. Please refer to individual foods.

There is less information on the menaquinone content of foods. It is known that animal liver contains substantial concentrations of menaquinones, which normally greatly exceed the phylloquinone content. The livers of ruminants contain particularly large concentrations of long-chain menaquinones (MK-6–13), which derive from bacterial fermentation in the rumen. The only other known sources of significant amounts of menaquinones in the Western diet are fermented foods, such as cheese and yogurt. All cheeses contain relatively high concentrations (≤ 20 μg per 100 g) of MK-8 and MK-9, with the latter predominating. Natto, the Japanese fermented soya bean food, contains substantial amounts of MK-7. Whereas menaquinones are detectable in cow's milk at much lower concentrations than phylloquinone, MK-4 has been confirmed to be present at comparable, or higher, levels than phylloquinone in the milk of several mammalian species.

Foods containing hydrogenated vitamin K-rich oils will also include a contribution from 2′,3′-dihydrophylloquinone. The biological activity of this K-vitamer is currently under investigation, and hence its abundance in the diet is of uncertain nutritional significance.

The processing of foods can have a variable effect on retention of vitamin K, with conventional cooking, canning, γ-irradiation, and freezing practices having a relatively minor influence, whereas significant and rapid loss occurs on exposure to UV light.

Use in Food Fortification

Since the requirements for vitamin K are low, fortification of foods with vitamin K is not common, with the exception of infant formula feeds to which synthetic preparations of phylloquinone are invariably added. Depending on the method of chemical synthesis, the ratio of the natural *trans* to the inactive *cis* form will vary, but is typically *c.* 7:1. (*See* **Food Fortification**; **Infant Foods**: Milk Formulas.)

Although national guidelines for fortification of infant formulas differ, their common aim is to protect against rare, but life-threatening, bleeding due to deficiency of vitamin K in early life. It is now known that the typical fortification levels of *c.* $50\,\mu g\,l^{-1}$ (as fed) are several times higher than human breast milk concentrations of phylloquinone, which average *c.* $2\,\mu g\,l^{-1}$. Although the reasons for adopting such high levels of fortification are somewhat empirical and based on the erroneously high estimates of vitamin K in breast milk by early bioassays, there has been little impetus for change because the low concentrations in breast milk are an established risk factor for neonatal vitamin K deficiency.

The synthetic vitamin K derivative menadione is no longer used to fortify infant formulae because of its association with neonatal hemolytic anemia and liver damage. In fact, the vitamin K activity of menadione is dependent on its *in vivo* conversion to biologically active MK-4. Nevertheless, because menadione is much cheaper to manufacture than phylloquinone, menadione derivatives are widely used in animal husbandry, particularly in poultry feeds, since poultry are very prone to bleeding due to dietary deficiency of vitamin K. In the poultry industry, the birds' dietary requirements may be further increased by the use of antibiotics, the effect of which may be either to inhibit the growth of intestinal microorganisms that synthesize menaquinones or to interfere directly with vitamin K metabolism. Consequently, stabilized water-soluble derivatives of menadione, such as crystalline menadione sodium bisulfite complex, are used universally as poultry feed supplements.

Measurement of Vitamin K in Food

In the 1930s, shortly after the discovery of vitamin K, Dam and colleagues developed a curative bioassay that involved the feeding of substances to vitamin K-deficient chicks and measuring the response on blood clotting. Although values that have been derived from this early work are often given in textbooks and handbooks of nutrition, a closer evaluation of the methodology shows that attempts to use these results as the basis for absolute food values are unjustified. Although such bioassays were greatly improved in the 1960s, little further work has emerged on their routine use and validation for food analysis.

The introduction of modern HPLC techniques has revolutionized the measurement of vitamin K in tissues. This powerful technique has met the criteria of high selectivity and sensitivity, which are also necessary for measurement of the low concentrations in most foods. Although several diverse protocols have been developed for phylloquinone, only one procedure has been validated by collaborative study. A range of sample extract purification strategies may be implemented prior to the final chromatographic analysis, which is usually accomplished by analytical reversed-phase HPLC. Due to the instability of vitamin K at high pH, saponification techniques commonly utilized for other fat-soluble vitamins are inappropriate for vitamin K analysis. The need for preliminary enhancement techniques is dependent principally on food type, analyte level, and final detection mode and may incorporate one or more techniques including (1) lipid extraction, (2) enzymatic lipid digestion, (3) solid-phase extraction (SPE) and (4) semipreparative normal-phase HPLC. (*See* **Chromatography**: High-performance Liquid Chromatography.)

Extraction and Clean-up

No universal extraction and purification procedure exists for vitamin K analysis in all foods. Nonpolar lipid solvents including hexane, isopropanol, dichloromethane, acetone, diethyl ether, and methanol, used either singly or in combination, have been used for initial total lipid extraction depending on the food type. For certain high-fat foods (fats, oils and milk), bulk lipid may be effectively removed with enzymatic digestion prior to hexane extraction of triglyceride-depleted lipid. For low-fat foods (vegetables, fruit, cereals, meats, and fish), acetone is an effective solvent, whereby, after the addition of water and hexane, the K vitamins partition entirely in the upper hexane phase, leaving polar lipids in the acetone–water phase. Alternatively, hexane:isopropanol or chloroform:methanol binary solvents are commonly used.

For protocols relying on a preliminary total lipid extraction, further purification is required in view of the overwhelming proportion of triglycerides and their incompatibility with reversed-phase HPLC.

Various combinations of lipase digestion, SPE and semipreparative normal-phase HPLC techniques are commonly recommended.

The extraction stage may also incorporate the addition of an internal standard, which, in general terms, compensates for procedural losses of the target analyte. This technique is essential when multidimensional protocols for vitamin K are implemented. The internal standard is chosen on the basis of several criteria that include its similar physical, chemical, and chromatographic properties to the analyte. Depending on the sample matrix, several vitamin K compounds and analogues (including radiolabelled compounds) have been found to be suitable internal standards for vitamin K assays.

A general scheme outlining commonly applied extraction and clean-up options is illustrated in Figure 2. Purification techniques usually comprise two successive stages based on the principles of adsorption chromatography, which facilitate the separation of K vitamers from most other potentially interfering lipid classes (e.g., hydrocarbons, sterols, fatty acids). If required, semipreparative normal-phase HPLC can also be used to isolate both K_1 and MK fractions and to separate the *cis* and *trans* isomers of phylloquinone.

The fraction(s) collected at the semipreparative HPLC stage may then be analyzed by reversed-phase HPLC using a variety of detection methods. For certain foods, a lipase digestion and hexane extraction scheme has been found to be sufficient to facilitate a direct analytical HPLC quantitation, without the need for additional purification steps.

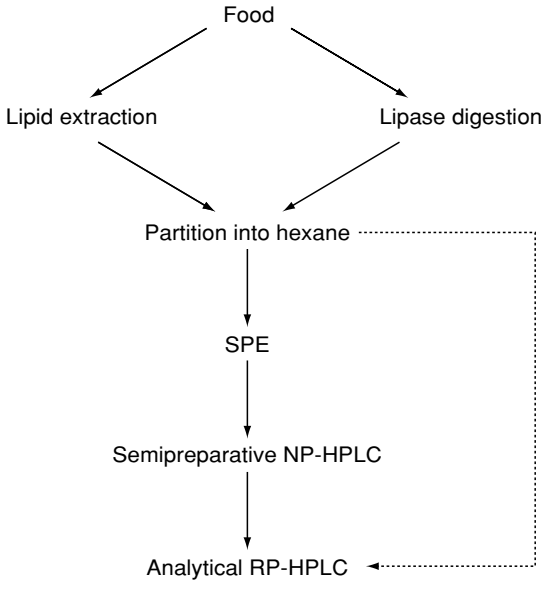


Figure 2 Flow chart summarizing extraction and purification of vitamin K from foods.

Detection and Quantification

The final analytical stage of HPLC is almost exclusively based on the principles of partition chromatography in the reversed-phase mode. This robust mode of liquid chromatography resolves the individual K vitamins from each other, while supporting the mobile phase additives necessary for the most sensitive detection techniques currently utilized. Whereas isocratic systems are generally used for the analysis of vitamin K_1, gradient elution is preferable when profiling the menaquinones, in view of their very wide hydrophobic range. The C18 functionality has most commonly been employed, although the recently developed C30 phase has been shown to allow resolution of the *cis* and *trans* isomers of phylloquinone, previously only accomplished under normal phase conditions.

The properties of K vitamins offer several avenues of approach to their detection by HPLC, and the most common options are summarized in Figure 3. The parent quinone form, in which the vitamin is isolated, may be detected with reasonable sensitivity (*c.* 500 pg) by ultraviolet absorbance detection, but this lacks selectivity and may be subject to interferences from other lipids. This detection method does, however, give reliable results for green vegetables, but is less satisfactory for animal tissues.

Alternatively, the more recently developed strategies exploit the reversible reduction of the quinone to the quinol, which may then be detected by either electrochemical or fluorescent techniques. For electrochemical detection, the greatest sensitivity and selectivity is obtained by employing a redox technique in which the detector has a dual-electrode cell with the electrodes arranged in series. Vitamin K is first

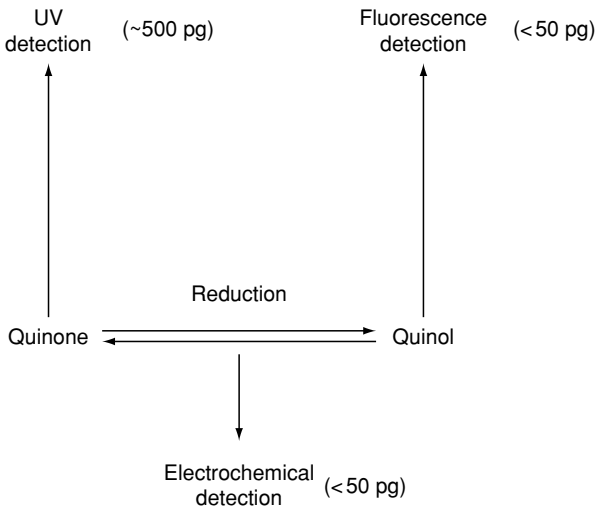

Figure 3 Detection options for vitamin K.

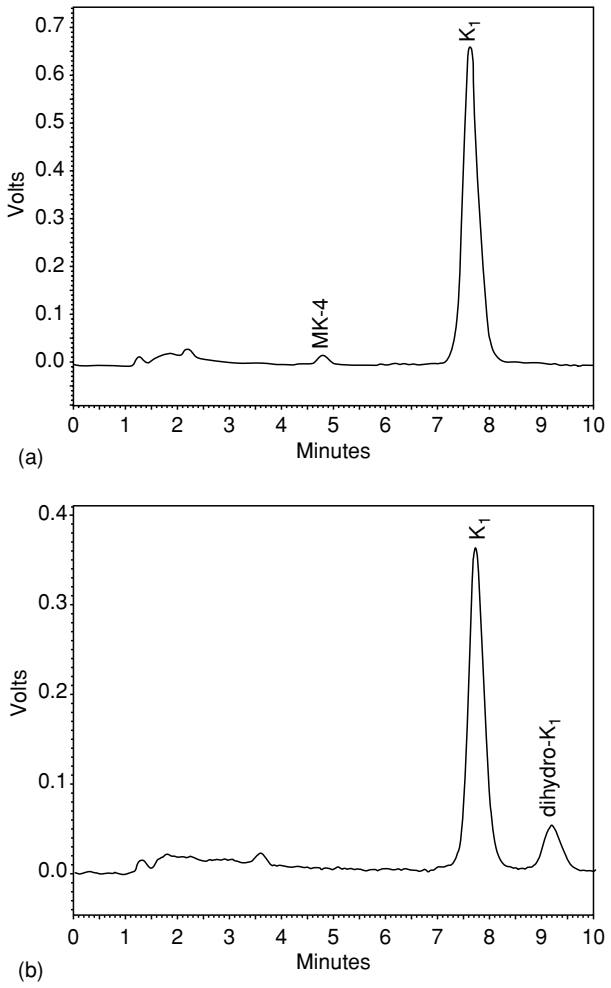

Figure 4 Liquid chromatography obtained for (a) infant formula and (b) margarine. C18 column, isocratic elution, postcolumn reduction, and fluorescence detection.

reduced at the upstream (or generator) electrode to the quinol, which is then reoxidized at the downstream (or detector) electrode: the current generated in the second reoxidation step is measured by the detector and is proportional to the amount of vitamin K passing through the electrochemical cell. This method is capable of detecting 50 pg or less of phylloquinone. Fluorescence detection again requires the postcolumn generation of the quinols after the chromatographic separation of their respective quinones. Reduction can be achieved by chemical, photochemical, or electrochemical techniques, with fluorescence detection providing similar sensitivity to redox electrochemical detection (*c.* 25–50 pg). Currently, the most commonly employed reduction technique involves a short dry-packed zinc or platinum oxide column, configured between the separation column and detector. Examples of chromatography achieved for a representative infant formula and margarine are illustrated in Figure 4, utilizing a C18 column and fluorescence detection.

Further theoretical and practical details are provided in the methodological references listed in the Further Reading section.

Physiology

M J Shearer, St Thomas's Hospital, London, UK

Background

From the 1930s until the 1970s, the only known role of vitamin K was as an essential antihemorrhagic factor, which initially had been shown to promote the synthesis of active prothrombin (factor II), but later also of factors VII, IX, and X. Collectively, these four factors, all synthesized in the liver and then released into the circulation, became known as the classical vitamin K-dependent coagulation factors. In 1974, it was shown that vitamin K was required as a cofactor for the enzymic conversion of specific glutamate residues in the prothrombin molecule to γ-carboxyglutamate (Gla) residues. The elucidation of this biochemical pathway leading to the synthesis of a new amino acid was the impetus that led to the discovery of many more vitamin K-dependent proteins. These proteins, also known as Gla proteins, are now known to have a widespread tissue distribution. They include further coagulation proteins (proteins C, S, and Z) and others with putative roles in the regulation of bone turnover (osteocalcin), and bone calcification (matrix Gla protein (MGP)). New evidence suggests that MGP is also a powerful inhibitor of vascular calcification. Other suspected functions of Gla proteins are in vascular repair processes (Protein S), cell-cycle regulation, cell–cell adhesion (Gas6), and signal transduction (Gas6 and proline-rich Gla proteins). For the most part, the precise physiological function of these new Gla proteins is poorly understood. However, nutritional and epidemiological studies in humans suggest that optimal intakes of vitamin K are necessary to maintain skeletal and cardiovascular health. Despite the possibility of these new health roles, the only clearly defined deficiency syndrome is bleeding due to a lack of functional molecules of the vitamin K-dependent coagulation factors II, VII, IX, and X. Bleeding due to vitamin K deficiency is rare in adults but is more common in infants during the first 6 months of life. The potential risk of serious life-threatening bleeding in infancy means that most countries recommend that all newborns should receive vitamin K prophylaxis.

Intestinal Absorption and Bioavailability

Dietary vitamin K, mainly as phylloquinone, is absorbed chemically unchanged from the proximal intestine after solubilization into mixed micelles composed of bile salts and the products of pancreatic lipolysis. In healthy adults, the efficiency of absorption of phylloquinone in its free form is about 80%. The bioavailability of vitamin K from foods varies according to food type and the associated matrix. Thus, the efficiency of absorption of phylloquinone may be as low as 10% from green leafy vegetables (e.g., spinach) in which the vitamin is tightly associated with chloroplast membranes. Less is known about the absorption of dietary menaquinones, but the efficiency of absorption decreases with increasing length of the side-chain.

Menaquinones (MKs) are also synthesized by the intestinal microflora, predominately in the colon. Major forms are MK-10 and MK-11 synthesized by *Bacteroides* species, MK-8 by *Enterobacteria*, MK-7 by *Veillonella*, and MK-6 by *Eubacterium lentum*. It is commonly held that microfloral synthesis provides an important nutritional source of vitamin K for humans, but direct evidence is lacking. A microfloral contribution of vitamin K is supported by the findings that very-long-chain MKs 10–13 are rare in foods but make up the majority of hepatic stores. However, all experimental evidence suggests that the absorption of menaquinones from the large intestine is an extremely inefficient process.

Transport in Plasma and Tissue Distribution

After intestinal absorption, vitamin K is incorporated into chylomicrons, secreted into the lymph, and enters the blood via the lacteals. Once in the circulation, phylloquinone is rapidly cleared at a rate consistent with its continuing association with chylomicrons and the chylomicron remnants that are produced by lipoprotein lipase hydrolysis at the surface of capillary endothelial cells. After an overnight fast, more than half of the circulating phylloquinone is still associated with triglyceride-rich lipoproteins, with the remainder being equally distributed between low-density and high-density lipoproteins. Phylloquinone is the major circulating form of vitamin K, but menaquinones MK-7 and MK-8 have been detected at lower concentrations.

Dietary vitamin K is delivered to the liver and possibly other tissues, including bone marrow, in the form of chylomicron remnants. The cellular uptake of vitamin K is mediated by apolipoprotein E in the chylomicron remnants and heparin sulfate proteoglycans on the cell surface. The liver, the site of synthesis of the vitamin K-dependent coagulation proteins, has a limited capacity for storing phylloquinone. Thus, the hepatic reserves of phylloquinone are several thousand-fold lower than those of vitamin A, despite the fact that dietary intakes of phylloquinone are

only about 10-fold lower. The distribution of molecular forms of vitamin K in the liver is quite different from that in plasma in that the major transport form, phylloquinone, represents only about 10% of total stores; the remainder comprise bacterial menaquinones, mainly MKs 7–13. Long-chain menaquinones are also present in other nonhepatic tissues but at lower concentrations than the liver. Some tissues such as the brain and pancreas seem to have the capacity to selectively convert phylloquinone to MK-4, but little is known about the biochemistry or physiological significance of this enrichment.

Catabolism and Turnover

The metabolic transformations leading to the elimination of vitamin K from the body occur exclusively in the liver. Phylloquinone is rapidly degraded with about 20% of a single dose being excreted in the urine within 3 days and about 40–50% excreted in the feces via the bile. The hepatic reserves of individuals on a low-phylloquinone diet decline rapidly. The overall picture is that phylloquinone has a fast turnover time, suggesting that the body stores are being constantly replenished.

The route of hepatic catabolism leading to the urinary excretion of vitamin K proceeds by oxidative degradation of the phytyl side-chain, probably involving the same enzymes used for the ω-methyl and β-oxidation of fatty acids, steroids, and prostaglandins. The end products of this pathway are shown in Figure 1. Two major aglycone metabolites have been identified; they are carboxylic acids with 5 and 7 carbon atom side-chains that are excreted in the urine as glucuronide conjugates. The biliary metabolites have not been clearly identified but are initially excreted as water-soluble conjugates and become lipid-soluble during their passage through the gut, probably through deconjugation by the intestinal microflora. There is no evidence that body stores of vitamin K can be conserved by an enterohepatic circulation, since vitamin K itself is not excreted in bile, and the side-chain shortened carboxylic acid metabolites are not biologically active.

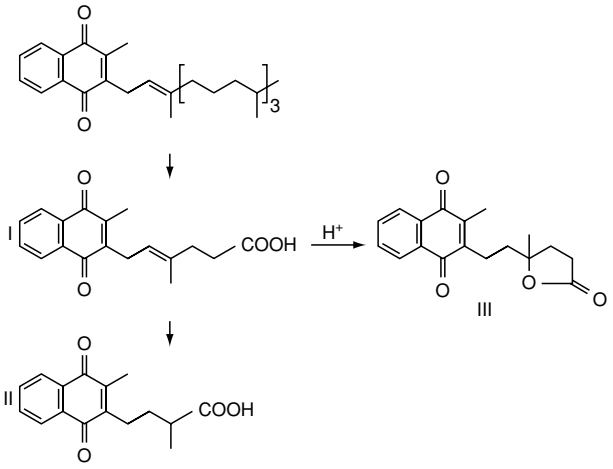

Figure 1 Simplified pathway and chemical structures of the two major urinary metabolites of phylloquinone in their aglycone forms (structures I and II). In acidic conditions, metabolite I may cyclize to produce phylloquinone γ-lactone (structure III). (I) 2-Methyl-3-(5′-carboxy-3′-methyl-2′-pentenyl)-1,4-naphthoquinone; (II) 2-methyl-3-(3′-carboxy-3′-methylpropyl)-1,4-naphthoquinone;(III) 2-methyl-3-(5′-carboxy-3′-hydroxy-3′-methylpentyl)-1,4-naphthoquinone lactone.

Cofactor Role of Vitamin K

Vitamin K-dependent Carboxylation of Glutamate Residues

The only unequivocal biochemical role for vitamin K is as a cofactor for a unique posttranslational chemical modification confined to a small group of unusual calcium-binding proteins. The vitamin K-dependent step is a carboxylation reaction that transforms selective glutamic (Glu) residues in the protein precursor into Gla. The reaction shown in Figure 2 is catalyzed by a microsomal enzyme called vitamin K-dependent (γ-glutamyl) carboxylase and requires molecular oxygen and carbon dioxide. The form of vitamin K required as the cofactor is not the stable quinone structure found in the diet but the reduced quinol (or hydroquinone) structure (KH_2). The subsequent oxidation of vitamin KH_2 to vitamin K 2,3 epoxide is coupled to the abstraction of a proton from the γ-carbon of the Glu residue to generate a carbanion that reacts with CO_2 to yield the final Gla product. The biological relevance of the Gla structure is that it forms a cage structure to which divalent metal ions such as calcium may be bound. In the case of the vitamin K-dependent procoagulants, this induces the conformational change and

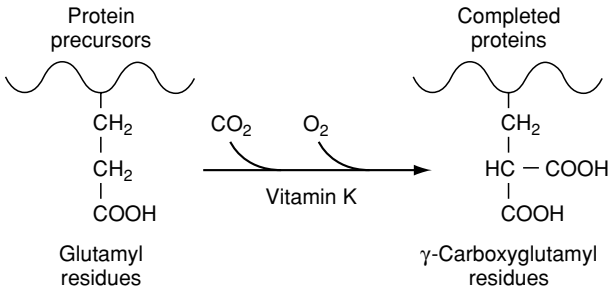

Figure 2 Posttranslational vitamin K-dependent carboxylation reaction showing the conversion of protein-bound glutamyl residues (Glu) to γ-carboxyglutamate (Gla) residues.

membrane-binding properties that are essential for their biological activity.

Vitamin K Epoxide Cycle

In all tissues and cells that synthesize Gla proteins, vitamin K-dependent carboxylation is intimately linked to a metabolic sequence known as the vitamin K-epoxide cycle. This cycle and the associated enzyme activities are shown in Figure 3. During γ-glutamyl carboxylation, vitamin KH_2 is transformed to vitamin K epoxide (enzyme activity E_1). The epoxide product is recycled in two steps; first by a vitamin K epoxide reductase activity (E_2) to produce vitamin K quinone, and second by a quinone reductase activity (E_3) to produce the coenzyme vitamin KH_2. Both these activities are thiol-dependent and are probably effected by the same enzyme.

An important property of the dithiol-dependent epoxide and quinone reductase activities is their sensitivity to certain antagonists, especially those based on 4-hydroxycoumarin (e.g., warfarin) or indandione structures. Drugs based on these structures have long been used as oral anticoagulants, and it is now clear that their anticoagulant action is based on their ability to inhibit the epoxide reductase activity (E_2) and block the recycling of the vitamin. The dithiol-dependent quinone reductase (E_3) is also sensitive to warfarin, but there is a second quinone reductase activity catalyzed by an NAD(P)H-dependent enzyme activity (E_4) that is less sensitive to warfarin inhibition, and this provides an alternative pathway for the reduction of vitamin K to KH_2 in the presence of warfarin or other oral anticoagulant drugs. Therapeutic anticoagulation is dependent on a balance being achieved between the inhibition of the recycling enzymes and the amount of dietary vitamin K that can enter the cycle to support carboxylation at a reduced efficiency.

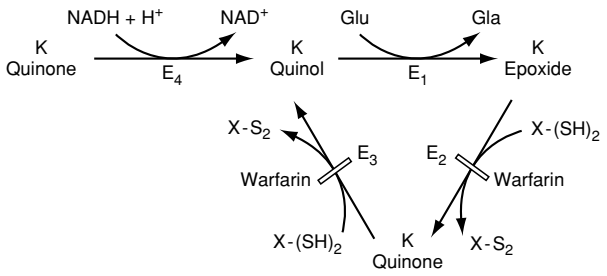

Figure 3 Scheme showing the reactions and enzyme activities (denoted by E_1, E_2, E_3, and E_4) of the vitamin K-epoxide cycle. The active form of vitamin K needed for the conversion of glutamate residues (Glu) to γ-carboxyglutamate (Gla) residues is the reduced form, vitamin K quinol (K quinol). The carboxylation reaction is driven by a vitamin K-dependent carboxylase activity (E_1), which simultaneously converts K quinol to vitamin K 2,3-epoxide (K epoxide). K epoxide is reduced back to the quinone (K quinone) by vitamin K epoxide reductase (E_2). The cycle is completed by the reduction of recycled K quinone by a vitamin K reductase activity (E_3). Both E_2 and E_3 reductase activities are dithiol-dependent (X-(SH_2) and X-S_2 denote reduced and oxidized dithiols) and are inhibited by coumarin anticoagulants such as warfarin. Dietary vitamin K (K quinone) may enter the cycle via an NAD(P)H-dependent vitamin K reductase activity (E_4), which is not inhibited by warfarin.

Vitamin K-dependent (Gla) Proteins

Distribution and Structure

γ-Glutamyl carboxylase activity is present in a wide variety of extrahepatic tissues such as bone, kidney, placenta, pancreas, skin, spleen, lung, testis, and the vessel wall. New Gla proteins continue to be discovered; the present list together with their tissue distribution is shown in Table 1. Some of these Gla proteins are found in only one major tissue (e.g., procoagulant factors in liver and osteocalcin in bone), while others (e.g., matrix Gla protein and protein S) are more widely distributed.

All Gla-containing proteins are secretory proteins and are characterized by an intracellular precursor form possessing a leader sequence that facilitates specific posttranslational events and is then normally cleaved before secretion. Within the leader sequence, a hydrophobic presequence facilitates the translocation of the precursor Gla proteins across the endoplasmic reticulum, while a second prosequence serves as a recognition signal for the vitamin K-dependent carboxylase. With the exception of matrix-Gla protein, the prosequence of currently characterized Gla proteins is located immediately before the N-terminal of the mature protein. In matrix-Gla protein, the carboxylation recognition site is internal and is retained in the mature protein. The number of Gla residues varies: the four classical vitamin K-dependent clotting factors contain 10–12 Gla residues, whereas the much smaller MGP and osteocalcin contain five and three Gla residues, respectively.

Role of Gla proteins

Hemostasis (procoagulants and anticoagulants) The vitamin K-dependent coagulation proteins comprise four plasma procoagulants (factors II, VII, IX, and X) and two feedback anticoagulants (proteins C and S). The physiological function of a seventh plasma protein (protein Z) is less established but seems to play a role in dampening coagulation by acting as a cofactor for the inhibition of factor Xa. The four vitamin K-dependent procoagulants have long been known to play a central role in the blood clotting cascade leading to the formation of a fibrin clot. Circulating

Table 1 Distribution and roles of vitamin K-dependent (Gla) proteins

Gla protein	*Tissue*	*Role*
Prothrombin (factor II), factors VII, IX, and X	Liver (then plasma)	Blood clotting (procoagulants)
Protein C	Liver (then plasma)	Blood clotting (anticoagulant)
Protein S	Liver (then plasma), endothelium, bone	Anticoagulant role (cofactor for protein C); role in bone unknown
Osteocalcin (or bone Gla protein)	Bone	Implicated in bone remodeling
Matrix Gla protein	Most tissues	Inhibits calcification of arteries and cartilage
Gas 6	Most tissues	Implicated in cell-cycle regulation, cell survival, cell proliferation, cell adhesion, platelet signaling
Proline-rich Gla proteins	Most tissues	Unknown, but protein structures suggest roles as cell-surface receptors

as inactive forms (or zymogens) of serine proteases, their biological activity is dependent on their ability to bind to anionic phospholipid surfaces where cleavage of the zymogens yields the active protease clotting factors. The Gla residues of these clotting factors provide an efficient chelating site for calcium ions that enables ion bridges to be made between the factor and the surface phospholipids of platelets and endothelial cells where, together with other cofactors, they form membrane-bound enzyme complexes. The intricate control of coagulation is illustrated by the fact that another Gla protein (protein C), once activated, performs an anticoagulant role by specifically degrading phospholipid-bound activated factors V and VIII in the presence of calcium. This anticoagulant activity of activated protein C is dependent on yet another Gla protein (protein S) that acts as a synergistic cofactor by enhancing the binding of activated protein C to negatively charged phospholipids.

Bone metabolism The discovery in 1975 that bone tissue contains a Gla protein, which is also one of the most abundant proteins in the body, has revolutionized earlier thinking that vitamin K is only needed for coagulation. This protein, called osteocalcin or bone Gla protein, accounts for about 15% of the noncollagenous proteins in the bone of most vertebrate species, although this proportion is less in humans. The three Gla residues of osteocalcin project away from the Gla helix, and their periodic spacing complements the interatomic spacing of the calcium ions of the hydroxyapatite lattice; this is thought to account for the strong mineral-binding characteristics of the fully carboxylated form of osteocalcin. The adsorption affinity of osteocalcin for hydroxyapatite and other features such as its high degree of conservation throughout evolution, its regulation by vitamin D, and its chemotractant properties suggest an important role for osteocalcin in bone metabolism, although the nature of this role still remains unknown. Osteocalcin is specifically synthesized by osteoblasts, and since its concentration in blood reflects osteoblastic activity, measurements of total osteocalcin have become clinically important in the diagnosis of bone disease.

Besides osteocalcin, bone tissue contains lower concentrations of other Gla proteins; matrix Gla-protein (MGP), protein S, and Gas6 (Table 1). MGP is a 10-kDa secretory protein, with five residues of Gla. It was first isolated from demineralized extracts of bone by Price in 1983 but is expressed by a wide variety of tissues and cell types. Its function in bone is unclear but is probably related to its capacity to inhibit localized calcification as recently shown for arteries. Transgenic MGP-deficient mice show inappropriate calcification of the cartilage, including the growth plate, and a phenotype characterized by short stature, osteopenia, and fractures. This function is consistent with the effects of the vitamin K antagonist warfarin, which, when given *in utero* or to young animals, results in excessive mineralization and premature closure of the epiphyseal growth plate. An important role for Gla proteins during human fetal bone development is suggested by the bone defects often seen in infants born to mothers who had received vitamin K antagonists such as warfarin during the first trimester of pregnancy. Evidence that warfarin embryopathy is mediated by a dysfunctional MGP comes from the demonstration that mutations encoding MGP are responsible for a rare inherited disorder called Keutal syndrome, which is characterized by a similar abnormal calcification of cartilage. The functions of protein S and Gas6 in bone are presently unknown.

Vascular calcification A series of remarkable studies since 1997 have firmly established MGP as a potent inhibitor of calcification of arteries and cartilage. Thus, targeted deletion of the *MGP* gene in mice resulted in rapid focal calcification of the elastic

lamellae of the arterial media but not of the arterioles, capillaries, or veins. This process begins at birth and by 3–6 weeks is sufficiently severe to cause the arteries to become rigid tubes that fracture, causing death from bleeding. Most of the phenotypic features of arterial calcification seen in MGP-deficient mice can be mimicked, albeit to a somewhat muted degree, by the vitamin K antagonist warfarin. This effect of warfarin points to the need for Gla residues, and hence vitamin K, to the function of MGP. Overall, the dramatic features of both genetic and biochemical models of MGP depletion strongly suggest that MGP is central to the process by which calcification of arteries is normally inhibited *in vivo* and that there is no effective alternative inhibitor at aortal sites.

Assessment of Vitamin K Status

The traditional criterion for vitamin K sufficiency is the maintenance of normal plasma concentrations of fully γ-carboxylated vitamin K-dependent procoagulants II, VII, IX, and X. The presence of a clinically significant vitamin K-deficient state is usually investigated by global coagulation assays such as the one-stage prothrombin time. Such assays are insensitive to small changes in γ-carboxylation of the vitamin K-dependent coagulants and, while appropriate for detecting overt vitamin K deficiency, are not useful for picking up suboptimal states of vitamin K deficiency.

Modern assessments of vitamin K status need to take into account both coagulation and noncoagulation roles of Gla proteins and their different sites of synthesis. When vitamin K is in short supply, or its action is blocked by an oral anticoagulant such as warfarin, undercarboxylated (des-γ-carboxy) species of Gla proteins are produced at the tissue site of synthesis and, in some species, including humans, are secreted into the circulation. Collectively, these undercarboxylated species are known as **p**roteins **i**nduced by **v**itamin **K** **a**bsence or antagonism (PIVKA). In the case of the coagulation protein prothrombin, specific and sensitive immunoassays for undercarboxylated prothrombin (PIVKA-II) provide a powerful marker of the coagulation status of vitamin K because they can detect small decreases in the Gla content of prothrombin well before any changes occur in conventional coagulation tests. Similarly, the assay of circulating undercarboxylated species of osteocalcin provides a specific functional marker to assess the sufficiency of vitamin K for the carboxylation of bone Gla proteins. Since prothrombin and osteocalcin are synthesized in the liver and bone, respectively, the detection of their respective undercarboxylated species allows the vitamin K status of these tissues to be assessed independently. Such studies have shown that the carboxylation of osteocalcin in bone is more susceptible to reduced dietary intakes of vitamin K than the carboxylation of the classical coagulation proteins. Measurements of undercarboxylated osteocalcin are being increasingly used to assess the importance of optimal vitamin K intakes with respect to bone health. The excretion of free Gla in urine represents the final catabolic product of all Gla proteins, and its measurement has also been shown to reflect dietary intakes and status. Another method for assessing vitamin K status is from direct serum assays of phylloquinone, the predominant transport form of vitamin K. A low serum phylloquinone is a good indicator of a poor overall vitamin K status.

Vitamin K and Health

Role in Hemostasis

Overt vitamin K deficiency in adults, resulting in clinical bleeding, is almost unknown except as a consequence of underlying disease, most commonly resulting from hepatointestinal disorders that disturb the absorption or utilization of the vitamin. However, oral coumarin anticoagulant drugs, such as warfarin, are widely used in the prevention and management of thromboembolic disease. These vitamin K antagonists are used to induce an artifical but controlled state of vitamin K deficiency, the aim being to reduce the circulating levels of the vitamin K-dependent clotting factors to within a predetermined target range depending on the clinical condition.

In contrast to adults, bleeding due to vitamin K deficiency may occur spontaneously in the first few months of life. The resulting bleeding syndrome is traditionally known as hemorrhagic disease of the newborn, in recognition of the Boston physician Townsend, who is credited with the first description of the syndrome in 1894. The modern name is vitamin K deficiency bleeding (VKDB) of early infancy. Until the late 1960s, VKDB was considered to be solely a problem of the first week of life (classical VKDB), but two other forms (early and late VKDB) have now been recognized (Table 2). Late VKDB, peaking between the third and sixth weeks of life, is the most common syndrome and is still a significant worldwide cause of infant morbidity and mortality. In different parts of the world, some two to 100 cases per 100 000 births of late VKDB have been reported, with a particularly high incidence in the Far East. Unlike the classical form, late VKDB has a high incidence of intracranial hemorrhage, resulting in death or severe and permanent brain damage in

Table 2 Classification of vitamin K deficiency in the newborn (VKDB)

VKDB syndrome	*Time of presentation*	*Common bleeding sites*	*Etiological factors*
Early	0–24 h	Cephalohematoma, intracranial, intrathoracic, intraabdominal	Maternal drugs (e.g., warfarin, anticonvulsants)
Classical	1–7 days	Gastrointestinal, skin, nasal, circumcision	Mainly idiopathic, breast-feeding (may be related to low milk intakes)
Late	2–26 weeks	Intracranial, skin, gastrointestinal	Mainly idiopathic, breast feeding, some degree of cholestasis often present; May reflect underlying disease (e.g., biliary atresia, α-1-antitrypsin deficiency, cystic fibrosis)

around 50% of cases. One major risk factor, exclusive breast-feeding, is common to both classical and late syndromes and is probably related to the relatively low concentrations of vitamin K in breast milk ($1–2\,\mu g\,l^{-1}$) compared to about $50\,\mu g\,l^{-1}$ in formula feeds. Another probable etiological factor is the precarious hepatic stores of vitamin K in newborns because of poor placental transfer of phylloquinone and the lack of neonatal stores of bacterial menaquinones, which only build up slowly after bacterial colonization of the intestine. Some infants who develop late VKDB have abnormalities of liver function, leading to cholestasis and an impaired absorption efficiency of vitamin K.

By the early 1980s, reports in the literature were suggesting a worldwide rise in the incidence of late VKDB. This resurgence may have been related to both a decline in routine vitamin K prophylaxis and the promotion of exclusive breast-feeding. In recent years, many countries have reemphasized the need to give all babies extra vitamin K as a public-health measure. Often, this was given as a single intramuscular dose at birth, but since 1992, concerns about an epidemiological association between the intramuscular route and later childhood cancer has seen a shift in some countries towards oral prophylaxis. However, there is evidence that even multidose oral regimens fail to give full protection against late VKDB and that this is because there is an underlying reservoir of infants who have a reduced efficiency of absorption due to underlying and unrecognized cholestasis. Several epidemiological studies conducted since 1992 have not substantiated the link between vitamin K prophylaxis and cancer.

Role in Bone Health

Despite mechanistic gaps in our knowledge, a picture is emerging that a suboptimal vitamin K status may play a role in the pathogenesis of osteoporosis. Much of this evidence is still circumstantial, being based on associations of fracture risk and bone mineral density with indices of poor vitamin K status and low dietary intakes. Of particular note is that undercarboxylated osteocalcin is an independent risk factor of both hip-fracture risk and bone mineral density. However, osteoporosis is a complex disease, and without a fuller understanding of the biological function of osteocalcin, the interpretation of these associations with vitamin K status remains uncertain.

In the near future, the results from a number of long-term intervention studies on the effects of vitamin K supplementation on bone health will become available. These may help to answer the question of whether extra intakes of vitamin K can influence bone mineral density and bone turnover. Most of these studies have used phylloquinone because this is the major dietary form, but in Japan, the effects of very large doses of MK-4 (menatetranone) on bone health are being studied. Both phylloquinone and MK-4 are known to promote the γ-carboxylation of osteocalcin, but these forms differ in other important respects. Thus, there is evidence that tissues can convert phylloquinone into MK-4 *in vivo* (but not vice versa) and that MK-4 may have a direct inhibitory effect on bone resorption. In an intervention study in which Japanese women with osteoporosis were treated with a high-dose MK-4 regimen, the incidence of fractures was significantly reduced, and the rate of bone loss was decreased.

Dietary Intakes and Requirements

The major dietary source of vitamin K is phylloquinone. In Western societies, the majority of phylloquinone intakes (up to 50%) comes from green leafy vegetables followed by certain vegetable oils such as soybean, canola (rapeseed), and olive oils. Mixed dishes and meals contribute about 15% of total phylloquinone intake, largely because of their oil content. The wide range of the vitamin K content of different food items means that individual daily intakes may vary widely, but average adult intakes mostly range from 60 to 120 μg per day. Intakes of this order are more than sufficient to maintain normal hemostasis, and even intakes as low as 10 μg per day for a few weeks have no effect on global coagulation assays.

However, more sensitive measures of vitamin K status (e.g., undercarboxylation of Gla proteins, urinary Gla excretion, and serum phylloquinone) respond readily to moderate changes in dietary intakes. One conclusion from nutritional depletion/repletion studies is that the daily intakes of vitamin K needed to sustain the posttranslational γ-carboxylation of extrahepatic Gla proteins such as osteocalcin are higher than those needed for the coagulation Gla proteins synthesized in the liver. Therefore, previous recommendations of a daily intake of 1 μg per kilogram of body weight, which have been based on the coagulation role of vitamin K, may need to be revised upwards if evidence continues to harden on other potential health benefits such as the amelioration of osteoporosis and arterial calcification. Studies in the UK and USA already suggest that a substantial proportion of their populations have intakes below 1 μg per kilogram of body weight. What this optimal intake should be must await further research on the physiological function of Gla proteins, the further delineation of functional markers of vitamin K status, and studies of the health consequences of different intakes.

Overview

This article covers the definition, a brief historical account of the discovery, classification and nutritional role, forms found in food, and effects of processing on vitamin stability.

Vitamins are defined as a group of complex organic micronutrients present in small amounts in food or nutritional supplements that the body requires for its normal metabolism and function. They cannot be synthesized by humans in sufficient quantity for normal metabolic requirements. Certain substances that are considered vitamins can be synthesized in small amounts by intestinal-tract bacteria (e.g., B-groups). Each vitamin consists of a mixed group of compounds, which may not be related to each other chemically and are therefore classified by function. (*See* **Microflora of the Intestine:** Role and Effects.)

History

It was not until the early 1900s that the existence of the 'accessory food factors' was recognized. Indeed, the term 'vitamine' was first used by a Polish biochemist, named Funk, to describe an 'accessory food factor.' However, deficiency diseases were well known many centuries earlier, the earliest documented disease being beriberi, which was recorded in China around 2600 BC. Yet, it was not until the end of the eighteenth century that the nutritional etiology of the disease was established. In 1885, a Japanese physician named Takaki succeeded in reducing the effect of beriberi among Japanese sailors by feeding them a diet containing more meat and vegetables, and less rice. Then, in 1890, a Dutch doctor named Eijkman reproduced symptoms of the disease in chickens fed exclusively with shelled rice. His collaborator, Grijns, showed that these symptoms disappeared by adding rice husks to the chicken diet. Finally, in 1912, Funk isolated the antiberriberi factor from the cuticle of the rice and named it 'vitamine,' the 'life-essential amine.' This term was adopted to name all the nutritional factors responsible for deficiency diseases.

Similarly, scurvy and night blindness were described in ancient Egypt around 1500 BC. During the period AD 1400–1600, the explorers Vasco de Gamma and Magellan described in detail the scurvy and night blindness that had devastated their ships' crew. A century earlier, Jacques Cartier had succeeded in saving a good many sailors thanks to an Indian medicine based on pine needles. Finally, in 1747, James Lind found the preventive effect of citrus fruit using controlled experiments at sea, and this was shortly followed by the demonstration, during the voyages of Captain Cook in the period 1768–1771, that prolonged sea voyages were possible without the ravages of scurvy. (*See* **Hypovitaminosis A; Scurvy.**)

Thirteen vitamins were isolated, identified, and synthesized between 1929 and 1975. The last vitamin to be discovered was vitamin B_{12} in 1948. Many researchers who contributed to the fundamental discoveries have been honored by the Nobel Prizes Committee, among them: Szent-Gyorgyi and King for the simultaneous discovery of ascorbic acid in 1928; Karrer for his work on vitamin A and β-carotene between 1928 and 1933; Dam and Doisy for the discovery and chemical nature of vitamin K in 1943; and Hodgkin for the structural determination of vitamin B_{12} in 1964. (*See* **Carotenoids**: Physiology.)

Nowadays, vitamin research is still very active. The understanding of the precise, complex role of vitamins has made remarkable progress owing to the study of vitamin-dependent metabolite diseases of genetic origin. More recently, because of their antioxidant properties, some fat-soluble vitamins, notably vitamins A, E, and C, and provitamin A compounds (carotenoids; including β-carotene, lutein, and lycopene), are also considered to play an important role in the prevention against chronic degenerative diseases and cancers. Also, it has been shown that folic acid can reduce significantly the incidence of neural tube defects (such as spina bifida), and folates, in general, may protect against vascular diseases and some cancers, notably colonic cancer.

Classification and properties

A number of factors can make the identification and classification of vitamins difficult: (1) a vitamin can exist in a number of different structures with similar, or different, biological activities; (2) the biological activity is organism-dependent; (3) the physiologically or metabolically active form of a vitamin *in vivo* may be different from that found in food (e.g., B vitamins are active in coenzyme forms; 1,25-dihydroxycholecalciferol is the active form of vitamin D_3; (4) several forms of the same vitamin can interconvert during extraction (e.g., pyridoxine, pyridoxamine, pyridoxal, and their phosphorylated derivatives; and (5) synthetic forms of a vitamin are often available commercially in a more stable form, e.g., α-tocopherol acetate and retinol acetate are more stable compared with the free vitamins and are converted to the letter in the body.

Vitamins are generally classified by their solubility characteristics into fat-soluble and water-soluble groups. A full list of vitamins, forms, functions, and health benefits is given in Table 1. The fat-soluble vitamins (A, E, D_3, and K, and carotenoids) are derived from the isoprenoid pathway, whereas the synthesis of the water-soluble vitamins (B_1, B_2, B_6, B_{12}, C, biotin, niacin, and pantothenic acid) is much less connected, and several of them have multiple biosynthetic pathways. Other 'vitamin-like' compounds are sometimes associated with the classical vitamin compounds. These include vitamins F (essential fatty acids), L (*o*-aminobenzoic acid), P (bioflavonoids), U (L-methioninylmethylsulfonium chloride), and B_{13} (orotic acid), choline, α-lipoic acid, myoinositol, plastoquinone, pyrroloquinoline quinone, and ubiquinones. *Refer to* individual vitamins.

During the early years of vitamin discovery, their chemical composition was largely unknown and were each assigned a letter of the alphabet for convenience. This was further complicated when it was found that the activity attributed to a single vitamin was, in some instances, the result of a combination of several vitamins, e.g., B-complex vitamins. Once a vitamin had been isolated from a food and its chemical structure determined, variations in the structure were found within compounds having the same vitamin activity but in different species. A system of numerical subscripts was therefore adopted to overcome this problem, e.g., D_2 and D_3.

In order to simplify the system, letters were sometimes replaced with names, e.g., thiamin (vitamin B_1), riboflavin (B_2), pantothenic acid (B_5) and biotin (vitamin H), based on the chemical structure of a specific function or source. 'Thiamin' contains the prefix 'thi,' which is derived from the Greek word for sulfur, and refers to its sulfur content. 'Riboflavin' indicates the chemical structure and is derived from the chemical names 'ribose' (a pentose sugar) and 'flavin' (a heterocyclic ketone). 'Pantothenic acid' is derived from the Greek word *pantos*, meaning 'found everywhere.' 'Biotin' originates from the German word *haut*, meaning skin, as this vitamin protects the skin.

Occurrence in Food

One of the main differences between fat- and water-soluble vitamins is their distribution in biological tissues. The water-soluble vitamins are found in all living tissues, whereas the fat-soluble vitamins are completely absent from some tissues. Vitamins A and D occur widely in plant tissues in the form of a provitamin. Similarly, the amino acid tryptophan can be converted into nicotinic acid in the body. Although it is generally assumed that sufficient amounts of vitamins can be absorbed from a balanced diet for normal requirements, the use of vitamin supplements, either as single compounds or in multivitamin products, is widely consumed. The major vitamin forms found in foods, some commercial forms, and some examples of rich food sources, are given in Table 2.

Nutritional Aspects

Vitamins are required in trace amounts in the diet for the maintenance of optimal health, growth, and reproduction. Deficiency symptoms will occur if a single vitamin is omitted from a diet of a species that requires it. Many of the vitamins act as coenzymes, whereas others have no single role but perform certain essential functions. A list of known functions for each vitamin is given in Table 1. Vitamin requirements based on metabolic needs are similar for animals and humans, but dietary needs widely among species. (*See* **Coenzymes**.)

The recommended intakes of nutrients, including vitamins, are intended as daily intake guidelines for preventing deficiencies and maintaining body reserves among healthy individuals. The values are derived from studies on volunteers on nutrient balance studies, measures of tissue saturation, normal vitamin intakes in the general population, and extrapolation

Table 1 Fat- and water-soluble vitamins: forms, function, and potential health benefits

Vitamin	*Vitamers and related forms*	*Function*	*Potential health benefits*
Fat-soluble vitamins			
A	Retinal, retinoic acid, retinol *cis*-isomers, β-carotene, other carotenoids	Needed for normal vision, reproduction, and various tissues; immune function	Protection against various cancers
D	Cholecalciferol (D_3), ergocalciferol (D_2), 1-α-25-dihydroxycholecalciferol	Enhances calcium absorption; regulates calcium/phosphate metabolism; promotes bone mineralization	Reduces risk of osteoporosis
E	All-rac-α-tocopherol, β-, δ-, γ-tocopherols, various tocotrienols	Prevents lipid oxidation of membranes and PUFAs from autoxidation; normal immune function and healthy tissues	Reduces risk of cardiovascular disease, precancerous lesions, and cancer
K	Phylloquinone (K_1), menaquinone (K_2), menadione (K_3)	Essential for normal blood clotting, formation/maintenance of healthy bones	Reduces risk of blood clotting and osteoporosis
Water-soluble vitamins			
B_1	Thiamin, thiamin monophosphate (TMP), thiamin pyrophosphate (cocarboxylase, TTP) complexed to proteins	Helps convert carbohydrates into energy metabolism; required by brain, nervous system and heart	Important role in energy metabolism
B_2	Flavin mononucleotide (FMN), flavin adenine dinucleotide (FAD)	Involved in carbohydrate, protein and fat metabolism; helps release energy into cells	Important role in energy metabolism; healthy skin
Niacin	Nicotinic acid, niacinamide (nicotinamide), nicotinamide adenine dinucleodite (NAD) and nicotinamide adenine dinucleotide diphosphate (NADP)	Involved in carbohydrate, protein and fat metabolism	Reduces risk of arteriosclerosis
B_6	Pyridoxine, pyridoxal, pyridoxamine and related phosphorylated forms	Essential for proper protein utilization; involved in homocysteine metabolism	Reduces risk of cardiovascular disease (with folate and B_{12}) and osteoporosis
B_{12}	Cyanocobalamin, methyl- and hydroxycobalamins, adenosylcobalamin (coenzyme B_{12})	Needed for red blood cell formation, DNA and RNA syntheses, involved in homocysteine metabolism	Prevents certain anemias and reduces risk of cardiovascular disease
Folic acid (folacin)	Pteroylmonoglutamic acid, 5-methyl- and 10-formyltetrahydrofolic acid, tetrahydrofolic acid as both mono- and polyglutamates	Involved in amino acid interconversions and methylation reactions, needed for red blood cell formation, DNA and RNA syntheses, involved in homocysteine metabolism and protects against neural tube defects	Prevents certain anemias and birth defects, reduces risk of cardiovascular disease (with B_6 and B_{12}) and certain cancers
Pantothenic acid	Coenzyme A, pantetheine and acyl carrier protein (ACP)	Active in protein, carbohydrate and fat metabolism, formation for certain nerve-regulators	General health and well-being
Biotin	Biotin, desthiobiotin	Active in protein, carbohydrate, and fat metabolism	Helps develop healthy nails
C	Ascorbic and dehydroascorbic acids, isoascorbic acid	Helps form/maintain collagen; important for healthy tissues and wound healing; enhances iron absorption; protects against free-radical damage and infection	Protects against cancer, cardiovascular and eye diseases; reduces symptoms of colds and flu, and risks of osteoporosis

Table 2 Vitamins: commercial forms, food forms and rich dietary sources

Vitamin	*Major commerical forms*	*Main food forms*	*Rich dietary sources*
Fat-soluble vitamins			
A	Retinol acetate & palmitate, β-carotene	Retinly esters, carotenes (provitamin A compounds)	Fatty fish, butter, margarines and liver
D	Cholecalciferol, ergocalciferol	Cholecalciferol	Fatty fish, eggs, margarines
E	(*RRR*)-α-Tocopherol, (*RRR*)-α-tocopherol acetate, all-*rac*-α-tocopherol, all-*rac*-α -tocopherol succinate	Tocopherols (α-, β- & γ-forms) and tocotrienols (α- & β-)	Vegetable oils
K	2-(*R,S*-)-Vitamin K_1 (*cis/trans* mixture), menadione sodium bisulfite	Phylloquinone (K_1), menaquinones (K_2)	Green leafy vegetables, beef, liver
Water-soluble vitamins			
B_1	Thiamin chloride HCl, thiamin mononitrate, thiamin diphosphate	Thiamin; thiamin mono- and pyrophosphates complexed to proteins	Cereals, potatoes, liver, yeast extract
B_2	Riboflavin, riboflavin sodium phosphate	Riboflavin; riboflavin mononucleotide, flavin adenine dinucleotide complexed to proteins	Liver, milk, eggs, green vegetables
Niacin	Niacin, niacinamide	Nicotinic acid; nicotinamide adenine dinucleotide (NAD) and its phosphate form (NADPH) complexed to proteins	Meat and meat products, cereals
B_6	Pyridoxine hydrochloride, pyridoxal-5′-phosphate	Pyridoxine, pyridoxal and pyridoxamine and their phosphorylated forms bound to proteins	Meat and meat products, eggs, cereals
B_{12}	Cyanocobalamin, hydroxycobalamin	Methyl-, adenosyl-, hydroxy-, and sulfitocobalamins	Kidneys, eggs, milk, and cheese
Folic acid (folacin)	Folic acid	Folic acid; 5-methyltetrahydrofolate, 10-formyltetrahydrofolate, tetrahydrofolate as mono- and polyglutamates	Leafy green vegetables, cereals, yeast, and vegetable extracts
Pantothenic acid	Calcium pantothenate, D-panthenol	Pantothenic acid, coenzyme A and acyl carrier protein (ACP)	Liver, kidney, yeast, wheat germ, and egg yolk
Biotin	D-Biotin	Biotin and biotin bound to lysine and proteins	Widely distributed especially liver, kidney, yeast and eggs
C	Ascorbic acid, ascorbyl palmitate, sodium ascorbate	Ascorbic acid, dehydroascorbic acid and isoascorbic acid	Citrus fruits and vegetables

RNI												
Males	19–50	700				1.0	1.3	17	1.4	1.5	200	40
Females	19–50	600				0.8	1.1	13	1.2	1.5	200	40

[a]Taken from Food and Nutrition Board, National Research Council (1989) *Recommended Dietary Allowances* (10th edition), Washington, DC: National Academy Press; Report of the Panel on Dietary Reference Values of the Committee on Medical Aspects of Food Policy (1991) *Dietary Reference Values for Food Energy and Nutrients for the UK*. London: HMSO.

[b]RE, retinol equivalents.

[c]TE, α-tocopherol equivalents.

[d]Nicotinic acid equivalents.

[e]Dietary folate equivalent (DFE) for adults in the USA, rising to 600 μg per day during pregnancy and 500 μg per day during lactation (*See* **Folic Acid**: Physiology). Taken from Food and Nutrition Board, Institute of Medicine. National Academy of Sciences, Subcommittee on Folate, other B-Vitamins and Choline (1998) *Dietary Reference Intakes: Thiamin, Riboflavin, Niacin, Vitamin B-6, Folate, Vitamin B-12, Pantothenic Acid, Biotin and Choline*. Washington, DC: National Academy Press.

from animal studies, and are generally revised every 5–10 years by panels of expert scientists. The recommended intakes can vary from country to country owing to a number of factors such as different interpretations of investigations into the determination of requirements, the level of the safety margin needed, and the amounts needed to allow for individual variation in the general, healthy population. The recommended dietary allowances (RDA) and recommended nutrient intakes (RNI) used in the USA and the UK, respectively, are given in Table 3 for adult males and females. (*See* **Coronary Heart Disease**: Intervention Studies; **Dietary Reference Values**; **Dietary Requirements of Adults**; **Dietary Surveys**: Surveys of National Food Intake.)

It is also becoming evident that some vitamins have additional health benefits when given, via the diet or by supplementation, at levels above those required for eliminating classical deficiency states. Although, for most vitamins, the optimal levels are not yet established, for some vitamins such as folic acid, the health benefits have been clearly demonstrated for taking higher intakes to protect against spina bifida or other neural tube defects. (*See* **Cobalamins**: Properties and Determination; Physiology **Folic Acid**: Properties and Determination; Physiology **Food Fortification**.)

Availability

The way in which vitamins are absorbed and utilized in the body can be affected by a number of factors that can be broadly divided into dietary-related, and physiological factors related to the host. The vitamin may not be in a form that can be readily absorbed by the body. For example, nicotinic acid occurs in cereals in a form that is not absorbed from the gut. Other components in the diet may also interact with the vitamin, causing an enhancement, or depression, of absorption. Thus, the nutritive value of a diet for a given vitamin may be somewhat different from the amount actually analyzed chemically. Thiamin requirements are higher when the diet contains large amounts of carbohydrate or alcohol. Similarly, when the intake of polyunsaturated fat is high, vitamin E requirements are also raised. (*See* **Bioavailability of Nutrients**.)

In general, for food tables, allowances are normally made for reduced biological activities of different forms of three vitamins: 13-*cis*-retinol and retinaldehyde (vitamin A), carotenes other than β-carotene (provitamin A compounds), and tocopherols and tocotrienols other than α-tocopherol (vitamin E).

Adverse Effects

Along with increasing evidence of health benefits from consumption of diets containing vitamins at levels much higher than the RDAs, there is concern over potential adverse effects and even toxicity. Vitamins can be generally divided into two groups: first, those vitamins with a safety level of 100 times or more the RDA for that vitamin for which there is no clear indication of any adverse effects, including most of the water-soluble vitamins and the tocopherols; Second, those vitamins with a safety level of about 10 times the RDA, above which serious adverse reactions can occur. These vitamins include retinol, calciferols, phylloquinone, and pyridoxine.

In particular, chronic intakes of vitamins A and D are to be avoided. For example, an excessive intake of vitamin D can lead to vitamin D intoxication, which is characterized by an increase in serum 25-OH-D and is associated with hypercalciuria and hypercaemia. The safe upper limit for vitamin D is 25–50 μg per day (1000–2000 IU per day). Pregnant women should avoid large doses of vitamin A, either by avoiding foods, such as liver, that contain high concentrations of vitamin A, or by avoiding multivitamin supplements that contain doses of vitamin A of > 5000 IU.

As for the water-soluble vitamins, there has been some concern about excessive intakes for nicotinic acid and pyridoxine. Vitamin B_6 intakes as low as 50 mg per day can be associated with possible neurological damage in patients. Similarly, the potential benefits of lipid-lowering effects of high nicotinic acid intakes (2–6 g per day) have to be considered alongside the possible toxic effects, particularly for the liver. One of the main concerns of folic acid fortification is its potential to mask the diagnosis of pernicious anemia, which is caused by vitamin B_{12} malabsorption, at intakes of ≥ 1 mg per day, causing progressive and irreversible nerve damage. (*See* **Bioavailability of Nutrients**; **Functional Foods**.) Refer to individual vitamins.

Effects of Processing on Vitamin Stability

Vitamin stability varies greatly and depends on a number of factors such as temperature, oxygen, acid or alkali strength, and so on. Table 4 provides general information on stability (S) or instability (U) under several conditions. Several processes have been developed to produce stabilized forms of the vitamin, including spray drying in a suitable matrix (e.g., gelatin) and encapsulation.

Consumer interest over recent years in the nutritional labeling of foods, and the increased awareness in health benefits of vitamins, has focused attention on the effects of food processing on vitamin stability. It should be remembered also that one of the major benefits of processing is that it has a marked effect on preserving vitamin concentrations by inactivating

food enzymes despite any immediate loss. (*See* **Food Composition Tables**.)

The content of vitamins in processed foods is determined initially by the content of the raw materials used. There is a wide variability in vitamin concentrations of commercially grown foods. For example, carrots may vary in their carotene concentration 100-fold, and vitamin C can vary by as much as 35-fold. This can be due to a number of factors, including variety differences, climate and growing conditions, maturity at harvest, and postharvest storage conditions. Thus, the vitamin content of raw materials for processing can vary enormously, in many cases exceeding that found in normal processed food.

The different chemical and physical properties of the vitamins mean that they vary widely in their degree of stability. In the pure crystalline form, they retain their activity for long periods of time. However, when foods are processed, vitamins are subjected to a range of conditions that can be detrimental to their stability such as light, moisture, oxygen, heat and pH, these being typical environmental factors to which the food will be subjected in the food chain (see Table 4). The most labile vitamins are retinol, ascorbate, folate, and riboflavin. Niacin and biotin are the most stable, but information on some of the vitamins, especially vitamin D, is incomplete.

Domestic Cooking

Typical percentage losses of vitamins on cooking for selected food groups are given in Table 5.

Table 4 Vitamin stability under different conditions[a]

Vitamin	*Oxygen*	*Light*	*Heat*	*Acid (pH < 7)*[b]	*Alkali (pH > 7)*[b]	*Metals*[c]	*Reducing agents*

[b]In milk-based drinks and custards.
[c]15% in bread-making and toasting.

Vitamin C is one of the most labile of all the vitamins and is readily leached into water on boiling, particularly when the surface of the food has been cut or damaged. Vegetables are an important source of vitamins in the diet, and typical losses on boiling vegetables are quite variable. The use of microwaving can reduce vitamin losses for cooked vegetables (see below). (*See* **Cooking**: Domestic Techniques.)

Meat is also an important source of several vitamins. A considerable amount of B-group vitamins, especially thiamin, can be lost when meat is grilled or fried (up to 40%). Losses are less when pot roasting and braising are used. Some vitamins that leach into the meat juices during cooking will not be lost if the sauce or the gravy is eaten as part of the actual dish. This means that average losses in meat dishes are no higher than for grilled or fried meat, even though the cooking times are longer. (*See* **Meat**: Dietary Importance.) Similarly, when bread is baked, 30% of the thiamin content can be destroyed, and this can increase to as much as 80% if alkaline baking powders are employed.

Microwave cooking can result in retention of vitamins equal to, or greater than, conventionally cooked vegetables. However, a number of studies have shown that cooking time, water volume used, etc. affect considerably vitamin retention with microwave cooking, as with other cooking procedures. For meat and meat products, the effect of microwave versus conventional cooking on vitamin retention seems to be less pronounced. A higher degree of riboflavin retention and a lower degree of thiamin retention have been found, but no difference in niacin concentrations. (*See* **Cooking**: Domestic Use of Microwave Ovens.)

Other Processing Methods

There has been only limited work reported on the effects of extrusion cooking on vitamin retention. In one of the few studies, the retention of B-group vitamins was investigated during crispbread production. The destruction of the more labile vitamins (thiamin, folate, B_6, and B_{12}) was directly proportional to the energy input, although other factors, such as moisture content, mass temperature, screw geometry, and rate of throughput, are also thought to influence retention. It appears that retention can be improved by increasing both the rate of throughout and moisture content. However, carotenoids in corn starch are fairly stable to extrusion, although some of the forms can be oxidized further. Losses of vitamin C during extrusion of 25–40% have been found. (*See* **Extrusion Cooking**: Chemical and Nutritional Changes.)

Radiation-induced changes in vitamin concentrations in foods during irradiation have been reviewed extensively in the literature. At low irradiation doses (< 1 kGy) used for disinfectant treatment, losses are negligible compared with the larger variations in the vitamin content of the raw materials. The most thermolabile vitamins are thiamin, tocopherols, and ascorbate, but, with the medium-dose range (1–10 kGy) used to control microbial contamination, losses can be minimized. (*See* **Irradiation of Foods**: Applications.)

It is well known that fermentation can increase the B-vitamin content (e.g., folates) of some foods, such as cheese, milks, yogurts, and other dairy foods, and this is a potential area for production of foods with enhanced health benefits. There does appear to be some potential for producing significant amounts of vitamins with various fermentation conditions and organisms.

Vitamins and Food Composition

From a metabolic and human health aspect, understanding of the roles that vitamins play is rapidly expanding. Concurrently, new and more precise information on food composition has been required by the scientific community. One of the more challenging areas of food composition research is the development and application of methods suitable to accurately assay water- and fat-soluble vitamins in foods. We have seen this area of bioanalytical chemistry expand rapidly over the past three decades to the point that, for most of the vitamins, we can confidently provide accurate measurements from most matrices. In the following discussion, we present a brief review of useful approaches for the analysis of vitamins in food. Also included are tables giving pertinent details of methods useful for the analysis of the specific vitamins. These approaches from the current literature show the state-of-the-art methods developed by leading vitamin researchers. Because of the significance of microbiological and chromatographic techniques to the area, our discussion is limited to these analytical approaches.

Analytical Methods

Methods available for vitamin assay can be classified as bioassays using animals or humans, microbiological assays that are based upon specific vitamin requirements of bacteria, yeast, molds, or protozoans, and physicochemical methods that are based on instrumental methods of analysis, including, but not limited to, spectrophotometric, fluorometric radiometric, immunological, and chromatographic techniques. Most recent advances in vitamin analysis have come through development and application of high-performance liquid chromatographic (LC) techniques specifically designed for food analysis. Factors influencing the suitability of a method for analysis of a vitamin(s) in food include the specificity of the assay, sensitivity of the method and levels of the vitamin in the food matrix to be assayed, the method's proven value as documented by validation studies including precision and accuracy, the applicability of the method to the food matrix, numbers of samples to be assayed in relation to manpower and sample throughput needs, availability of required instrumentation, and cost requirements. While excellent, sophisticated methods are available for most vitamins, these techniques are often not available for limited analytical efforts because of initial set-up economic considerations. In such instances, lower-cost, older methods of analysis must be utilized. This should not be considered as a limiting factor of the quality of the data because, if properly conducted, older methods based on wet chemistry or microbiological assay can provide data of excellent quality.

Because of the instability of many vitamins to oxidation, light inactivation, pH, heat, and various other chemical and environmental factors, precautions must be taken throughout the analysis to ensure stability of the analyte. For this reason, it is important that the analyst be thoroughly informed about the chemical properties of the specific vitamin being assayed (*See* **Vitamins**: Overview). Additionally, because the stability of the vitamin must be considered throughout the sample-handling period (collection through storage through analysis), poor-quality data will be obtained if degradative processes occur through improper maintenance of conditions necessary to ensure vitamin stability. This outcome negates the worth of even the most advanced analysis technique.

Extraction Methods

Except for bioassays that require the feeding of intact food samples, the vitamin(s) must be extracted from the food matrix in a medium designed to stabilize the vitamin prior to the determinative analytical step. Because of the diverse stability characteristics of the vitamins, specific extraction procedures have been developed over the years that accomplish efficient extraction of the various vitamins. Extraction media must be compatible with the determinative method and at the same time stabilize the vitamin against degradation. Table 1 outlines some common approaches used to extract the various vitamins along with the primary routes that might lead to degradation. Most extraction procedures use a combination of physical and chemical effects to ensure analyte stability. The overall extraction includes physical treatment combined with use of the extraction solvent to remove the vitamin with a high rate of recovery from the sample matrix, provide stability to the extracted vitamin, and provide the chemical environment required for compatibility with the determinative procedure. Physical disruption to reduce the particle size of the food sample is often accomplished through grinding, sonication, or other means. Following the initial sample treatment, solubilization of the vitamin into the extraction solution is completed by heat, acid, alkali, or enzyme digestion, often applied in combination. Extraction procedures

Table 1 Extraction procedures applicable to vitamin analysis of food

	Method	*Example*	*Primary routes of degradation*
Fat-soluble vitamins			
Vitamin A, vitamin A esters, provitamin A, carotenoids, vitamin E, vitamin D	Direct solvent extraction	Hexane or ether containing an antioxidant. Maintain darkness.	Oxidation Light Heat Acid
Vitamin A, vitamin A esters, provitamin A, carotenoids, vitamin E, vitamin D	Saponification	Reflux at 70 °C in ethanolic KOH containing antioxidant. Extract digest with hexane or combination of organic solvents containing an antioxidant.	Oxidation Light Heat Acid
Vitamin K	Hydrolysis and solvent extraction	Lipase hydrolysis. Pentane extraction. Maintain pH control. Solid-phase clean-up.	Unstable at alkaline pH
Water-soluble vitamins			
Ascorbic acid	Metaphosphoric acid extraction	Solvent usually contains reducing agent and metal chelating agent	Oxidation Temperature Light Ascorbic acid Oxidase
Thiamin	Acid hydrolysis followed by enzyme hydrolysis of phosphate esters	0.1 N HCl, autoclave, phosphatase digestion	Heat Unstable at alkaline pH
Riboflavin	Acid hydrolysis	0.1 N HCl, autoclave protect from light	Light Heat
Niacin	Acid or alkaline hydrolysis	HCl or H_2SO_4 digestion cereals – alkaline digestion	Few stability problems
Vitamin B_6	Acid extraction or enzymatic hydrolysis of phosphate esters following extraction in buffered solvent	Plant products – 0.44 N HCl, autoclave. Animal products – 0.055 N HCl, autoclave.	pH, stable in acid solutions, light
Folate	Multienzyme digestion in the presence of a reducing agent	Trienzyme digestion with Pronase® α-amylase and conjugase	Oxidation Light Heat Avoid pH below 5.0
Vitamin B_{12}	Phosphate buffer containing reducing agent	Autoclave in phosphate buffer containing citric acid and sodium metabisulfate	Light Optimum stability between pH 4.0 and 7.0 Oxidation
Biotin	Acid hydrolysis	Autoclave in 2 N H_2SO_4 (plant products) or 6 N H_2SO_4 (animal products)	Oxidation Stable between pH 4.0 and 9.0
Pantothenic acid	Multienzyme digestion	Digestion with alkaline phosphatase and pantotheinase	Stable between pH 5.0 and 7.0

are available for single vitamins and for multianalyte assays in which more than one vitamin is assayed from the same extract.

Water-soluble Vitamins

Microbiological Analysis

The microbiological assay of water-soluble vitamins represents one of the earliest approaches for accurate analysis of water-soluble vitamins in foods. Except for vitamin C, microbiological assays are available for each of the water-soluble vitamins. These methods were originally developed in the 1940s concurrently with, or shortly after, the development of bioassays for the different vitamins. The assays have withstood the test of time, often being applicable to the analysis of low-concentration samples that are problematic for other methods. Microbiological assays are highly specific and sensitive, although less technologically advanced, compared with many physicochemical procedures.

All microbiological vitamin assays are based upon the development of a dose–response curve resulting

from the growth of a microorganism in a medium containing the vitamin that is essential for the specific microorganism. The microorganism must have an absolute nutritional requirement for the vitamin that is not modified by other components in the food extract. If this requirement is met by the microorganism, a basal medium can be formulated that provides all of the growth requirements for the microorganism except for the vitamin being assayed. When a standard or an extract of the material to be assayed is added to the clear growth medium, the microorganism grows in proportion to the amount of added vitamin. Over a defined vitamin concentration range, the growth response will be directly proportional to the amount of vitamin in the growth medium. Within this range, sample and standard solutions can be accurately compared. The dose–response curve is developed by adding known amounts of standard to the growth medium. Unknown levels in the sample are calculated from the dose–response curve using the growth response resulting from the vitamin added to the growth medium through a known amount of sample extract. Growth is measured by turbidity, by production of a metabolite such as lactic acid, by respiration, or gravimetrically.

Characteristics that microorganisms must possess to be useful for water-soluble vitamin assay include: (1) a specific requirement for vitamin forms that are biologically active in higher animals; (2) inability to synthesize the vitamin; (3) inability to utilize metabolites that are not biologically active for the human; (4) inability to utilize compounds that are structurally related to the vitamin that are not biologically active; (5) a rapid growth cycle; (6) a growth response that is not easily modified by other substances present in the food extract (stimulators or inhibitors); (7) genetic stability and (8) nonpathogenicity. A list of accepted microorganisms available from the American Type Culture Collection (ATCC), Rockville, MD is provided in Table 2. Table 2 also lists the Association of Official Analytical Chemists (AOAC) International methods for each water-soluble vitamin assay.

Microbiological vitamin analysis remains an important tool for laboratories involved in food-composition studies. Advantages of the analytical approach include: (1) high sensitivity; (2) capacity to assay naturally occurring levels from complex food samples without concentration of the extract; and (3) low cost due to minimal laboratory requirements for space, materials, and instrumentation. Disadvantages include (1) labor intensiveness; (2) poor precision; (3) difficulty to automate, which leads to low sample throughput; (4) varying growth responses of the microorganism to different vitamin forms, including bound forms and multichemical forms (e.g., folates); and (5) susceptibility of the assay microorganism to stimulators or inhibitors in the food extract that produce drift. In relation to human nutrition, the assays do not provide information on the bioavailability of the vitamin from the food sample.

Chromatography for the Assay of Water-soluble Vitamins

High-performance LC methods are available for analysis of water-soluble vitamins in foods. These methods offer speed, selectivity, accuracy, precision, and, depending upon the chemical properties of the specific vitamin, a high degree of sensitivity. Reversed-phase chromatography systems using C-18 or other bonded supports with varying adsorption properties are widely applied to specific analytical methods for the analysis of water-soluble vitamins. Specific applications depending on the chemical properties of the analytes include ion exchange for vitamin C, folates, and niacin, PLRP-S (polymeric styrene reversed-phase macroporous supports) for riboflavin and vitamin C, and C-18 for most water-soluble vitamins. Useful mobile phases for water-soluble vitamin analysis on reversed-phase systems are usually based upon

methanol or acetonitrile, together with water, acetic acid or buffers. Ion-pair chromatography, which combines the principles of bonded-phase and ion-exchange chromatography is often used to improve analyte resolution, retention time, and peak shape.

Often, the only limitation to application of LC to water-soluble vitamins in foods is the low natural levels that must be quantified. Detection systems useful for LC analysis of the water-soluble vitamins include UV, fluorescence, and electrochemical; however, the choice of the detection mode depends entirely on the properties of the vitamin being assayed. Low natural levels in foods are often below the detection capabilities of the LC system. In this case, sample extract concentration using solid-phase extraction (SPE), affinity chromatography, or other means such as freeze-drying might be applied to bring the analyte into the required concentration range. Often, with low-concentration samples, microbiological assay offers a workable solution to the analytical problem.

Pre- and postcolumn derivatization can be used for vitamins such as thiamin, folate, and others to induce or increase the fluorescence of the analyte to increase the sensitivity of the analysis. Fluorescence, because of its sensitivity and selectivity, is a preferred detection mode for LC procedures and should be incorporated into an analysis protocol if chemically feasible. Multianalyte procedures useful for food analysis are mostly limited to fortified foods or supplements in which the analytes are present in high concentrations, as opposed to low concentration in natural foods. Some successful simultaneous assays are available for thiamin and riboflavin, which possess excellent spectral properties that make sensitivity less problematic.

Because of the breadth and complexity of the applications of LC to water-soluble vitamin analysis, examples of literature methods that have been proven useful for food composition research are characterized in Table 3. The reader is urged to access the Further Reading list for detailed information.

Fat-soluble Vitamins

Chromatography presents versatile and highly useful methods for the analysis of fat-soluble vitamins from foods and other biological samples. The analytical field has progressed from applications of paper chromatography, thin-layer chromatography, and gas chromatography to the almost universal use of LC for fat-soluble vitamin analysis. Both normal-phase and reversed-phase systems are applicable to fat-soluble vitamin analysis.

Efficient extraction of the fat-soluble vitamins from the sample matrix is as important as the determinative chromatography. With the fat-soluble vitamins, many LC-based procedures require that the vitamin be isolated from the lipid material prior to injection of the vitamin extract on to the LC column. Applicable extraction methods rely on alkaline hydrolysis or saponification, enzymatic hydrolysis, solvent extraction, and supercritical fluid extraction. Saponification is the most accepted method for extraction of vitamin A, carotenoids, vitamin D, and vitamin E from foods. Saponification involves refluxing the sample with ethanolic KOH solution in the presence of an antioxidant (pyrogallol or vitamin C) at 70 °C. The unsaponifiable fraction in the aqueous digest containing the fat-soluble vitamins, sterols, carotenoids, and other material is extracted with hexane, ethyl ether, or a mixture of hexane and ethyl acetate, leaving the fatty acid salts and other water-soluble components in the aqueous phase. Saponification has the ability to efficiently destroy the sample matrix, which facilitates vitamin extraction, frees cellular bound forms of the vitamins, and destroys substances such as chlorophyls that might interfere with the chromatography. Because of the instability of vitamin K under alkaline conditions, saponification cannot be used for extraction.

If the LC method is a normal-phase system, limited amounts of lipid can be injected directly on to the column. In this case, solvent extraction of the sample can be used with direct injection of the extract containing the fat-soluble vitamins on to the normal-phase column. Direct solvent extraction has been used to develop multianalyte procedures capable of assaying several analytes including ester forms of vitamin A (retinyl palmitate and acetate) and vitamin E (α-tocopheryl acetate).

Vitamin A and Carotenoids

Most recently published methods for retinoids and carotenoids use reversed-phase LC on C-18. The advantages of reversed-phase compared with normal-phase LC include: (1) less sensitivity to changes in retention time due to the presence of water; (2) more easily cleared of contaminants; (3) more stable to small changes in mobile phase composition; (4) more quickly equilibrated to mobile phase composition changes, permitting use of gradients; and (5) capable of resolving compounds with a wide range of polarities. Both isocratic and gradient mobile phases are useful (see Table 4). For vitamin A (retinol) assay, reversed-phase chromatography with simple, isocratic mobile phases consisting of methanol:water, acetonitrile:water, or gradients based on these solvents can be used. Resolution of retinol *cis*- and *trans*-isomers is best accomplished with normal-phase LC.

The conjugated double bond system of vitamin A and its closely related retinoids gives specific and

strong ultraviolet (UV) absorbance properties. Most LC procedures use UV aborbance between 320 and 380 nm for detection. Fluorescence (excitation: 320 nm, emission 470 nm) is an excellent detection mode for retinol and retinyl esters. Carotenoids absorb strongly in the visible region due to the long conjugated double-bond system. For β-carotene, 450 nm is universally used for detection. Variable wavelength, programmable UV/visible and photodiode array detectors have greatly aided the chromatographic study of complex, natural carotenoid mixtures characteristic of fruit and vegetable samples.

Vitamin D

Vitamin D analysis of nonfortified foods is difficult due to the low concentration and the relatively poor spectral properties of the vitamin. Both normal- and reversed-phase LC efficiently resolve vitamin D_2, D_3, previtamins, and hydroxylated metabolites if properly prepared extracts are available. Excellent methods that use competitive protein binding assays (CPBA) or radioreceptor assays (RRA) using (^{3}H) metabolites are available for analysis of biological matrices. These methods use extensive prepurification of extracts by LC or solid-phase chromatography. CPBA and RRA are specific and sensitive enough to measure circulating levels of hydroxylated vitamin D metabolites; however, the methods have not been applied to food analysis. Radioimmune assay with ^{125}I-labeled metabolites is used extensively in clinical chemistry.

Provided the extraction protocol provides an extract that meets the detection limits of the assay, reversed-phase LC with UV detection at 265 nm is useful as the determinative assay. More recent methods applicable to food analysis incorporate preparative LC for sample clean-up and concentration prior to LC resolution on C-18.

Vitamin E

Vitamin E exists in nature as eight closely related compounds (α-, β-, γ-, δ-tocopherols and corresponding tocotrienols). Normal-phase LC on silica resolves the eight vitamin forms. Reversed-phase LC cannot resolve the β- and γ-positional isomers; therefore, most methods for food analysis use normal-phase LC. Detection does not pose a problem because of the strong fluorescence exhibited by the chromanol family. α-Tocopheryl acetate is normally used for food fortification. This compound is much more stable than α-tocopherol and possesses much less native fluorescence. However, highly sensitive fluorescence detectors that are now readily available can quantify α-tocopheryl acetate at the levels that are commonly used for food fortification.

Vitamin K

Methods for vitamin K analysis of foods use a combination of adsorption chromatography for sample clean-up, and reversed-phase LC on C-18 supports for the quantification. Mobile phases are simple, isocratic systems of methanol modified with dichloromethane. The mobile-phase composition depends on the detection mode. If electrochemical detection is used, an electrolyte must be added to the mobile phase to provide for conductivity. More commonly, vitamin K compounds are converted from the quinone form to the highly fluorescent hydroquinone form by postcolumn zinc metal reduction. This conversion allows the use of fluorescence for detection. The instability of vitamin K at alkaline pH dictates that saponification cannot be used for extraction. Because lipids must be removed from vitamin K extracts before reversed-phase LC, novel lipid removal procedures have been developed for vitamin K extraction. Recent methods (Table 4) use lipase hydrolysis followed by solid-phase extraction to provide a suitable concentrated extract for LC resolution.

Multianalyte Procedures for Fat-soluble Vitamin Analysis

Historically, fat-soluble vitamin analysis of foods has been difficult due to methodology deficiencies of poor detector sensitivity, poor precision due to interferences, and labor intensiveness of the methods. Technological advances in detectors and LC instrumentation together with research on extraction methods for the fat-soluble vitamins from foods have led to the availability of methods with improved precision, specificity, and sensitivity. These improvements have led to the development of multianalyte approaches for fat-soluble vitamin analysis that are especially useful for the analysis of foods fortified with combinations of the fat-soluble vitamins. Such methods, when incorporated into the laboratory analysis program, can save a great deal of time and present significant cost savings.

A recent multianalyte approach developed in our laboratory at the University of Georgia is presented to show the analytical power of multianalyte analysis. The procedure is capable of simultaneously assaying, retinol, retinyl palmitate, retinyl acetate, β-carotene, natural vitamin E, and α-tocopheryl acetate. In this method, the vitamins are extracted in 2-propanol and hexane without saponification. Quantification is by normal-phase LC with fluorescence detection of retinol, the retinyl esters, α-tocopheryl acetate and the vitamin E alcohols. β-Carotene is quantified at 450 nm. Fluorescence and photodiode array detectors

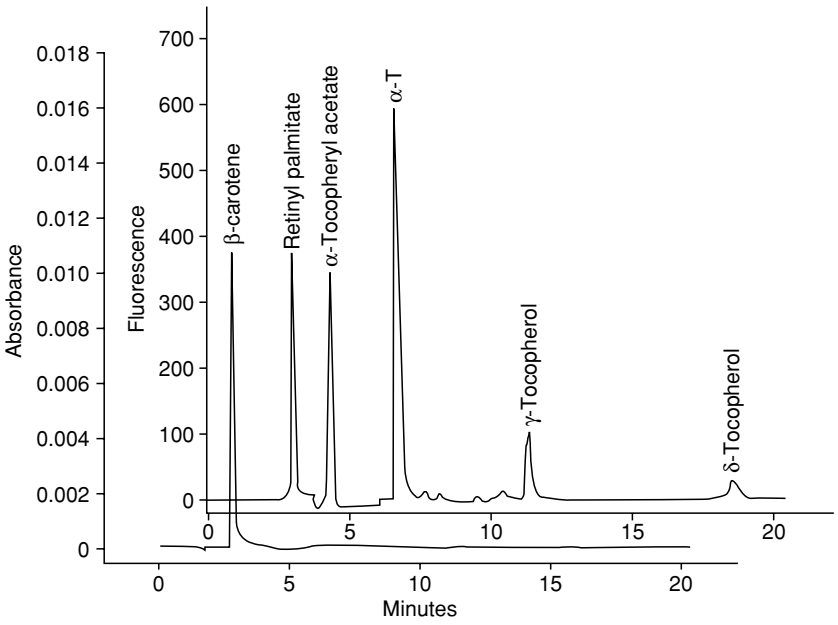

Figure 1 Chromatogram of fat-soluble vitamins in margarine. Chromatography parameters: mobile phase, 0.27% IPA in Hex, gradient flow, 0.9–1.5 ml min^{-1} over 5.3 min. Absorbance β-carotere, 450 nm; fluorescence retinyl palmitate, λ_{ex} 325 nm, λ_{em} 470 nm, α-tocopheryl acetate, λ_{ex} 285 nm, λ^{em} 310 nm; tocopherols, λ_{ex} 290 nm, λ_{em} 330 nm.

in series allow quantification of all analytes from a single injection. Figure 1 shows the elution profile obtained from a margarine sample fortified with retinyl palmitate, β-carotene, and α-tocopheryl acetate.

VODKA

C F Hayman, Hayman Limited, Witham, Essex, UK

Introduction

The exact origin of vodka is unknown, although both Russia and Poland claim to be the first producers. Vodka was distilled in Russia in the early twelfth century and, as with other spirit drinks, began its life more for medical purposes rather than for enjoyment.

Origin

The word vodka or wodka means 'little water'. It is derived from the Russian word voda. Today the Russians refer to it as vodoshka. Although the origins of vodka may date back some eight centuries, it is generally accepted that vodka as we know it today first appeared during the sixteenth century.

Characteristics of Production

Vodka is a fairly tasteless and neutral spirit product which is mainly derived from the fermentation and distillation of grain. However, some producers will use other raw materials such as potatoes, sugarbeet, grapes, or cassava instead of grain, depending on the local availability and cost. Once the grain or similar has been converted into neutral alcohol by fermentation and distillation, the vodka producer will start the process. Different producers have developed their own methods of production.

Some distillers will further distil or rectify the spirit, retaining only the middle part of the distillation for additional processing. The foreshot and feints are disregarded. The spirit will be passed through charcoal or carbon filters which remove the remaining flavors and odors to give vodka its clean and smooth character.

The various producers have developed their own, often secret, ways of filtering but are very concerned about the contact time of the spirit with the charcoal. Some distillers have a single filter (Figure 1) while others require the spirit to pass through a series of filters. The choice of charcoal varies as it affects the final product. One producer uses charcoal specially made from Sussex oak trees; another uses carbon derived from peat found in the Dutch polders. After filtration, some distilleries will regenerate the charcoal using steam whilst others discard the spent charcoal.

The character of the water added to the finished vodka to reduce it to the required bottling strength is very important. The increased technology of water demineralization plants allows a greater consistency in quality than ever before. Water quality is of a vital significance in the final taste of the product.

In the European Community, the minimum level of alcohol acceptable for vodka is 37.5% (v/v), but often higher-strength vodkas are available, particularly coming from eastern Europe, e.g., 45–55%.

Many vodkas are flavored and this again originated from both Poland and Russia. One Polish vodka is flavoured by steeping buffalo grass (*Hierochloe odorata*) in the product to give it an additional aromatic flavor, and it also takes on some of the green color from the grass. An old Russian vodka is prepared with an infusion of leaves from apple and pear trees, to which is added brandy and port-type wine. This vodka is mellow in taste and pleasing to drink. Some high-strength vodkas are aged in wood, often giving them a brown color derived from the cask. In more recent times, Pepper vodka has been produced,

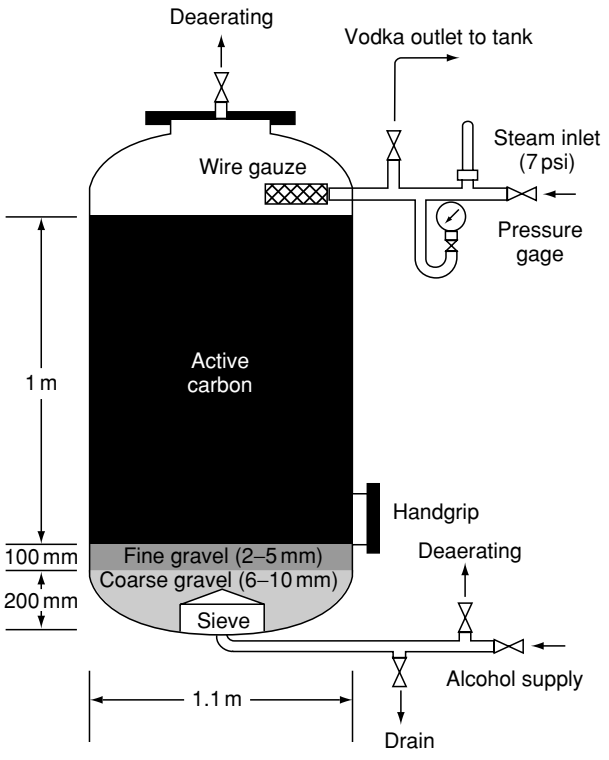

Figure 1 A typical vodka filter. Reproduced from Vodka, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

the pepper enhancing its aroma and giving it a slight burning sensation on consumption. Other vodkas flavored with the addition of lemon, peach, and other fruit flavors are now appearing. WALNUTS AND PECANS

R B N Prasad, Indian Institute of Chemical Technology, Hyderabad, India

Introduction

Many of the species of trees in the family Juglandaceae produce edible, oil-rich nuts, and these include walnuts and pecans. The valuable part of the commercial crop is the whole nut. This article reviews the varieties, global distribution, commercial importance, morphology, and anatomy of the fruits and seeds, chemical and nutritional composition, handling, and storage of walnuts and pecans.

Walnuts

Varieties and Global Distribution

Walnuts are common, large, forest deciduous trees primarily of temperate areas, but also of subtropical regions, mostly of eastern North America, Central America, western South America, and Eastern Asia. Walnuts belong to the genus *Juglans*, which consists of about 15 species.

The most important species, producing the common, Persian, or English walnut, is *J. regia* L. It was probably moved by migrating populations from ancient Persia to Greece and later distributed throughout the Roman empire. The early colonists from the UK brought seeds to North America, and the settlers called the resulting trees 'English walnuts' to distinguish them from the native American black walnuts. The English walnut is cultivated commercially in the USA, France, Italy, former Yugoslavia, Poland, Germany, Czech Republic, Bulgaria, Turkey, Chile, Northern India, China, and Australia.

The second principal variety is the black walnut (*J. nigra* L.), which is native to the USA and is found distributed along the coast, west to Michigan and throughout most of the midwestern states.

A third walnut variety, less important from a commercial standpoint, is the butternut (*J. cinerea* L.). This tree is native to North America and is found in the eastern regions.

Other popular species of walnut trees include the following: Arizona (or Nogal) walnut, *J. major* Helier (distributed in New Mexico and Arizona); the California walnut, *J. californica* Walt. (southern California); the Chinese walnut, *J. cathayensis* Dode (central and western China); the Hinds walnut, *J. hindsii* Sarg. (California); the Texas walnut, *J. rupestris* Engelm. (south-western USA to Mexico); the Manchurian walnut, *J. mandshurica* Maxim. (eastern Commonwealth of Independent States and northern China); and the Japanese walnut, *J. sieboldiana* Maxim. (Japan). Some of these species are favored for garden and park plantings.

Commercial Importance

Although the most important and best known commercial species is undoubtedly the English walnut, many commercial varieties of different species are grown around the world. China is the leading producer of walnuts, at 300 000 mt in the year 2000, out of 1 183 898 mt of the world production. The other important walnut-growing countries are the USA (222 260 mt), Iran (142 906 mt), Turkey (122 000), India (31 000 mt), France (27 780 mt) and Romania (25 000 mt). The nuts of all species are edible, and the young green fruits, before the nuts harden, are also eaten pickled in vinegar. Mature nuts can be eaten raw or salted, and are excellent for dessert, in icecreams and candy, and also in baking and

confectionery. Walnuts are a part of holiday celebrations around the world and especially in places with German tradition. Families sit around the table and crack walnuts, eating the fresh meats. Although the black walnut has a richer flavor than the English walnut, it is not as popular because its shell is much thicker and harder to remove without breaking the kernels. The kernel forms 42–60% of the nut. About 300–600 t of walnut oil is produced from waste material from shelling and processing plants, e.g., the inedible kernels rejected during shelling and fragments of kernels recovered from shells. Walnut oil makes a good salad oil, and can also be used in the preparation of soap, and as a drying oil in paints. Defatted walnut cake is useful as an animal feed.

The walnut shells, reduced to flour of various mesh sizes, have found applications as fillers in synthetic resin adhesives, plastics, and industrial tiles, and as an insecticide diluent. About 50% of the annual production of walnut shell is used in the plastics industry alone. The shell powder is also used for drilling mud in oil fields, and as an abrasive in polishing metal castings. Dyes prepared from walnut shells and leaves are still used in Turkey, and the high tannin content of green walnut shells is useful in leather manufacture. A pharmaceutical grade of activated charcoal can be prepared from the inedible parts of the fruit. Various parts of the walnut tree, such as bark, leaves, shells, fruits, and kernels, have been used in folk medicine throughout the world. The timber of walnuts possesses excellent mechanical strength and very good shock resistance, and hence it is much valued for veneers, furniture, boat-building, and gunstocks.

Morphology and Anatomy of the Fruits and Seeds

Walnuts are usually tall, broad-headed, deciduous trees that grow 10–50 m in height. They have rough bark, and compound pinnate leaves that exude an aromatic fragrance when crushed or bruised, a property which varies in degree from one species to another.

The English walnut is a large, deciduous tree attaining over 30 m in height and with a trunk of 6 m in girth; the bark is gray, smooth on young trees, and fissuring with age. The staminate (male) flowers of this species are borne on twigs of the previous season's growth, and the pistillate (female) flowers, usually few, are borne on the twigs of the current season's shoots. Pollination occurs naturally via the wind, but numerous cultivated varieties have recently been developed by other means. The green fruit is 3.7–5.0 cm in length with a subglobose, gland-dotted, and glabrous structure. The fruit is a drupe, and consists of an outer layer and an inner nut, inside which is the single seed containing abundant oil. When the seed is ripe, the husk opens and the ovoid-shaped stone falls to the ground. The surface of the stone is wrinkled, showing the suture of the carpels in the median vertical plane. The walnut has an outer green husk which is a perfect seal from insects. Inside there is a hard shell. Nature has created a perfect package. The seed consists mainly of two large cotyledons storing fatty substances.

The macroscopic and microscopic structures of the walnut (*J. regia*) seed are given in Figure 1a–c. Most of the endocarp consists of stone cells with brown walls. The outermost of these have very thick walls with slit-like pits, but towards the interior the walls are thinner, with relatively large pits. Inside the endocarp there is a zone of flattened parenchyma cells with brown walls. The outer epidermis of the testa consists of rather radially elongated cells up to 90 μm in length. In some places, this layer is biseriate; pigment is found in some of these cells. It has been reported that raised stomata are present in the outer epidermis. The rest of the testa consists of three or four rows of flattened parenchyma cells with brown walls, and also some vascular tissue. The endosperm is normally represented by a single layer of cells, up to 16 μm in radial diameter, with small aleurone grains and oil drops. The parenchyma cells of the cotyledon possess intercellular spaces and oil drops, and contain aleurone grains, up to 10 μm in diameter (Figure 1a–c).

The black walnut tree grows up to 50 m in height and has brownish bark with fissuring. The drupelike fruits are solitary or in pairs, 2.5–5.0 cm in length, globose, oblong and pointed at the apex, or slightly pyriform with a thick husk. The nut is oval or oblong, slightly flattened, 3.0–3.8 cm in diameter, deeply divided on the outer surface into thin or thick, often interrupted, irregular ridges.

Chemical and Nutritional Composition

Chemical characteristics of oil Walnut oil is generally produced from the inedible meat rejected during shelling, plus meat fragments recovered from the shell. The oils from the different species of walnut bear a close resemblance to each other in terms of both physical and chemical characteristics. They are light yellow in color with a greenish tinge and a faint, nutty odor. The range of chemical characteristics of walnut oil is given in Table 1.

Fat content Walnut kernels generally contain about 60% oil, but vary from 52% to 70% depending on the variety. The major constituents of the oil are triacylglycerols. Free fatty acids, diacylglycerol, monoacylglycerol, sterols, sterol esters, phospholipids, and vitamins are present in minor quantities. The triacylglycerol moiety of the oil is a mixture of

Data compiled from: Krischenbauer (1960) In: *Fats and Oils – An Outline of their Chemistry and Technology*, pp. 198–203. New York: Reinhold; Eckey EW (1954) In: *Vegetable Fats and Oils*, pp. 378–382. New York: Reinhold; Jamieson GS (1943) In: *Vegetable Fats and Oils*, pp. 158, 333–334. New York: Reinhold; Mehran M (1974) Oil characteristics of Iranian walnuts. *Journal of the American Oil Chemistry Society* 51: 477–478; Council of Scientific and Industrial Research (1959) *The Wealth of India – Raw Materials*, vol. V, pp. 298–305. New Delhi: Council of Scientific and Industrial Research.

triunsaturated and nonsymmetrical diunsaturated glycerides that form up to 83–95% of the total fraction. The 2-position of the triacylglycerol contains primarily linoleic acid. The fatty acids of the walnut oil are predominantly unsaturated and consist mainly of linoleic and oleic acids (Table 2). The linoleic acid content in English walnut is higher than that in black walnut. (*See* **Fatty Acids**: Properties; **Triglycerides**: Structures and Properties.)

Walnut oil contains about 0.9–1.3% phospholipids; the composition of individual components of total phospholipids is: phosphatidylcholine, 18–20.4%; phosphatidylinositol, 28.2–45.0%; phosphatidylethanolamine, 15–30.5%; cardiolipin, 0–20.4%; phosphatidylserine, 0–5%; phosphatidic acid, 0–7%; lysophosphatidylcholine, traces to 2.0%; lysophosphatidylethanolamine, traces to 2.0%.

Walnut oil contains at least 29 volatile components, such as terpenes, alcohols, and carbonyls, and the characteristic odor of the oil is attributable to the collective effect of a number of constituents. (*See* **Sensory Evaluation**: Aroma.)

Protein content Walnut kernels contain about 14.5–24% of protein, and this is enriched up to 61–66% in dry defatted cake. Full details of the nature of the protein are not available, but the molecular weight of the three main proteins was estimated to be about 43 000, 39 000, and 25 000. The content of the sulfhydryl and disulfide bonds in the walnut protein was reported to be higher than that of soybean and yeast protein. Walnut cake contains more arginine and less lysine than does casein and soybean cake. The walnut kernel protein contains 18 amino acids, and glumatic acid (2.809 g per 100 g of kernel) is the main amino acid, followed by arginine (2.103 g per 100 g of kernel). The essential amino acid composition is given in Table 3. (*See* **Amino Acids**: Properties and Occurrence.)

In addition to the normal amino acids, walnut kernels are found to contain a sulfur amino acid, taurine (2-aminoethanesulfonic acid) in concentrations of about 15–46 nmol g^{-1}, depending on the variety. In humans, taurine deficiency may lead to a

Data compiled from: USDA Database for Standard Reference *Release 11* September 1996 and *Release 13* November 1999; Considine PEDM and Consodine GD (eds) (1982) Pecan and walnut. In: *Foods and Food Production Encyclopaedia*, pp. 1345–1350. New York: Van Nostrand Reinhold; Young CT (1996) Nuts. In: Kroschwitz J and Howe-Grant M (eds) *Kirk-Othmer Encyclopaedia of Chemical Technology*, 4th edn, vol. 17, pp. 544–579 New York: John Wiley.

decreased electroretinogram (ERG) and to pigmentary degeneration of the retina. Hence walnut kernels have the potential to replace meat as a source of dietary taurine. (*See* **Protein**: Requirements.)

Carbohydrate The total carbohydrate content in different varieties of walnut varies from 12.1 to 18.3 g $100\,g^{-1}$ kernels. English walnut is rich in carbohydrate compared to the black variety. The fiber content in walnut varieties is about 1.7–6.5 g $100\,g^{-1}$ kernel. Some varieties of walnut kernels contain large amounts of sugar(s). (*See* **Carbohydrates**: Classification and Properties.)

Vitamins Walnut kernels are a good source of vitamins. Walnuts contain about 30–300 IU of vitamin A, 0.22–0.45 mg thiamin, 0.10–0.16 mg riboflavin, and 0.7–1.105 mg niacin $100\,g^{-1}$ of kernel. The richest sources of vitamin C are the immature fruits or their green hulls, and the leaves of walnuts. Unripened walnuts are reported to have a very high vitamin C content (2400–3700 mg $100\,g^{-1}$), displaying an activity 40–50 times as high as that of oranges and lemons. However, the dry walnut kernels are reported to contain only 0.4–8.5 mg $100\,g^{-1}$ after ripening. Reports of large amounts of vitamin C in green walnuts have yet to be fully confirmed.

Walnuts contain about 7.3–28.7 μg α-tocopherol, 1.0–8.2 μg β-tocopherol, 205–375.8 μg γ-tocopherol and 28.0–62.1 μg δ-tocopherol g^{-1} of its oil. Walnut kernels are also found to contain vitamin K (0.9–1.1 mg $100\,g^{-1}$). Refer to individual vitamins.

Phenolic acids In food products, the presence of phenolic acids has been associated with astringency, discoloration, inhibition of enzyme activity, and antioxidant properties. Defatted kernels are found to contain some phenolic acids, namely phenylacetic, protocatechuic, syringic, vanillic, gallic, caffeic, and ferulic acids, in very small quantities ranging from 0.02 to 0.20 μg g^{-1} of kernels. (*See* **Phenolic Compounds**.)

Pectic substances Walnuts contain about 2% (dry matter in the edible portion) pectic substances (expressed as anhydrogalacturonic acid). Pectic substances, which make up a component of dietary fiber, are basically polymers of galacturonic acid and may have important physiological and nutritional consequences, such as hypocholesterolemic effects, increased excretion of fecal sterols, and the capacity to bind bile salts. Pectic substances may also slow down the absorption of soluble carbohydrates, causing a smaller increase in the postprandial level of blood sugar; hence walnut kernels could play a role in the design of pectic-rich diets if required for medical reasons.

Juglone Juglone (5-hydroxy-1,4,-naphthoquinone), a yellow-brown compound, was shown to be a host factor that may be associated with resistance of walnut to scab caused by fungus. Juglone is present in considerable amounts in all green and growing parts of the trees and unripe hulls of the nuts. Juglone was also reported in the surface waxes of English walnut leaves (1800 μg g^{-1} of fresh leaf) and fruits (97 μg g^{-1} of fresh fruit) along with hydrocarbons, wax esters, aldehydes, fatty alcohols, and fatty acids. However, juglone levels in kernels was either very low or absent.

Minerals Walnuts are considered to be a good source of dietary minerals. English and black walnuts contain almost similar quantities of minerals, except calcium, which is present only in black walnuts. Potassium, phosphorus, magnesium, and iron are found in significant quantities in these nuts. The mineral composition of walnuts is given in Table 4. Refer to individual minerals.

Nutritional Quality

Walnut kernels exhibit high nutritive value compared to cereals and legumes and therefore find a great

Table 4 Minerals of walnut and pecan kernels

Minerals	*Mineral content (mg 100 g^{-1})*	
	Walnuts	*Pecans*
Calcium	Traces–108	21–139
Copper	0.31–3.2	0.8–1.4

importance in food industry. A high level of fat, containing unsaturated fatty acids with considerable amounts of natural antioxidants like tocopherols and phenolic acids, enhances its importance as a good edible oil source. Defatted walnut kernels are useful as a dietary supplement as they contain a very high content of digestible protein and all the essential amino acids, taurine, and significant amounts of vitamins and minerals. Walnuts are claimed to have a hypocholesterolemic effect on the basis of richness in magnesium and fiber, and a low lysine and arginine ratio. The positive nutritional advantages of walnuts in lowering blood cholesterol come from the high levels of mono- and polyunsaturated fatty acids and possibly the tocopherol content. A diet that includes moderate quantities of walnuts without an overall increase in total dietary fat and calories decreases serum cholesterol levels and favorably modifies the lipoprotein profile in normal men. Walnut kernels are a good source of energy and provide about 2686 kJ $100\,g^{-1}$. (*See* **Energy**: Measurement of Energy Expenditure.)

Industrial Uses of Oil

Walnut oil is similar to linseed oil in composition, and its drying properties have been extensively used in paints and artists' colors from early times. In comparison with black walnut oil, English walnut oil contains more linoleic acid and has more active drying properties. Walnut oil is also used in the manufacture of soaps, varnishes, alkyd resins, and styrenated oils. In addition, since the Second World War, walnut oil has been consumed as a specialty food oil.

Handling and Storage

Rancidity is one of the first signs of deterioration in walnuts because they are rich in oil containing unsaturated fatty acids. High temperature and humidity, as well as sunlight, favor the development of rancidity in kernels, and the best storage conditions are therefore low temperature, low humidity, and little or no light. Aflatoxin presents another problem. In general, aflatoxin production occurs during the harvest period after the nuts have begun to dry; the nuts must therefore pass quickly through this critical moisture zone. Storage of nuts under proper temperature and humidity will prevent further contamination, and there are many well-established methods of destroying aflatoxins in the kernels and oils. (*See* **Mycotoxins**: Occurrence and Determination; **Oxidation of Food Components**.)

The optimum moisture level for the storage of walnuts is 3.2–3.8%, and stability of the shelled nuts is significantly reduced at higher or lower moisture levels. Very elaborate machinery is used for cleaning, grading, bleaching, cracking, and packaging of edible tree nuts, including walnuts. Skin color of the nuts is very important, and methods such as the photometric estimation of absorbance of a methanol extract of the whole nuts are useful for determining the rate of darkening of walnuts at regular intervals during storage. Walnuts are bleached for market by dipping them for 5–10 s in an aqueous solution of bleaching powder and sodium carbonate, with a small amount of sulfuric acid to clear the liquid. In another method, walnuts are exposed to ethylene (one part ethylene to 1000 parts air) to preserve the natural color of the kernel. This treatment prevents the hulls from sticking and staining the shells. After hulling and washing, the walnuts are placed in bins and dried with warm air (not over 43 °C) to reduce the moisture content. The best storage conditions for walnuts are 0–2 °C, accompanied by ventilation with air of relative humidity in the range 65–75%. The storage methods adopted for pecan nuts are also useful for walnuts. (*See* **Preservation of Food**; **Storage Stability**: Parameters Affecting Storage Stability.)

Pecans

Varieties and Global Distribution

The species *Carya illinoensis* Koch, or *C. pecan* Marsh, are known internationally as pecans. Botanically pecan is classified as a hickery (carya) and is a member of the walnut family (Juglandaceae). Native to North America, the pecan is grown mainly in southern and central USA and northern Mexico, with limited cultivation in Australia, South Africa, Brazil, and Israel. Commercially, well over 300 varieties of pecan are offered. Pecan is one of the major commercial edible nuts, and is produced in quantities exceeding 153 500 t $year^{-1}$ in 2000–2001 in the USA.

Commercial Importance

The nuts of pecan have been of value for human consumption in North America for the last three centuries. Pecan is next in importance to the English walnut for its valuable nuts; hence more and more orchards are being planted, not only in southern USA, but also in other countries. The coarse, brittle wood is not as strong as walnut, but it is used occasionally to make tool handles and agricultural implements, and as fuel.

The nuts are eaten raw or salted, and are excellent for dessert, icecreams, cakes, bread, candies and other confectionery, and in vegetarian croquettes and sandwiches. Pecans have a mild, sweet, walnut-like flavor.

About 300 t of pecan oil is produced annually from the pecan-shelling industry. The oil is refined and used for edible purpose or for the production of soap cosmetics and some drugs; the cake is used in animal feed.

Waste materials from the pecan-shelling industry have shown commercial possibilities for the recovery and production of oil, tannin, shell flour, and activated charcoal. Tannic acid produced from pecan shells is used by the tanning industry and by the oil industry to control the viscosity of drilling muds. The shell flour of pecan, in common with that of walnut, has many industrial applications.

Morphology and Anatomy of the Fruits and Seeds

The pecan is a large, deciduous tree which grows up to 9–12 m high – some specimens may reach a height of 50 m – and the trunk can be up to 2 m in diameter, with gray, furrowed bark.

The male flowers are borne in three-branched pendulous catkins, the female in (two to 10) spikes. The fruit is a drupe (3–7 cm long) which, at maturity, splits into four valves to reveal the smooth, brown kernel. The nut is ovoid to ellipsoidal, nearly cylindrical or slightly four-angled towards the pointed apex, rounded and usually apiculate at the base. The brown shelled nut is about 3.5 cm in length and is wrapped in a husk which usually splits and falls away. If the husk does not break away, the nuts are usually defective. The nuts contain 39–55% meat, most of which can be separated in a stable form, but a small portion (about 3%) remains with the shell.

The macroscopic and microscopic structures of the pecan nut are shown in Figure 1d–f. The endocarp of the pecan nut has essentially the same structure as the walnut endocarp, except that some of the outermost stone cells have diamond-shaped crystals in their cavities. Some of the cells of the outer epidermis, in a transverse section of the testa, are square-shaped and others tangentially elongated, with a radial diameter of up to 18 μm and a tangential diameter of 11–32 μm. Some of these cells contain a brown pigment, which may also be found in the guard cells of the stomata. The rest of the testa consists of vascular tissue and parenchyma, some cells of which contain pigment. The endosperm of the pecan nut is the same as that of the walnut. The embryo is also similar, but the aleurone grains are smaller, about 5 μm in diameter, and there may be minute starch grains present (Figure 1d–f).

Chemical and Nutritional Composition

Chemical characteristics of oil On account of the value of the nuts for edible purposes, pecan oil is not prepared commercially. However, the unusable fine nut fragments which accumulate at shelling plants can be utilized for the production of oil. The chemical characteristics of pecan oil are given in Table 1.

Fat content Pecan kernels contain 60–75% oil depending on the cultivars. Triacylglycerol forms more than 95% of total lipids, while monoacylglycerols, diacylglycerols, complex lipids, free fatty acids, and sterols are present at levels of less than 1%. The fatty acids of pecan oil are mainly unsaturated, with oleic acid as the predominant fatty acid (unlike walnut oil, in which linoleic is the major acid; Table 2).

Protein content The protein content of pecan kernels varies from 7.8 to 17% depending on the cultivar. The pecan kernel protein also contains 18 amino acids and glutamic acid is the main amino acid (1.829 g 100 g^{-1} kernels), followed by arginine (1.177 g 100 g^{-1} kernels) in pecan kernels. The essential amino acid content of the kernels is given in Table 3.

Carbohydrate content The total carbohydrate and fiber contents of pecan kernels are about 13.9–18.3 and 1.6–9.6 g 100 g^{-1}, respectively. The total reducing sugar content is lower in pecan than most other nuts; the amount of sucrose is 2.0 g 100 g^{-1} kernel.

Juglone Juglone is also present in all green and growing parts of the trees and unripened hulls of pecan nuts. However, the kernels contain minute amounts of juglone.

Vitamins Pecan nuts contain about 77–130 IU vitamin A, 0.66–0.86 mg thiamin, 0.11–0.13 mg riboflavin, 0.89–1.167 mg niacin, and 1.1–2.0 mg ascorbic acid 100 g^{-1} kernel. The nuts contain 170 μg γ-tocopherol and 15 μg α-tocopherol g^{-1}. The δ-isomer is present in minute quantities.

Minerals Although some minerals, such as copper, iron, cobalt, and chromium, decrease the stability of vegetable oils, many minerals are essential for normal metabolic functions and are required components in a balanced diet. Pecan kernels are rich in dietary minerals as they contain phosphorus, potassium, magnesium, and sulfur in fairly large quantities (Table 4), and others, such as iron, copper, zinc, and molybdenum, in microquantities.

Tannins The integument of the pecan contains up to 25% tannin, and hence the crop is a very good source

of commercial vegetable tannin. Tannic acid produced from pecan shells is used by the tanning industry. It is also used by the oil industry to control the viscosity of drilling muds. (*See* **Tannins and Polyphenols**.)

Phenolic acids Pecan kernels also contain phenolic acids, namely gallic, gentisic, vanillic, protocatechuic, *p*-hydroxybenzoic, and *p*-hydroxyphenylacetic acids. Coumaric acid and syringic acids are present in trace amounts. The phenolic compounds were located only in the testa of the kernel. The total phenolic acid content in the defatted kernels was found to be about 171.4 $\mu g\,g^{-1}$; gallic acid was predominant and constituted about 78% of those present. The content of all the major phenolic acids except *p*-hydroxy phenylacetic acid progressively decreases during storage, and thus they appear to function as antioxidants to maintain the chemical integrity of the kernel. (*See* **Antioxidants**: Natural Antioxidants.)

Nutritional Quality

Pecan nuts are mainly used as appetizers and additions to salads, cakes, candies, and cookies or as emergency rations for persons expending great amounts of energy, rather than a basic diet. These kernels are high in fat content with a calorie count close to butter. Pecan kernels are nutritious and a good source of energy and vitamins. Defatted kernel powder is useful as a dietary supplement as it contains all the essential amino acids and significant amounts of minerals and natural antioxidants like phenolic acids and tocopherols. The oil is used in cooking and salads and has good keeping qualities. Pecan kernels are a good source of energy and provide about 2891 $kJ\,100\,g^{-1}$. (*See* **Energy**: Measurement of Food Energy.)

Industrial Uses of Oil

Like walnut oil, pecan nut oil is used in food, soap, enamel paints, oil colors, and printing inks. The refined oil is a clear, neutral, edible oil but is sold mostly for special uses to the pharmaceutical, essential oils, and cosmetics industries. In the foreseeable future, pecan oil will remain a byproduct oil, since the main part of the crop is too valuable in the form of nuts or nut meats.

Handling and Storage

More than 50% of pecan kernels offered for sale may, in any one year, fail to meet minimum US Department of Agriculture (USDA) requirements because of discoloration, rancidity, and staleness. Hence it is very important to harvest at the appropriate time, and store the crop under proper conditions to maintain the quality of the nuts.

Early harvest has distinct advantages as a means of avoiding unfavorable weather conditions, and the color and flavor scores of early advanced pecans that are dried and refrigerated promptly change at a much slower rate during storage than do late-harvested crops. A moisture content of 4–5% is recommended to maintain the color.

Very elaborate machinery is used for cleaning, grading, bleaching, cracking, and packing the pecan nuts. In commercial shelling plants, in-shell pecans are conditioned prior to cracking and shelling to improve the yield of halves. In general, conditioning can be achieved by soaking pecan nuts in large vats of water containing chlorine at 1000 p.p.m. for 1–2 h, and then holding them for 12–24 h before cracking. Another method used by processors is soaking the pecans in water (85 °C) for 3–5 min, followed by holding for 12–24 h before cracking. The most effective process for improving the yield of halves from shells, and for maintaining the quality of the kernels, is the 3-min atmospheric steam process. Immediately after cracking, the moisture content is reduced to less than 4.5% for pecan halves and less than 3.5% for pieces in order to maintain quality.

Acidification of pecan kernels with dilute acid solutions significantly lightens the color of the kernels, and phosphoric acid has proved to be the most effective. Dilute solutions of citric acid can also enhance the color but, unlike phosphoric acid, they adversely affect the taste. Treatment with dilute hydrochloric acid, ammonia, and sulfur dioxide can improve the color but responses are variable. The color of the pecan kernels is considered a primary quality parameter of the shelled nuts and, in the USA, they are graded into four color classes by the USDA: light, light amber, amber, and dark amber.

Rancidity is the major problem for pecan kernels during storage, as the oil is rich in unsaturated fatty acids. The development of rancidity also influences the flavor of pecans, and they can be kept for about 3–4 months only, at ordinary temperatures, without developing rancidity. However, they may be stored, soon after harvest, at 3 °C for 1 year, without developing off-flavors at − 4.5 °C for 3 years and at −17.5 °C for more than 5 years. It is believed that kernels do not become rancid more rapidly after being removed from storage than fresh pecans exposed to the same conditions.

In pecans, molds which are capable of producing aflatoxins are of great concern to processors and marketers because fungi like *Penicillium*, *Aspergillus* and *Fusarium* species are capable of growing on pecans at 0 °C and, to a lesser extent, at −6–5 °C.

However, pecan kernels can be preserved against fungal deterioration and discoloration by reducing the moisture content rapidly, after harvest, with moderately warm (< 40 °C), dry air circulated constantly around the nuts, followed by storing in ventilated chambers containing air of relative humidity in the range 60–68%. Chlorine or propylene oxide treatments are also employed by the pecan industry to disinfect in-shell pecans, halves, and pieces.

WASTAGE OF FOOD

C Hunt, University of Huddersfield, Queensgate, Huddersfield, UK

Background

Some food wastage is inevitable during storage, distribution, processing, and cooking. However, avoidable wastage of food at any point in the food chain, from crop losses in harvesting and storage to food left on the plate, could be considered undesirable in moral, economic, and nutritional terms. There have been relatively few studies on this topic, but interest intensifies if commodities become scarcer and/or more expensive. Pollution problems relating to disposal of organic waste, including food and food by-products also need to be addressed.

Discrepancies between total food supplies and actual food consumption of populations have long been recognized but not fully understood. For example, recent estimates in the UK suggest that there is sufficient food and drink available to provide approximately 13.4 MJ (3200 kcal) per head per day.

These estimates relate to edible food available from farms and from imports after allowance had been made for exports, nonfood usage and any changes in year-end stocks. Yet the actual average energy intake in 1998 (National Food Survey) was calculated at 8.8 MJ (2110 kcal) per person per day, about 12% of which derived from food and drink consumed outside the home. The survey included a sample of 5973 fully participating households, and the home food consumption was based on a 7-day food diary of all food entering the household. The above energy intake figure does not include food wastage in the home. However, in further calculations relating energy intakes to dietary reference values (DRVs), the report assumes that 10% of edible food is wasted via plate wastage, spoilage in the kitchen or on the plate, or fed to domestic pets or livestock. This assumed figure is slightly higher than that measured in the study mentioned below.

Thus, on a national scale, there appears to be a 'crude energy gap' of approximately 30–35% comparing food energy available with energy consumed. Possible contributors to this loss in the food chain could be distribution and storage losses, and waste in markets and shops, food factories, hotel and catering outlets, and domestic households.

Definition

Food waste can be defined as 'any potential source of food that has knowingly been discarded or destroyed,' e.g., food discarded in factories, food not

sold in shops or restaurants, kitchen scraps, and plate waste. *Food loss* could be used to refer to food that has inadvertently been destroyed or spoiled, e.g., stored grain eaten by rats, meat spoiled by bacterial growth and nutrients destroyed or going into solution in vegetable canning.

Food waste and loss can be described in terms of *weight, cost*, or *nutritional value* but does not refer to inedible material such as egg shells, potato peelings, and bones.

Household Waste

In a major study in the UK conducted by the Ministry of Agriculture, Fisheries and Foods (1980) food waste was measured in 672 representative households (338 in summer and 334 in winter). The householders collected all potentially edible food wasted in their homes during 1 week and also kept a record of the food other than commercial pet food, which they gave to pets and wild birds. Each food sample received was weighed and its energy content determined calorimetrically.

Significantly more waste food was collected in summer than in winter, equivalent to 9.3 MJ (2220 kcal) and 7.1 MJ (1700 kcal) per household per week, respectively. In terms of energy, cereals, fat and meat wastage predominated, whereas in terms of weight, milk was more important, and fat less so. Significant quantities of otherwise edible food were also given to pets and birds, accounting on average for a further 2.4 MJ (570 kcal) and 3.0 MJ (710 kcal) per household per week in summer and winter, respectively.

The energy content of all food wasted in the home therefore averaged 11.7 MJ (2790 kcal) per household per week in summer and 10.1 MJ (2410 kcal) in winter, equivalent to an average 0.55 MJ (140 kcal) per person per day. This was therefore less than one-quarter of the gap between food supplies and the amount of food thought to be eaten in the UK. When assessed against the expected usage of food in the home, wastage accounted for 6.5% of the energy intake in summer and 5.4% in winter. Wastage was not related to income or geographical area but was greater per person in smaller compared with larger households.

In another study conducted in Cambridge, UK (1985) on 82 families, wastage of edible energy averaged 3.8% (with a further 3.0% of purchases being consumed by visitors).

Domestic food wastage in the USA is probably higher than in the UK. Few data exist, but one study in Arizona, based on measurement of waste food in garbage cans, estimated approximately 10% of the weight of food that entered the home being discarded. However this did not include food given to pets or washed down sinks or through garbage disposal units.

Catering and Hotel Waste

As mentioned previously, this is another area where food wastage occurs. Reliance by consumers on food provided by the caterer varies widely within and between different groups of people and between countries. In the UK, on average, three to four meals per week per person are consumed outside the home. (*See* **Catering:** Catering Systems.)

Catering outlets vary greatly in size ranging from small cafés, snack bars, and restaurants to large industrial canteens and hospitals. Wastage can occur at various stages of the catering operation. Firstly, poor storage conditions for incoming goods can lead to food being discarded, e.g., from temperatures rising too high in refrigeration, cold storage, etc. Meat, meat products, fruits, and vegetables are particularly vulnerable in this respect. Also, excessive humidity can lead to spoilage of dry goods particularly if unpackaged. (*See* **Catering:** Nutritional Implications.)

Secondly, losses can occur in preparation such as in the trimming of meat, vegetables, and fruit. Spillages can occur, and also significant drip-thaw loss of water-soluble protein, vitamins, and minerals can occur in the defrosting of frozen meat.

Cooking can cause further loss, e.g., loss of weight due to evaporative loss, as in roasting of meat, also a reduction in fat and hence energy content in the grilling of meat. Destruction of heat-labile vitamins (B complex and C) inevitably will occur as well in cooking, together with leaching of water-soluble vitamins. These losses can be minimized by good catering practice. Unserved food may also be discarded, and finally, plate wastage may occur, particularly if the meal is unappetizing, e.g., not hot enough or poorly presented. There have been a few studies of wastage in catering. Platt *et al.*, in a study of UK hospitals, drew attention to alarmingly high levels of food waste, with 25–35% of food (by weight) sent from the kitchen being left over in serving dishes and plate waste averaging a further 10%. In a later study of a variety of UK catering establishments, 30% of total edible food energy input was found to be wasted throughout the catering operation in the hospital sector, but was less in other sectors (cafés and snack bars 4.8%; schools 6.5%; place of work 10.2%; restaurants, hotels and pubs 15.5%; and other welfare 17%), giving an overall average of 11.4%. Higher overall wastage occurred with generally poor control procedures, and high plate wastage was also

noticeable with high fat and high energy meals (served particularly in hotels and restaurants).

A recent study on long-stay elderly patients in hospital maintained concerns about the nutritional impact of waste. The data suggested that, although adequate energy and nutrients per patient were provided from the kitchens, service loss and plate waste resulted in actual intakes being inadequate, on average.

In this respect, arguments remain as to the relative merits of plated meals or bulk trolley service, but there have been recent suggestions that bulk trolleys, when operated on an appropriately 'personalized service' basis, can significantly reduce plate waste and improve patient intakes.

Factory Waste

The extent of wastage, however defined, in food-processing factories varies greatly with country and with the particular food products concerned.

Stocks of raw food materials and of food products after processing are held in factories for variable periods and are potentially open to attack by microbes, insects, rodents, etc. The extent of losses will range from considerable to minimal, depending on how tightly storage conditions are controlled and monitoring procedures enacted.

In developing countries, the food-processing industries are generally less well developed and regulated, and the potential for waste is considerable. In developed countries, processing has been increasingly concentrated in very large factory units with enormous throughputs of food. Control and quality-assurance procedures in the latter are relatively sophisticated and waste can be minimized. Inevitably, though, there is still some loss either directly of the food raw materials and food products or of potentially utilizable byproducts. For example, it has been estimated that 1–4% (by weight) of the milk input to a modern dairy plant is wasted and that 2–5% of total carcass protein is lost in the effluent from abattoirs and poultry plants. However, interest in recovery of waste food products and byproducts has been increasing for both economic and ecological reasons, since very large quantities of biodegradable materials are involved, e.g., aqueous 'washings' from the processing of fruit, vegetables and cereals containing starch, sugars and protein, blood from slaughterhouses, and whey from the dairy industry. These wastes have been sprayed directly on to fields, where they can act as fertilizer but can be degraded by soil bacteria in the process, or discharged into the sewage system, or directly into rivers. Excessive use of the last option has been increasingly controlled since the relatively high biochemical oxygen demand of these biodegradable substances can overwhelm the natural capacity of the river to deal with them.

The technology exists for recovery of these materials by chemical and microbiological means either directly for human food or by conversion to animal feedstuffs, but the extent to which this is done is likely to depend largely on economics and environmental legislation.

WATER

Contents

Structures, Properties, and Determination

M M Pierce, University of Nebraska Lincoln, Lincoln, NE, USA

Introduction

In most food systems, water is a major component and influences food structure, appearance, flavor and susceptibility to spoilage.

Shape of the Molecule

The water molecule is made up of two hydrogen atoms with an oxygen central atom. The water molecule is a polar, angular structure (Figure 1). There is a 105° angle between the covalently bonded hydrogen atoms. The hydrogen bonds are covalent σ bonds with a dissociation energy of 4.614×10^2 kJ mol^{-1}.

Pure water can contain as many as 33 chemical variants of the molecule HOH. These include the common isotopes ^{16}O and ^{1}H, as well as ^{17}O, ^{18}O, ^{2}H (deuterium) and ^{3}H (tritium). Water also contains ionic particles including hydronium ions (H_3O^+), hydroxyl ions (OH^-) and their isotopic counterparts. (*See* **pH – Principles and Measurement.**)

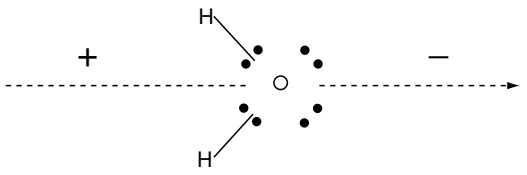

Figure 1 The water molecule. Reproduced from Water: Structure, Properties and Determination, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Hydrogen Bonding

As mentioned, water has a bond angle of 105°, which allows for an approximate tetrahedral structure. The hydrogen atoms are found along two of the axes of the tetrahedron, and the lone pairs of the oxygen atom are located approximately where the other two tetrahedron axes would be. This balance of two hydrogen bond donor and receptor sites allows for three-dimensional hydrogen bonding with a maximum of four other water molecules.

Structure of Ice

It has been shown that the ice crystal structure has a hexagonal symmetry (Figure 2). Three of the hydrogen bonds of the tetrahedron are in the same plane, and the fourth is directly above or below. In the ice crystal, these basal planes are parallel (Figure 3). Therefore, the structure of ice is a series of parallel planes. When ice melts, the structure collapses as hydrogen bonds break. The arrangement becomes more closely packed and, thus, liquid water occupies less space than ice.

Physical Properties

When compared with molecules of a similar molecular weight and composition, water has unusually high melting and boiling points. Water also has large values for surface tension, dielectric constant, heat capacity, and heats of phase transition and a low value for density. Also, the thermal conductivity is large compared with other liquids and nonmetallic solids. These physical properties are influenced by the highly polar nature of the water molecule, which

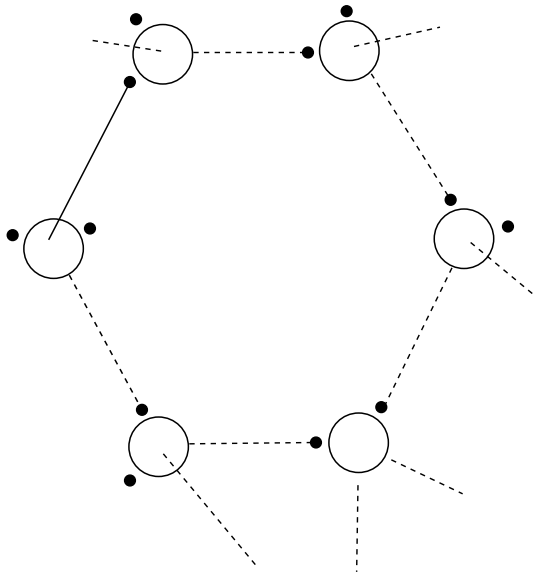

Figure 2 Diagram showing the hexagonal structure of an ice crystal. Reproduced from Water: Structure, Properties and Determination, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), (1993), Academic Press.

allows such phenomena as hydrogen bonding and ionization to occur. Table 1 lists some of the physical properties of water.

Nature of Water in Foods

When associated with food, water can be placed into three categories, free, absorbed, and bound. Free water is the water found within the pores or intergranular spaces of the food. This water retains the usual physical properties of water and often acts as a solvent or dispersing agent for crystalline or colloidal substances. Water absorbed on the surface of macromolecular colloids is termed absorbed water. The macromolecular colloids to which water may be absorbed include starches, pectins, cellulose, and proteins. This absorption is due to Van der Waals' forces and hydrogen bonding. Bound water is the proportion of the water that is in combination with constituents of the food, e.g., water of hydration. This classification system is arbitrary, and there are numerous definitions and variations for water types.

Table 1 Physical properties of water

Molecular weight	18.015	
Phase transitions		
Melting point at 1 atm (°C)	0.00	
Boiling point at 1 atm (°C)	100.00	
Heat of fusion at 0 °C (kJ)	6.012	
Heat of vaporization at 100 °C (kJ)	40.63	
Heat of sublimation at 0 °C (kJ)	50.91	
	0 °C (liquid)	*0 °C (ice)*
Density (kg l^{-1})	0.9998	0.9168
Viscosity (Pa s)	1.787×10^{-3}	—
Surface tension (N m^{-1})	75.6×10^{-3}	—
Heat capacity (J kg^{-1} K^{-1})	4.2177	2.1009
Thermal conductivity (J m^{-1} S^{-1} K^{-1})	5.644×10^{2}	22.40×10^{2}
Thermal diffusivity (m^2 s^{-1})	1.3×10^{-5}	$\sim 1.1 \times 10^{-4}$

Determination in Food

The amount of water in a food is often referred to as the 'moisture content.' This moisture content is important for many reasons. The most important of these is the effect of moisture on the stability and quality of the food substance. This refers to microbiological spoilage as well as undesirable chemical reactions. Moisture is of great economic importance because it is inversely related to the amount of dry material. Other important moisture content issues are processing problems, such as material balance and optimizing processing techniques affected by moisture content. Moisture content is also necessary for calculation of nutritional information, as a means of expressing analytical data on a uniform basis (dry weight basis) and meeting compositional standards and laws. (*See* **Preservation of Food; Spoilage**: Bacterial Spoilage; **Water Activity**: Principles and Measurement; Effect on Food Stability.)

Heating Methods

One of the oldest methods of determining moisture content is heating, and several variations of heating methods exist. They are all common in that the water is driven from the food by the use of a heat source. The loss in weight is measured and assumed to be the moisture content of the food.

The accuracy of these methods is greatly affected by drying temperature, relative humidity and movement

of the air in the chamber, vapor pressure of the chamber (vacuum), sample particle size and quantity, oven construction, position and number of samples in the chamber, the surface of the sample, and the rate of diffusion of water vapor. The drying temperature must be at least the boiling point of water at the given vapor pressure of the chamber. When the chamber is under vacuum, a lower drying temperature must be used. The humidity of the air must be low, and movement of the air is important. Continuous sweeping of the chamber with dry air aids drying and decreases drying time. Using a sample of small particle size increases the surface area and aids drying. A thin layer of sample in a shallow aluminum pan also increases the rate of drying. Allowing liquids to evaporate on a water bath before oven drying is the preferred method. To allow for uniform drying of several samples, pans need to be evenly spaced in the center of the oven 2–5 cm from the walls and 5–8 cm from the door.

There are two common types of ovens, air ovens and vacuum ovens. Air ovens include both convection and forced-air types. Vacuum ovens allow for complete drying with less change to the organic composition of the product.

A less traditional heating method is infrared drying. This type of drying reduces the drying time to 12–33% of the conventional drying time. Infrared drying consists of a 250–500 W lamp, which heats to 2000–2500 K. The lamp is placed above the weighed sample at a distance of about 10 cm. The sample pan may rest on a torsion balance with an indicator scale reading in grams and/or percent moisture. This normally has a drying time of 10–40 min. Microwave ovens can also be used for drying and allow very short drying times.

Distillation Methods

Distillation is almost as old a method as drying. There are two types of distillation apparatus. The first uses a high-boiling-point water-immiscible liquid such as a mineral oil. The sample is suspended in this oil and heated to a temperature high enough to allow the water to be vaporized. As the water is distilled off, it is condensed and collected in a vessel and measured. The second type of distillation involves the use of a solvent that is immiscible with water. Again, the sample is suspended, and the solvent and water are codistilled and collected in a measuring device or moisture trap. The two liquids separate, and the water layer is measured. Often, a reflux system is used to allow recycling of the solvent. **Figure 4** shows a typical distillation system, and **Figure 5** shows various types of moisture traps.

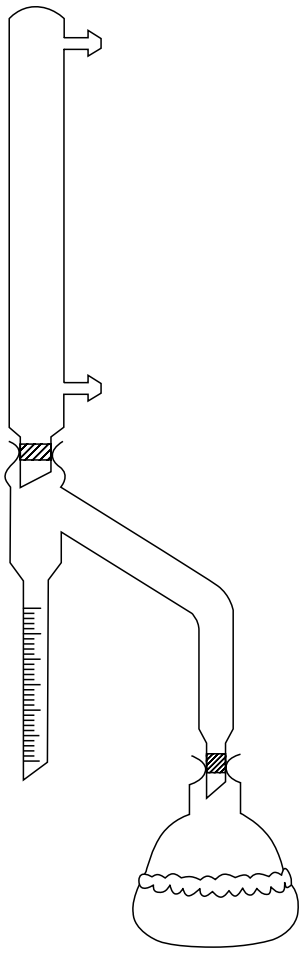

Figure 4 A typical distillation system for determining the water content in food. Reproduced from Water: Structure, Properties and Determination, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Chemical Methods

The Karl–Fischer titration is a good method for samples that are low in moisture, high in sugar, and high in reducing sugar and protein, or samples that give erratic results. The Karl–Fischer method is based upon the reduction of iodine by sulfur dioxide in the presence of water. Methanol and pyridine are used to dissolve the iodine and sulfur dioxide. The reaction occurs in two steps (eqn (1)).

$$C_5H_5N \cdot I_2 + C_5H_5N \cdot SO_2 + C_5H_5N + H_2O \rightarrow 2C_5H_5N \cdot HI + C_5H_5N \cdot SO_3 \quad (1)$$

$$C_5H_5N \cdot OSO_3 + CH_3OH \rightarrow C_5H_5N(OH)SO_4CH_3. \quad (1b)$$

Normally an excess of methanol, pyridine, and sulfur dioxide is used, the strength being dependent on the

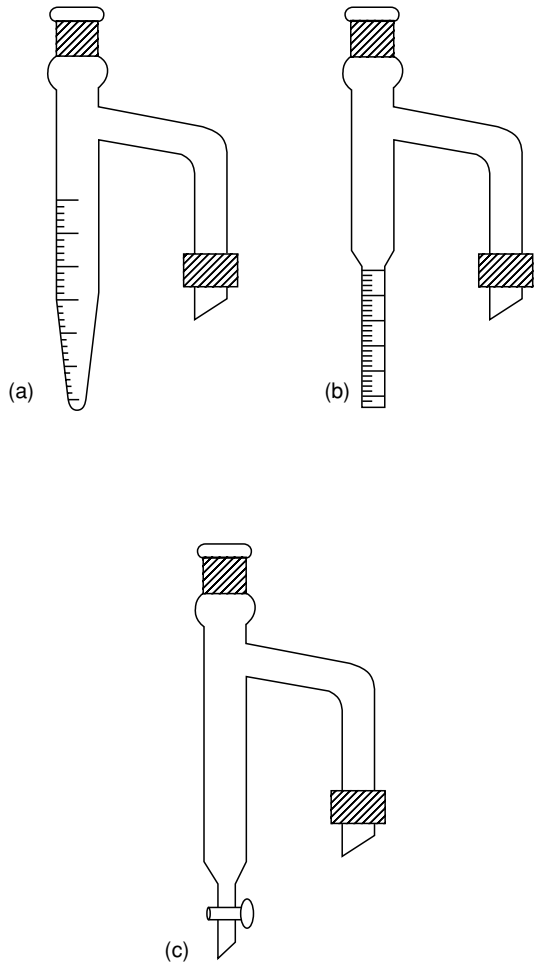

Figure 5 Moisture traps for distillation methods of water determination: (a) Stark and Dean, (b) Bidwell and Sterling, and (c) Barrett. Reproduced from Water: Structure, Properties and Determination, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), (1993), Academic Press.

concentration of iodine. Karl–Fischer reagents can be obtained commercially as two solutions: (1) iodine in methanol and (2) sulfur dioxide in pyridine.

The titration can be carried out in one of two ways. The first requires that the reagents be mixed just before use and the sample dispersed in a solvent (e.g., methanol). The dispersed sample is then titrated with the four-component reagent until a yellow–mahogany brown end point is reached. In the second method, the sample is dispersed in a mixture of sulfur dioxide, pyridine, and methanol. This is then titrated with iodine in methanol. In order to enhance the end point, a few drops of methylene blue may be added, giving a green end point. Alternatively, a photometric or electrochemical method can be used instead of a visual method.

Instrumental Methods

Infrared determination Infrared spectrophotometry is based on absorption of wavelengths characteristic of molecular vibrations. In water, the fundamental vibrational modes are 3000 and 6100 nm with the first overtone of the OH stretch at 1400 nm. (*See* **Spectroscopy**: Infrared and Raman.)

Near-infrared determination This type of spectrophotometry is similar in nature to infrared spectrophotometry. The wavelengths of interest are 1940 nm, as the primary OH bend and stretch, and 1450 nm, from the first overtone of the OH stretch. (*See* **Spectroscopy**: Near-infrared.)

Gas chromatographic determination Moisture can be determined by gas chromatography using a thermal conductivity detector, provided that the water can be extracted using a solvent such as methanol/butanol and that separation of water from other volatiles is possible. (*See* **Chromatography**: Gas Chromatography.)

Nuclear magnetic resonance (NMR) determination NMR determination uses a magnetic field of constant frequency that is applied to the sample, and the strength of the field is varied. The peak-to-peak amplitude of the signals is measured, and moisture is determined by using a standard curve. This method, however, is hydrogen-specific, not water-specific, and may be useful for materials only with a very low solids content. (*See* **Spectroscopy**: Nuclear Magnetic Resonance.)

Electrical determinations Several instruments exist that use conductivity as a method to measure moisture. Most of these instruments use a modified Wheatstone bridge. In these instruments, an electrical current is applied to a food, and the resistance of the food is measured and related to moisture content.

Another electrical method is capacitance. This type of instrument relies on the fact that the dielectric constant of water is higher than that of most other liquids. The sample is placed between two plates, with alternating opposite charge at a fixed frequency, resulting in an alternating current. Polar substances with permanent dipoles orient themselves in this alternating field, increasing the charge of the plates.

Problems of Determination

All of the methods discussed have drawbacks, and while some are excellent methods for one product, they may yield poor results for others. In drying, the most common source of error is the formation of a crust or case hardening. Lowering the oven temperature and increasing the vacuum may help. In the case

of some liquids that are high in sugar, mixing with sand may help. A two-stage drying procedure can also be used, where the temperature starts low and is increased very slowly.

Distillation methods also have many difficulties associated with them. These include adherence of moisture to glass and improper drainage of water into the measuring device, difficulties in reading the meniscus, and low precision of the measuring device. Also, water-soluble components may be distilled, causing erroneous results.

The main difficulty of the Karl–Fischer titration is incomplete extraction of water from the sample. Also, ascorbic acid, a common additive, is an interferent and has an additive effect. Aldehydes and ketones release water when mixed with methanol, causing a fading endpoint.

Thus, although chemical and instrumental methods are, in general, very fast, they have a narrow range of products with which they can be used.

Introduction

Body water cannot be poured out to measure its volume; it must be determined indirectly. A good indirect method is to introduce a known quantity of a harmless solute and measure its concentration in the blood plasma after mixing is complete. The results depend upon the solute chosen. Very diffusible substances such as urea, ethanol, or isotopic forms of water, give large values that correspond to the total amount of water in the body, 35–45 l, or 50–70% of body weight. Proteins or other colloids that cannot leave the blood give the volume of plasma, around 3 l, or 4–5% of body weight. Substances of intermediate molecular size that cannot penetrate into cells give estimates ranging between 12 and 20 l, or 16–30% of body weight. (*See* **Body Composition**.)

Provided that these substances can penetrate into dense connective tissues and tendons, this intermediate estimate should give the sum of the extracellular fluid outside the blood vessels and the plasma inside them. The results are consistent with the obvious anatomical fact that the water of the body is not one homogeneous phase. The most important subdivision is into two major fluids: one is intracellular, discontinuous, in 10^{14} or so separate tiny portions, each surrounded by a cell membrane; the other is extracellular, the continuous medium in which the cells live, and which provides the medium for their communication with each other, and, through the circulating blood, with the external environment across interfaces at the lungs and the alimentary tract.

These two major fluids are as distinct in composition as in anatomical location (**Table 1**). The solutes in the intracellular fluids (ICFs) are potassium salts, and the anions are mostly organic, chiefly phosphoric esters and proteins, with only a little chloride. The extracellular fluid (ECF) is more like a dilute sea water; its chief solutes are sodium and chloride, with small but important concentrations of potassium, calcium and bicarbonate, together with organic nutrients such as glucose and amino acids, and waste products such as urea.

Table 1 Composition (mmol per kg of water) of typical intracellular and extracellular fluids

	Muscle ICF	*Plasma ECF*
Potassium (K^+)	150	5
Sodium (Na^+)	10	150
Magnesium (Mg^{2+})	10	1
Calcium (Ca^{2+})	10	2
Organic phosphate (Org P^-)	130	5
Bicarbonate (HCO_3^-)	10	27
Chloride (Cl^-)	5	110
Phosphate ($H_2PO_4^-$)		2
Protein ($Prot^{17-}$)	2	1
pH	7.1	7.4
Osmolality (mosmol per kg of water)	285	285

Taken from Table 1.1 in Bray JJ, Cragg PA, Macknight ADC, Mills RG and Taylor DW (1989) *Lecture Notes on Human Physiology*, 2nd edn. Oxford: Blackwell Scientific with permission.

The membranes surrounding the cells are of remarkably low and highly selective permeability, but they are not totally impermeable to sodium, potassium, and other ions. Consequently, the characteristic differences in composition have to be maintained actively, and a major proportion of 'resting' metabolism is required to provide energy to pump out sodium that continually diffuses into cells, and to recover potassium that escapes or is lost through activities such as muscular contraction or conduction of nerve impulses. The membranes are permeable to water, so that the fluids on either side are in osmotic equilibrium. (*See* **Potassium**: Physiology; **Sodium**: Physiology.)

Role as Transport Vehicle for Nutrients and Metabolites

Within the body, nutrients and metabolites are in solution, and the transport system is based on water carriage. That part of the ECF which is the blood plasma is contained in the arteries, capillaries, and veins, and circulated rapidly; even at rest, the heart pumps about 5 $l\,min^{-1}$ from the aorta. The lymph, which is also in vessels, circulates much more slowly in returning escaped plasma proteins from tissue spaces to the blood. The flowing plasma carries nutrients and metabolites close to cells, but cannot quite reach them. Transport of consumables to cells, and products away, depends on diffusion through the capillary walls and across thin layers of interstitial fluid between the capillaries and cells in the tissues. Diffusion in water is slow over distances greater than 0.1 mm, but at distances of the order of cell diameters, it is remarkably rapid, 90% equilibration taking less than 0.05 s at 10 μm, even at room temperature. Between adjacent cells 1 μm apart, it would take less than 5×10^{-4} s, across a synapse, 0.1 μm wide, $< 5 \times 10^{-6}$ s. Thus, the circulating blood provides long-distance transport of oxygen from the lungs, metabolites from the liver, and nutrients from the gut to the tissues; it also carries carbon dioxide to the lungs and nonvolatile waste products to the kidneys for disposal. Diffusion provides rapid transport in the ICFs between organelles within the cells, and rapid exchanges with the ECF in which they live. Both these mechanisms of transport depend on the water in which the transported materials are dissolved. The blood also carries 'messengers' such as carbon dioxide from active tissues to the respiratory center, and hormones from endocrine glands to cells all over the body, which makes transport by water extremely important for the coordinated function of a vast population of separate cells as one organism.

Protection and Lubrication

There are some smaller collections of fluid that are not inside cells and yet cannot exchange freely with the main mass of ECF by diffusion across highly permeable capillary membranes. Examples are the vitreous and aqueous humors in the chambers of the eye, the cerebrospinal fluid that surrounds the brain and the spinal cord, and the synovial fluid in the capsules of joints. These are by no means ICFs, but they are secreted by layers of specialized cells (e.g., in the ciliary body, choroid plexus, or synovial membranes) which surround them and separate them from the main body of ECF. They may be called transcellular fluids, because the only approach to them by diffusion from the continuous ECF is across cellular membranes with their specialized and restricted permeability. These specialized fluids serve to maintain the size and shape of the eyeball, to protect the brain from trauma due to sudden movements by reducing its effective weight by flotation, and to lubricate the joints.

The cells are tiny aquatic organisms, and the ECF is the pond in which the live. It has been aptly called a middleman fluid because it accommodates exchanges of matter and energy between cells and other cells in remote parts of the body as well as between cells inside the body and the external environment from which they eventually derive their nutrients and the oxygen they need to utilize these. The famous French physiologist, Claude Bernard, died in 1878 correcting the proofs of the book in which he characterized the ECF as an internal environment within which the cells live a sheltered life, protected from the vicissitudes of an external world that is variable and often hostile. Bernard enunciated the principle that the constant properties of this internal environment are a necessary condition for the free, independent life of higher organisms. Indeed, a substantial part of the subject matter of physiology is concerned with homeostatic mechanisms that operate to stabilize the chemical and physical properties of the internal environment.

Role in Body Temperature Regulation

The rates of the chemical reactions catalyzed by enzymes have substantial temperature coefficients, so that proper coordination of the activities of the body's many enzymes depends on maintaining a fairly constant temperature despite the variable output of heat by active tissues. The large thermal capacity of water minimizes local increases in temperature at sites where heat is evolved; flowing blood carries heat away from active sites far more rapidly than is possible by conduction, so that the extra heat is

shared with a larger volume of blood and other tissues. Heat produced at active sites within the body must ultimately be conveyed to an external surface before it can be lost; the high heat capacity of water allows this to be achieved with only small changes in temperature of the blood. When the surroundings of the body are warmer than the skin, heat cannot be lost at all by conduction and convection; but the large latent heat of vaporization of water enables large amounts of heat to be lost to hotter surroundings without undue losses of body fluids. The skin is cooled by the evaporation of sweat, a special dilute solution secreted by sweat glands that are activated when the temperature of the blood bathing receptors in the brain rises. Maximal sweating may exceed $1\,l\,h^{-1}$, and people working or exercising in hot environments may lose 15 l per day; but if the latent heat of vaporization were to be 10 times smaller (as were those of some liquids Henderson (1913) took for comparison), 10 times as much would have to be lost, up to three or four times the total amount in the body in the course of a single day! Conversely, in circumstances of extreme cold, a modest flow of blood suffices to bring heat from within the body to combat chilling of the extremities, and the large latent heat of fusion of water protects these extremities from quickly freezing.

Other Inevitable Losses of Body Water

The secretion of sweat is almost entirely dictated by the need to prevent overheating of the brain; sweating cannot be turned off to save water. There is an equally unavoidable loss of about 0.5 l every day in the form of vapor from moist skin between the ducts of the sweat glands ('insensible' because, unlike liquid sweat, it is not obvious). The skin must remain moist to retain its flexibility and avoid cracking (with the risk of bacterial infection) with bending and stretching. The alveolar lining of the lungs must also be moist to permit deformation and to allow oxygen and carbon dioxide to exchange in solution between alveolar gas and blood. Since the expired air is saturated with water vapor at the temperature of the respiratory tract, while the inspired air is drier, an inevitable loss of about 0.5 l of water by evaporation accompanies breathing at sea level. The loss is proportional to the volume of expired gas; mountaineers breathing large volumes of thin air at great heights may lose as much as 2 l in a day. This inevitable loss of water vapor takes with it the latent heat of evaporation, so that they risk severe impairment of their physical condition from chilling as well as dehydration, especially if their exertions lead to additional losses in sweat.

Losses in feces are unimportant unless there is diarrhea. However, one very important function of body water that can only be carried out by expending it is the removal of soluble waste products in the urine. About 600 mmol must be excreted every day, and this requires 0.5 l of maximally concentrated urine, or a minimum of 2 l if, because of impaired function, the kidneys cannot make the urine more concentrated than the blood.

Hence, everyday living involves unavoidable daily losses of 1.5–2 l of water; since water is an essential part of the living machinery of the cells, and effective transport around the body requires adequate volumes of blood to circulate and of ECF to bathe the cells, these losses must be replaced. A small amount of water, about 300 ml, is actually generated each day in the cells by metabolism; solid food (which contains as much, or, if vegetable, more water than our own tissues) provides about a liter, and the rest must be taken in as beverages or soups.

Maintaining the Water Balance of the Body

When water is lost without solute and not replaced, the osmotic pressure of all the body fluids increases, and their combined volume shrinks. Osmoreceptors in the supraoptic nucleus of the hypothalamus at the base of the brain respond by evoking the sensation of thirst and by releasing into the blood an antidiuretic hormone (ADH), which causes the kidneys to conserve water by making the urine more concentrated (if it is not already maximally concentrated). The subject is encouraged to drink more watery fluid, and the kidneys retain water in the body. If the subject drinks more water than is required, the body fluids become diluted, thirst fades, the release of ADH ceases, and the kidneys rapidly excrete excess water in a copious flow of dilute urine. (*See* **Renal Function and Disorders**: Kidney: Structure and Function.)

Not only do the kidneys act with thirst to preserve the total amount of water in the body, but they also regulate the distribution between cells and ECFs. As stated above, the ICFs are primarily solutions of potassium salts, and the ECFs of sodium salts. Neglecting the other ions, human ECF can be likened to a $0.154\,mol\,l^{-1}$ (0.9%) solution of sodium chloride. Hence, for every 9 g of sodium chloride, there is a liter of ECF. The kidneys are controlled by a number of factors, including the adrenal hormone, aldosterone, so that they retain more salt in the body when the volume of blood is diminished. Metabolic activity keeps the extra sodium out of the cells, in the ECF, so that its volume, and that of the blood in the vessels, is restored. (*See* **Hormones**: Adrenal Hormones.)

The volume of ICF is fixed by the prevailing osmotic pressure and the amount of solute that the cells keep within them by metabolic activity. The kidney, controlling the excretion of water under the influence of ADH, fixes the osmotic pressure in the body, thus setting the stage for the cells to maintain their appropriate volume of ICF. Fixing the osmotic pressure throughout the body also determines the amount of water to go with each unit of sodium in the ECF. Hence, with osmotic pressure and the volume of ICF stabilized by controlling the excretion of water, the kidneys can also regulate the volume of ECF by excreting or retaining salt.

Effect on Food Stability

Principles and Measurement

Y H Roos, University College Cork, Cork, Ireland

Introduction

Water is the main component of most food materials. The control of water content is often used to increase food stability, e.g., by dehydration. It is also known that high concentrations of sugars and salts may increase food stability by affecting the availability of water to microbial growth, although the water content may remain high. It is obvious that the water contents of different foods vary substantially, and water content as such cannot be used as a measure of water availability or food stability. The water availability for microbial growth is a function of the vapor pressure of water in a food, which has led to the development of the *water activity* concept. It has been shown that food storage stability and microbial safety, i.e., rates of chemical and enzymatic reactions and microbial growth, can be controlled by water activity in addition to other factors, such as pH and temperature. Therefore, the development of methods to control water activity of foods and water activity measurement has received much attention in the food industry. Furthermore, reference values for water activity are used in legislation and regulations to insure food safety. This article discusses the basic concepts of water activity, its definition, temperature dependence, measurement, relationship with water content, and mathematical approaches to predict water activity in food systems.

Water Activity

The water activity, a_w, in a solution or a food is derived from its chemical potential, μ_w. The chemical potential, μ, of a pure substance is given by its molar Gibbs free energy, G_m. The Gibbs free energy is pressure-dependent, and it can be shown that the Gibbs free energy of a perfect gas at a pressure, p, can be related to its value, G^*, at a standard pressure, p^*. Then, the Gibbs free energy will be given by eqn (1).

$$G = G^* + nRT \ln \frac{p}{p^*}. \qquad (1)$$

Assuming perfect behavior and taking into account that for water vapor $\mu_{w0} = G_w/n$, eqn (2), where μ_w^* is

the chemical potential at the standard pressure, p^*_w, is obtained.

$$\mu_{w0} = \mu^*_w + RT \ln \frac{p_w}{p^*_w}. \quad (2)$$

The vapor pressure of pure water can be taken as $p_{w0} = p_w/p^*_w$. Thus, the chemical potential is expressed by eqn (3). If water exists in a solution, its chemical potential will be μ_w and vapor pressure $p_{w(liquid)}$. At equilibrium, the chemical potential in the liquid and vapor states is equal, and, therefore, the chemical potential of water in a solution, μ_w, is defined by eqn (4). Eqns (3) and (4) can be combined to give eqn (5) and the chemical potential of liquid water in the solution. The activity, in the case of water, the *water activity*, a_w, is defined by eqn (6).

$$\mu_{w0} = \mu^* + RT \ln p_{w0} \quad (3)$$

$$\mu_w = \mu^* + RT \ln p_w \quad (4)$$

$$\mu_w = \mu_{w0} + RT \ln \frac{p_w}{p_{w0}} \quad (5)$$

$$a_w = \frac{p_w}{p_{w0}}. \quad (6)$$

As defined by the preceding equations, the chemical potential, vapor pressures, and water activity are all temperature-dependent. Therefore, the water activity is a measure of water availability at equilibrium at a constant temperature, e.g., room temperature.

The relative humidity, RH, of an atmosphere is defined as the ratio of the quantity of water present to the saturation quantity at the temperature of the atmosphere, and it is also the ratio of the vapor pressure of water present to that of saturated water vapor at the same temperature, i.e., the relative vapor pressure (RVP), as given by eqn (7).

$$RH = \frac{p_w}{p_{w0}} \times 100\%. \quad (7)$$

If a solution or a food is placed in an atmosphere, it will lose or gain water until equilibrium is reached and the chemical potential and, therefore, the water activity in the atmosphere and the solution or food have become equal. This has a great importance in a_w measurements, because a_w is often derived from the equilibrium relative humidity (ERH) of the headspace of a food system.

Raoult's Law

The vapor pressure of ideal solutions is related to the mole fraction of water, as defined by Raoult's law. Raoult's law is based on the observation that the partial vapor pressure of each component in a solution is a function of its mole fraction and the vapor pressure of a pure liquid at the same temperature. In the case of water, assuming that the solution behaves as an ideal solution, Raoult's law is given by eqn (8). However, Raoult's law assumes linearity, it applies for ideal solutions, and often the vapor pressure deviates from ideal behavior with increasing solute concentration. For real solutions, an activity coefficient is defined, and the water activity is related to the mole fraction of water, x_w, by eqn (9), where γ_w is the activity coefficient of water. Therefore, water activity may also be considered as the 'effective' mole fraction of water.

$$p = x_w p_{w0} \quad (8)$$

$$a_w = \frac{p_w}{p_{w0}} = \gamma_w x_w. \quad (9)$$

Raoult's law is important in understanding the boiling temperature elevation and freezing temperature depression of solutions. The freezing temperature depression may also be measured to derive water activity.

Water Activity Measurement

The water activity of simple, ideal solutions can be derived from Raoult's law by applying eqn (8) and real solutions from eqn (9). Unfortunately, food systems are very complex, the water activity is difficult to estimate, and it must be measured for most foods. A simple, but rough, water activity estimation is based on placing samples in several environments (chambers) with various relative humidities and estimating the water activity from a plot showing weight gain or loss against RH.

The water activity of food materials can be measured using various systems to observe the vapor pressure of water in a food sample or by measuring the relative humidity of air in equilibrium with a food sample. The measurement of the vapor pressure of water can be carried out using a manometer and other relatively simple laboratory equipment. Simple, commercial instruments may apply hair hygrometry. Such devices are not very accurate and require that appropriate time is allowed for the sample material in a container to equilibrate with the measuring unit. Various other commercial hygrometers have been applied in water activity measurements. For these measurements, an appropriate amount of sample material often needs to be placed in a closed container or jar at a constant temperature. The sensor of the instrument is placed in the headspace, and the relative humidity at equilibrium is recorded and expressed as water activity.

Several commercial water activity measurement devices have been developed for rapid and accurate water activity determinations. These devices use either a chilled-mirror dew-point technology or measure relative humidity with sensors that detect electric resistance or capacitance. The dew-point instruments provide relatively rapid and accurate water activity measurements. The main principle of such instruments is based on cooling air at equilibrium water vapor pressure with a food sample without changing the water content and determination of the temperature at which water in the air saturates at a chilled-mirror surface. The water activity of the sample is given by the ratio of the saturation vapor pressure at the dew-point temperature and the saturation vapor pressure at the sample temperature. Instruments using relative humidity sensors require equilibration with the sample at the same temperature in a closed container or jar, as described earlier for hygrometer measurements.

Instrument Calibration

Water activity measurements require adequate and accurate instrument calibration. This is usually carried out with the help of saturated salt solutions or other substances with known water vapor pressures at a given temperature. Different instruments may require different specific calibration procedures, but most instruments should be checked for correct water activity readings. Saturated salt solutions are probably the most common means of producing atmospheres with known relative humidities or water vapor pressures. Saturated salt solutions can be prepared to give a wide range of water activities in a number of temperatures. Although the solutions are relatively easy to prepare, accurate, and safe, appropriate procedures and safety precautions should be followed. The water activities of common saturated salt solutions are listed in Table 1. Other materials, which in various concentrations in solutions with water can be used to adjust water activity, include glycerol and sulfuric acid (H_2SO_4).

Water Sorption

It is often beneficial to establish water sorption isotherms, which show the relationship between water content and water activity for particular food systems. Sorption isotherms can be obtained experimentally by using dehydrated, for example freeze-dried, samples of food solids. The samples should be initially stored over a 'zero' relative humidity in a hermetic container with $CaSO_4$ or P_2O_5. These samples can be used to obtain the 'anhydrous' weight, and the samples are then placed in hermetic containers, preferably evacuated desiccators at a constant temperature over saturated salt solutions with known water activities. The samples in each container are weighed at intervals until subsequent weighings level off, and the weight gain can be considered as equilibrium water content corresponding

to the water activity of the particular salt solution. The equilibration times may vary depending on the container design, water activity, and sample material among other factors. However, equilibration in evacuated desiccators is rapid and often occurs in a few hours and should not take more than a week. Equilibration in nonevacuated containers may take substantially longer and is more subject to errors caused by nonequilibrium conditions and water transfer between the container and external atmosphere.

Food materials exhibit two basic types of sorption isotherms reflecting their either amorphous or crystalline state. Most foods are noncrystalline or partially crystalline systems and have a sigmoid shaped sorption isotherm. Crystalline materials, e.g., crystalline sugars, show a low water sorption until solubilization, and other changes occurring at high water activities result in a substantial increase in sorbed water (Figure 1). Food materials also have a hysteresis between desorption and adsorption isotherms, i.e., the water content in desorption at the same water activity is higher than in adsorption (Figure 2). The hysteresis results most likely from retention of water in capillaries and structural differences. Sorption isotherms are extremely useful in practical applications, as only water content needs to be known to derive water activity. Furthermore, changes in storage relative humidity of low moisture foods can be related to corresponding changes in water content.

Water activity and water sorption isotherms are temperature-dependent. The temperature dependence of water activity follows the well-known Clausius–Clapeyron relationship (eqn (10)), where a_{w1} and a_{w2} refer to water activity at absolute temperatures T_1 and T_2, respectively, Q_s is the heat of sorption, and R is the gas constant ($8.3144\,\mathrm{J\,K^{-1}\,mol^{-1}}$). A schematic representation of the temperature dependence of water activity is shown in Figure 3.

$$\ln\frac{a_{w2}}{a_{w1}} = \frac{Q_s}{R}\left(\frac{1}{T_1} - \frac{1}{T_2}\right). \qquad (10)$$

In general, the water activity of a food with a constant water content increases with increasing temperature, while the water sorption decreases with increasing temperature at the same water activity. This is observed from sorption isotherms determined for the same food at different temperatures (Figure 4). Understanding the temperature dependence of water sorption is extremely important, for example, in estimating the effects of temperature fluctuations on water activity changes inside a food package. The

temperature change under normal storage conditions may result in a water activity shift exceeding 0.1 a_w.

Water Sorption Models

A number of mathematical models have been used to fit experimental water sorption data of food materials. The most common models are the Brunauer–Emmett–Teller (BET) model (eqn (11)) and the extended Guggenheim–Anderson–De Boer (GAB) model (eqn (12)). These models originate from studies of sorption of gases on solid surfaces. The BET model relates the water content (m) to water activity using two parameters, m_0 and C, defined as the monolayer value and a constant related to the excess enthalpy of sorption, respectively. The monolayer value gives the amount of water sorbed initially to first available sorption sites, and it is often found to correspond to the water content of low moisture food systems with improved stability. The BET sorption model can be written to the form of eqn (12), which gives a linear relationship between $a_w/(1-a_w m)$ and a_w. Thus, experimental water activity and water content values obtained from sorption studies can be used to derive the constants m_0 and C. The BET equation, however, fits experimental data only between 0 and 0.5a_w.

$$\frac{m}{m_0} = \frac{Ca_w}{(1-a_w)[1+(C-1)a_w]} \tag{11}$$

$$\frac{a_w}{(1-a_w)m} = \frac{1}{m_0 C} + \frac{C-1}{m_0 C}a_w \tag{12}$$

$$\frac{m}{m_0} = \frac{KC'a_w}{(1-Ka_w)[1+(C'-1)Ka_w]} \tag{13}$$

$$\frac{a_w}{m} = \frac{K}{m_0}\left(\frac{1}{C'}-1\right)a_w^2 + \frac{1}{m_0}\left(1-\frac{2}{C'}\right)a_w + \frac{1}{m_0 KC'}. \tag{14}$$

The GAB model (eqn (13)) has been shown to fit experimental sorption data for most food materials over the entire a_w range. Experimental data may also be used to derive the three parameters, the constants C' and K, and the monolayer value, m_0, of the GAB model. This can be carried out, for example, by using nonlinear regression or rearranging the equation to a form of a second-order polynomial and plotting experimental values of a_w/m against a_w, as suggested by eqn (14). However, the BET and GAB monolayer values are not equal, and neither of these values can be considered as a water content giving maximum stability in a low-moisture state.

Water Activity in Food System

Water is the main component of most fresh foods, and their water activities are high and close to 1. The water activity has increasing importance in concentrated foods, dehydrated foods or systems that contain salts, sugars, and other compounds reducing water activity to provide stability, for example highly salted meats and fish or confectionery and candies. Therefore, it is often of great interest in food product development to estimate effects of food composition and recipe components on end-product water activity. It is also important in packaging of mixtures of different foods, such as dry ingredients, to understand how water activity in a sealed package with several components may change owing to differences in component water activities. Furthermore, water activity in different parts of foods may differ and result in time-dependent water migration until equilibrium is attained. This is often the case in bakery products, which may have a high water activity filling in a lower water activity matrix. However, it is important to note that lipids and fat are not water-soluble, and water activity is mainly affected by water-soluble and water-miscible food components only. Therefore, high-fat products with relatively small amounts of water, such as butter and margarine, may have a relatively high water activity.

The water activity of dilute sugar and salt solutions can be calculated using Raoult's law (eqn (8)) and for more concentrated solutions when the activity coefficient is known using eqn (9), as discussed above. Many food systems, however, deviate from ideal

behavior, and Raoult's law cannot be used. Then, either sorption isotherms or other water activity calculation methods must be followed to estimate water activity in food product development. Several equations are available for predicting water activity of a food product based on the product composition. These include the Norrish equation, which extends the use of mole fractions of food components with additional coefficients to calculate water activity, and the Grover equation, which uses different empirical constants for the various components in a polynomial. The Ross equation (eqn (15)) gives probably the most accurate water activity predictions for complex solutions. The equation is relatively simple and does not require the use of empirical constants.

$$a_w = a_{w1} \times a_{w2} \ldots a_{wi}. \qquad (15)$$

Mixtures of two or more ingredients or food components with different water activities in a sealed package will exchange water until the water activity of the components becomes the same. The water content of the components initially and after equilibration may differ significantly, owing to differences in sorption properties. There are several approaches, which can be applied to estimate the final water activity of a food mixture in a sealed package. These methods are based on knowledge of the sorption isotherms and their use to predict the equilibrium water activity. A simple approach is to establish a sorption isotherm for the mixture and predict water activity using the total water content of the ingredients. Another approach assumes that the sorption isotherms of the components over the applied water activity range follow a straight line. This leads to eqn (16), which can be used to predict the equilibrium water activity, a_w. The method is also useful in estimating an appropriate ratio of food components to keep the final, equilibrium water activity at an acceptable level.

$$a_w = \frac{a_{w1}b_1w_w + a_{w2}b_2w_2 \ldots + a_{wi}b_iw_i}{b_1w_1 + b_2w_2 \ldots + b_iw_i}, \qquad (16)$$

where a_{w1}, $a_{w2} \ldots a_{wi}$, b_1, $b_2 \ldots b_i$, and w_1, $w_2 \ldots w_i$ refer to the initial component 1, 2 . . . i water activity, slope of the sorption isotherm, and weight of dry solids, respectively.

The role of water activity as a food stability parameter has been well recognized. Water activities can be measured with commercially available equipment, and sorption isotherms are available for most food components. Furthermore, computer software for water activity calculations and establishment of sorption isotherms has been developed and used widely in the food industry.

Effect on Food Stability

Y H Roos, University College Cork, Cork, Ireland

Introduction

Water activity, together with pH and temperature, is often an important factor in controlling food stability. These three parameters all, but not alone, influence microbial activity, rates of chemical and enzymatic reactions, and changes in food texture. Water activity,

however, has a significant role in controlling texture formation and textural changes in intermediate-moisture foods (IMF) and low-moisture foods. In such foods, removal or sometimes sorption of water results in concentration changes of food solids and thereby has an effect on reaction rates. Enhanced reaction rates resulting from water removal may be desired, as in baking to provide color and flavor, or they may be detrimental as in production of many food powders, such as dairy powders. That makes the time–temperature–water or water activity control in food production and storage extremely important.

In some cases, the maximum food stability at low water contents is achieved at a water activity corresponding to the Brunauer–Emmett–Teller (BET) monolayer water content. Furthermore, water affects the physical state and water plasticization, i.e., softening of water miscible food solids. As a plasticizer, water controls the glass transition of food components, such as carbohydrates and proteins. The glass transition is a well-known property of all inorganic and organic amorphous materials. The glass transition occurs over a temperature range, which is often referred to with the glass transition temperature, T_g. The physico-chemical properties of amorphous materials change considerably over the glass transition, as the transformation includes a change between the liquid-like and solid-like material states. There are also established and possible relationships between the physical state, water plasticization, and rates of diffusion-controlled reactions, such as nonenzymatic browning, enzymatic reactions, and oxidative changes.

In general, water activity provides valuable information of the effects of water content on water availability and the physical state of food solids. Such information can be described using sorption isotherms and state diagrams. They provide *critical* values for water content, water activity, and temperature, which are important in the characterization of food behavior in processing and in establishing criteria for packaging requirements and appropriate storage conditions. These areas and the role of water activity in controlling food stability are discussed in the present article.

Water Activity and Food Stability

Most fresh foods are high-moisture materials, and their shelf-life is reduced by enzymatic changes, the growth of microorganisms, and mechanical damage. High-moisture foods have an a_w of 0.90–0.999, and they often contain more than 50% (w/w) water (Table 1). These foods include fresh meats and seafood, various dairy products, fruits, vegetables, and beverages. Most bacteria, molds, and yeasts are likely to grow in high-moisture foods. However, the types of spoilage microorganisms and the growth of various species are highly dependent on pH, temperature, and water activity.

Table 1 Examples of water activity ranges of various foods

Food systems	*Water activity range*
Fresh meat, fish, vegetables, < 40% (w/w) sucrose, < 7% (w/w) salt	> 0.95
Bread, cooked sausages, medium aged cheese	0.90–0.95
Salami, old cheese, > 65% sucrose, > 15% salt	0.87–0.90
Dried beef, sweet condensed milk, cereals with 15% (w/w) water	< 0.86
Jam, marmalade, old salami, > 26% (w/w) salt	0.80–0.87
Flour, cereals, nuts	0.75–0.80
Caramels, honey, toffee	0.60–0.75
Breakfast cereals, snack foods, food powders	0.20–0.60

IMF have a water activity within the range of 0.60–0.90a_w, and their water contents normally vary between 10 and 50% (w/w) (Table 1). These foods include many traditional low-moisture foods, such as grains, nuts, and dehydrated fruits, but also a number of processed foods or foods designed and manufactured to have a known composition to provide stability. Such foods may have particular applications and requirements for stability, e.g., when used as fillings in bakery products or confectionery. Although microbial spoilage is prevented below 0.60a_w, and many microbes do not grow in IMF, their stability and shelf-life are reduced by deleterious changes, such as structural transformations, enzymatic changes, browning reactions, and oxidation, depending on a_w, pH, and temperature. The rates of such changes are often at least to some extent affected by the physical state of the materials and the extent of water plasticization of water-miscible solids.

Low-moisture foods obviously have the lowest water contents, often below 10% (w/w), and their water activity is lower than 0.6a_w (Table 1). Such foods are not subject to microbial spoilage. Their shelf-life, however, is often limited by chemical and textural changes, particularly browning and other changes in color and flavor as well as oxidation. These foods may be exceptionally hygroscopic and exhibit water sorption from their surroundings. Water sorption is reduced by the use of protective packaging, but sorption occurs during storage as a result of permeation or damage of protective packaging. Many low-moisture foods have a solid appearance, or they have a crispy, solid texture. Water sorption in such foods may lead to stickiness, structural changes, such as loss of crispness and sogginess,

and coincident increases in the rates of browning and enzymatic changes. A number of products contain amorphous components, for example, lactose in dairy powders and sucrose in many bakery products and confectionery. Such amorphous components may crystallize during water sorption, as water activity increases. It is important to notice that low-moisture foods are often glassy materials with T_g values above their normal storage temperature. Water sorption and associated plasticization may decrease the T_g, and the glass transition may occur over the range of the concurrent increase in water activity.

Stability Control

Microbial Stability

Microbial growth requires a minimum a_w, in addition to pH, temperature, and other appropriate conditions that are important for the growth of bacteria, molds, and yeasts. The water activity of high-moisture foods, especially processed foods, can be manipulated to some extent by the addition of salts and sugars or other ingredients, which are known to reduce water activity. Such compositional alterations are highly advantageous in product development and food safety control. For many products, the effects of compositional changes on water activity can be predicted on the basis of composition and confirmed by measuring water activity of the final product. This allows an understanding of storage requirements and estimation of the product shelf-life in various storage conditions. In high-moisture foods, the main role of water activity control is to govern and reduce the risk of the growth of pathogenic and spoilage bacteria. Examples of water activity limits for the growth of selected microorganisms are given in Table 2.

The lowest water activity limit for microbial growth of $0.60a_w$ allows the growth of xerophilic yeasts. Above this limiting water activity, IMFs have an increasing possibility for the growth of various microorganisms with increasing water activity. However, the water activities of IMFs are such that pathogenic bacteria are unable to grow, but there is a possibility for the growth of molds and yeast. The growth of these microorganisms must be controlled by careful adjustment of product water activity, use of protective packaging to avoid contamination, and selection of appropriate humectants, pH control, and use of antimicrobial agents.

Microbial stability is an obvious, and often the most important, criterion in food preservation. The a_w limits for growth of various microorganisms, as shown in Figure 1, are well established and successfully used in food product development and manufacturing as well as control of product safety. Furthermore, in high-moisture foods and several IMF products, water activity is relatively constant and dependent on composition, especially solids content, and the type of water-soluble components.

Table 2 Water activity (a_w) limits for the growth of selected pathogenic and spoilage microorganisms

Microorganism	*Minimum* a_w
Bacteria	
Bacillus cereus	0.930
Bacillus subtilis	0.900
Campylobacter jejuni	0.990
Clostridium botulinum	0.940
Clostridium perfringens	0.945
Escherichia coli	0.935
Halobacterium halobium	0.750
Lactobacillus plantarum	0.940
Listeria monocytogenes	0.920
Salmonella spp.	0.940
Shigella spp.	0.960
Staphylococcus aureus	0.860
Vibrio parahaemolyticus	0.936
Yersinia enterocolitica	0.960
Molds	
Aspergillus candidus	0.750
Aspergillus flavus	0.780
Aspergillus niger	0.770
Erotum echinulatum	0.620
Penicillium citrinum	0.800
Penicillium expansum	0.830
Penicillium patulum	0.810
Rhizopus nigricans	0.930
Xeromyces bisporus	0.610
Yeasts	
Saccharomyces bailii	0.800
Saccharomyces cerevisiae	0.900
Saccharomyces rouxii	0.620

Chemical and Enzymatic Stability

The chemical stability of high-moisture foods is not significantly affected by water activity, as the microbial quality is the main determinant of product shelf-life. The role of water activity in determining the chemical and enzymatic stability of IMF and low moisture foods is more important. As the water activity and water content decrease, the concentration of reactants in the water phase of foods becomes obviously increased. Therefore, rates of several reactions may increase with decreasing water activity. The relative rate of deteriorative changes in intermediate and low moisture foods is traditionally related to water content and a_w, as shown by the 'Food stability map' in Figure 2. Early studies applying nuclear magnetic resonance spectroscopy found 'mobilization points' (water activity allowing reactant mobility) for solutes in low-moisture food matrices. The mobilization

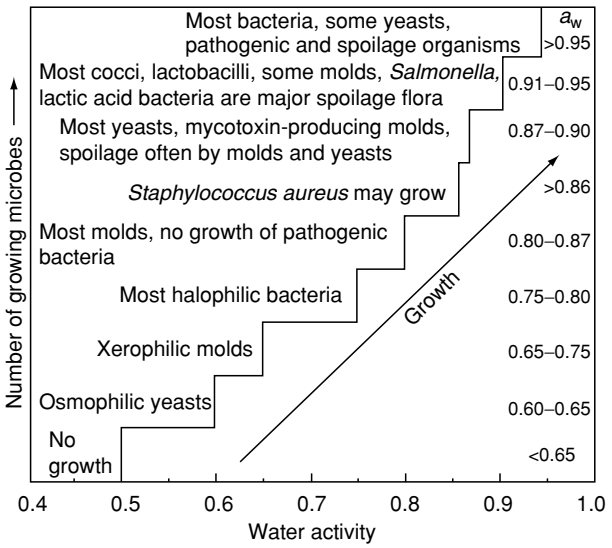

Figure 1 Growth of various microorganisms at different water activity conditions.

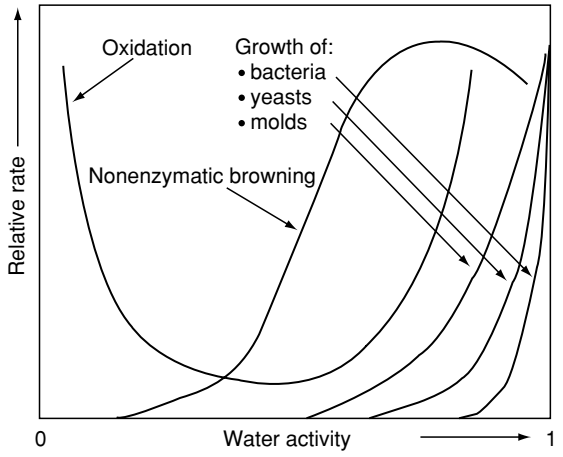

Figure 2 Food stability map describing the relationship between water activity and food stability.

point was peculiar to the system, and the level of hydration needed to achieve mobility was solute-dependent. No solute mobilization occurred below the BET monolayer value, and, for example, experimental data of nonenzymatic browning reaction rates suggested that browning initiated at the mobilization point. An increase in the reaction rate was apparent with increasing a_w, and the rate maximum occurred at the water activity corresponding to a hydration level allowing complete mobilization. However, several other factors, including the glass transition, are important in controlling changes occurring in intermediate and low moisture foods.

Enzyme activity in low-moisture foods is often related to hydration. At low water activities enzymatic activity is generally not observed, as water cannot enhance diffusion of substrates to enzyme molecules. Such water activity dependence applies to hydrolases and oxidases, unless the substrates are nonaqueous liquids, allowing changes to occur fairly independently of water activity. It seems that not only water activity but also the ability of water to give a known mobility to enzymes and substrates is important in controlling enzyme activity. The amount of water needed increases with increasing molecular size owing to impaired diffusion, in particular for enzymes, which are active in the water phase of foods. Therefore, for example, lipase activity is not necessarily related to the mobility provided by water.

Lipids exist often in a separate phase apart from the water phase. At low water activities and water contents, lipids become more accessible to the atmospheric oxygen, and oxidation rates may increase (Figure 2). The rate of oxidation, however, decreases rapidly with increasing water activity, as the lipids may become protected from atmospheric oxygen owing to the formation of protective aqueous layers in the food microstructure. In several low-moisture foods, lipids, flavors, and other oxygen sensitive compounds are entrapped within the amorphous structure. Such encapsulated compounds also exhibit reduced rates of oxidation as compared with 'free' lipids.

Traditional shelf-life predictions of low-moisture foods were based on the information of rates of deteriorative changes and loss of nutrients at various temperatures and water contents. An increase in water content above the BET monolayer value at a constant storage temperature often results in rapid deterioration as reaction rates increase at intermediate water contents. The main factors affecting reaction rates in low-moisture food materials, however, can be controlled by a number of factors, which include food composition and the type of the reaction, temperature, pressure, water content, and pH. In concentrated food systems, changes in viscosity and relaxation times in the vicinity of the glass transition may also affect diffusion and thereby contribute to reaction rates and product shelf-life.

Water Plasticization

Intermediate and low moisture foods often exist in an amorphous (noncrystalline, no defined structure of molecular arrangement), elastic, 'rubbery,' or 'leathery' state or in a solid-like, glassy state. The amorphous state is typical of liquids and remains in

many biological materials owing to complicated chemical composition, rapid removal of solvent water, or quench cooling of a liquid melt in processes not allowing component crystallization. For example, many sugars typical of foods do not crystallize in dehydration, but remain in a supercooled, liquid state after removal of the solvent water. Glassy, solid-like foods may suffer the glass transition as a result of water sorption, which may be observed from rapid changes in structure and appearance, and enhanced rates of chemical and enzymatic reactions.

The glass transitions of food components have a wide range of temperatures depending on the component itself and also on its molecular weight. In general, high-molecular-weight food components, such as carbohydrate polymers and proteins, have glass transition temperatures at very high temperatures well above 100 °C. Low-molecular-weight components may have very low glass transition temperatures, for example, the glass transition of amorphous water occurs at around −135 °C, whereas many anhydrous sugars have a T_g between 0 and 100 °C. The T_g is often measured using differential scanning calorimetry, and it can be observed with a number of other thermal and spectroscopic techniques. These include dielectric analysis, dynamic mechanical analysis, electron spin resonance spectroscopy, infra-red and Raman spectroscopy, and nuclear magnetic resonance spectroscopy. Examples of glass transition temperatures of food components are given in Table 3.

Table 3 Examples of melting and glass transition temperatures of food components

Food component	*Melting temperature of crystalline solids (DSC onset,° C)*	*Glass transition temperature (DSC onset,° C)*
Carbohydrates		
Fructose	108	5
Galactose	163	30
Glucose	143	31
Lactose	223	101
Maltose	160	87

[a]Estimated values.

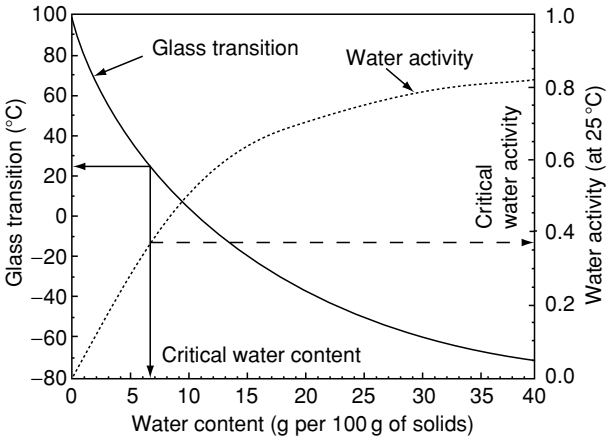

Figure 3 Relationships between glass transition temperature, water activity, and water content for amorphous lactose with critical values for water content and water activity at room temperature.

Carbohydrates and proteins in foods are water-miscible components, and they are plasticized by water. Water plasticization of the amorphous structure results in a decrease in T_g. The decrease in T_g is substantial even at low water contents, and at high water contents, the T_g approaches that of amorphous water. Therefore, at a constant temperature, e.g., room temperature or a typical storage temperature of intermediate- and low-moisture foods, a water activity or water content range can be established, which corresponds to the glass transition of the material. The relationships between glass transition, water activity, and water content are described in Figure 3. The water activity and water content, which correspond to the T_g depression to the storage temperature can be defined as 'critical water activity' and 'critical water content,' respectively.

$$T_g = \frac{w_1 T_{g1} + k w_2 T_{g2}}{w_1 + k w_2}, \qquad (1)$$

where w_1 and w_2 and T_{g1} and T_{g2} are the weight fraction and glass transition temperature of solids (1) and water (2), respectively.

The relationship between the glass transition temperature depression and water content is often predicted with the Gordon–Taylor relationship (eqn (1)). The model can be fitted to experimental T_g and water content data and used together with water sorption data to establish relationships between the T_g and water sorption properties, as shown for amorphous lactose in Figure 3. Such predictions are useful in food product development, because they allow estimation of food stability in terms of the physical state and water activity.

Water Activity and Material Properties

Several properties, such as dielectric properties, mechanical properties, and viscosity, of amorphous food materials are greatly affected by the glass transition. These changes are related to relaxation times and molecular mobility, which may substantially change and affect food stability over the glass transition. Such changes may contribute to observed changes in textural characteristics, e.g., loss of crispness and sogginess, and reaction rates, e.g., nonenzymatic browning and oxidation. Furthermore, the solid, glassy state supports the amorphous state of food components, but many crystallizing components, e.g., sugars, may crystallize in the supercooled liquid state. Both textural changes and crystallization of amorphous components contribute to a loss of flavor and aroma compounds as well as release and oxidation of encapsulated lipids in numerous dehydrated foods and food powders.

In general, the relaxation times of molecular rearrangements in the glassy state are sufficient to provide stability for low-moisture food systems. The changes occurring over the glass transition and in the supercooled liquid state reduce the relaxation times, and the materials lose their long-term stability. For example, amorphous, glassy lactose in food systems is stable, but an increase in water content resulting in glass transition leads to a rapid decrease in viscosity and flow of the material (transformation from solid state to a syrup) accompanied by a loss of structure (stickiness and collapse) and lactose crystallization. Crystallization of amorphous sugars is often observed from water sorption isotherms. When crystallization occurs, sorbed water is not maintained in the crystals, and a decrease in water content is recorded. Such crystallization is time-dependent and detrimental to the quality of amorphous powders.

Stiffness

A single model based on the Fermi's distribution model, as given in eqn (2), allows modelling of the decrease in relaxation times of mechanical properties (stiffness) in the vicinity of the glass transition. According to the model, *stiffness* can be expressed in terms of a defined and measurable stiffness parameter, Y, which may refer to viscosity, flow, sensory crispness, etc. The stiffness parameter values can be modelled as a function of a_w, T, or m relative to its value at a reference state, Y_s. A constant, a_X, defines the broadness of the transition, e.g., the water activity range over which changes in stiffness occur. The reference value, X_s, obtained from $b = -X_s/a_X$, indicates the value for a_w, T, or m that decreases Y to 50% below Y_s.

$$\ln\left(\frac{Y_s}{Y} - 1\right) = b + \frac{1}{a_X}X, \qquad (2)$$

where Y is the stiffness parameter, Y_s is the stiffness parameter at a reference state, X is a_w, T, or water content, m, and b and a_X are constants.

The term *collapse* relates to stiffness and covers various time-dependent structural transformations that may occur in amorphous food and other biological materials at temperatures above the T_g. These changes reflect the effect of changes in relaxation times of mechanical properties on the rates of structural transformations and flow that occur over and above the glass transition temperature range. The rates of these changes increase rapidly above the critical water content or a_w during food storage. Stickiness and caking of food powders and collapse of structure are collapse phenomena that are related to water activity and glass transition. The main cause of stickiness is plasticization of particle surfaces by water, which allows interparticle binding and formation of clusters. Collapse of the structure occurs when the decrease in viscosity results in flow, and the material cannot support its own weight. Structural collapse often leads to a reduction in quality of dehydrated, especially freeze-dried, foods, whereas stickiness and caking are detrimental to the quality of spray-dried foods, such as dairy powders.

Crystallization of Food Components

Crystallization of amorphous sugars is known to result in serious quality losses in food powders. For example, crystallization of amorphous lactose in dehydrated milk products has been observed to result in acceleration of the nonenzymatic browning reaction as well as other deteriorative changes and caking. Crystallization of lactose coincides with an increase in free fat, which presumably facilitates lipid oxidation in milk powders. Crystallization in low-moisture carbohydrate matrices, which contain encapsulated volatiles or lipids, results in a complete loss of flavor and release of lipids from the matrix. Water plasticization and depression of T_g to below the ambient temperature are responsible for crystallization of amorphous sugars in foods as a result of increased free volume and molecular mobility, decreased viscosity, and enhanced diffusion. Crystallization seems to initiate at T_g or corresponding a_w and proceed with a rate determined by the temperature difference $T - T_g$ to a maximum extent also defined by the $T - T_g$. The kinetics of crystallization of sugars and other amorphous food components at a constant temperature above T_g can be related to water content and a_w, which define the rate controlling $T - T_g$.

Water Plasticization and Reaction Rates

It has been well established that water as a plasticizer has a significant effect on molecular mobility and probably rates of quality changes above a critical, temperature-dependent a_w or water content. A chemical reaction requires sufficient mobility of reactants and reaction products in addition to the driving force, e.g., temperature or concentration, of the reaction or change in quality. Information on factors affecting rates of various kinetic processes can be used to manipulate and control rates of changes occurring in food processing and to develop food products that are less sensitive to detrimental changes during storage.

Nonenzymatic Browning

The nonenzymatic browning reaction is one of the most studied deteriorative reactions affected by water activity. Other reactions include destruction of vitamins, enzymatic changes, and oxidation. The rates of most reactions are affected by water activity and glass transition. However, there are no single determinants of rates of chemical reactions and food stability, although an understanding of both the water activity and glass transition of a food material is important in predicting and controlling food stability.

Nonenzymatic browning is often considered as a series of condensations that can be assumed bimolecular. The reaction occurs between a reducing sugar and an amino acid or amino group and produces typical flavors of several foods in processing. When uncontrolled, the reaction produces unpleasant flavors and colors, and decreases dehydrated food quality during storage. The nonenzymatic browning reaction in several foods exhibits increasing rates above the critical a_w values or water contents corresponding to the glass transition. However, reactions in amorphous foods are complex and may be controlled by several other factors, including concentration changes, pH, and temperature. Established relationships between T_g and the rate of the nonenzymatic browning reaction have, however, suggested that the reaction may become diffusion-controlled, and the rate may be affected by the T_g. The size of the reactants may also be important in diffusion-controlled reactions. It may be assumed that the rate of diffusion decreases with increasing size of the diffusant.

The effect of glass transition on the reaction rate has been related to observed discontinuities in Arrhenius plots suggesting a high activation energy in the vicinity of the transition. Studies of effects of glass transition on reaction kinetics and the nonenzymatic browning reaction in particular are complicated, because of several factors affecting plasticization and reaction rates. Several studies, however, have suggested that the reaction rate increases considerably above the glass transition or the critical water activity.

Oxidation

Oxidation is a common reaction in low-moisture foods. Oxidation of lipids directly exposed to atmospheric oxygen at food surfaces or surfaces of porous dehydrated materials may occur freely. It is well known that 'free fat' in dairy powders, for example, is highly susceptible to oxidation causing quality defects. The stability of dairy powders is related to the glassy state of lactose, and the lipids are at least partially encapsulated within the lactose–protein matrix in the spray-drying process.

Enzymatic Changes

Studies of glass transition effects on enzymatic changes have included, for example, sucrose inverson by invertase. Sucrose inversion by invertase in low-moisture systems is dependent on water activity. The reaction rate increases at water activities above 0.6, but does not seem to be affected by the glass transition of the main food matrix. It is possible that the enzyme mobility is not sufficient to allow the reaction to occur until the reacting molecules are plasticized by water to an appropriate extent above $0.6a_w$.

Modern Stability Maps

Deteriorative changes affected by water activity include such changes as enzymatic changes, nonenzymatic browning, lipid oxidation, microbial growth, and overall stability. The rate of these changes seems to be related to water activity. However, water activity limits for chemical, enzymatic, and mechanical changes are material-specific, similarly as the 'mobilization points,' and they may also be related to the physical state, molecular mobility, water plasticization and glass transition of amorphous food solids. Structural transformations, as well as diffusion-controlled deteriorative reactions and changes affected by crystallization phenomena, occur at increasing rates with increasing water activity above the critical a_w of the material. It is likely that water contents lower than the critical water content are needed for maximum stability. Therefore, modern stability maps provide information on both the water activity and material physical state on the relative rates of deteriorative changes (**Figure 4**). In addition, state diagrams and sorption isotherms are useful as stability maps. Knowledge of material properties is extremely useful in the production of encapsulated flavors, extruded products, confectionery, development of new food products, and avoiding quality

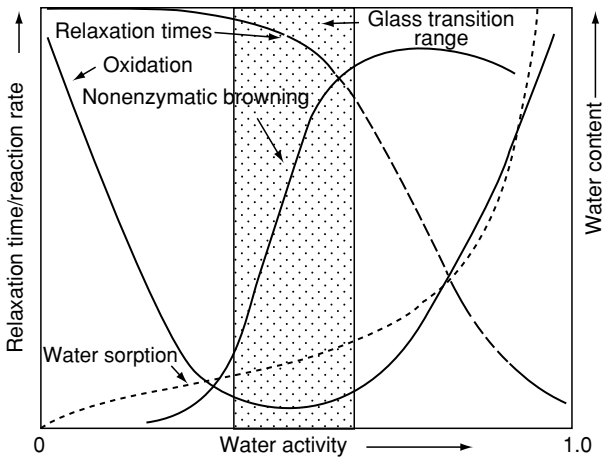

Figure 4 Food stability map taking into account water activity and physical state effects on relaxation times and reaction rates.

changes that may result from mechanical changes, e.g., loss of crispness. The temperature-, water content-, and time-dependent changes that are often problems in manufacturing and storage of food powders and other low-moisture foods can be reduced by avoiding exceeding their critical values of water activity based on the T_g determination or by compositional adjustments that provide sufficiently high values for critical a_w and T_g. The most important applications of producing high-quality dehydrated foods include reduced collapse and improved flavor retention in dehydration processes. The kinetics of enzyme activity is important to food quality, and applying the knowledge in food industry may allow the design of improved products with extended shelf-lives or even improved retention of activity, e.g., in enzyme preparations. Water activity has been successfully used in setting limits for microbial stability in foods and qualitative characterization of relative rates of deteriorative reactions in low-moisture foods. The combined use of a_w and glass transition has a high practical applicability as it provides criteria for critical a_w and, together with sorption isotherm, can be applied to adjust water content at a constant temperature to achieve the maximum food stability.

WATER PLANTS

T M Koyama, Ninon University, Fujisawa City, Japan

Lotus (*Nelumbo nucifera* Gaertner) (Nymphaeacea: Waterlily Family)

Lotus is a well-known water plant in Asia, and is widespread from Iran and the Caspian Sea eastwards to China and Japan, and southeastwards to India and Indo-China, then to northern Australia. In India, Thailand, China, and Japan, it is the sacred flower of Buddhism, and is the national flower of Thailand.

It is a large, emergent herb, growing in marshes and shallow ponds with rhizomes creeping in mud and sending out leaves and flowers over the water. The slender rhizomes spread extensively, branching and rooting at nodes, which bear a single leaf and a flower at the axil of some leaves; the round leaf blades are deeply glaucous-green, 70 cm or more across, slightly bowl-shaped and have some 20 nerves radially arranged. They are peltate on a petiole up to 2 m in length, usually sparsely bearing brownish spines. The large flowers are 10–20 cm across, appear in summer in temperate regions, are subtended by four large bracts, and terminate in a scape (about 2 m long) which is sparsely spiny. The petals are many, originally deep pink but sometimes white. In the center of the flowers, there are many yellow stamens and an obconical receptacle with many holes, each containing an ovary. The receptacle develops into a large, obconical, spongy structure, flat on top, and maturing some 20–30 nuts. The nuts are ellipsoidal or obovoidal, deep brown in color with hard shells, and about 2 cm long.

The history of the lotus can be traced back to the diluvian epoch, the formation of which, in central Japan, contains the fossil rhizomes and fruits of lotus. Records show that it was grown in ancient Egypt and that a white-flowered variety was grown in India as early as 500 BC. It reached Japan during the seventh century, at which time it was used mostly as an ornamental. Now, in Japan, there are over 100 cultivars of lotus, including some 10 varieties as food crops, showing varying colors (white, pink-tinged, pink-striped, pink-variegated, yellow, orange–yellow, etc.) and shapes (double-flowered and polycephalous) of flower in the ornamental forms. In Japan, it was also hybridized with the North American yellow-flowered lotus, *N. lutea* Persoon, to produce another ornamental lotus.

The edible parts of the lotus are principally its rhizomes and seeds, though in China, immature receptacles are occasionally eaten boiled or fried as a delicacy, and whole plants are used as a Chinese medicine against high blood pressure.

In China and Japan, lotus cultivated in paddies begins producing tuberous apices of rhizomes in late autumn and early winter. These fat, tuberous apices of rhizomes are much thicker than the leaf-bearing parts of the rhizome, with one to three internodes up to 30 cm long by 10 cm wide, bearing some 10 pipes as air spaces; these are called the 'lotus roots' and are widely marketed. Recently, water-boiled lotus roots have been exported from China as a canned vegetable. In Japan, lotus roots are eaten boiled and seasoned with soy sauce and sugar, or fried as tempura (Japanese fritters), or sometimes pickled, while in China, occasionally, a kind of arrowroot starch is produced, which is used with spice and pork or with pork spareribs for making a popular soup.

After removal of the dark brown, hard shell, the obovoidal-to-round seed is covered with thin brown testa and is 13–17 mm long. To prepare the edible parts, which are the thick cotyledons, rich in raffinose, the testa and hypocotyle, which is bitter, must be removed. Slightly immature seeds have a very sweet taste and can be eaten raw. The cotyledons of mature seeds are hard and must be boiled prior to eating. Water-boiled lotus seeds are canned and exported. They are also candied (i.e., preserved in sugar) and eaten as a dessert sweet.

The yellow-flowered lotus, *N. lutea* Persoon, from the eastern USA, is the American counterpart species of lotus. Its rhizomes are not as thick as those of the Asian lotus, but it has been eaten by American Indians in the past. *Euryale ferox* Roxb., of the same family is an annual water plant occurring in India, China, and southern Japan. It has large, orbicular leaf blades, 30–100 cm across, floating on the water surface, and smaller flowers of some 4 cm in diameter. A rather sweet starch extracted from the seeds is used for making a kind of rice-cake in Japan. In Central China, the caudices and leaf petioles (with the skin removed) of this species are sometimes used as vegetables.

Water Chestnut, also called Water Caltrops or Trapa Nut (*Trapa natans* L.) (Onagraceae: Willow Herb Family)

Water chestnut is an aquatic annual herb that grows in ponds or marshes with its roots in the muddy soil at

the bottom of the water and with its upper leaves floating on the water surface. Its slender stems are of varying length, depending upon the depth of the water, and bear feathery submerged leaves at the nodes. The leaves of a normal kind, with a rhombic blade shallowly serrate on the upper margins, are gathered in a rosette at the tip of the stem; they are deep green and shiny on the upper surface, slightly hairy and often colored with purplish brown beneath. The leaf petioles are swollen at the midway, enclosing spongy aerial tissue, which helps the blade to float on the water surface. Flowers are borne at the leaf axils of floating leaves, and are pedicelled. They have a four-part calyx, four white petals, four stamens and a pistil. Fruits are nut-like, 4–5 cm wide and purple–brown with two 1-cm-long, horn-like spines, one on each side.

The nuts are the edible part of water chestnut, and are eaten boiled, or occasionally roasted; alternatively, the dried nuts are ground into a starchy flour to prepare a kind of gruel or for fermentation into a local liqueur. Young nuts are sometimes eaten raw, with the greenish skin removed. In China, the fruits are listed as a Chinese medicinal plant, to be used as an antipyretic and as an astringent.

The use of the water chestnut as a food can be traced back to Neolithic times, and the fruits are found abundantly in Tertiary sediments. People of Central Europe and Asia eat the typical water chestnut, collecting the fruits from wild plants, but in central and southern China and in India, the variety *T. bispinosa* (Roxb.) Kakino is cultivated in paddy fields. Related species, which are occasionally cultivated in China and Korea, are *T. bicornis* Osbeck and *T. quadrispinosa* Roxb. While the former species bears larger fruits of 7–8 cm in width, the latter bears four-horned fruits. In northeast China, there occurs another wild species, *T. maximowiczii* Korsh., of which the smaller nuts (*c.* 1–1.5 cm in width) are also eaten locally, and sometimes used for fermentation into a local spirit.

Chinese Water Chestnut (*Eleocharis dulcis* Trinius cv. *tuberosa* (Roxb.) T. Koyama) (Cyperaceae: Sedge Family)

The Chinese water chestnut, also known by the Chinese names '*Ma-ti*' or '*Pitzi*', is a stem vegetable crop derived form its wild stock, *E. dulcis* Trinius, which is sporadically, but widely, distributed from Madagascar through the Indian subcontinent and southern China to northern Australia and the Pacific Islands, and also to southern Japan. It is rather widely cultivated in both mainland China and Taiwan, and some parts of Thailand, not only for local consumption but also as a source of preserved (canned) vegetables for export.

Grown in paddy fields, often as a substitute crop of rice (where rice is overproduced), plants of the Chinese water chestnuts form a tuft of many slenderly tubular stems, which are 60–90 cm high, deeply green, hollow inside and transversely septate. Leaves of a 'normal' kind disappear, being reduced to pale or purple–brown sheaths surrounding the base of the stems. Small flowers are borne in cylindrical spikes at the apices of some stems; the spikes bearing yellow–brown scales imbricatedly. The base of the plants send out slender, elongated, underground runners that form a tuber at the apex. Tubers are depressed-globose, 2–5 cm in diameter and 1.5–3 cm high, and are clothed with thin, purple–brown to black–brown scales. Being a high polyploid with approximately 150 chromosomes, the cultivated Chinese water chestnut does not produce seeds and must be propagated by tubers.

The edible part of the Chinese water chestnut is the tuber (see Table 1). It is a considerably popular 'root' vegetable (strictly speaking, a stem vegetable) among the Chinese, and is also used in Thailand, the Philippines and Indonesia, but not in the traditional Japanese kitchen. There, they eat the tubers boiled and seasoned in various vegetable dishes, and extract fine-quality starch grains. In addition, minutely chopped tubers are mixed with ground meat when making Chinese meatballs. The tubers, rich in starch, are crispy and slightly sweet, making a good ingredient in vegetable salads; hence the water-boiled tubers are exported to various parts of the world as a canned vegetable.

Table 1 Chemical components of Chinese water chestnut tubers (with skins removed)

	America data[a]	*Chinese data*[b]
Major components (%)		
Water	78.3	86.0
Protein	1.4	1.2
Fat	0.2	0.1

In 1947, importation of canned Chinese water chestnut into the USA reached 1154 tonnes per year. The yield of this variety in China is 18–37 tonnes per hectare. The wild stock of Chinese water chestnut differs from the cultivated in having much smaller tubers (only as large as 10 mm across) and due to the fertile nature (seed-bearing) of the flowers. Rumphius in 1750 had noted that the natives of Java were eating the tubers of this wild Chinese water chestnut, which were seen in morning markets between August and December. The cultivated Chinese water chestnut, apparently developed from the wild stock in northern Vietnam or adjoining southern China, has two obvious forms: the red-skin type (comparatively large, soft tubers with reddish–purplish skin), and the black-skin type (comparatively small tubers with a harder flesh and covered with black–brown skin). The former is for vegetable use, whereas the latter is used for extracting high-quality starch grains called the Ma-ti powder; the latter is principally used both for cooking and as a stomach powder in Chinese medicine.

Arrowhead (*Sagittaria trifolia* L. cv. *sinensis* (Makino) T. Koyama) (Alismataceae: Arrowhead Family)

A marsh plant of Chinese origin, arrowhead is cultivated in the paddy fields of temperate China and Japan for the tubers. The cultivated arrowhead, cv. *sinensis*, is much larger than its wild counterpart, with its leaves attaining a height of 100 cm. Several leaves grow from a short rhizome; they have a long petiole, emergent from the water. The leaf blades are sagittate (arrow-shaped) with two rather broad and elongated basal lobes, and are 10–15 cm long. Cultivated arrowhead seldom bears flowers. The scape, if produced, is normally lower than the leaves, and bears three branches at several nodes. Flowers are monoecious and unisexual, and the staminate flowers are borne on the upper part of the raceme, the pistillate ones on the basal part of the raceme. Flowers are about 2.5 cm across, and have three green sepals and three white, roundish petals. Staminate flowers have many yellow stamens. Pistillate flowers have a pistil of many carpels, each maturing into an achene.

The short rhizome sends out several slender underground runners, and each develops a tuber at its tip from late summer to autumn. Tubers are globular to somewhat depressed-globular, 3–5 cm across, and their white or bluish surfaces are zonate, bearing deciduous, membranous scales. In winter, the tubers bear a beak-like terminal bud at the apex.

The edible parts of the arrowhead are the tubers, which are considerably rich in starch (24.8%); the other components are water (68.2%), protein (4.4%), fat and oil (0.23%), fiber (0.4%), and inorganic salts (1.37%). Arrowhead tubers are eaten boiled and seasoned in both Chinese and Japanese cooking.

Water Shield (*Brasenia schreberi* Gmelin) (Nymphaeceae: Water Lily Family)

This is a cosmopolitan water plant occurring in Asia, North America, Australia, and Africa, but is eaten only in Japan. The slender rhizome is located in the mud of ponds or lakes, and stretches out its stems into the water. The leaves are alternately arranged on the stems, with the blades floating on the water surface. The blades are broadly elliptic, 5–10 cm long, 'freshly' green and shiny above, and tinged with purple beneath. Their petioles are peltately attached to the center of the blade. Flowers appear during the summer. They are about 2.5 cm across and are a purplish brown color with six petals, some 16 stamens and six to 18 carpels. Sac-like fruits are indehiscent, and usually mature in the water.

The stems, petioles, and lower surface of the leaf blades are covered with a semitranslucent, agar-like substance that is secreted from glands on the plant surfaces. The young shoot apices, in particular, are copiously covered with this gelatinous substance, and this portion is eaten as a delicacy, but rather commonly, in Japan. They are used in Japanese-style clear soup, salads, etc., or they are stored in vinegar and/or in salt. Recently, water-boiled shoots of this plant have been preserved in bottles and cans, and widely sold.

Water Treatment

J Manning, Wessex Water, Bath, UK

Introduction – Why Treat the Water?

The aim of all water providers throughout the world must be to collect, treat, and distribute a safe supply of drinking water to their consumers that complies with all legislative requirements in a cost-effective way. The natural water cycle provides the raw material but treatment processes are needed to remove chemical and bacteriological contaminants that would otherwise be damaging to health or affect the esthetic appearance of the product at the customer's tap. Technical advances in treatment processes and an understanding of the effects of raw-water contamination on consumers' health will continue to make cost-effective solutions to treatment more accessible. This should mean that compliance with legislation becomes an easier task, but is also likely to mean that quality standards will continue to become more stringent in the UK and Europe.

Water Sources

As the aim is to provide safe clean water, it makes sense to take the raw material from the point in the water cycle where water is least contaminated, in sufficient quantity and well placed geographically, for the supply to reach the customers. Sources can be derived from deep aquifers using boreholes, shallow groundwater such as springs, surface water collected in reservoirs from lowland areas, or less polluted upland areas, or direct abstractions from rivers. Contaminants can come from agricultural sources, surface water drainage or runoff, and sewage treatment. Industrial pollution can also affect water supplies. Harmful bacteria and viruses will be found if there is fecal contamination of the source.

Generally, raw groundwater from boreholes is of good quality as the ground above the aquifer provides a filtration medium to remove particles such as bacteria. However, the time for water to travel through strata can be sufficiently long to dissolve other soluble contaminants such as naturally occurring calcium and magnesium (hardness) but also pesticides and nitrate from agricultural activities. Wherever water is stored for a long period of time, be it as naturally occurring aquifer or an artificial impounding reservoir, reduced oxygen concentrations will dissolve iron and manganese and produce hydrogen sulfide (characterized by a rotten-egg smell). This will result in a dirty and foul-smelling water source, although this can still be successfully treated. The long travel time from surface to aquifer, with naturally occurring treatment on the way, means that groundwater sources are very consistent in their quality and hence desirable for ease of treatment. A large proportion of the UK's water supplies is abstracted from boreholes in both chalk and greensand aquifers.

Springs collect water from the ground into horizontally laid pipework, and as this is very much closer to the ground surface than a borehole, they are more at risk from variable quality and surface water intrusion.

Reservoir, lake, and river water sources, by their nature, are generally contaminated with fecal material, colored yellow or brown by the organic debris of rotting vegetation and turbid from mud and silt, and algae which will grow in suspension. The quality of a surface water source can vary within hours, depending on weather conditions. This is especially true in river intakes and seasonal changes must be expected in reservoirs and lakes. Wet winter conditions will cause runoff of agricultural contaminants such as pesticides and nutrients that can cause excessive algal growth (eutrophication). This can be controlled to some extent by mixing of the reservoir using compressed air lines or wind-powered mixing.

Storage reservoirs provide protection against shortages of rainfall but also blending of source waters to a more consistent quality suitable for treatment. A storage or retention time in excess of 7 days can provide some settlement and a significant reduction in bacterial numbers.

With improvements in technology, we are now seeing a greater variety of source waters becoming available for treatment. For example, reverse osmosis is widely used for desalination of sea water where other sources of fresh water are not available. Many manufacturing industries will use complex treatment processes to recover or reuse effluent produced in manufacturing processes.

Treatment Processes

A summary of some commonly used treatment processes is shown in Table 1. The treatment objectives of a water treatment plant will be site-specific and depend on the raw water quality, and the quantity and standard of the treated water quality that it is required to produce. The main objective will always be to provide water that is microbiologically safe for the consumers to drink. This is achieved using appropriate disinfection processes either to kill or remove bacteria, viruses, and cysts. The control of the disinfection process is therefore considered critical.

Disinfection

Chlorination is the most commonly used disinfection process in the UK. Chlorine is effective because it is toxic, highly oxidizing, soluble in water, and its germicidal effectiveness lasts for days. It is also widely available and therefore cost-effective.

Chlorine will react in water to form hypochlorous acid, which can then dissociate into hydrogen and hypochlorite ions, according to Eqn (1).

$$Cl_2 + H_2O = HOCl + H^+ + OCI^- \qquad (1)$$

This reaction is very important, as the disinfecting power of HOCl, hypochlorous acid, is about 40–80

Table 1 Summary of treatment processes

Example	*Uses*
Disinfection	
Chlorination, ozonation, chlorine dioxide, ultraviolet irradiation	Oxidants used to kill bacteria and viruses
Coagulation	
Aluminum sulfate, ferric chloride, or polyaluminium chloride	Combines small, suspended, and colloidal particles into larger, flocculated particles by chemical attraction. Algae, iron, manganese, color, and turbidity can be entrained in floc particles which are then removed by solid/liquid separation processes
Solid/liquid separation	
Microstraining	Large (20–100 μm) particles such as algae and leaves removed by straining
Dissolved air flotation	Removal of coagulant sludges by floating on a curtain of small air bubbles
Sedimentation	Removal of coagulant sludges by settlement. Suited to sludge with high inorganic content
Slow sand filtration	Removal of colloidal, organic, and suspended material by straining and biological activity on the surface of sand filter beds
Rapid gravity filtration	Removal of suspended material by straining and entrapment within the depth of sand filter beds
Membrane micro- and ultrafiltration (size exclusion)	Removal of submicron-sized particles using membranes manufactured from polymeric material
Membrane nanofiltration and reverse osmosis (diffusion control)	Removal of submicron particles and dissolved inorganic species of high molecular weight
Membrane ion exchange or electrodialysis (charge-controlled)	Removal of salts, i.e., desalination of sea water or nitrate removal
Adsorption	
Granular-activated carbon filtration (fixed bed) or powdered activated carbon (requires filtration process)	Adsorption of pesticides and volatile organic compounds, removal of taste and odors
Aeration	
Packed towers or cascades	Removal of H_2S, volatile organic compounds, or carbon dioxide for corrosivity control. Oxidation of iron and manganese
Chemical addition	
Acid and alkali for pH adjustment	Mineral acid and/or sodium hydroxide, sodium carbonate, or lime for optimum coagulation
Phosphoric acid	Provides phosphate coating on lead pipes to control lead concentrations in water
Softening	
Lime addition	Removal of calcium carbonate by precipitation at high pH. Reduces scale formation in downstream structures

times that of OCl^-, hypochlorite. Chlorination is more effective at pH values below 6 as there is a high proportion of HOCl present and very little OCl^-. The quantity of HOCl and OCl^- that is present in the water is known as the free chlorine. The effectiveness of chlorination will depend on factors listed in Table 2.

Chlorine reacts within minutes with a variety of substances, including nitrite and ferrous ions. The demand for chlorine from these reactions must be satisfied before the slower reactions with the bacteria cell walls can take place and hence provide disinfection.

To insure the disinfection process has taken place satisfactorily, continuous monitoring of the residual chlorine concentration will normally be used along with regular analysis for fecal and heterotrophic bacteria.

For surface water, where there may be higher concentrations of organic contaminants or ammonia, superchlorination, followed by dechlorination, may be used. The chlorine concentration is held for some time at a value much higher than that expected to be found at the customer's taps – around 2–5 mg Cl_2 l^{-1}. This will quickly satisfy the chlorine demand of the water, and the concentration is then reduced to an acceptable level by adding sulfur dioxide. Treated water will leave the plant with a residual of around 0.3 mg Cl_2 l^{-1} to control any subsequent regrowth of bacteria in the distribution pipework to the customers.

Surface waters often contain humic and fulvic acids from the decomposition of vegetation. This reacts with chlorine to form trihalomethanes (THMs) such as chloroform, which are suspected carcinogens. The formation of THMs can be controlled by insuring chlorination takes place after removal of the precursor compounds. Concern in forming these byproducts has led to an increase in alternative disinfectants such as ozone, ultraviolet radiation, and chlorine dioxide.

Research over the last decade has increased awareness and concern over organisms that are harmful to health and not affected by normal disinfection techniques. *Cryptosporidium* and *Giardia* are both difficult to identify analytically, resistant to chlorine, and form very small (2–5 μm) oocysts outside the host. Fecal in origin, they are commonly found in rivers, lakes, and surface water sources, but because of their persistence in the environment and very small size they can also be found in groundwater sources. Alternative treatment strategies based on removing the organisms, using barrier treatment, rather than killing them are required. Accepted practice is to use well-controlled coagulation and rapid gravity filtration, preferably with an additional solids removal stage such as DAF (dissolved air flotation) or sedimentation, or using membrane micro- or ultrafiltration.

Coagulation and Flocculation

Suspended, colloidal, and dissolved material is commonly found in surface water, such as fine clay particles, algae, and color from humic substances. These dissolved substances and submicron-sized particles can react with coagulant to form larger, agglomerated solid particles that can more easily be removed by solid–liquid separation processes. The surfaces of very small particles are charged and the repulsive forces between them help to keep them in suspension. The coagulation mechanism is essentially twofold. First, the coagulant forms highly charged hydrolyzed ions in water which destabilize the charge on the surface of the particles. Second, once the charge has been destabilized, attractive forces, which cause the particles to agglomerate, replace repulsive forces and larger particles called floc are formed. This agglomeration is referred to as flocculation. There are many complex chemical and physical reactions taking place during the coagulation/flocculation process, making exact conditions difficult to predict. The factors affecting efficiency are summarized in Table 3.

Predicting coagulation conditions is very difficult and specific to each water source. Conditions can change quickly with changing raw-water quality.

Table 2 Factors affecting the efficiency of chlorination

Parameter	*Effect on chlorination*	*Typical value for good disinfection*
Turbidity	Absorbs chlorine and protects entrapped bacteria	0.4 NTU or less
pH	Alters the proportions of hypochlorous acid and hypochlorite ion present	pH 6–7.5
Contact time	Allows the oxidizing reactions to take place	30–60 min
Chlorine dose rate	High concentrations will increase reaction rates	0.2–2 mg Cl_2 l^{-1}
Organic contaminants	Reacts to form less effective chloroorganic compounds	Less than 5 mg C l^{-1} as total organic carbon
Temperature	Increases the decay rate of free chlorine to chloride	Up to 20 °C
Ammonia	Reacts to form chloramines	Trace

NTU, nephelometer turbidity units.

Table 3 Factors affecting the efficiency of coagulation/flocculation

Parameter	*Effect on coagulation/flocculation*	*Typical value for coagulation/flocculation*
Coagulant type	Ability to form large polymeric hydrolyzed ions	Aluminum sulfate or iron (III) chloride, polyaluminum chloride
pH	Affects charge destabilization reactions; coagulants become soluble at very high and low pH	pH 6.0–7.5, depends on coagulant used
Coagulant dose rate	Insufficient will cause small floc and ineffective removal, excess may cause dissolution of aluminum/ferric or excess solids	1–10 mg l^{-1} (as aluminum or iron) depending on raw-water conditions
Mixing speed	Coagulation requires immediate contact, i.e., rapid mix; flocculation requires slow mixing to allow particles to coalesce without breaking up	Velocity gradients G, 1000 s^{-1} for coagulation, 20–200 s^{-1} for flocculation
Contact time	Sufficient time is needed to allow reactions to take place	Seconds for coagulation, 5–20 min for flocculation
Organic contaminants	Typically, large molecules with charged surfaces and therefore more difficult to remove	High concentrations will require high coagulant doses and lower pH
Alkalinity	Alkalinity (bicarbonate/carbonate) is used in the hydrolysis reaction. Low-alkalinity water will form weak floc	Greater than 30 mg $CaCO_3$ l^{-1} alkalinity
Temperature	Affects reaction rates	5–25 °C

Solid–Liquid Separation

After coagulation, the flocculated particles must be removed. Removal of gross solids can be achieved with sedimentation or dissolved air flotation and residual smaller particles can be removed using rapid gravity or other filtration techniques.

Sedimentation Flocculated particles are denser than water and will settle readily by gravity. Generally, plants are designed to operate continuously as upflow clarifiers. Water enters at the bottom of the tank at a low-enough velocity (1–3 m h^{-1}) for the particles to settle to the bottom, where the sludge can be removed. The tanks combine the flocculation and removal mechanisms in one plant as flocculation occurs when water entering the bottom of the tank has to travel through the sludge 'blanket' settled at the tank base.

Dissolved-air flotation Algae often have low specific gravity and algae-laden waters are therefore suited to dissolved-air flotation because of their tendency to float. A recirculated stream of clarified water (8–10% of the flow) is saturated with dissolved air under pressure using compressed air introduced into packed pressure vessels. This is returned to the inlet of the flotation tank with the flocculated water where, on releasing the pressure, a curtain of very small bubbles forms as the air comes out of solution. These rise to the surface, attaching floc particles on the way, to form a blanket of sludge that floats on the surface. Periodically, the sludge is removed by scraping the surface. Both sedimentation and dissolved-air flotation will remove coagulant sludge to around 0.2–1.0 mg l^{-1} of aluminum or iron. Sand filtration will be required to remove residual coagulant.

Rapid depth filtration Depth filtration is achieved by passing water that contains particles through a bed of filtration media, usually sand, at relatively high velocity or filtration rate. At a filtration rate of 3–10 m h^{-1}, the particles are drawn into the medium rather than remaining on the surface of the bed. This has two advantages; a smaller structure is required because of the high hydraulic capacity and the pressure drop or head loss is reduced by avoiding the build-up of a blinding layer of particles on the surface. Filters can be constructed as either operating under gravity or enclosed and under pressure. A schematic diagram of a rapid gravity filter is shown in Figure 1.

As particles block the filter, head loss will increase until either flow from the filter reduces or a breakthrough of particles is seen in the filter outlet water as turbidity. Before either of these happens, the filter should be washed. The bed is partly drained and air

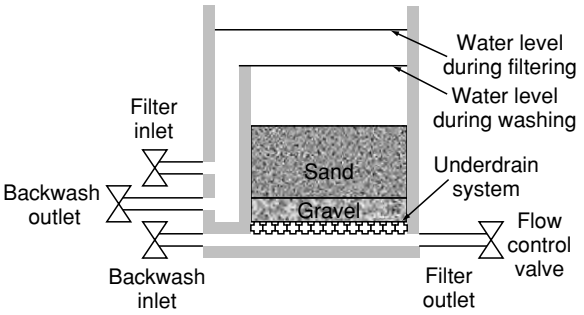

Figure 1 Schematic diagram of a rapid gravity filter.

scoured using compressed air introduced through the underdrain to break up compacted solids. Previously filtered water is then passed upwards, at a velocity of around 20 m h^{-1} for 10 min, to remove entrained solids. Rapid gravity filtration is an important barrier treatment for *Cryptosporidium* and *Giardia*, so close attention is paid to conditions that may cause breakthrough of solids into the filtered water. Improvements in laser techniques to measure particle numbers and size distribution have led to a greater understanding of the correct coagulation conditions, minimization of flow changes through filters, and the ripening phase immediately after a backwash as important factors in controlling the numbers of oocysts in the treated water. The dirty backwash water will contain a higher concentration of oocysts than the raw water and must be disposed of carefully. Often this water is returned to the raw inlet, at a very low dilution rate, following settlement to remove the coagulant sludge.

Slow sand filtration Slow sand filters are used without the addition of coagulant. The lower velocities used mean more particles are retained which in turn encourages biological activity. Within days the layer of organic material on the surface, known as the schmutzdecke, becomes capable of removing color and turbidity and large numbers of bacteria. Principal mechanisms are straining and entrapment but digestion of dissolved organics also takes place by a variety of organisms, such as protozoa, algae, and bacteria living in the schmutzdecke. A comparison of rapid and slow and filtration is shown in Table 4. Slow sand filters are cleaned by removing the surface layer of sand and schmutzdecke.

Membrane filtration Membrane filtration has been in use in the food industry for some decades. Very fine filtration generates a relatively high pressure but produces a very-high-quality product. More recently, improvements in the membrane-manufacturing process and a growing market have made the technology more cost-effective. Increasing public concern over *Cryptosporidium*, a chlorine-resistant, spore-forming organism that can cause severe illness, has resulted in membranes being installed as one of the few effective treatments.

Iron and manganese removal Many groundwater sources can be found that are of good microbiological quality but esthetically unsuitable because of high concentrations of iron and manganese salts resulting in black or brown discolored water. These waters can be successfully treated using filtration techniques. However, the metal salts must be in an insoluble, particulate form to be removed effectively. Soluble metal ions can be converted to particulate forms by oxidation using aeration, chlorination, or ozone. Due to their relative oxidizing power, oxidation can be achieved in minutes with ozone but may take hours with air. Removal of manganese requires a longer reaction time or a stronger oxidant than iron; potassium permanganate or ozone is often used. The oxidation reaction kinetics are dependent on pH and best performed at around pH 8.0.

Organics Removal

The UK and Europe have treatment- and health-related standards for various organic compounds. Contamination can occur from both agricultural and industrial sources. Soluble organic compounds such as herbicides, particularly triazines, chlorophenoxy

Table 4 Comparison of rapid and slow sand filtration

Parameter	*Rapid gravity/pressure*	*Slow sand*
Filter media	Sand, granular-activated carbon or anthracite	Sand
Filtration rate (m h^{-1})	3–10	0.2
Filter run length	24 h	60 days
Cleaning	Air scour and upwash	Surface skim
Mechanism	Physical entrapment in media depth	Physical entrapment on media surface, biological digestion
Pretreatment	Almost always used with coagulation	Microstraining or roughing filtration

acids, and urons, are often found. Industrial solvents, carbon tetrachloride, and trichloroethene (TCE) can also be found to contaminate groundwater. Coagulation and filtration techniques are ineffective but ozonation, granular-activated carbon, and air stripping can be used to remove these contaminants.

Ozone will degrade many pesticides and other organics. Concern for the health effects of the degradation products and the potential for bacterial regrowth mean it is often used with granular-activated carbon to absorb the degraded organics.

Granular-activated carbon (fixed bed) will absorb a number of organic compounds and is commonly used for pesticide removal and for the removal of taste- and odor-causing compounds. It can also be used as a rapid gravity filtration medium, thus combining two processes in one. The carbon has a finite lifetime and, depending on the organic loading and type, will require regeneration. This involves returning the medium to the manufacturer to undergo a high-temperature regeneration process to oxidize the adsorbed organic compounds.

Powdered activated carbon can have similar uses but is dosed into a contact tank or similar structure and is subsequently removed by a downstream separation process such as filtration.

Removing Dissolved Salts

Nitrate Removal

Increasing levels of nitrate in groundwater sources are generating a need for nitrate removal plant in the UK and Europe. Ideally, the problem is best approached by reducing the levels at source, by minimizing the levels of nitrate applied to the land within the water catchment area. There are, in the UK, government-aided grants to identify and assist farmers in controlling the application of nitrate fertilizers.

Where treatment is required, ion exchange and electrodialysis have been used in the past. The principal of ion exchange is to pass the water through a bed of synthetic resin beads, which exchange nitrate ions for chloride. Once the resin is saturated with nitrate, it is regenerated with brine and a waste product containing high concentrations of nitrate and sulfate is produced. Electrodialysis, which is also commonly used for desalination of brackish and sea water, involves applying an electrical current across a membrane that is capable of selectively passing nitrate ions but not water. More recently, with improvements in membrane manufacture, reverse osmosis is becoming a cost-effective solution for nitrate removal.

Softening

Softening is not extensively used in the UK water industry but is used to protect industrial boilers from scaling. Precipitation using lime can be used to precipitate calcium and magnesium. This process produces large quantities of sludge. Alternatives are ion exchange and, more recently, reverse osmosis. Ion exchange resins will replace calcium and magnesium ions for chloride ions and, once saturated, they can be regenerated using brine.

Distribution Systems

Water Quality in Distribution Systems

Water that has been treated at the treatment plant can take days to reach the customer through the underground distribution network of pipes and service reservoirs. To insure that the quality and especially the microbiological safety of the water do not deteriorate on the way, residual disinfectant, pH stabilization, and other corrosivity control processes are used at the treatment works.

A free chlorine residual concentration of around $0.3\,\mathrm{mg\,Cl_2\,l^{-1}}$ will insure bacterial regrowth will not occur for several days. This will however depend on the distance and time of travel, the water temperature, as chlorine will decay more quickly at higher temperatures, the condition and age of the distribution network, and the quality of the water. If the water contains THM precursors, the additional contact time with chlorine in the distribution network can lead to higher concentrations of THMs reaching the customer's tap than found at the treatment works.

Corrosion Control

The chemical balance between carbonates and bicarbonates is especially important in corrosion control. A protective layer of calcium carbonate will form on the inside of distribution pipes if the water is adequately stabilized. This requires the balance of free carbon dioxide, carbonate, and bicarbonate concentrations to be controlled, usually by adjusting the pH to control Eqn (2).

$$CO_2 + CaCO_3 + H_2O = Ca(HCO_3)_2 \qquad (2)$$

Excess carbon dioxide will dissolve calcium carbonate, and cause corrosion to distribution pipework. Carbon dioxide is an acidic gas. If it is removed, for example in an aeration process, it is likely that the pH of the water will rise and calcium carbonate will be precipitated. The corrosivity of water can be estimated using corrosion indices; the most commonly used index is the Langelier saturation

index. The saturation pH is calculated from ionic strength, calcium, alkalinity, and temperature and compared to the measured pH of the water. A positive index indicates the water will precipitate calcium carbonate and a negative index shows that it has corrosive potential. The index can therefore be controlled by adjusting the pH, commonly with lime, as this has the advantage of also adding calcium which reduces the saturation pH. Mineral acid or caustic soda is also used.

Lead plumbing was extensively used in the UK at the turn of the 19th century, but concern over very low levels of lead contamination have prompted the need to replace pipework wherever possible and control lead solubility. This is achieved by dosing phosphoric acid to around 0.2–2.0 mg $P l^{-1}$ as the water enters the distribution network from the treatment works. A protective coating of lead phosphate is formed which reduces the concentration of lead in the water.

Plant Design

In summary, the aim of the design of a water treatment plant will essentially address the following criteria:

1. Establish the difference in quality of the raw source compared to the required treated water quality.
2. Specify process plant, and its operating limitations, capable of producing sufficient quantity and quality to meet customer demand and legislative requirements.
3. Place the plant geographically to insure minimal cost of transport and potential for quality deterioration.
4. Provide a treatment solution at an acceptable capital and operating cost.

Chemical Analysis

P J Walker, Thames Water Utilities Ltd, UK

Introduction

Most of the water supplied for human consumption has to comply with national or international standards with regard to its chemical composition and the concentration of material present. The limits placed on the permitted concentrations of these compounds are not always health-based; some may be set for esthetic reasons or they may be limited by the practicalities of the analytical methods, limit of detection at the time of setting. Chemical analysis of water will provide information about compliance with these standards. It will also assist treatment plant operators to insure that the production processes are working efficiently and that the purity of the water is maintained within the distribution system.

The World Health Organization (WHO) regularly updates and issues drinking-water quality guidelines

with the aim of protecting public health and forming the basis for national water quality criteria. National policy may vary between countries and as a result there are often differences between the limits expressed in the WHO guidelines and those in the national legislation.

In addition to concentration limits, it is becoming more common for national legislation to specify that a quality system must be in place to insure that the results of chemical analysis are valid. Validity in this sense usually means:

- The performance of the analytical method is known and documented for the sample type
- This performance complies with regulatory criteria for limit of detection, systematic, and random error for both analytical standards and samples
- There is documented evidence that there is a system of monitoring instrumental performance and analyst training, and use of formalized methods
- Analytical quality control (AQC) standards are routinely used as additional samples
- There is regular participation in recognized analytical proficiency schemes.

A system where quality control is specified will insure that results from different laboratories can be compared or used in national statistical exercises.

Laboratory standard methods of analysis are published by national agencies e.g., US Environmental Protection Agency (EPA), and the Environment Agency in the UK. They are also produced by the International Standards Organization (ISO), the CEN standards body in Europe, national standards bodies, e.g., BSI and DIN, and also professional bodies such as the American Public Health Association.

Sampling

It is essential that sampling is performed correctly. Failure to sample properly will affect the result and invalidate it. A sample must be representative of the bulk material, it must be taken into the correct container, with an appropriate preservative if required, and the sample container must be clearly and unambiguously labeled.

The sampling procedure is dependent on the analysis required. In most circumstances the sample must be representative of the drinking water delivered to the sample point. To achieve this the water is allowed to flow to waste for a suitable 'flushing period' to clear any nonrepresentative water in the pipes from the supply main to the sampling point. The exception however is when lead analysis is to be carried out. It is essential that the sample collected is representative of the water that has been in prolonged contact with the pipework and any plumbing metals associated with it. In these circumstances no flushing occurs as the sample is drawn directly from the sampling point into the sample container.

The sample container must not affect the sample by adsorption, absorption, or contribution, e.g., leaching or carry-over from previous samples. Glass was the preferred material for sample containers, but the newer plastic materials, e.g., polyethylene teraphthalate (PET), are replacing glass in many circumstances. Metals, inorganics, and some pesticide determinands have all been shown to be stable within plastic bottles. Compared to glass the advantages of plastic bottles are that they are light-weight, more robust, inexpensive, and disposable. Quality control becomes easier in insuring bottle cleanliness as a small representative sample from each delivered batch can be checked before use. As the bottles are used once only and then discarded, there is no problem with carry-over from the previous sample.

Special care has to be taken if the analyte can undergo degradation or reaction between the time of sampling and start of analysis. Most samples are preserved by refrigeration, but dissolved oxygen, sulfide, and polynuclear aromatic hydrocarbons (PAH) all require 'fixing' on-site at the time of sampling. Mercury can be lost prior to analysis and is usually preserved with nitric acid and/or potassium dichromate. Recent work has shown that the addition of gold solution up to $5\,\mathrm{mg\,l^{-1}}$ Au has excellent preservation properties for both glass and plastic (PET) containers. This works well with inductively coupled plasma – mass spectrometry (ICP-MS), but significantly depresses the signal from a cold vapor fluorescence instrument system.

Basic Characterization

By using a suite of simple tests it is possible to characterize water. These tests are pH, electrical conductivity, color, turbidity, alkalinity, and hardness. Additionally, where drinking water has been disinfected with chlorine, the determination of free and combined chlorine is also determined. The organoleptic properties of taste and odor also provide useful monitoring data.

pH

This determinand indicates the acidity or alkalinity of the water. It is measured using a pH meter connected to an electrode combination that is responsive to pH. Calibration utilizes standard pH buffer solutions over the required range. It is usual to supply drinking

water in the range pH 6.0–9.5. Water supplied outside this range is increasingly corrosive.

Electrical Conductivity

The electrical conductivity of drinking water is measured using a pair of electrodes set a specific distance apart. The conductivity of the water is dependent upon the number and type of ions present and will also indicate the amount of dissolved material present in the sample. The meter is calibrated using a standard solution of potassium chloride.

Color

The unit of color is defined by the platinum cobalt method, being the color produced by $1\,mg\,l^{-1}$ platinum as chloroplatinate ion. There is a direct relationship with the Hazen scale.

Color is measured using visual comparison against liquid standards, calibrated colored glass disks, or spectrometrically. With spectrometry the wavelength used determines the result.

The Hazen scale is primarily used in nonlaboratory situations. It comprises a range of colored glass disks, calibrated in color and intensity to match the chloroplatinate colorimetric test. The sample is poured into a viewing tube and matched to the Hazen standard against a white background. A variety of manufacturers produce these calibrated glass disks; ranges of $0–70\,mg\ Pt\,l^{-1}$ are common. The chloroplatinate method involves the preparation of the standard colors from potassium chloroplatinate standard solution.

Color in water is mainly due to free sediment, iron or manganese material, organic matter, and industrial pollutants, e.g., dyes.

Turbidity

This determinand is a measure of the clarity of the water. It is usual to measure turbidity in formazin turbidity units (FTU), following calibration. A variety of techniques exist to measure turbidity but the most popular uses nephelometry, where the intensity of scattered light is measured. It is usual to have the detection at 90° to the light source.

Alkalinity

This general term covers the combined concentrations of hydroxide, carbonate, and bicarbonate present in the sample. Actual concentrations are dependent upon pH, temperature, and total dissolved solids content. A series of nomograms are used to calculate actual concentration.

Alkalinity is determined either colorimetrically or by titration with acid.

Hardness

Calcium and magnesium salts present determine the hardness of the water. Permanent hardness (noncarbonate hardness) is due to the presence of chlorides, sulfates, and nitrates. Carbonate hardness is due to carbonate and bicarbonate salts of calcium and magnesium.

Metals Analysis

A variety of instrumental techniques and colorimetric methods can be used to detect metallic elements. Electrochemical systems, i.e., anodic striping voltametry, atomic absorption – flame or furnace – inductively coupled plasma-optical (OES) or mass spectrometry (MS) are all practical instrumental systems. The correct choice of system is dependent upon:

1. limit of detection required
2. number of samples to be analyzed
3. number and type of metal analyses per sample
4. degree of automation required
5. skill required of analyst

The lowest limits of detection (LoDs) are most likely to be achieved by the use of an ICP-MS, which, when used with an autosampler system, has the potential to analyze large numbers of samples for most metals/metalloids unattended.

However, with ICP-MS, problems arise with sodium, potassium, calcium, and magnesium due to their high concentration in drinking water, and also with a range of interferences developed within the plasma. Use of gold with matrix-matched standards (Na, K, Ca, Hg) allows the determination of mercury (Hg), arsenic (As), selenium (Se), and antimony (Sb). The use of an ultrasonic nebulizer (USN) or specialized nebulizers (e.g., Minehardt) can significantly improve the performance of an ICP-OES instrument, resulting in lower LoDs than the conventional instrument alone. Many ICP-OES instruments have true simultaneous detection for many metals by the incorporation of charge-coupled arrays or similar devices within the detector unit.

Electrochemical methods such as anode striping voltametry can produce results with good precision and low LoDs but they are disadvantaged by being slow compared to ICP use. Improvements have been made by automating sample analysis and the use of multiplace sample holders, but they are not in common use in high-throughput situations.

Mercury, arsenic, selenium, and antimony can be detected using an ICP-MS, but most other flame or plasma systems cannot produce acceptable LODs or precision for these elements. Furnace systems can get low LoDs by multiple additions of analyte to the

pyrolizing component, but this is a slow technique. Mercury is frequently analyzed using the cold vapor fluorescence technique. In this a reducing agent, i.e., stannous chloride or sodium borohydride solutions, reduces the inorganic mercury to its elemental form in solution. Bubbling a gas, usually argon, through this solution strips out the elemental mercury vapor. Detection is usually by fluorescence, although absorption and other systems have been used. Arsenic, antimony, and selenium can be converted to corresponding hydrides by reaction with sodium borohydride solution. These volatile forms can then be directed to flame or optical systems for detection. It is vital to insure that the element of interest is in the appropriate oxidation state, As^{III} Sb, Se^{IV}, prior to hydride formation. Use of an inappropriate oxidation state will lead to a low result or no result being obtained.

In addition to occurring naturally, aluminum salts can be used within the water treatment process to assist coagulation and subsequent settlement. With a WHO limit of 200 $\mu g\,l^{-1}$, aluminum can be analyzed colorimetrically or instrumentally. However aluminum in drinking water can have a detrimental effect on kidney dialysis at concentrations as low as 20 $\mu g\,l^{-1}$ Al. Any method chosen for aluminum should be capable of detecting this concentration where kidney dialysis patients are treated in the supply area.

The metals present in high concentrations – sodium, potassium, calcium, and magnesium – can be determined using flame photometry in addition to flame absorption or ICP-OES.

WHO guidelines for metals are given in Table 1.

Anion Analysis

Ion-selective electrodes, ion chromatography, and many forms of automated and manual colorimetric techniques are used to analyze anionic compounds. Automated methods include air-segmented and flow injection analyzers or discrete systems derived from clinical analyzers. The choice of technique is dependent upon daily sample numbers and range of analysis required.

Table 1 World Health Organization guidelines for metals present in water

Aluminum	200 $\mu g\,l^{-1}$ Al
Antimony	5 $\mu g\,l^{-1}$ Sb
Arsenic	10 $\mu g\,l^{-1}$ As
Barium	700 $\mu g\,l^{-1}$ Ba
Boron	300 $\mu g\,l^{-1}$ B
Cadmium	3 $\mu g\,l^{-1}$ Cd
Chromium	50 $\mu g\,l^{-1}$ Cr
Copper	2000 $\mu g\,l^{-1}$ Cu
Iron	2000 $\mu g\,l^{-1}$ Fe
Lead	10 $\mu g\,l^{-1}$ Pb
Manganese	500 $\mu g\,l^{-1}$ Mn
Mercury	1 $\mu g\,l^{-1}$ Hg
Molybdenum	70 $\mu g\,l^{-1}$ Mo
Nickel	20 $\mu g\,l^{-1}$ Ni
Selenium	10 $\mu g\,l^{-1}$ Se

National limits exist for beryllium, calcium, magnesium, silver, sodium, tin, and zinc.

Ammonia, Nitrite, and Nitrate

These nitrogen-based ions can be determined using all of the above techniques. The calculation of nitrate is usually obtained by subtracting the nitrite result from that of total oxidized nitrogen (TON). Total oxidized nitrogen is determined by the selective reduction of nitrate to nitrite and its determination as nitrite, along with any nitrite in the sample.

Chloride

Chloride can be analyzed by all the above methods plus titration with silver or mercuric nitrate solution. Colorimetric analysis is based on the reaction that liberates thiocyanate ions from mercuric thiocyanate solution. In the presence of iron III ions, the highly colored ferric thiocyanate is formed and this is measured at 480 nm.

Fluoride

Fluoride may occur naturally or may have been added to reduce the occurrence of dental caries. It can be analyzed by all the above techniques.

Sulfate

This ion is usually determined using gravimetry and turbidity following reaction with barium chloride solution to form insoluble barium sulfate. Ion chromatography is also used, as is the colorimetric methyl thymol blue method.

Phosphates

Phosphates exist in a variety of forms in water. The simplest form is orthophosphate, with the increasingly more complex pyro-, meta-, poly-, and organophosphates occurring less frequently and at lower concentrations. Apart from the determination of total phosphorus by ICP, separation into type is dependent upon conversion to soluble orthophosphate by increasingly more vigorous acid/hydrolysis/digestion. Subsequent colorimetric determination of the orthophosphate using the vanodomolybdophosphoric acid method, stannous chloride method, or ascorbic acid method is dependent upon the expected orthophosphate concentration.

Process Byproduct Analysis

The most familiar process byproducts are the formation of the trihalomethane group of organic compounds following the reaction of chlorine with organic material in the water supply. These compounds (chloroform, bromodichloromethane, dibromochloromethane, and bromoform) are normally analyzed by head space gas chromatography using an electronic capture detection (GC-ECD). Other systems, e.g., purge-and-trap (P&T) and GC-MS, have been used.

The more frequent use of ozone as a pretreatment prior to activated charcoal for the removal of complex pesticides has established a need to analyze for bromates, chlorates, and chlorites. These compounds can be formed from the reaction of the ozone with bromide and chloride ions in the supply water. Ion chromatography, usually using a concentration column, is the preferred method of detecting these compounds. A new procedure, which appears to offer very good LoDs, is currently being adopted. It uses postcolumn derivatization with ultraviolet detection with the advantage that all compounds of interest can be analyzed from the same sample injection. Existing methods for bromate require a multistage preparation to remove interfering chloride and sulfate ions. Samples prepared in this way are analyzed using differing chromatographic conditions. For these reasons it is necessary to analyze bromate separately.

Organics Analysis

A large number and range of compounds fall within this area of analysis. They vary from simple molecules to large complex compounds with differing stabilities and solubilities. It is unrealistic to expect one instrument to analyze the whole range of these compounds. The current techniques used are specifically targeted to obtain the best detection performance. Preferred techniques readily utilize technical advances in instrumental techniques, as these become commercially available.

When analyzing for organic compounds present at very low concentrations in water, the first stage of analysis is usually the concentration of the analytes to be determined. Concentration is achieved either by extracting the compound(s) of interest into another solvent – liquid/liquid extraction (LLE) – or on to a specially prepared inert or polymeric material – solid-phase extraction (SPE). In LLE the choice of solvent is critical. It must not interfere with compound(s) being concentrated, nor must it affect the chromatography by obscuring the peaks of interest with the solvent peak. Once extracted, the solvent phase is usually reduced in volume by either evaporation under a gentle flow of inert gas, e.g., nitrogen, or using specialized equipment, such as the Kuderna Danish evaporator.

Where a complex mixture of compounds is being extracted, the relative solubilities and absorption capabilities of each component can differ significantly. These fundamental differences will lead to unequal extraction ratios occurring which, unless corrected, will lead to errors later in the analysis. It is normal in these circumstances to evaluate the analysis of each compound independently so that the percentage extraction ratio is understood for each matrix type. Once the information is available then the constancy of extraction can be monitored by the addition of surrogate standards to each sample prior to extraction. Surrogate standards are usually compounds very similar to the target analyte, differing either by the inclusion of a different substituted chemical group within the molecule, or by the use of deuterated compounds where mass spectrometry is used in the final analysis. By appropriate choice of surrogate standard, the range of extraction efficiencies can be monitored during the extraction and corrected for in the final result.

Internal standards are standards that are added to the extracted material or concentrate and are used to monitor the constancy of the analytical instrument system used. The addition of compound(s) to the extracted material enables the analyst to correct for both random and systematic variations, e.g., partially blocked/worn injection systems, temperature variation, loss of column efficiency, and detector deterioration.

The instrument systems used rely on chromatographic separation using either GC or high-performance liquid chromatography (HPLC). Different detectors are used according to the sensitivity required, but the reduced size and cost of mass spectrometer detectors has led to their increased use, particularly when deuterated compounds are used for surrogate or internal standards. Large libraries of 'most significant masses' for organic compounds have been compiled to assist the analyst to identify compounds when using single-ion mode(s) (SIMs) of MS-detector operation. Two or more 'significant masses' can be used specifically to identify and quantitate a compound, particularly when it has one mass fragment value that is identical to those produced by other different compounds. The use of total ion count (TIC) mode on an MS-detector will produce a more conventional chromatogram of the separation, showing peak height against time.

Typical organic compounds determined are described below.

Phenols

These compounds have detectable tastes at low concentrations and may react with chlorine to produce chlorophenols which have even lower taste thresholds. They are analyzed by LLE using methylene chloride and detected by GC using FID, ECD, or MS detectors as appropriate. Derivitization using pentafluorobenzylbromide produces lower detection limits.

Trihalomethanes (THMs)

These are normally produced when chlorine reacts with naturally occurring humic or fulvic material during disinfection. Industrial contamination can add THM and other chlorinated hydrocarbons to the raw water. THMs are analyzed by head space or P&T techniques, followed by GC-ECD or GC-MS.

Pesticide Residues

Organochlorine (OCP) or organophosphorus (OPPs) can be analyzed together with polychlorinated biphenyls (PCBs) using methylene chloride LLE and GC-ECD or GC-MS instruments.

Phenoxy Acid Herbicides

MCPB and 2.4.D are analyzed for by extraction into diethylether and derivitized using diazomethane to produce their methyl ethers. Analysis of the derivitized compounds is by GC-MS.

Triazine and Uron Herbicides, Including Atrazine, Diuron, and Prometryn

These compounds tend to be thermally unstable and are best suited to analysis using liquid chromatography-MS detection following either methylene chloride LLE or solid-phase extraction using cartridges preprepared for this specific extraction.

Polynuclear Aromatic Hydrocarbons

This class includes the most frequently found compound – fluoranthene – and the most toxic – benzo(a)pyrene. The presence of these compounds is mainly due to the coal tar pitch lining applied to water distribution pipes. The limits applied to these compounds are health-related. Analysis is by HPLC.

Organic Carbon

This empirical determinand is frequently used as a coarse monitor of quality in both supply and treated water. There are many different techniques for analysis, including combustion furnace or chemical oxidation, with or without ultraviolet light to give carbon dioxide, and reducing conditions to give methane. The detection system is appropriate to the preparative stage, e.g., infrared detectors for CO_2 and FID for methane. The term 'total organic carbon (TOC)' is the summation of the various forms of organic carbon capable of being distinguished by differing preparative stages.

1. Dissolved organic carbon (DOC) – not retained on a 0.45-μm filter
2. Particulate (POC) – the fraction retained as 0.45-μm filter
3. Purgeable or volatile (VOC) – the fraction removed by gas stripping
4. Nonpurgeable (NPOC) – the residue after gas stripping

Radioactivity

The determination of radioactivity is sometimes required due to geological or artificial circumstances. It is rare for there to be a requirement to investigate specific radiochemical isotopes, although the monitoring of gross α- and gross β-emitters is used for establishing and monitoring trends. WHO recommends a limit of 1 Bq l^{-1} for α- and 100 Bq l^{-1} for β-emitters. (A becqueral (Bq) is one disintegration per second.)

Samples can be analyzed directly or in most cases concentrated by boiling. Boiling removes any radon present so this must be determined separately. Final sample preparation is dependent upon the limit of detection required and the instrument/detector used to count the sample. Counting times vary between 3 and 10 h.

Quality Control

Quality control is very important if the results obtained are to be credible and useful for comparison. Analytical quality control is only a part of the total system which should include information on the actual performance of the instrument system used at the time of analysis, the status of the analyst, i.e., trained or under training, the performance of the technique on various sample types or matrices, and the conditions under which the analysis was made.

The methods used to establish and maintain analytical quality control include the use of standards as samples, analysis of duplicates, measures of drift, and others, as appropriate. These values are plotted on charts which show when the analysis is moving away from the target value in a regular way or when the results are outside the statistically established method performance. Shewhart and cusum charts are both used to determine if a procedure is within or outside control.

Microbiological Analysis

C Fricker, CRF Consulting, Reading, UK

Introduction

The dramatic reduction in disease associated with the consumption of drinking water over the last century has been brought about largely by increased awareness and by the considerable advances made in treatment, disinfection, and distribution of potable supplies. The microbiological and chemical examination of water plays an important part in the control of water treatment processes. Microbiological examination of potable water is performed to insure the safety of supply. In general, the tests used are based on indicator organisms, the presence or absence of which provides a measure of the microbiological quality of water. This article deals with aspects of microbiological examination of water from sampling through to detection of some organisms that are important pathogens for human beings.

Sampling and Handling of Samples

Sampling issues have tended to receive less attention than water quality issues in the various standards and regulations that have been laid down. The recommended frequency of sampling varies widely between different regulatory authorities. In designing a microbiological monitoring program, the major consideration is of course the health of the consumer. The program should be designed to take account of the size of the distribution network and should insure that samples are taken from all areas of the network. The frequency with which a particular supply needs to be sampled depends primarily on the number of consumers it supplies; the higher the number of consumers, the more frequently sampling should take place.

An ideal sampling regime should be completely randomized. However, owing to the complexity of many distribution systems, this is seldom possible. For this reason, stratified random sampling is probably the best approach. The entire distribution should be divided into discrete areas such that it is composed of regions where contamination could occur without being detected by sampling other areas. However, whilst this approach may be ideal in theory, it is seldom, if ever, adopted. In general, the sampling of potable water supplies begins with the water entering the distribution system. Samples from large water treatment plants are usually taken on a daily basis, whilst at smaller works regular monitoring of residual chlorine levels, together with less frequent microbiological checks, is often used. In addition to samples of water entering the supply, other sites such as service reservoirs and break-pressure tanks are regularly sampled. Samples from distribution are randomized as much as possible and this also involves sampling from consumers' premises.

The type of sample taken depends on the reason for sampling. Generally bacteriological sampling (for detection of *Escherichia coli* and coliforms) involves the collection of a relatively small volume of water (300–500 ml), whereas samples for detection of specific pathogens such as enteroviruses, *Cryptosporidium*, *Giardia* and *Salmonella* involve larger volumes (10–1000 l). Samples for bacteriological and virological analysis require sterile bottles and the addition of sodium thiosulfate. The sodium thiosulfate is used to neutralize the effects of free chlorine in the water sample. Samples for parasites such as *Cryptosporidium* and *Giardia* may be taken by passing large volumes of water through cartridge filters and the filters are then taken to the laboratory for examination. Alternatively, smaller volumes of water (10–100 l) may be collected into containers and transported to the laboratory for subsequent concentration. Microbiological samples should be examined as soon as possible after collection. This is particularly important for samples for bacteriological and virological examination, where ideally samples should be analysed within 6 h.

Colony Counts

Water contains a variety of bacteria that may have different temperature optima. Bacteria whose natural habitat is cold water will, in general, have a lower optimal growth temperature than those that enter the water distribution system as contaminants. The temperatures most often employed for providing colony counts on potable water are 22 °C and 37 °C. Generally, plate counts are performed as pour plates where a small amount of water (usually 1 ml) is transferred by pipette into a Petri dish and molten agar (at about 47 °C) is added. After mixing, the agar is allowed to solidify and the plates are incubated at the appropriate temperatures for 1–7 days before the colonies are counted. The agar medium used varies between different laboratories, but a general-purpose medium such as yeast extract agar is most often employed, although the less nutritious R_2A is becoming more widely used, as it usually allows detection of a higher number of bacteria. It is sometimes necessary to prepare serial 10-fold dilutions of samples to insure that an accurate plate count can be achieved. It is not appropriate to record plate counts that exceed 300 colonies on a plate, as the results are likely to be highly inaccurate. Plates with this number of colonies are likely to give a count that is lower than the true count owing to two or more bacteria forming a single colony and because colonies will tend to lie beneath one another. Furthermore, some bacteria produce bacteriocins which will inhibit the growth of other organisms. The resultant plate counts are by no means a measure of the total count of bacteria in a water sample but merely indicate the number of organisms that are able to form colonies in the particular medium used under specified growth conditions.

Colony counts are not essential for assessing the safety of potable water, but may be useful operationally and may give an early indication of future problems. The value of colony counts lies in the comparison of a number of counts from an individual source taken over a period of time. When subjected to trend analysis, any significant changes may indicate problems. A sudden increase in the plate count at 37 °C may indicate a pollution incident. Plate counts at 22 °C are subject to environmental and seasonal influences. Plate counts are also particularly useful in determining the efficiency of water treatment processes such as filtration, coagulation, and chemical disinfection.

Use of Automated Methods

The development of automated procedures for the microbiological testing of water samples has been slow. To date, very little has been implemented. Some automation of colony counts has begun and it is not uncommon for laboratories to produce pour plates using commercially available plate pourer/stackers. Water is added to the Petri dish, a defined volume of agar at the appropriate temperature is added and, after mixing, the plates are cooled to allow the agar to solidify. It is also possible to utilize automatic colony counters to perform plate counts. Colony counters composed of a solid-state video camera coupled to sophisticated electronics and software are often used. Such instrumentation can lead to considerable time savings in a busy water microbiology laboratory. New systems are being developed which allow the enumeration of bacteria in a sample without the need to grow them. Such systems employ the use of viability markers such as fluorescein diacetate which is converted to a fluorescent product by viable bacteria. This fluorescent product which is held inside the bacterial cell wall allows sophisticated instrumentation to enumerate the bacteria present on a membrane surface.

Special Problems Associated with Viruses

All warm-blooded animals may harbor enteric viruses and therefore have the potential for contaminating water through defecation. In addition, other viruses from other sites such as the respiratory tract may be found in sewage and therefore may pass into source waters. Fortunately, most viruses are extremely host-specific and will infect only a small number of species. (*See* **Viruses**.)

Human enteric viruses, which are now known to occur frequently in raw water, were first isolated from the environment over 50 years ago. This group includes viruses such as the polio virus and hepatitis A virus. Whilst a direct association between the presence of virus in drinking water and human disease has not been proved for all enteroviruses, their presence in drinking water should be seen as a public health hazard.

Viruses are small in size and may travel long distances through soil. Consequently they may be found in sites where bacteria have been filtered out. For this reason, the absence of indicator bacteria from water does not mean that viruses are absent. It is therefore appropriate to examine water for viruses in some instances. This creates several problems. Because viruses are intracellular parasites incapable of replication outside a host cell, they cannot be cultured on artificial culture media as can most bacteria. Viruses must be grown in tissue cultures, which are cells, usually derived from animal or human tumor cells, which can be grown in the laboratory. Because of

their host-specificity and particular tissue tropism, an individual class of virus will only grow in certain types of tissue culture and some viruses grow very poorly or not at all *in vitro*. In practice, very few methods exist for the detection of viruses in water. Examination for enteroviruses (specifically the polio and Coxsackieviruses) is undertaken most frequently as the methods for these viruses are simple and well established. These viruses are used as indicators of the potential presence of other viruses in much the same way as *Escherichia coli* is used as an indicator of the potential presence of pathogenic bacteria.

The procedure used for the detection of enteroviruses in water involves concentration of the viruses from a large volume of water (usually a minimum of 10 l) on to an electropositive membrane, followed by elution using a small volume of a proteinaceous solution such as beef extract. The concentrated material is used to inoculate cultured cells, which are then incubated at 37 °C for several days. Viruses are detected as holes or plaques in the cell sheet which are created by the virus killing the cells in a small area. Some viruses are not able to cause this so-called cytopathic effect, although they may be able to replicate to some extent within the cell. These viruses are generally detected using enzyme-linked or fluorescently labeled antibodies. More recently, molecular methods based upon the polymerase chain reaction (PCR) have been introduced and these are usually applied to tissue cultures a few days after addition of the sample, to insure that only infectious viruses are detected. (*See* **Immunoassays**: Radioimmunoassay and Enzyme Immunoassay.)

Parasite Problems

In recent years *Cryptosporidium parvum* has become recognized as a major pathogen of human beings and some domestic animals. It causes a self-limiting diarrhea in immunocompetent individuals, but may cause mortality in immunocompromised hosts. One of the modes of transmission is through consumption of contaminated water and several waterborne outbreaks have been reported. The organism survives in water as an environmentally robust oocyst containing four sporozoites. The organism has been reported in drinking water and it survives chlorination during normal water treatment. (*See* **Parasites**: Occurrence and Detection.)

Examination for Specific Groups

Much of the microbiological work within the water industry involves the use of indicator organisms as opposed to specific groups of bacteria or viruses. The organisms most frequently sought in this connection are coliform and *E. coli*. The term coliform has been given several definitions, but in general, a working definition is that it produces P-galactosidase and grows at 37 °C on laboratory media containing bile salts. The definition of *E. coli* is of course much clearer, it being a species in its own right.

Both *E. coli* and coliforms are cultured in the same way. Water is passed through a membrane filter and placed on the surface of a pad soaked in medium containing proteinaceous nutrients, lactose, bile salts (or similar compounds), and a pH indicator. The combination of lactose and an indicator allows the identification of lactose fermenters (a trait common to coliforms and hence to *E. coli*), whilst the bile salts inhibit the growth of nonintestinal bacteria. Nowadays bile salts as such are not generally used, and they have been replaced by purified detergents such as Teepol or sodium lauryl sulfate. The membranes are incubated at 37 °C for coliforms or 44 °C for *E. coli* and incubation is continued for at least 18 h. The incubation often includes a 4-h period at 30 °C to allow organisms that may be slightly damaged to adapt to their new environment. After incubation, the membranes are examined and lactose-fermenting colonies are counted on membranes incubated at 37 °C and 44 °C. These counts are termed 'presumptive coliforms' and 'presumptive *E. coli*,' respectively. Confirmation of the presumptive counts was based on production of acid and gas from lactose, and indole from tryptophan at their respective temperatures (37 °C and 44 °C). However, it has been known for some time that these confirmation tests are not 100% effective because of differences between strains within the groups (e.g., anaerogenic strains). It is becoming a more common practice to identify the isolates by means of more detailed physiological tests, often using one of the commercially available batteries of tests for identification of the Enterobacteriaceae. This permits a much more accurate 'confirmed' result.

The use of simpler tests for the detection of coliforms and *E. coli* is becoming more common and in particular defined substrate technology is extremely popular. These tests rely on the detection of two enzymes, β-D-galactosidase (for coliforms) and β-D-glucuronidase (for *E. coli*) in a medium which contains little carbon and energy source other than the substrate for the two enzymes. Enzyme activity is detected by a color change (for coliforms) and the production of fluorescence (for *E. coli*).

Other groups of indicator organisms which are sometimes used include the enterococci and *Clostridium perfringens*. These organisms are generally more resistant to chlorine than the coliform group

and also tend to survive longer in the water. They may be used to identify waters which have been subjected to less recent fecal contamination. Isolation of these groups of organisms generally involves membrane filtration, followed by incubation on an appropriate selective medium. Specific enteric pathogens such as *Salmonella* spp. and *Campylobacter* are rarely looked for in potable water. However, when they are sought, techniques similar to those employed in food microbiology are used. (*See* ***Campylobacter***: Detection; ***Clostridium***: Detection of *Clostridium perfringens*.)

The two major enteric pathogens that are looked for specifically in water are the protozoan parasites *Giardia* and *Cryptosporidium*. Examination for these organisms involves a very different procedure to those used for bacteria and viruses. Large volumes of water (typically 100–1000 l) are filtered through cartridge filters. The filter matrix is then 'washed' in a dilute detergent solution in an effort to release as much of the retained material as possible. The washings from the filter are then concentrated by centrifugation, purified by immunomagnetic separation, dried on to microscope slides, and stained by immunofluorescently-labeled antibodies. Examination of water samples from 'at-risk' water treatment plants is now a regulatory requirement in the UK and a specific method has been published which must be used for examination of these regulated samples. The process involves concentration of large volumes of water, separation of *Cryptosporidium* oocysts from background debris by immunomagnetic separation, and epifluorescence microscopy. A similar method (USEPA (United States Environmental Protection Agency) method 1623) has been recommended for use in the USA.

WEIGHING

R Schulthess, Mettler-Toledo AG, Greifensee, Switzerland

Introduction

Well-organized and effective quality assurance in the food industry is a must for all companies, whatever their size. A quality assurance system has to meet demands from both the legislative and the industrial economic standpoint. Scales and weighing systems represent important tools to enable such quality assurance systems to fulfill these requirements.

The Scale as a Control and Management Tool

The degree of automation of all types of production processes must be constantly increased to withstand the growing pressure from the competition. At the

same time, the demands on quality are increasing, tolerance limits are becoming narrower, and integrated control processes are assuming more and more importance. This makes the use of 'intelligent' (computerized) scales and weighing systems as tools in quality assurance an important factor in production. (*See* **Quality Assurance and Quality Control.**)

Sometimes, only a few grams or even fractions of a gram decide the quality and the profit and loss in mass production. Even minor weight deviations, e.g., losses incurred through the overfilling of solid or liquid foods, can cost a great deal of money. Difficulties must also be anticipated with underfilling. In addition to customers, consumer and other protection associations, which react extremely sensitively to underfillings, each country has its own statutory regulations which, particularly in the food-processing industry, require a weight control.

The Scale: Electronics as Standard

In the last two decades, balance and scale construction has undergone a fundamental changeover from mechanics to electronics. As a result, electronic balances and scales are now standard equipment. They offer the user incomparably more convenience than their mechanical counterparts, and thus make possible extensive rationalization of operations. Electronic scales, however, are also intelligent scales, which offer a wide variety of possibilities to process the weight values further.

Thus weight determinations in different units are currently performed on one and the same scale; percentage weighings and formula weighing (net total determination) are part and parcel of the daily work routine. Furthermore, electronic scales are system-compatible, i.e., they can be incorporated in automated operational routines in a wide variety of ways.

The Measurement Technology: Decisive Factor for the Performance Class of a Scale

Electromagnetic Force Compensation: Synonym for Extremely High Accuracy

At the start of the 1970s, the balance and scale manufacturer Mettler (Switzerland) used the principle of electromagnetic force compensation commercially for the first time. The measurement principle is shown in Figure 1. With this measurement technology, the force action on the weighing platform is compensated by means of a coil in a magnetic field. The current needed for this is proportional to the weight of the loaded sample. It is transformed into a digital signal that can be processed by a powerful microprocessor. This principle allows an extremely high resolution greater than 300 000 certified points (e) and the maximum possible precision, even in surroundings not conducive to highly precise work.

The most conspicuous feature of these scales is the drastic reduction in the number of controls. A single key is all that is needed to initiate all functions, such as on–off switching of the scale, setting the display to

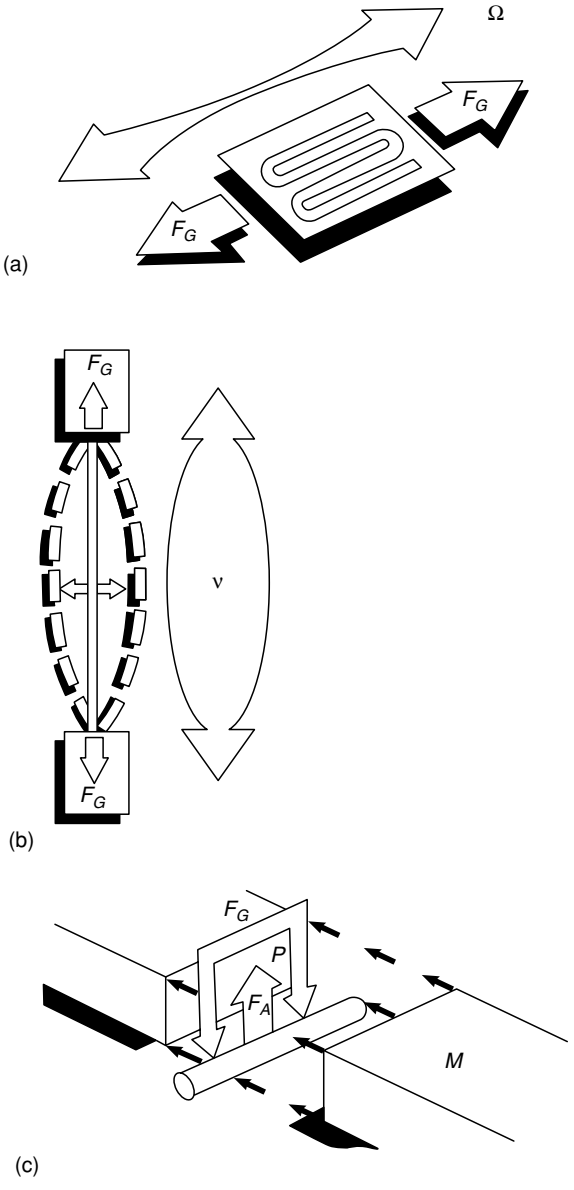

Figure 1 (a) The principle of frequency-modulated force measurement. (b) The principle of strain-gage technology. (c) The principle of electromagnetic force compensation. zero, taring a vessel on the scale, and selection of additional functions from the menu (Figure 2).

Strain-Gage Technology for the Harsh Industrial Environment

Weighing stations in a harsh industrial environment must be characterized by ruggedness and endurance. With scales employing strain-gage technology, the strain gauge, an electrical resistive film, is mounted on an elastically deformable body and thus allows leverless measurement of loads weighing up to several tonnes. This technology, with its various designs, e.g., extremely flat platforms for wheeled access, and particularly flat ring-load cells, offers weighing results of unvarying accuracy in the lower resolution range at 3000 e (Figure 1).

Frequency-Modulated Force Measurement – Precise and Economically Attractive

The combination of extremely simple mechanics (monobloc) with state-of-the-art sensor technology (vibrating string) allows a very good multirange resolution. A value of 3×3000 e assures flexible use and offers advantages in a wide range of applications, especially in situations where the industrial ruggedness of the sensor (IP67-type protection) is essential. The frequency-modulated force measurement is distinguished by a very high accuracy and, at the same time, by its attractive price: performance ratio (Figure 1).

All three basic weighing technologies described above are used in commercial instruments. The user thus has available a balance or scale product line up to 6 t that is geared to practically all conceivable applications.

Automatic Calibration

To ensure that 100 g is actually measured as 100 g the world over, reference weights (so-called calibrated mass weights) are used with a mass based on the standard stored in Paris. With traditional, mechanical two-pan scales, each weighing was of necessity a comparison with the loaded reference weights. With electronic scales, however, a comparative measurement is performed only when the scale is adjusted on-site with a known weight. This process is called calibration.

Figure 2 Modern electronic balance with a single control bar. Reproduced from Weighing, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Accurate Results – Even Under Unfavorable Ambient Conditions

Anyone who performs weighings wants more than merely accurate results. They should also appear rapidly on the display and be stable. However, rapidity and stability are properties which are mutually inconsistent. For example, an analytical balance with 0.1 mg read ability reacts sensitively to loaded weights, but vibrations of the support and draughts can also influence the displayed weight values. The effects of building oscillations, open windows, and air-conditioning units with their powerful air currents must therefore be effectively suppressed. The measured values were summed over an adjustable time, the so-called integration time, and shown as a mean value. However, this averaging method is associated with a relatively long stabilization time.

Modern technological developments allow better solutions. The built-in processor system performs a trend analysis so that the actual weight value can be displayed rapidly despite a less than ideal location.

Display Behavior Meeting Application Demands

To match the requirements of the application, the behavior of the display can be adjusted with the so-called weighing process adapter: the last decimal place in the display is switched off during rapid weight changes until the weight has gradually stabilized. This prevents the operator being distracted and quickly becoming fatigued by rapidly changing figures that are completely superfluous at the time.

In fine addition, on the other hand, the display should follow the weight increase as rapidly as possible and show the weight continuously with its complete resolution.

Yet another, completely different behavior is demanded from the scale in check weighings. The weight result should be displayed as quickly as possible, and this is allowed for by filters. Intermediate values are of no interest, and hence the display shows all decimal places only when the actual weight has been determined.

Digital or Analog?

Digital numbers are still indispensable for the representation of extremely accurate measured values, but

digital numbers are not geared to the human senses. Our feeling for changing quantities is virtually nonexistent.

Even today digital gages, especially speedometers in cars, have gained little acceptance as it takes too long to read and acquire the measured value. For this reason dynamic analog displays have been developed. Similar to a clock with hands, this angular information supplements the digital values of the display (Figure 3).

Single Range, Dual Range, DeltaRange, MultiRange

The, at first sight, confusing multiplicity of terms hides a number of different advantages, depending on the scale type, which prove their worth in the appropriate application.

In principle, everything could be weighed with the single-range scale. However, owing to the often very high resolution, such scales take a relatively long time to achieve stability and are expensive to manufacture. Selection of the correct scale leads to the best and most favorably priced solution. The concepts can be characterized as follows.

Figure 3 DeltaTrac analog and digital display. Reproduced from Weighing, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Single-range scale provide the same readability over the entire weighing range, e.g., 0–200 g to an accuracy of 0.1 mg.

Dual-range scales have a range with a finer readability, e.g., 0–50 g to an accuracy of 0.01 mg for the weighing of light samples, and for the weighing of heavy samples a range of, for example, 0–200 g with a coarser readability of 0.1 mg. Switching between the ranges can be performed manually or automatically as a function of the loaded sample.

DeltaRange scales have a more accurate fine range which covers part of the entire weighing range and can be shifted at will. If this fine range is exceeded, the scale automatically switches over to the coarser range. By pressing the tare key, however, the start of the fine range can be reset to any position over the entire weighing range. This device is extremely useful primarily when several components have to be weighed very accurately into a relatively heavy tare vessel. After every taring, the fine range is again available.

Finally, multirange scales change the readability in a variable manner. Thus the numerical increments of the display increase from one to two to five increments with increasing load. For example, the multirange KA32s weighing platform has a range of 0–6 kg to an accuracy of 1 g, followed by 6–12 kg to 2 g, and 12–32 kg to 5 g.

Electronic Data-Processing (EDP) Attachment

The time-tested laboratory notebook can still be found next to the majority of scales. However, anyone who has discovered how simple it is to print out weight values or transfer them to a computer will need a lot of persuading to relinquish such conveniences.

Two interfaces with different standards and functions are steadily gaining acceptance as worldwide standards. RS232C is the most widespread standard for attachment to personal computers and printers. It allows data communication in two directions: to the computer and from the computer to the scale. Current loop (CL) is a standard interface that allows distances of up to 1000 m to be covered without any problems, which is not possible with an RS232C connection. This enables several scales and peripheral units, even those at different sites, to be linked and controlled and monitored by a central computer.

Matched to Harsh Surroundings

In the food sector, scales and weighing systems are often used in harsh ambient surroundings: wet conditions and dust, acids and salt, and other corrosive

substances can influence their functional dependability. Despite the harsh conditions, they must offer absolute reliability.

The use of electrolytically polished chrome–nickel steel and other high-grade materials ensures operational reliability even in adverse surroundings.

A high degree of protection (e.g., IP67) assures protection of the sensitive instruments and particularly that of the electronics against the ingress of water, moisture, and dust.

The Hygiene Factor

In the food-processing industry, hygiene is one of the central problems facing a plant. All production equipment must be appropriately designed to ensure strict compliance with the hygiene regulations. Thus the construction of the scales and weighing systems described above also takes into account the stringent requirements with regard to cleanliness. The instruments can be thoroughly cleaned once or several times a day in accordance with the regulations without any problems and without being damaged, whether this involves hosing down, the use of powerful cleaning agents, or other treatments. (*See* **Cleaning Procedures in the Factory**: Overall Approach.)

Increase in Efficiency Linked with Cost Savings

Modern material flow concepts can no longer be imagined without electronic scales and weighing systems. As integratable components, they fulfill a wide variety of functions over the entire goods flow from the incoming goods via production, storage, quality assurance, research and development, up to the outgoing goods. Thanks to its system capability, the scale can be integrated without any problems in fully automated and EDP-controlled production and flow processes.

The high accuracy, the extreme user-friendliness, and the highly diverse application capabilities make modern scales and weighing systems an essential factor to increase efficiency and optimize quality and costs.

The Selection of the Right Material Flow Scale

What are the essential points to consider in the use of scales in material flow? Basically, a distinction must be made between features specific to the scale and those specific to the application.

Bar Codes in Weighing Technology

The use of the bar code technique is now making headlong progress in general industry, and additional bar codes, superficially known as industry codes, have been developed to cover these needs. The main use lies in conveying and handling, as well as warehousing; here the material flow is tracked. In all phases of the transport process, attempts are being made to identify automatically the goods to be transported or stored i.e., by electrooptical reading of the bar code symbols on the packaging, transport containers, accompanying documents, etc., and to transfer the data to process or normal computers and perform automatic crediting and debiting by way of a permanent inventory.

Consideration of the scale as a sensor in material flow assumes increasing significance if the following simple application is pictured: read in the identification data of the weighing sample or sample to be counted directly at the weighing terminal from the bar-coded medium and, supplemented with the weighing result, transmit to an external data receiver via a data interface; alternatively, print out weighing results in bar code form for the rapid and reliable acquisition by bar code reading at the destination.

The features specific to the scale include properties such as industrial compatibility, weighing range and accuracy, user-friendliness, and system capability. The application-related characteristics depend on the location and the actual application. A number of companies offer a whole series of software packages with standard applications, such as weight controls (plus or minus checks), automatic weighing in the material flow, totalization, formula weighing, dispensing, and filling process control. The requirements of the specific departments must also be taken into consideration.

The entire inventory management of the complete chain stands or falls by the precise acquisition of weights and batches in the incoming goods department. Check weighings and data acquisition are of prime importance, whether they involve stationary or mobile, line-independent scales.

In production, the broad spectrum of applications proves its full worth. Here, the production performance has to be supported by efficient control systems. Time-tested standard applications provide assurance in checking and classifying, and in check weighing in the material flow. The use of EDP allows the weighing data to be processed further, and the function of the scale as a sensor to maintain quality and comply with quantity can be utilized to the full. In addition to high quality, the goal is always an increase in efficiency, whenever possible linked with a reduction in costs.

It is impossible to imagine modern warehouses and warehouse management without electronic scales and weighing systems. The precise acquisition of weight

data, piece counts, etc., provides a reliable basis for stock planning and logistics.

In the outgoing goods department – the last link in the production chain – scales again make a contribution by ensuring that with precise check weighings the preceding efforts in the entire material flow are not for nothing. Particularly in the food industry, rapid flows in this department are decisive to assure quality and freshness of the products, but without endangering the economic efficiency of the production.

From the Production to the Front

What is right for production should be proper for commerce. Even at the front, in the retail trade, the picture has changed drastically in the past few years. Scales with price-marking systems are today the order of the day, as is the linkage to form complete network systems in supermarkets. Similar to the situation in production, the scale network distributed over the selling space is centrally monitored and controlled. In the field of price marking and label design, all conditions required by law and economic efficiency can be met: bar code, layout, article data, up to the design of advertisements for the business in question.

Electronics also on the Road

In the era of the EC and the increase in the exchange of goods by road, it is essential to acquire complete delivery and dispatch data. Several vehicle scales employ the principle of strain-gage technology and have the same acquisition and processing possibilities of the weighing data as all other scales.

Filling Process Control in the Food Industry

One of the most important application areas of weighing systems in the food industry involves filling process controls. For here, as in all types of filling processes, the tolerance limits must be defined so that neither unnecessary losses owing to safety overfillings nor any violations of the legal regulations owing to underfilling occur.

The following example will illustrate this point. In the Hamburg factory of Tchibo, a major coffee-roasting company, every year 32 000 t of freshly roasted coffee beans are weighed to the nearest bean and immediately packed. Approximately 580 Tchibo branches and 15 000 fresh product depot partners assure the customer of the proverbial Tchibo freshness, in other words top-class quality and an unvarying fill quantity.

The filling machines run in a three-shift operation with a capacity of 100–120 packages per min and a net weight of 500 g. This high filling rate notwithstanding, the weight of every package must be exactly right. There are two contrasting reasons for this. First, the legislative authorities or the weights and measures office checks that the prepackaged goods regulations are complied with and the average weight is not less than the nominal fill quantity. Second, constant overfilling 'on the side of safety' would be hugely uneconomical with the amount that is processed. In order to handle these two problems, Tchibo has installed a filling process control system which operates on the basis of random sampling. At the 13 packaging lines, per day 3900 random samples are taken and processed by the system using statistical methods.

Use of this filling process control system ensures that not only are the legally specified tolerances complied with, but also approximately 40 kg of coffee is saved every day. Scaled up to the annual production, this means a saving of around 10 t. Assuming the price of green or raw coffee is \$1000 per t and taking into account the tax on coffee in Germany, at present around \$2 per kg, this results in a sum of approximately \$30 000 per year. This figure shows that a well-functioning control system pays for itself many times over after a short time.

The Filling Machine – A Complex System

As a rule, a filling machine is a complex entity. Various influences, which can be controlled only after a great deal of effort, lead to random fluctuations in the weight or volume of the packages. The magnitude of these fluctuations depends on the filling principle, the condition of the filling machine, on the packaged product, and numerous other factors.

Independent of these fluctuations, in the guise of the nominal fill quantity, a lower tolerance limit is more or less rigidly fixed by appropriate statutory regulations. Simple compliance with this lower limit makes a control of the filling process necessary; even with apparently large safety everfillings, a check must be made to ensure that they are actually large enough.

On the other hand, from the industrial economic viewpoint, the interest of the filling plant is centered on the upper limit. The efforts are thus always aimed at keeping the shaded area shown in Figure 4 as small as possible.

The distance between the upper and lower limit is to a large extent a question of the control outlay and is therefore decisive for the selection of a suitable

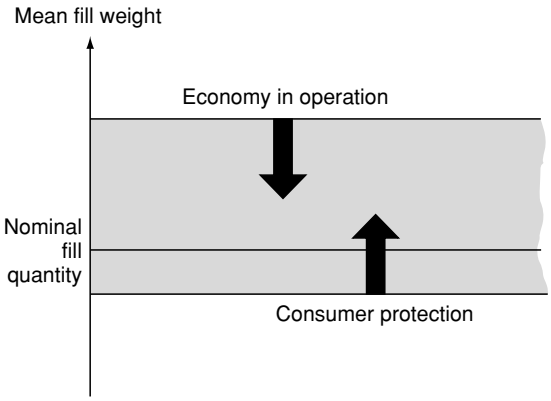

Figure 4 In the interest of the filling plant, the magnitude of the overfilling (shaded area) must be kept as small as possible. Reproduced from Weighing, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

control system. Decisive criteria in this case are the type and speed of the controls as well as the desired informative nature of the control results, rather than the number of packages to be checked.

The Control System – An Adjustment System

A control system should not only be used to check weights or volumes of packaged products, it must also be possible to influence the filling process actively with the aim of ensuring compliance with the statutory limit values in filling at all times with minimal material costs. This results in a control loop (Figure 5), which in practice is by no means easy to achieve.

As every filling process is subject to random influences, it goes without saying that the control and adjustment tasks must be solved by statistical methods. However, an important fact should always be noted even with the statistical weight check: nobody – and this applies however extensive the technical effort – can predict the weight of the next package.

In contrast to a widely held view, 100% inspection does not result in any improvement in this respect. With a check weigher integrated in the filling line, although every single package is checked, statistical methods must still be employed for control of the filling machine.

Selection of the Suitable Organizational Form

In the selection of the suitable organizational form, a fundamental choice has to be made right at the start: the options are statistical filling process control, or

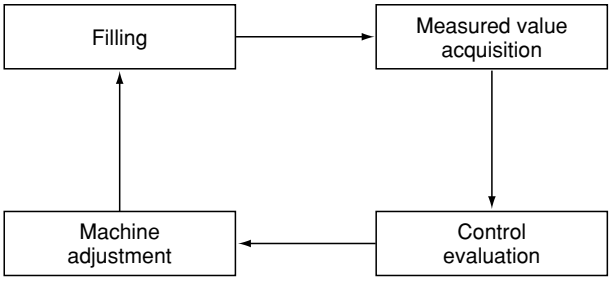

Figure 5 Control loop for active influencing of the filling process. Reproduced from Weighing, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

100% inspection, i.e., a check on every package with a check weigher.

The following description of the two types of control shows that each has certain advantages. It will be apparent that under certain conditions it can also be eminently practical to select a mixed organizational form employing both random sampling and 100% inspection.

100% Inspection

Basically, it is wrong to assume that only 100% inspection can provide the necessary assurance of strict compliance with the statutory regulations. In particular, it is the presence of a lowest tolerance limit which contributes to this erroneous belief; the regulations state quite clearly that to ensure the lowest tolerance limit 100% inspection is not obligatory and a random sample check is admissible.

However, there are a number of cases in which 100% inspection has advantages compared with random sampling:

- in a filling situation where frequently only half-filled or even empty packages are produced and there is no subsequent visual inspection
- if the produced packages have to be classified and/or sorted
- if a complete operational data acquisition or evaluation (production efficiency, throughput, etc.) is required
- if the product or the filling situation experiences extreme density fluctuations

The automatic feed of the packages to a check weigher allows a measured value acquisition without additional personnel costs. However, with a relatively large number of filling machines, the capital investment required for 100% inspection is considerable, as each filling line must be equipped with a check weigher (Figure 6).

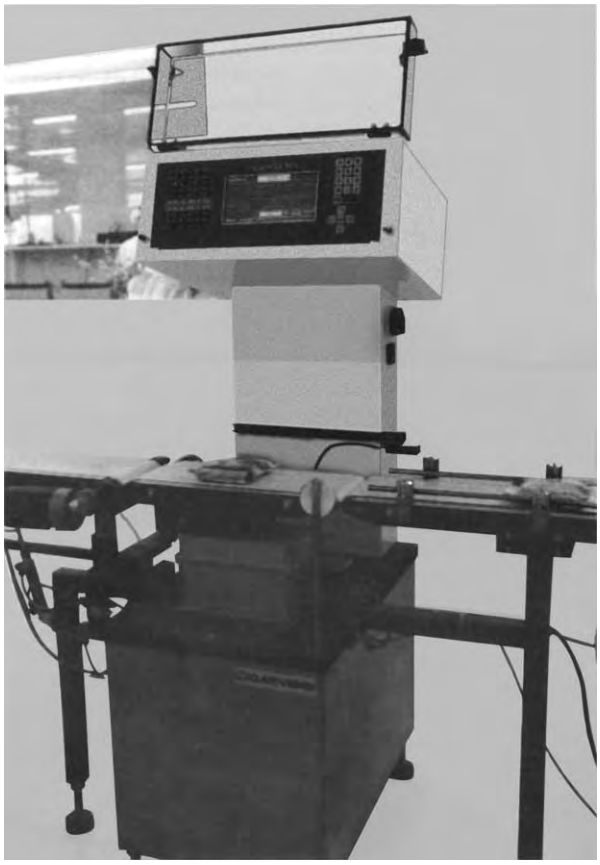

Figure 6 Check weigher (Leisi, Switzerland). Reproduced from Weighing, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Figure 7 Sampling operation (weighing/Leisi). Reproduced from Weighing, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Statistical Filling Process Control

In contrast to 100% inspection, the statistical filling process control has the following advantages:

1. The most important advantage of the statistical control is without doubt the appreciably lower capital investment required in comparison with 100% inspection. The disadvantage of the higher outlay, owing to the need for additional control personnel, is offset to some extent by selection of a suitable organizational form. Hence, in many plants, it is the task of the machine operators to undertake a check of their own machines by periodic sampling through a line inspection.
2. If a measuring station is assigned several machines, the inspection can be made with a so-called continuous inspection. Special control personnel make rounds through the production, collect samples, and then check the packages at the measuring station. This form of organization is selected primarily in plants in which the filling process control is performed by a department independent of the production – as a rule by the quality assurance.
3. Basically, the management of even large measurement series in a statistical filling process control poses no problems since the operating convenience and efficiency of modern electronic scales allow several thousand weighings in the course of a working day (Figure 7).

In summary, the statistical filling process control proves advantageous in those filling situations where a large number of filling stations must be monitored with low capital investment. In contrast, 100% inspection is advantageous in all cases where large batches of a single product have to be subjected to an automated filling control at a few filling stations and hence the ability of a modern check weigher to check several hundred packages per minute is of prime importance.

Selection of the Correct Control System

What criteria are used by the filling plant to select the control system that is optimum for its specific requirements? The cost-conscious plant will decide on the control system that brings it the greatest profit, i.e., the smallest possible overfilling that ensures no violations of the laws. With such a minimum configuration, the filling plant may well comply with the statutory regulations, but it sometimes gives away material worth a considerable amount through overfilling.

From the industrial economics viewpoint, however, a filling control is also indispensable even if there

were no regulations, for the correct selection and use of a control system can be profitable. In the final analysis the success of the filling process control depends to a large extent on the control personnel and machine operators. Only when the degree of automation has been increased will this dependence be reduced.

Filling Process Control in Practice: The SQC52 Quality Control System

The SQC52 quality control system is discussed here in some detail as a representative of the broad spectrum of systems on offer.

This system uses random sampling to supply all information decisive for the optimum adjustment of the filling machine and for the legally required records and evaluations.

The operating philosophy of the SQC52 system has been taken over from the window technique used successfully in EDP. The small number of operating keys and the easily surveyed graphics display contribute decisively to the simple and convenient operation (Figure 8).

All information is displayed in the form of windows. The status field provides general information on the operating mode; the dialogue window is used to support the operating sequences. It indicates when additional details are required or information or error messages have to be displayed for the operator. Each operating mode contains a number of working screens, which can be selected using the function keys.

Dependability – Thanks to Proven Menu Technique

For the control operation, all necessary data are available as a working window. In the working screen product definition, the user defines in a simple manner all necessary product parameters for the products to be checked. Other windows handle the parameter selection (selection of the possible weighing modes), the interface configuration, the memory allocation and instrument settings. The individual windows are selected using cursor keys. A help key is used to call up help texts with information on the respective entry or selection fields.

Graphical Evaluation, Informative Records

The sampling operations can be shown on the display as a mean-value trace together with the deviations with time in the filling process. The last 10 samples in each case are shown in the correct order as so-called box plots with mean value, standard deviation, greatest and smallest mean value.

The histogram reproduces a set of batch statistics with the distribution of all measured values. This allows a qualitative report on the filling plant and the production. On the basis of the statistical values calculated by the system, the machine can be adjusted manually (adjustment message) or automatically (Figure 9).

The SQC52 system allows comprehensive documentation of the samples in four detailed sets of statistics. All parameters, such as date, time, mean value, standard deviation and tolerance violations, as well as all requisite adjustments, are recorded and printed out. The system takes into account most national legal regulations (tolerance system) including pharmacopoeia (an official list with regulations for preparation, quality, and application of drugs).

The SQC52 System in Operation in Leisi

Leisi is a large Swiss bakery and producer of different types of ready-made pastry. It uses an SQC52 system

Figure 8 SQC52 display. Reproduced from Weighing, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

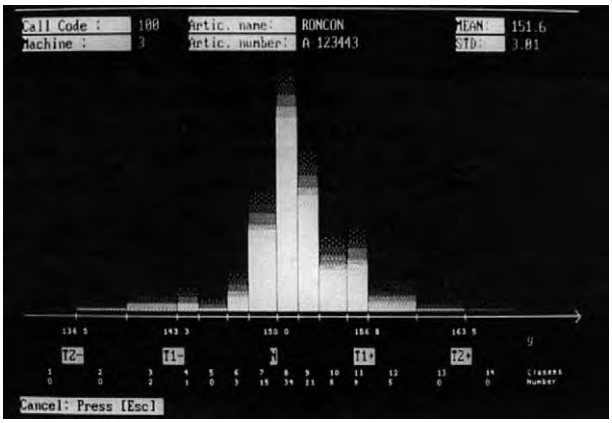

Figure 9 SQC61 evaluations. Reproduced from Weighing,*Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

with five weighing stations. At four of these, random sample checks are made with the machine operators performing the weighing. The fifth line has a Garvens check weigher attached. The reasons for such a distribution are as follows.

At four of the lines with random sample weighings, rolled-out, ready-made pastry is produced. On the basis of the adjustment message of the system (in grams), the machine operators set the pastry thickness on the machines, or they correct it if necessary. Although this information is received in grams and not in correction values in millimeters of pastry thickness, the machine control functions completely satisfactorily thanks to the experience of the operators.

In contrast to earlier generations of control methods, the system has the great advantage that it supplies adjustment messages in absolute values and decisions no longer have to be made on the basis of a mean value alone.

At the fifth line, always the same product, unrolled pastry, is produced and packaged in large quantities. The criteria listed earlier are therefore applicable here and a check weigher is used.

Leisi produces one or more batches daily for a major customer. The system thus supplies the summaries in the form of batch statistics. If necessary, these can be passed on to the customer.

In addition to the statutory requirements which the SQC52 system in operation with Leisi fulfills, it also offers attractive prospects from the economic efficiency standpoint. Quite apart from the savings in material owing to optimum fill quantities, it greatly rationalizes control operations. The data of approximately 50 articles are permanently stored. After every product change at a filling station, the control system is thus immediately ready for operation. If the packaging of a product is changed, only the new tare value must be entered. This is performed simply by overwriting the old value.

The Crop

S T Grundas, Dobrzanski Institute of Agrophysics, Polish Academy of Sciences, Lubin, Poland

Introduction

For 10 000 years, wheat (*Triticum*) has been an object of particular interest, owing to its specific taste and nutritional value, as well as its ease of cultivation and storage. Archeological evidence indicates that primitive unleavened bread, baked on heated stones, was first made in the Neolithic era. The early Egyptians were developers of bread and the use of the oven and developed baking into one of the first large-scale food production industries. Nowadays, wheat constitutes about one-third of the global production of cereals, and its yearly production in the mid-1990s reached 600×10^6 tonnes. Wheat has a predominant role in the grain trade and is utilized as food (67%), feed (20%), seed (7%), and industrial products (6%). Wheat meal used for human consumption provides 20% of all the energy consumed by the human population. It is consumed mainly as bread.

This article provides information on the following: the global distribution of wheat; its varieties and market classes; the morphology and anatomy of the spikelet and grain; its chemical and nutritional composition; grading, handling, storage; wheat processing and end uses; the role of wheat gluten proteins.

Distribution, Varieties, and Market Classes of Wheat

Distribution

There are over 20 species of wheat, differing in their basic number of chromosomes (diplo-, tetra-, and hexaploid), and several thousand varieties. The most economically significant species are the ordinary wheat *Triticum aestivum* sp. *vulgare* (hexaploid) and the hard wheat *T. durum* (tetraploid). The global area of wheat cultivation covers a total of about 240×10^6 ha, and approximately 90% of that is occupied by *T. aestivum*, which has the greatest number of crop-yielding varieties of starchy grains. There are numerous varieties of *T. durum* cultivated in continental climate zones and covering approximately 10% of the total area.

The geography of wheat cultivation is illustrated in Figure 1. The areas of wheat cultivation are mainly found in the northern hemisphere. Wheat is grown both as a winter and as a spring cereal in the moderate climate zones, and in the tropical regions in low lands and uplands alike. The distribution of wheat over the various parts of the world is related to the numerous species and varieties, and to their adaptability to particular environments.

Wheat harvesting is a continuous process around the world and every month is a period of harvest in one of the wheat-growing regions.

Wheat Varieties and Marked Classes

Five marked classes of wheat are distinguished: Hard and Soft Red Winter (HRW and SRW), Hard Red Spring (HRS), durum (Durum), and White, which is classified in the following subclasses: Hard and Soft Winter (HWW and SWW), and Hard and Soft Spring (HWS and SWS).

Although variety is an important factor affecting quality, wheats are seldom classified on the basis of a single variety. In practice, we adopt the classification of wheat according to its class. Each class consists

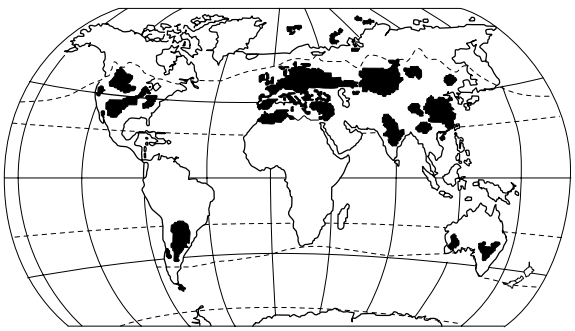

Figure 1 Main wheat-growing regions in the world; the northern and southern distribution boundaries are marked with a broken line. From Grzesiuk S and Kulka K (1988) *Biology of Cereal Kernels*. Warsaw: Polish Scientific Ed. (in Polish) with permission.

of a group of varieties of similar characteristics for specific purposes.

As an example, in Canada a model HRS wheat is the Marquis variety, for years now replaced in production by varieties genetically similar, but more valuable economically, such as Neepawa, Manitou, and Thatcher. Out of Amber classes (CWAD1 and CWAD2) *T. durum* wheats, representative varieties are Kyle and Plenty. Wheat varieties grown in USA are genetically similar to those grown in Canada. In Argentina, approximately 97% of the area of wheat cultivation is taken up by winter wheat similar in its value to the HRS class. In Australia, the primary crop is winter wheat, class ASW (see Grading below), of hard and soft white grain, genetically similar to the Argentinean wheat. In Europe, and especially in France and Germany, the high level of agriculture resulted in these two countries having virtually the highest grain yield per unit of area of cultivation. Recently, 'clubs' have been set up by wheat producers who achieve yields of 10–15 t ha^{-1}. In this region the dominant type are wheats of the SRW class. The EU countries have dozens of high-yield varieties of very good grain quality. In Mediterranean countries such as Italy and Spain some *T. durum* is grown. East European countries grow mainly red winter wheats, some of which have very good baking qualities. In the countries of the Commonwealth of Independent States (CIS) both spring and winter, red and white wheats are grown, as well as some durum wheats. The CIS has the largest area of wheat cultivation in the world. The leading varieties in terms of yield and grain quality are winter wheats Bezostaya 1 and Mironovskaya 808, and the spring wheat Saratovskaya 29.

Morphology and Anatomy of Spikelet and Grain

Spikelet

The central part of the ear or spike is a waveform rachis, composed of a number of short nodes and internodes (Figure 2a). Spikelets grow at the nodes, constituting modified shoots (Figure 2b). Two glumes, located at the base of each spikelet, are shorter than the rest of lemmas in florets. In floret the grain is enclosed between two pales (the palea, from the inside, and the lemma, from the outside). Ordinary wheats which have fusiform spikes are awned or awnless, and easily threshed.

Grain

The dorsal side (the same side as the germ) of the wheat grain can be oval, ovate, or elliptical, with a cluster of long or short brush hairs at the apex, and an oval or circular embryo at the bottom. Wheat kernels have a longitudinal crease or a deep groove the length of the ventral side (opposite the germ). The shape of the groove is a characteristic feature of some species and varieties.

The grain structure is presented in Figure 2c. The grain coat is made up of the fruit and the seed coat, adhering directly to the aleurone layer. The pericarp (fruit coat) consists of several layers of translucent cells, strongly lignified, elongated in shape and encrusted with mineral substances, and of a layer of perpendicular and tubular cells. The seed coat consists of a compact cell layer and pigment strand, providing the grain with its characteristic coloring, and a hyaline layer.

The aleurone layer, made up of large thick-walled cells filled with functional proteins and nutritional components, encloses the endosperm, and disappears around the embryo.

The endosperm consists of large, thin-walled cells, filled mainly with starch and protein. In the subaleurone area, especially on the dorsal side of the grain, the dominant cells are elongated in the direction of the endosperm center. Cells within the endosperm are less regular in shape. Starch grains are enclosed in the thin layer of adherent protein and located within a protein matrix which fills the individual cells of the endosperm to varying degrees. The highest protein content is observed in the cells of the subaleurone layer of the endosperm. The closer to the center of the grain, the lower the protein content.

Chemical and Nutritional Composition of Wheat Grain

Chemical Composition

The chemical composition of wheat grain and of its anatomical parts (Table 1) is determined by genetic and ecological (climate, soil, tillage) factors, and by the physical and chemical effects acting on the grain during its storage and processing.

The primary quantitative component of wheat grain is starch. Cereal grains store energy in the form of starch. The starchy endosperm varies in composition from its outer portion, just beneath the aleurone layer, to its center. The amount of starch contained in wheat grain varies but is generally between 60 and 70% of the weight of the grain. Starch is basically polymers of glucose. Chemically, at least two types of polymers are distinguishable: amylose, an essentially linear polymer, and amylopectin, which is highly branched. The ratio of amylose to amylopectin is relatively constant, at about $23 \pm 3\%$

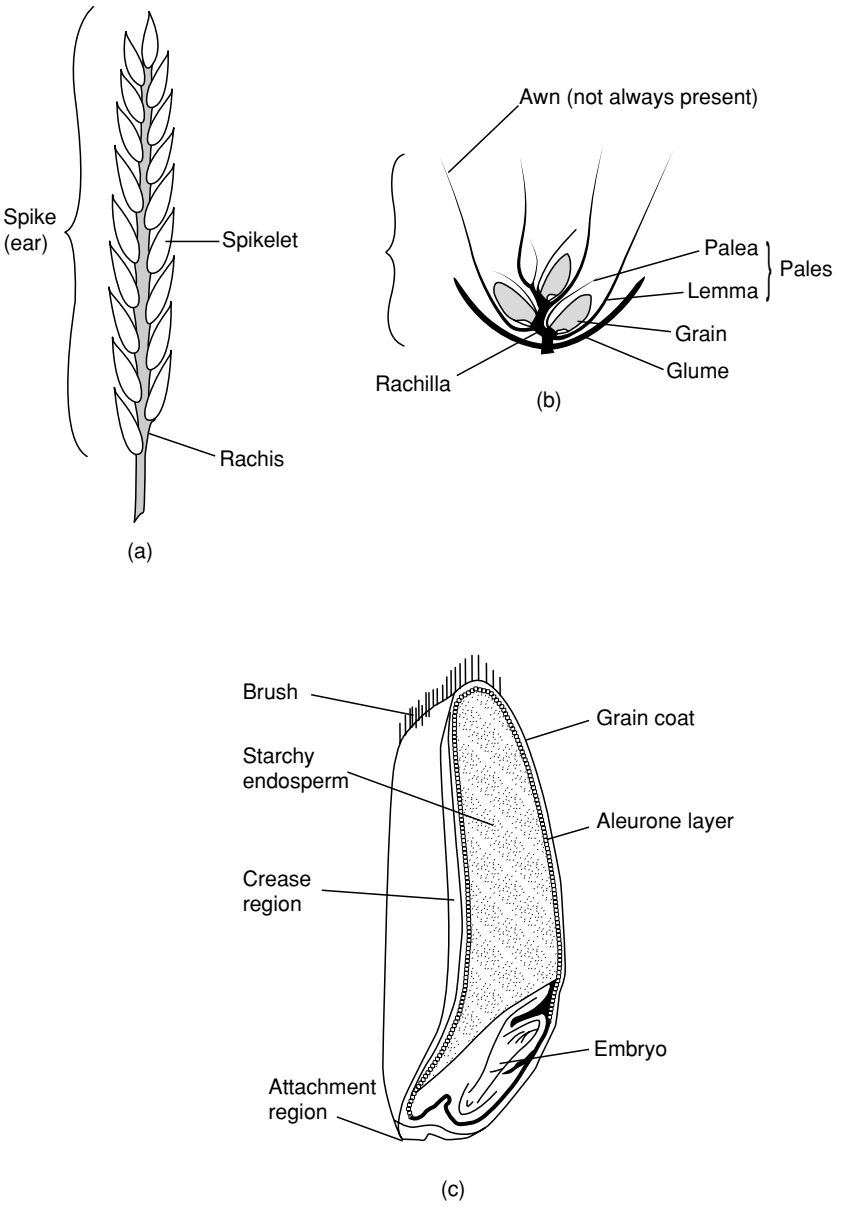

Figure 2 Structure of the spike (ear), spikelet, and grain: (a) spikelets arranged alternately on the main axis or rachis; (b) a mature spikelet; (c) grain structure.

amylose. Wheat endosperm has two types and sizes of starch granules: the large (25–40 μm) lenticular and small (5–10 μm) spherical granules. Apart from starch, the grain and especially the grain coat, the aleurone and the embryo, contain other carbohydrates, such as cellulose, hemicelluloses (pentosans), and sugars. Pentosans, although their content in endosperm is low (2–3%), form the basic structure of endosperm cell walls. Of particular interest is the concept that pentosans could, depending on their water-absorbing capacity (which is 10 times their mass), represent 'moisture pumps' that to a certain extent regulate moisture levels in different flour components after their hydration in the dough-making process.

Proteins are among the basic nutritional components of grain, and their quantity and quality determine the applicability of the grain and its products for particular purposes. The total protein content is determined on the basis of the nitrogen multiplied by factors of 5.7.

The protein substances of wheat are divided, in relation to their solubility, into the following subgroups: (1) albumins, in water; (2) globulins, in

10% sodium chloride; (3) prolamins, in 70% ethanol; (4) glutelins, in dilute alkaline or acid solutions. These substances form groups of particles of similar physicochemical and structural properties but, occurring in various grain tissues, they differ from one another in amino acid composition (Table 2). The proteins of the starchy endosperm contain small quantities of lysine, a considerable amount of glutamic acid, and some prolines. The proteins of the embryo and the aleurone layer of the endosperm are characterized by a relatively high content of leucine, lysine, and aspartic acid.

Fats are the third important component of wheat grain. Their highest contents are observed in the embryo and the aleurone layer (Table 1). A high content of fats in cereal products can result in their rapid spoilage. Carotenoids, found mostly in an embryo and in the aleurone layer, belong in a group of fats which are of practical importance. They have a considerable nutritional value, as they constitute the basis for the formation of vitamin A in humans and animals. They have a yellow or pale orange coloring, which determines the typical creamy look of wheat flour. Whitening flour by chemical processing results in a decrease in its nutritional value through the oxidation of the carotenoids.

The ash formed in the course of burning grain or flour originates from inorganic compounds and organic substances (Table 1). The highest content of mineral substances is found in the aleurone layer and in the grain coat, and the lowest in the endosperm.

Nutritional Composition of Grain and its Products

The nutritional value of wheat is determined by the technological properties of the grain (good milling and baking characteristics) and the nutritional qualities of its products, in combination with taste and digestibility.

The nutritional components of the grain provide energy and 'building materials,' and play a regulatory role. Primary components providing energy are sugars and fats and, less frequently, proteins. Components providing building materials are mainly proteins and minerals, while those performing a regulatory function include vitamins and minerals. The energy values of the major chemical components of grain and its products are presented in Table 3.

The nutritional value is also determined by the content of endogenous amino acid (lysine, methionine, tryptophan), the levels of which are relatively low in wheat. For this reason, an admixture of milk or soya flour to wheat flour improves the quality of bread or other bakery products. A typical day's healthy diet would include 55% or more of daily calories from complex carbohydrates, such as cereal grains. Eating six or more servings of bread, pasta,

and cereal grains each day is the right choice for an overall healthy lifestyle.

Wheat grain is relatively low in vitamins; only the B-group vitamins are present in any notable quantities. The B-group vitamins as a component of wheat grain are presented in Table 4. Likewise, fat, the content of which is low in wheat flour, plays no significant role in the nutritional value of wheat flour and its products.

Grain Grading, Handling, and Storage

Grading

The grading of wheat grain involves the isolation and valuation of grain portions based on the physical and chemical properties of the grain. The scope of wheat grain grading in use is related to the state and development of agricultural knowledge, as well as to the level of organization of the local cereal market (pricing polices, grain-purchasing system).

The systems of wheat grain grading include the following groups of grain properties:

1. Stable properties, related to genetic properties, such as grain size and coloring, protein content, and sedimentation factors.
2. Variable properties, subject to change as a result of drying, cleaning, sorting, and transport (moisture content, contamination, damage to grain), related to climatic conditions (bulk density).
3. Permanent faults and defects, such as stale smell, fermented smell, foreign smell, or faults that can be rectified, e.g., washing grain contaminated with soil or foreign matter.

The stability properties are primary properties, and it is on their basis that the market classes are distinguished. This is the most important group of properties characterizing the market grades of wheats in international trading.

The variable properties are secondary properties, although also important from the viewpoint of grain quality. The group of variable properties, systematized into several ranges in terms of values, constitutes grain grades, which are identical for all the market classes and varieties. The quality grading of wheat grain sometimes includes an assessment of mechanical damage, which occurs wherever grain is subjected to the destructive action of internal or external forces.

The results of research carried out using X-ray methods showed significant differences in grain endosperm cracks between common wheat varieties. It was stated that natural wetting of dry grain (below 15% of moisture content) during rainfall in field conditions is one of the main reasons for its cracking. Considering the results of endosperm cracks which can appear before harvest in some climatic regions of wheat production, special attention should be paid not only to proper combined adjustment but also to the state of natural continuity of endosperm tissue and to genetic features of the variety. The susceptibility of wheat to mechanical damage is determined by genetic factors (hard and soft grains), environmental effects (climatic condition during the preharvest period), and by the conditions of grain storage (excessive humidity). The combination and selection of these properties determine the unification of grain material in terms of quality.

The permanent faults and defects are excluded in grain grading, as their character disqualifies grain from food usage. Defined faults which can be rectified constitute special grades of defective quality.

The standards of wheat valuation have been established by Canada and the USA. These countries have a system of wheat grading with classes based on the varietal properties as expressed by the vegetation period (spring and winter wheats), grain coloring (red, white) and hardness (hard, soft). In recent years, an extra class, Utility, has been added to the grading system, and it is made up of certain genetically

similar varieties of winter and spring wheat. Wheat grading in the USA additionally provides, in the subclasses, for the proportion of vitreous grains, and it is simplified, compared to the Canadian system, by using identical grades for all classes and subclasses. The system also includes an additional grade, called Sample Grade, samples of which do not conform to established requirements of the basic-quality grades.

Argentina uses a system of bread wheat division into subclasses in relation to the grain type (hard, semihard, and soft), and into grades. Australia has developed a grading system for white-grain wheats. The grading is based on the health requirements, cleanliness and bulk density established for the basic class called Australian Standard Wheat (ASW). Grain of lower quality than that of ASW is classified as General Purpose, or as Feed grain.

Wheat grading in the CIS is based on principles similar to those followed in the USA, with the distinction that classes are replaced here by types, and subclasses by subtypes, primarily designed to take into consideration the proportions of vitreous grains. Some European countries (e.g., France, Germany) use a grading system based on the protein content, bulk density, and sedimentation factor. With only slight differences in the appearance of many varieties, and with the possibility of grain quality reduction as a result of environmental effects, grades have been developed to include, in addition, the contamination of the grain and the falling number.

Other countries, in which wheat is grown or only imported, also use specific standards for the evaluation of the quality of wheat grain and its products. Most frequently such systems are modifications of the systems presented above.

In relation to grading, the following definitions are applied:

1. Hard wheat is wheat which, as a result of variety or breeding in combination with environmental factors during growth, has a vitreous endosperm generally considered an advantage for the production of bread-making flours.
2. Soft wheat is wheat which, as a result of variety or breeding in combination with environmental factors during growth, has a white opaque endosperm generally considered more suitable for the production of cake and biscuit flours.

Handling

Grain handling includes harvesting, segregation, cleaning, and sometimes, drying. Preliminary segregation takes place during combine harvesting of the grain which, depending on its moisture content and level of contamination, is then additionally cleaned and dried.

With the use of various means of grain transport, both internal (in the grain-cleaning machinery and for grain loading and off-loading) as well as external (road, rail, or sea transport), loads of wheat grain of initially determined grades are sometimes subject to mechanical damage, which considerably reduces their technological value.

Grain stockpiling is a concentric process in which the grain is gradually moved from the farm to the world market. That movement passes the following stages: farm silos, local, regional, and terminal storage elevators (the latter frequently located at harbors). At every stage, grain is subjected to classification – from highly detailed to more general grading, improvement (drying, cleaning, sorting, and deinfestation, if required), and grouping of supplies into larger batches of constant quality. Isolated fractions of undersize grain and lower-grade wheat are sold on the local market. With depressed demand, the concentric movement may end at the local market. In case of oversupply it proceeds into the regional or the national markets. With grain exports, the concentric movement may flow out of the national borders and continue worldwide.

Storage

The principal factors affecting the intensity of the process of grain respiration, and therefore also the extent of quantitative losses to the mass of the grain in storage, are the following: grain moisture content, temperature, and grain condition relative to its history. Grain respiration is more intensive in soft grain than in hard grain. If grain moisture content is relatively low (below 14% weight basis, wb), and the bulk of grain of that moisture is homogenous, such grain can be stored for several years without significant losses. However, if proper air temperature and humidity conditions are not observed in the storage area, the increasing humidity resulting from the process of grain respiration may lead to the phenomenon of spontaneous heating of the grain, which excludes its use for human consumption.

In some wheat-growing regions, e.g., in the Scandinavian countries, wheat grain is relatively moist during harvesting and has to be dried to maintain its level of quality. Drying must be performed at specific levels of temperature and humidity of the drying air. Exceeding the required temperature may lead to the loss in the baking value of the flour. To avoid damaging grain meant for baking purposes, its temperature should not exceed 35 °C at moisture contents above 20% wb. There is a general view that the so-called 'critical moisture content' (14% wb), at

which changes related to fungal growth are at a minimum and the grain remains in an abiotic condition, can be maintained by air with a relative humidity of less than 70%.

Wheat Processing and End Uses

Processing

Grain for processing must be of a satisfactory technological quality, and is subjected to a process of preparation for milling. The process of preparation consists of sorting, decontamination, and grain surface cleaning. Most frequent is the process of dry cleaning, using the following equipment: winnowers, aspirators, dry stone separators, pearling mills, brushers, or wet brushing machines. An important measure in the process of grain preparation is the conditioning which brings the grain to the most favorable condition from the viewpoint of the grain milling quality and the flour baking value. This process strengthens the grain coat and facilitates the diminution of the endosperm, but usually eliminates the aleurone layer because it is tightly bound to the grain coat. The aleurone layer contains most of cereals' active anticancer compounds. Therefore, whole grain products are recommended. The embryo, on the other hand, owing to its high fat content, easily flakes off after passing between smooth-bore cylinders.

The milling of the wheat grain, understood as a process of grain diminution down to the level of flour, is realized currently in rather complex and highly mechanized processing plants, equipped with special machines for grain cleaning, grinding, and sorting.

One-time diminution of grain into a product of a specific particle size, so-called simple grinding, is used when grinding wheat grain for wholemeal flour. In graded flour production, the grain and the products of its diminution go through a process of repeat grinding, and such grinding is known as complex grinding.

Extraction is the ratio of the mass of flour obtained as a result of milling to the initial grain mass. The level of flour extraction is related to its degree of 'whiteness.' Flours obtained from mealy wheats, at the same level of extraction, is always brighter than flour from vitreous wheats. Fine flour, of fine granulation, is lighter than flour of the same extraction but of coarser granulation. Flours of fine and uniform granulation improve the process of dough formation. With increasing level of extraction, the baking value of the flour from soft wheat grain decreases. Flours of higher extraction have higher protein contents, and also contain more cellulose, vitamin B, and mineral substances such as phosphorus, iron, calcium, magnesium, zinc, and copper, but have a lower content of starch. More starchy flours, i.e., those of lower protein and cellulose content, are made of pure grits and fine-ground, while the highest content of cellulose and ash characterize flours made from the final milling passages. Sometimes, during the process of milling, wheat germs of high nutritional value but short storage life are isolated.

End Uses

Wheat is used in baking, primarily to make white bread and numerous other bakery products. Although wheat is consumed in many forms, including noodles, gruels, cooked cereals, and ready-to-eat cereals, bread has established itself worldwide as a major convenient and delicious food, especially when made according to regional preferences for flat breads, French bread (baguette), Italian breads, Vienna bread, white and variety pan breads, Polish bread specialties, and many other ethnic varieties. A specific form of bread, known in the countries of the Far East, especially in China, is steamed bread.

Soft wheat flour (of generally low extraction and protein content) is used mostly to make cakes, wafers, and dough that is used for cooked products (noodles and some types of pasta) and for special cakes and cookies made with butter and sugar.

Pasta and noodles are wheat-based products that are formed from a dough but are not leavened. It is generally believed that the ideal raw material for pasta is semolina from durum wheat. Durums are usually amber in color; they are high in carotenoid pigments. When durum wheat is expensive, common hard wheat farina (purified middlings from hard wheat) is often blended with durum or used by itself to produce pasta. In general, the hard-wheat farina produces good pasta except that it does not have the yellow color and is not as resistant to overcooking as that produced from semolina.

Generally, we can say that the baker converts the flour produced by the miller from wheat grown by the producer into delicious basic foods favored by the consumer and capable of being eaten with every meal, by every ethnic and age group every day of the year, regardless of economic level, from the cradle to the grave.

Role of Wheat Gluten Proteins

Gluten is a highly molecular complex of proteins – gliadins and glutenins – together with other components of the endosperm cells. Gladins and glutenins are typical storage proteins of wheat. Glutenins, as a

group of wheat proteins, are heterogeneous, and can be separated, using electrophoresis, into over a dozen fractions of different molecular weights. An appropriate percentage of high-molecular fractions in wheat flour is responsible for the baking value of the flour.

Gluten, as a specific and unique substance formed in the dough obtained from ordinary wheat flour, is characterized by physical properties such as cohesion, elasticity, and considerable stretchability. In bakery applications, the basic characteristics of gluten are its high water absorption (it can even triple its mass), and its ability to form viscoelastic films which play a direct part in the proving of the dough. The properties of film-forming are also used in the production of other foodstuffs, such as the glazing of sausage and meat pâté.

Among the different environmental factors affecting grain quality, temperature fluctuation during grain filling is seen to be the most important factor. Most of the studies have examined the effect of extreme temperatures on dough properties. Daily mean temperatures up to 30 °C during grain filling generally increased dough strength, while temperatures above 30 °C produced weaker dough.

In terms of nutritional value, gluten is at the bottom of the scale, owing to its low content of lysine, methionine, and tryptophan, but in combination with other proteins, e.g., with soya, it displays a higher nutritional value than each of the proteins by itself. One of the reasons for the increasingly frequent addition of gluten to wheat flour is the fact that new wheat varieties, grown under intensive cultivation conditions and providing high crop yield, produce protein of lower value.

Gluten cannot be considered as a natural substance occurring in wheat. It is a form given to protein components as a result of modifying measures applied during the extraction of flour for dough-making with the result that certain proteins can expand in a water medium or in a weak solution of sodium chloride, in combination with mechanical activity. No correlation has been ascertained between the amount of gluten washed out, and its quantitative characteristics. Proteins are considered to be a particularly labile (reactive) system of chemical compounds in the grain, and hence the yield of gluten – adopted as a basis for the qualitative evaluation of grain material – depends on the character and rate of interaction taking place within the material under analysis. Studies confirm the technological effects of protein–water, protein–mineral substance, protein–carbohydrate, or protein–lipid interactions. Each of these types of interactions may have a positive or a negative effect under specific conditions. Contemporary baking technology uses a complex system of dough kneading whereby, apart from the addition of water, various substances which react easily with gluten proteins are introduced. For these reasons, countries experiencing a need for standardization of flour and dough quality have developed numerous instrumental methods to support or supplant the determination of gluten yield.

Grain Structure of Wheat and Wheat-based Products

S T Grundas, Dobrzanski Institute of Agrophysics, Polish Academy of Sciences, Lublin, Poland

Introduction

The structure of wheat grain is a product of genetic and environmental effects acting on wheat during development. The structure of wheat grain is, for all practical purposes, the effect of a system of genetic

information that has been transferred during development. We can view wheat grain as the system waiting to be exploited to meet our needs. For 10 000 years, evolutionary changes have resulted in the wheat plant that is best suited to its environment. Human intervention in this process has given us the main wheat product – bread that has specific attributes which are not found elsewhere in the plant kingdom. We are only now beginning to understand better the genetics of a few storage proteins and how they relate to quality, let alone which genes are responsible for grain shape, size, and amount of storage components. Many factors that govern the quality properties of wheat grain are determined by the structure of the caryopsis. Indeed, every structural component of wheat kernel has some effect on grain quality as a basic material for human nutrition.

This article provides information on the following: wheat grain structure, techniques of wheat grain structure study, and wheat-based products.

Structure of Wheat Grain

The wheat grain is botanically a single-seeded fruit called a caryopsis or a kernel. The wheat kernel consists of an embryo called germ by millers and an endosperm enclosed by aleurone and bran layers. Location of the individual constituents of these components in the mature kernel is illustrated in both longitudinal and cross-section in Figure 1. In this figure a segment of bran layers with aleurone and endosperm cells is presented in detail.

In practice three dimensions determine the shape of the kernel: thickness, width, and length. The wheat kernel averages about 2.5–3.0 mm thickness, 3.0–3.5 mm width, and 6.0–7.0 mm length. Wheat kernels are rounded on the dorsal side (the same side as the germ) and on the ventral site (opposite the germ) they have a longitudinal cavity (crease). At the distal end of the kernel are a number of hairs (trichomes). The crease, which extends to its center, is masked by two flanks (cheeks). The crease occupies 0.7–1.9% of the total grain volume. The presence of wide and deep creases causes low test weights. Wheat kernels average about 30–35 mg in weight. All anatomical parts of the wheat kernel are presented in Figure 2.

Bran

The pericarp (fruit coat) surrounds the entire seed and consists of two portions, the outer pericarp and inner pericarp. The outer pericarp has the following layers: the epidermis (epicarp), the hypodermis, and the innermost layer, called the remnants of thin-walled cells. These thin-walled cells which have a discontinuous cellular structure form a natural plane of cleavage. Removal of the outer pericarp, which millers call beeswing, also aids movement of water into the kernel. The inner pericarp adjacent to the remnants is composed of intermediate cells – a single layer of cross cells and tube cells. The cross cells are long and cylindrical (about $125 \times 20\ \mu m$), and have a long axis perpendicular to the long axis of grain. They are tightly packed, with little or no intercellular space. The tube cells are of similar size and shape as the cross cells but have their long axis parallel to the long axis of grain. The tube cells are not packed tightly and do not form a continuous layer and thus have many intercellular spaces. They are only recognizable in the mid dorsal region of mature grains. The next layer inwards is the seed coat (testa or integument) which is firmly joined to the tube cells on the outside and the nucellar epidermis on the inside. The seed coat of red wheat consists of a thick outer cuticle, strongly pigmented layer, and thin inner cuticle. The seed coat in white wheat has cell layers containing little or no pigments. The color, usually red or white (although purple is also known), is related to pigment in the testa. Tightly bound to the internal surface of the seed coat is the nucellar epidermis (hyaline layer, perisperm). The thickness of the seed coat varies from 5 to 8 μm. The nucellar epidermis is about 7 μm thick and closely united to both the seed coat and the aleurone layer. The total pericarp has been reported to comprise about 5% of kernel volume.

The aleurone layer, which is generally one cell thick, completely surrounds the kernel, covering both the starchy endosperm and the germ except for that adjacent to the scutellum. Although the aleurone layer is anatomically a part of the endosperm, the miller regards the aleurone as the innermost layer of the bran. The majority of the mineral matter located in bran is found in the aleurone layer, which also contains one-third of the grain's thiamin content. The cytoplasm of the cells contains many small (3–4 μm), round aleurone granules surrounded by lipid droplets. The aleurone granules contain two types of inclusions: type I contains phytin and type II contains protein, carbohydrate, and bound nicotinic acid, which is largely unavailable for human nutrition. The phytin granules are the main source of mineral matter and hence the degree of aleurone (or bran) contamination of flour is frequently evaluated by an ash analysis. In addition, thiamin and riboflavin are higher in the aleurone than in the other parts of the bran, and enzyme activity is high. Over the embryo, the aleurone cells are modified, becoming thin-walled cells that may not contain aleurone granules. The thickness of the aleurone layer over the embryo averages about 13 μm, or less

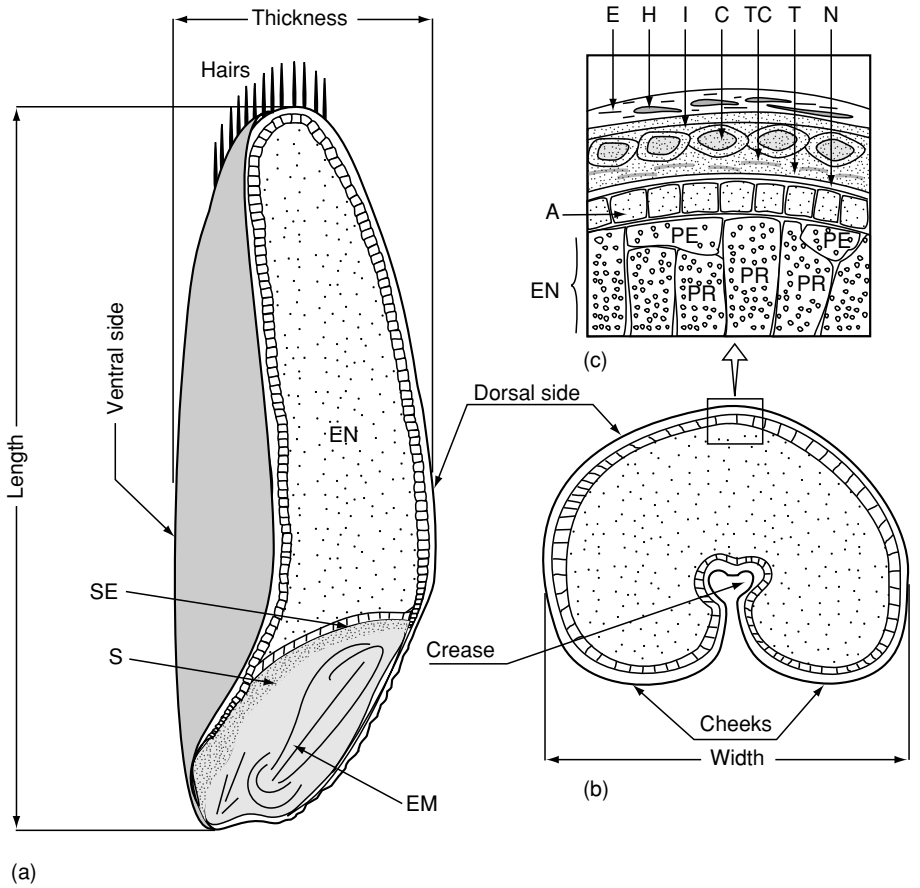

Figure 1 Main morphological components of a wheat kernel. (a) Longitudinal section; (b) cross-section; (c) segment of bran layer with aleurone and endosperm cells. than one-third the thickness found elsewhere. The aleurone cells are heavy-walled, essentially cube-shaped, and free starch. The aleurone cells can vary in thickness from 30 to 70 μm within a single kernel and have thick (6–8 μm), double-layered cellulosic walls.

Endosperm

The starchy endosperm, excluding the aleurone layer, is composed of three types of cells: peripheral, prismatic, and central. The peripheral cells are the last to be initiated during grain filling and tend to be smaller than the other endosperm cells (60 μm in diameter and 20–60 μm radially) and have thicker cell walls (8 μm). Several rows of elongated prismatic cells are found inside the peripheral cells. They extend inward to about the center of the cheeks and are about 150–200 μm. The central cells are more irregular in size and shape than are the other cells, and are located inside the central endosperm. The central endosperm cells are the first to be formed and have thinner walls (2 μm). Cell wall thickness also appears to vary among cultivars and between hard and soft wheat types. The differences between hard and soft wheat may be the result of selection: hard wheat (bread wheat) has been selected for high water absorption. The endosperm cell walls are composed of pentosans, other hemicelluloses, and beta-glucans, but not cellulose. The pentosans in them absorb large amounts of water. The endosperm cells are packed with starch granules embedded in a protein matrix. Starch is the major component of wheat endosperm, comprising approximately 64–75% of milled endosperm. Generally, the starch granules in wheat are classified into two size groups: large, lenticular (lens-shaped) A granules of up to 40 μm across the flattened side, and small, spherical B granules (2–8 μm in diameter), which are formed later in the grain filling process.

In common bread wheat (*Triticum aestivum*) the endosperm texture of grains varies both in texture

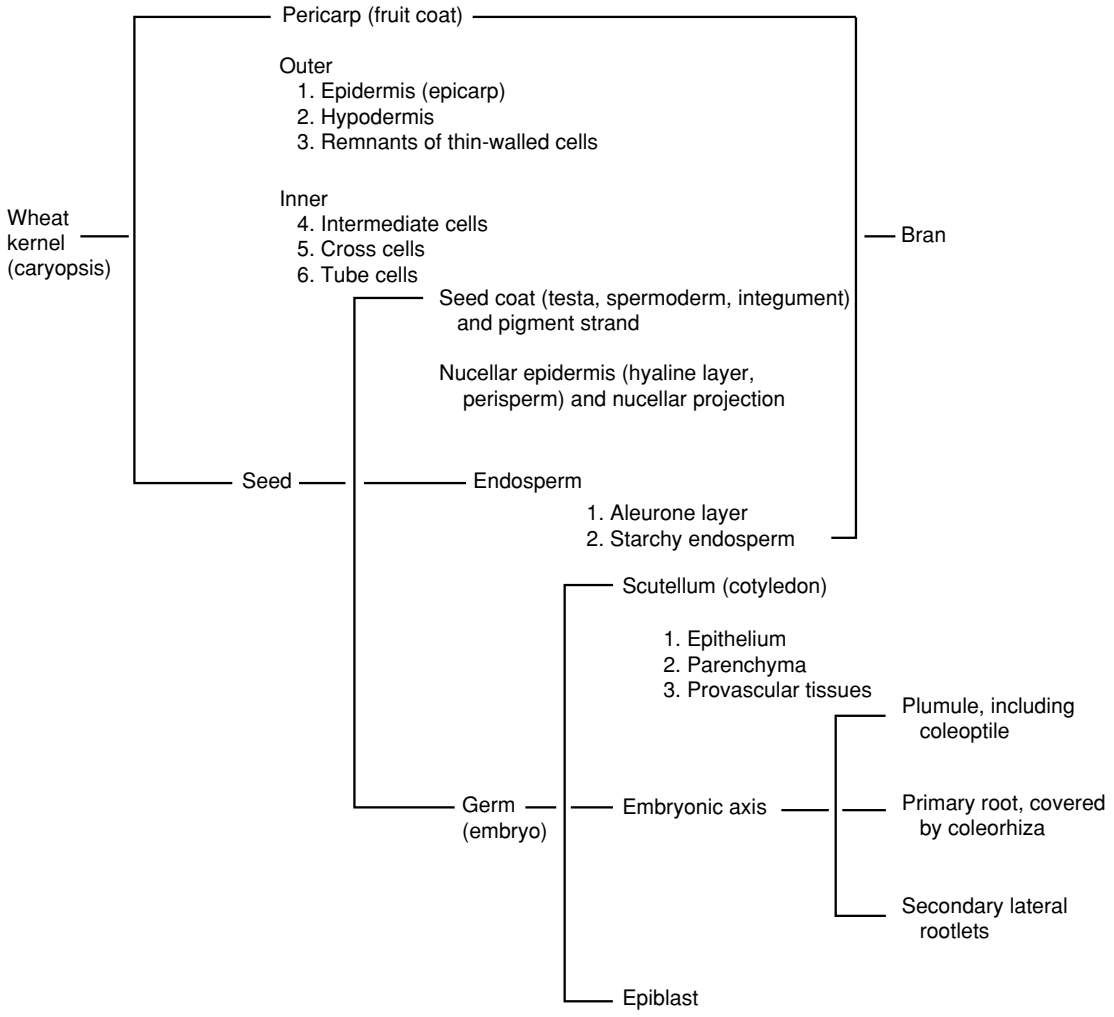

Figure 2 Parts of the wheat kernel. Reproduced from Hoseney RC (1994) Structure of Cereals. In: *Principles of Cereal Science and Technology*, 2nd edn. American Association of Cereal Chemists with permission.

(hardness) and appearance (vitreousness). In general, high-protein hard grains tend to be vitreous and low-protein soft grain tend to be opaque. Some wheat grains are vitreous or translucent in appearance, while others are opaque, mealy, or floury. In vitreous kernels, with no air spaces, light is diffracted at the air–grain interface but then travels through the grain without being diffracted again and again. With vitreous kernels, the protein shrinks but remains intact, giving a denser kernel. As expected, the presence of air spaces within the endosperm makes the opaque grain less dense. The air spaces are apparently formed during drying of the grain. If grain is harvested immature and dried by freeze-drying, it becomes entirely opaque. This shows that the vitreous character results during intensive drying in the field. It is also well known that vitreous grain wetted and dried in the field, or for that matter in the laboratory, will lose its vitreousness. In durum wheat (*T. durum*), which is much harder than the common hard bread wheats, a much larger number of broken starch granules occur when the grain is fractured.

Germ

The wheat germ is composed of two major parts, the embryonic axis (rudimentary root and shoot) and scutellum, which functions as a storage organ. The scutellum is adjacent to the endosperm and contains the remaining two-thirds of the grain's thiamin content. The germ is quite high in vitamin E (total tocopherol) and B-vitamins, and contains many enzymes. It is relatively high in protein (25%), sugar (18%), oil (16% of the embryonic axis and 32% of the scetullum are oil) and ash (5%). The sugars are mainly sucrose and raffinose. The wheat germ comprises 2.5–3.5% of the kernel. Recovery of the germs

during the milling process is an important step because of its value in the food and pharmaceutical industries.

Techniques of Wheat Grain Structure Study

Many cereal scientists and technologists have successfully employed the three main branches of microscopy – light (LM), scanning electron (SEM), and transmission electron microscopy (TEM) – to study the structure and composition of wheat and wheat-based products. The objective of the studies varies from gaining fundamental information on the accumulation of cellular constituents in the developing wheat grain to providing information which can improve our understanding of differences in processing ability or overall quality of wheat and wheat-based products. Microscopic observation should always be linked to other technological, chemical, or physical data. This information will assist the microscopist to select the most appropriate preparation techniques and evaluate the nature and magnitude of any artifacts that may be created. In many cases a number of microscopic techniques are used in order to gain the maximum amount of information on the original structure and composition of the product.

LM and TEM have the advantage that many staining techniques have been developed to assist recognition of constituents and provide data on chemical composition. However, these techniques generally require the use of solvents during sample preparation and these can give rise to artifacts (swelling, shrinking, or leaching of soluble material). Few specific stains are available for use in SEM, and constituents are generally identified by their shape or location. The advantage of SEM is that, in some cases, sample preparation artifacts can be minimized. Recently, X-ray techniques have been used to detect kernel cracks (Figure 3).

Light Microscopy

The main stages in the preparation of samples for examination by LM are fixation, embedding, sectioning, and staining. The aims of fixation are to preserve samples from attack by enzymes or microorganisms, render some constituents insoluble, and strengthen the sample to improve its structural integrity during sectioning. The most commonly used fixation is aqueous, buffered glutaraldehyde but specialized fixation has been developed for specific applications (e.g., fixation of lipid-rich samples). Baked samples, which have been heat-fixed, may not require chemical fixation. Embedding is used to provide additional support during sectioning, and commonly used embedding media are water and aqueous gums for cryostat microtomy, synthetic resins, or special waxes. Resins are generally used where thinner sections are required and are cut using glass knives. Cryostat microtomy and sectioning of wax-embedded samples are carried out using steel knives. Sections, supported on glass slides, are then usually stained prior to mounting and examination.

The stains commonly used for examination with transmitted bright-field illumination are listed in Table 1, together with their substrates. Fluorescence microscopy has been widely used and may rely on autofluorescence or the application of fluorescent dyes. The use of fluorescent dyes coupled to specific antibodies or lectins is rapidly expanding and several are listed in Table 2. Other coupled antibody techniques have been developed whereby colored reaction products are produced. Polarized light can be used to study external starch gelatinization or to provide detail of cell wall structure.

Scanning Electron Microscopy

SEM has a greater depth of focus than LM and therefore it is not necessary to section samples prior to examination. Samples are normally coated with a thin layer of an electrically conducting material, usually gold, platinum, or carbon, prior to examination. Samples of dry wheat (< 12% moisture) or similar products only require air-drying over a desiccant prior to coating. Samples which contain more moisture, may be rapidly frozen prior to dehydration using freeze-drying or critical-point drying. The

Table 1 List of stains commonly used for bright-field microscopy of wheat and wheat products

Substrate	*Stain*	*Comments*
Starch	Periodic acid–Schiff (PAS) reaction	Covalent, irreversible; may require aldehyde blockade if aldehyde-fixed
	Iodine or potassium iodide	Temporary stain only. Amylose stained blue-black; amylopectin stained red-brown
Protein	Fast green, Ponceau 2R, and other anionic dyes	Ionic, reversible. Intensity influenced by pH and differentiation
	Coupled antibody or lectin stains	Potentially more specific for selected protein
Lipid	Sudan IV or oil red O in 70% ethanol	Temporary stain only; intensity influenced by differentiation
Cell walls	Toluidine blue O	Metachromatic stain. Lignified walls stained green; testa stained purple; other cellulosic walls stained blue
	Zinc-chlor-iodide	Temporary stain only. Lignified walls unstained. Testa stained orange; other cellulosic walls stained blue
Yeast	Methylene blue, pH 4·6	Yeast stained blue; gluten unstained owing to low pH

Table 2 List of stains and conditions commonly used for fluorescent microscopy of wheat and wheat products

Substrate	*Stain*	*Comments*
Starch	Periodic acid–Schiff (PAS) reaction	More sensitive than bright-field PAS for thin sections
Protein	Acid fuchsin	More sensitive than bright-field stain for thin sections
	Coupled antibody or lectin	Potentially more specific
Lipid	Aqueous phosphine 3R	As aqueous solution, lipid distribution less likely to be altered compared to Sudan dyes
Cell walls	Autofluorescence	Walls containing lignin or phenolic acids autofluoresce
	Coupled lectin	Specific for selected glycoprotein

development of cold stages in SEM has obviated the need for drying and this technique, together with freeze-etching, has been successfully used to examine those cereal foods in which moisture is high and forms an integral part of the structure.

Transmission Electron Microscopy

Samples for TEM require fixation and thin sectioning. Initial fixation is usually with glutaraldehyde followed by fixation with osmium tetroxide. The fixed tissue blocks are rinsed, dehydrated, and embedded with a resin prior to sectioning. Heavy metal salts are used to stain the sections and enhance contrast; more recently, antibody staining has been developed whereby the antigenic sites are located at TEM level by the presence of colloidal gold particles, which are coupled to the antibodies.

Image Analysis and Other Quantitative Techniques

During the 1990s the value of all the above work was enhanced by high-tech methods such as magnetic nuclear resonance, laser, and autoradiography methods. More recently, the application of stereology techniques and automatic image analysis of grain have been used. Also, out-of-danger X-ray techniques have been proven to be highly suitable for visualization of inner cracks in kernels. Some internal cracks of wheat endosperm can occur in the field, even before harvesting, due to internal stresses which are mainly induced by high moisture gradients. The same process can be observed during intensive wetting of dry wheat kernel in laboratory conditions. In Figure 3 X-ray images of the same wheat kernel are presented with typical radial cracks of endosperm. X-ray detection makes it possible to identify the position of cracks and also to quantify cracks inside the kernel, and thus to evaluate the physical condition of the grain endosperm.

Wheat-Based Products

The major processing stages to be considered are milling, dough formation, and cooking. The structure of the wheat grain has important implications in the utilization of wheat-based products. This is because millers could grind the grain more finely than is now possible without damaging the starch – a common milling problem. Most breeding programs mainly emphasize grain yield, disease resistance, protein content, and quality while many other features that affect grain quality are considered second or not at all.

Milling

The aim of the milling processes is to remove the endosperm of grain efficiently from the germ and

surrounding bran so that the maximum yield of white flour is achieved with the minimum contamination of nonendosperm material. Fluted rollers are used to break open the grain and scrape the endosperm from the bran; smooth rollers are used to reduce the endosperm particles into flour. The moisture content of cleaned wheat is adjusted to between 15% and 17% prior to being fed to the fluter. This process is called conditioning and its aim is to facilitate separation of bran and endosperm, and to toughen the bran, thereby reducing the amount of ash in the flour.

Conditioning can be completed in approximately 6 h for soft wheat, but hard wheat may require 24 h or longer. The X-ray method has shown that added water moves rapidly through the bran layers, but may remain at the aleurone–endosperm interface for several hours. The rate of water penetration through the endosperm is dependent on protein content, initial moisture, and grain hardness. The air spaces that are present in the endosperm of the soft wheat allow water to move more rapidly and hence conditioning time is less than that required for hard wheat.

Of morphological factors which can influence the yield of clean, white flour, the shape of grain and the amount of endosperm within the grain are particularly important. Grain size has been shown to be significant; larger grains have a higher potential flour yield. Image analysis has been used to measure a large number of morphological parameters, and extraction has been shown to correlate with grain length parameters. However, the manner in which these parameters influence extraction is not clear and further work is required to determine their potential as a screening system at wheat intake.

In addition to the amount of endosperm contained in the grain, the efficiency with which bran and endosperm can be separated ('bran clean-up') is also a major factor influencing flour yield. Because of intrinsic differences in the structure of hard and soft wheat, they must be milled differently. The cell structure of soft wheat is very weak and readily broken. In addition, the endosperm of soft wheat appears to adhere more strongly to the bran. Durum wheat is designed to produce semolina, a granular material analogous to the farina or flour middling of the hard-wheat-milling process. Granular products such as semolina and farina are used for pasta, baby foods, and other specialty foods.

Endosperm hardness influences the manner in which grains fragment, and this can also influence flour yield. Grain hardness is, in turn, influenced by moisture and this is another objective of the conditioning process. The efficiency with which floury endosperm is removed from overlying bran and the degree to which bran is powdered or otherwise damaged are both influenced by the manner in which grain fractures during milling. If fracturing occurs at the boundary between the endosperm cell wall and cell contents (Figure 4), the endosperm is efficiently

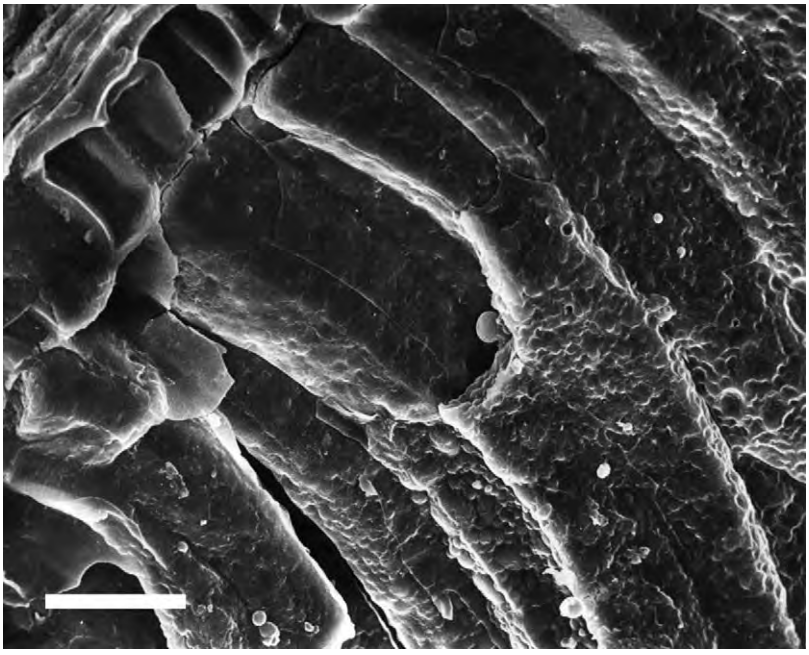

Figure 4 Scanning electron micrograph of subaleurone region of a mealy kernel of spring wheat var. Jara. Note that fracture has taken place at the interface between cell contents and endosperm cell wall. Bar, 50 μm.

removed from the bran, but the bran is fractured into small pieces.

When the endosperm is fractured intracellularly (Figure 5), bran clean-up is poor, but large pieces of bran are produced. The manner in which the grain is fractured is determined by both the inherent hardness of wheat grain and its moisture content. It is thus possible to optimize the relationship between grain hardness, bran clean-up, and powdering by adjustment of moisture level and conditioning time.

Another difference between hard and soft wheat is the point of the endosperm fragmentation. In hard wheat it takes place mainly at the boundary between adjacent cells as the contents of the cells are more firmly bound together by a continuous matrix protein. Thus, hard wheat endosperm can be removed more efficiently from bran as the shear forces imparted by the fluted rollers are directed along the boundary between adjacent endosperm cells towards the bran (Figure 6).

When they reach the bran, some of the forces are deflected along the aleurone–endosperm interface, facilitating separation of endosperm from bran. Of course, as the kernel is reduced to flour size, the hard wheat cell contents are also fractured. In soft wheat, the discontinuities in the protein matrix allow endosperm contents to break apart more easily and cleavage takes place intercellularly. Thus the shear forces are dissipated within the endosperm and are not redirected towards the bran.

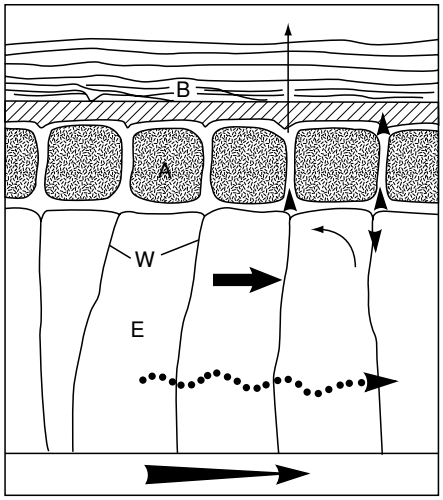

Figure 6 Diagrammatic representation of the forces acting on one endosperm cell of a wheat grain. Large arrow at the base of the figure indicates the direction of the shear force caused by the differential speed of the break rollers. In hard wheat the contents of the cell behave as one unit and hence the cell is cleanly torn from the overlying aleurone layer (indicated by the dashed line). In soft wheat the shear force passes through the content of the cell, as indicated by the dotted arrow. B, bran layer; A, aleurone layer; W, endosperm cell wall; E, endosperm. Reproduced from Wheat: Grain Structure of Wheat and Wheat-Based Products, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

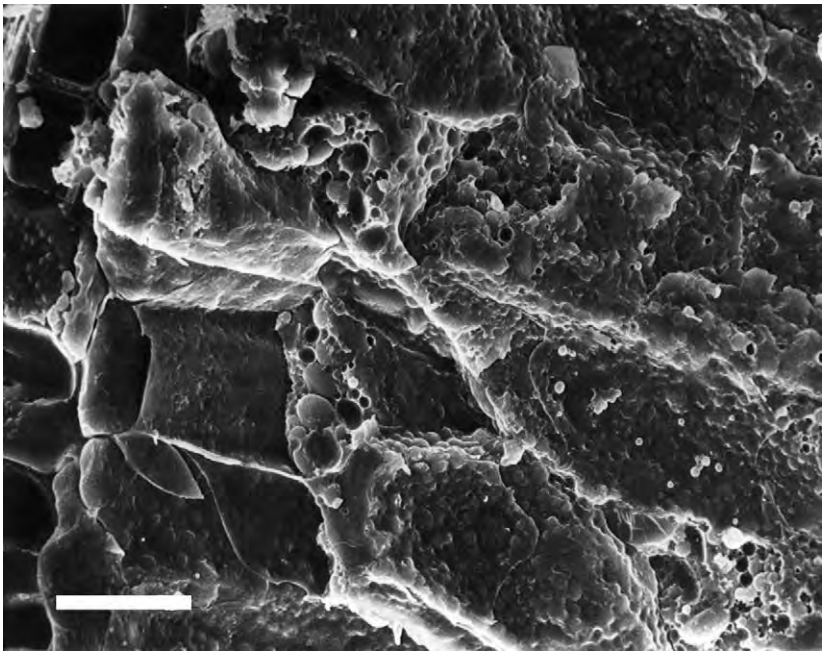

Figure 5 Scanning electron micrograph of the subaleurone region of a mealy kernel of spring wheat var. Jara. Note that the fracture is intercellular. Bar, 50 μm.

Microscopy can also be used to study the mode of action of different items of mill equipment and the effect of processing variables on flour quality. Starch damage is regulated by the amount of pressure applied by the smooth reduction rollers. The physically damaged granules absorb more water and are more susceptible to enzyme attack. A controlled level of starch damage is required for bread flours. The higher roller pressures produce thin flakes of endosperm and microscopic examination has indicated that the appearance of the protein is altered. The protein has been spread over the surface of the starch granules and its functional properties are adversely affected so that cohesive elastic gluten cannot be formed from the protein in the flakes. The appearance of the starch granules in flaked endosperm is usually similar to that seen prior to flaking and the damage is only apparent on hydration, when the granules absorb water and rapidly swell. The amount and nature of bran and wheat germ in stock or flour steams can be determined using microscopy. Bran contamination is important as it adversely influences flour color and ash. Typical wheat has an ash content of about 1.5%. However, the ash is not distributed evenly in the grain. The inner endosperm may only contain 0.3%, whereas the bran may contain 6%. Wheat germ has less effect on flour color, but reduces gluten strength and influences improved requirement in breadmaking.

Dough

When water is added to flour and energy is imparted to the dough by a mixer, the gliadin and glutenin proteins interact to form elastic, cohesive gluten. The mechanism and rate of gluten development depend on the level of water addition and rate of work input. In bread dough the level of water addition (55–62%) is sufficient to cause the mixer initially to pull the gluten away from the starch granules and form coarse, poorly connected masses (Figure 7). As mixing proceeds, these masses are gradually stretched out and become more interconnected and eventually form a uniform, continuous, extensible network, which surrounds the majority of the starch granules in the dough (Figure 8).

Such a gluten network gives dough a smooth external appearance and prevents loss of carbon dioxide produced by yeast during fermentation. This ultimately results in a fine porous structure that is typical of good-quality bread. If mixing is prolonged the protein may become overdeveloped and flow over all starch granules in a thin, veiling film. Carbon dioxide can diffuse through the thin film and escape from the dough, which ultimately results in a small, dense loaf of bread. Overdevelopment only takes place if rate of work input from the mixer is above the critical level for that flour and dough system. If the rate of work input is below the critical level, overdevelopment does not occur and the protein matrix gradually becomes more coarse and discontinuous. This phenomenon has been termed 'unmixing'. Much emphasis has been placed on the mixing process, but

Note the coarse gluten masses have become more interconnected and form a continuous network (N) that surrounds the majority of the starch granules (G). Bar, 60 μm. Reproduced from Wheat: Grain Structure of Wheat and Wheat-Based Products, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

the dough structure formed by mixing can be modified by the nature and timing of subsequent dough-processing stages. Dough pieces are usually molded into shape by passage through sheeting rollers. The dough molder can further develop the gluten network or unmix it. Which phenomenon occurs depends on dough strength and the time between molding and the previous processing stages. Generally, flour from the hard wheat grains gives a more adequate structure of dough for breads.

In other types of dough the pattern of gluten development is modified owing to lower levels of water addition or the presence of other ingredients, particularly high levels of fat. In flaky pastries or short, sweet biscuits, a continuous gluten matrix is undesirable, as it would give rise to a tough or hard end product.

The level of water addition in noodle or pasta dough is considerably less (30–33% addition) than that in bread, and no protein pullback occurs during mixing. The function of mixing in these processes is to insure uniform distribution and hydration of ingredients. The continuous gluten matrix is formed by sheeting rollers in the case of noodles and by high-pressure extrusion in the case of pasta.

Cooked Products

One of the major changes that can take place during the cooking of baked products is gelatinization of the starch granules, and the extent to which this has occurred is easily followed using polarized light microscopy. Starch gelatinization can also result in the formation of more significant sample preparation artifacts than occur when samples containing ungelatinized starch are prepared using similar techniques. In some products, the gelatinized starch granules absorb a large amount of water, and freezing or dehydration can give rise to artifacts. However, these can be minimized and appropriate allowance made when interpreting data. In expanded, extruded products the gelatinized starch granules have a high capacity for absorbing water and this gives rise to a high degree of swelling if aqueous reagents are used during processing for LM.

For gelatinization to occur there must be an appropriate combination of heat and moisture and in many baked products the latter can be insufficient. In bread, only a narrow zone of starch granules in the crust still shows some birefringence. However, in biscuits and pastries that contain a high level of fat the majority of the starch granules are frequently still birefringence (i.e., not gelatinized). In some cooked cereal foods the continuous phase, responsible for sample integrity, is gelatinized starch (e.g., products made from batters or from high-pressure cooker-extruders), whereas in others (e.g., all breads, noodles, and pasta) it is gluten. The nature of the continuous phase influences raw material selection and the organoleptic properties of the end product.

Generally, flour from soft wheat grains gives a structure of dough which is more adequate for cooked products. Recent investigations have shown that it is possible to identify the two molecular proteins called puroindolines – pin A and pin B – which correlate perfectly with wheat texture. This discovery should help wheat breeders in the future to develop a supersoft variety for making new kinds of cakes and cookies.

WHEY AND WHEY POWDERS

Contents

Production and Uses

J G Zadow, Mount Martha, Victoria, Australia

Origins and Characteristics of Liquid Whey

For many years, whey, the byproduct of casein and cheese manufacture, was treated as a waste product. Most whey was disposed of by feeding to animals, or running to waste in streams or on to the land. The comparatively small amount that was used was mainly directed at the animal-feed market. In the past few decades, however, environmental pressures, coupled with a recognition of the inherent value of whey solids, have resulted in the development of processes for the conversion of liquid whey into a range of valuable food ingredients. Today, whey and whey products are in considerable demand, both as replacement ingredients for more expensive existing products and, more often, as functional and nutritional ingredients in their own right. The use of whey products in the animal feed market is still very important, but in many major markets, such as the USA, domestic utilization of whey powder for human foods is greater than that for animal feed. In Europe, however, animal feed still remains the dominant use for whey powder. This section reviews the source of wheys, compositional factors affecting utilization, alternatives for processing of whey properties of whey powders, and their uses in the food industry.

Little information is available on worldwide production of whey. In 1987, it was reported that the annual world production was about 110 million tonnes, of which about 47 million tonnes were produced in Western Europe, 27 million tonnes in North America, 30 million tonnes in Eastern Europe, and 8 million tonnes elsewhere; Australia produces about 1.8 million tonnes. Given the considerable increase in cheese production worldwide since 1987, it is probable that the current world production of whey is up to 50% higher than the figure quoted above.

Therefore, two pressures exist on whey processors to increase whey utilization. First, there is the rapid increase in the total volume of whey produced, owing to increasing cheese manufacture, and second, there is much greater pressure from environmental regulatory bodies to reduce disposal, and increase utilization of whey. A detailed survey of whey utilization and disposal practices was carried out in Australia in the early 1990s, and many of the conclusions are probably applicable to other major whey-producing countries. In Australia, about 50% of the total whey produced is used (an increase from 46% utilization in the mid-1980s), with the remainder being disposed mostly on to land. However, in spite of the considerable increase in whey production over the past decade, the percentage of whey used is believed to have remained approximately constant. In the 1980s in Australia, membrane processing was a popular means of whey utilization, representing about 25% of the whey used. By the early 1990s, this level had decreased to about 10% and is currently believed to have fallen even lower. By far the greatest means of whey utilization now is via whey powder manufacture (of interest is the fact that, although membrane processing represented only a comparatively small amount of the whey processed, all of the permeate produced was used).

It should be noted that the greatest disposal problems were encountered by factories that produced only moderate amounts of whey. The major options for disposal of whey, either through drying or through membrane processing and permeate utilization, were often too capital-intensive and scale-sensitive to be an option for such companies. The development of economic whey utilization techniques for such manufacturers would be of considerable benefit to the industry.

Source and Composition of Wheys

Whey is the watery substance remaining after coagulation of the casein in milk, either through the

addition of acid (as in casein manufacture) or through the action of a protease such as chymosin (as in cheese manufacture). Clearly, the composition of whey varies considerably, depending on the source of the milk and the manufacturing process involved. However, on average, whey contains about 65 g of solids per kilogram, comprising about 50 g of lactose, 6 g of protein, 6 g of ash, 2 g of nonprotein nitrogen, and 0.5 g of fat. Casein whey generally has a significantly higher level of ash than cheese wheys.

It is convenient to classify whey into three major types:

1. Sweet wheys: titratable acidity 0.10–0.2%, pH typically 5.8–6.6. This category would include wheys produced from chymosin-coagulated cheeses with a low level of acidity.
2. Medium acid wheys: titratable acidity 0.20–0.40%; pH, typically 5.0–5.8. This class could include whey from the manufacture of fresh acid cheese such as ricotta or cottage cheeses.
3. Acid wheys: titratable acidity greater than 0.40%, pH less than 5.0. This class would include casein wheys made by addition of mineral acids, and some fresh acid cheese wheys.

A detailed composition of dried sweet and acid wheys is shown in Table 1.

The following points are of particular relevance in assessing options available for the processing of whey streams:

1. Whey has a total solids of about 6.5%, i.e., it is a fairly dilute product. Thus, to produce 1 kg of whey powder requires the removal of about twice as much water as does the production of 1 kg of milk powder. Removal of water is a costly unit operation, and this factor alone mitigates against many options for whey processing.
2. Of the total solids in whey, more than 75% is lactose. The effective utilization of whey is therefore inextricably linked with the effective utilization of lactose. Unfortunately, lactose is not a commercially valuable sugar, as it is not particularly soluble, and it is not particularly sweet (Table 2). These factors limit the commercial applications of whey solids considerably.
3. The proteins present in whey comprise about 50% β-lactoglobulin, 25% α-lactalbumin, and 25% other proteins. Whey proteins have a very high nutritional profile, are rich in essential amino acids, and can have excellent functional properties. Clearly, the whey proteins are the most valuable components of whey, and most whey-processing operations (e.g., ultrafiltration, manufacture of lactalbumin) therefore aim to increase

Table 1 Typical composition (%) of sweet and acid whey powders, and whey protein concentrates

the proportion of whey proteins in the end product.
4. The mineral content and low pH of casein wheys severely limit their commercial exploitation. The vast majority of whey-based products are manufactured commercially from low- or medium-acid wheys.
5. Whey has a very high biochemical oxygen demand (BOD), which poses major difficulties for its disposal. It should be noted also that a number of options for whey processing, particularly those that increase the proportion of protein in the product, also result in the production of a waste product, which contains most of the lactose originally present. This stream, in turn, requires further processing. Thus, the problems posed by the biochemical oxygen demand of the original whey are often only slightly affected by many of the whey-processing options.

Processing Options

The processing options for whey fall into four main areas:

1. Those concerned with simple removal of water (spray or roller drying to yield whey powder).
2. Those concerned with increasing the ratio of protein in the end product (ultrafiltration for the manufacture of whey protein concentrates, fractionation processes for the manufacture of protein isolates, heat treatment for the production of lactalbumin).
3. Those concerned with utilization of the lactose in whey (treatment with lactase or heat/acid for lactose-hydrolyzed products, fermentation to a range of products such as lactic acid, citric acid, and single-cell protein).
4. Those designed to alter the mineral composition of the product (electrodialysis and ion exchange for the manufacture of demineralized products).

Each of these is considered in turn below.

Drying of Whey

The production of whey powder from whey is a mature technology. Perhaps the major difficulty involves the holding period required prior to drying in the manufacture of nonhygroscopic whey powder. Such a holding period (sometimes also involving seeding) is required to allow for crystallization of the lactose into a nonamorphous, nonhygroscopic form prior to drying. The development of technology to reduce this holding period could result in significant savings to the industry.

The spray drying of whey is a fairly straightforward operation, with conditions employed similar to those used for the spray drying of milk. Thus, the whey is concentrated to 40–70% total solids and spray (or roller) dried to a moisture content of less than 5%. As indicated above, the drying of whey is complicated by its high lactose content. Lactose exists in two isomeric forms, α-lactose and β-lactose. α-Lactose crystallizes as a hydrate, whereas solid β-lactose contains no water of crystallization. However, when solutions of whey are dried rapidly, there may be insufficient time for the α-lactose to form as the monohydrate, and it forms as amorphous α-lactose. The dry lactose in the whey product is then essentially in the same form as in the liquid. Neither α-lactose hydrate nor β-lactose is hygroscopic. However, amorphous α-lactose is highly hygroscopic and will absorb moisture from the air, resulting in a hydrate that occupies more space than the amorphous form. This effect causes the commonly observed lumping and caking in many whey powders.

Both hygroscopic and nonhygroscopic whey powders are manufactured. The former are produced by simple drying of the whey concentrate. The manufacture of nonhygroscopic whey powders relies on the conversion of much of the lactose in the liquid concentrate to a crystalline form prior to drying. This is achieved by holding the concentrate under appropriate conditions to allow for extensive formation of α-hydrate crystals. The traditional process requires holding the concentrate for about 16–24 h after addition of seeding crystals. This process requires holding tanks of considerable size and is energy-intensive (good agitation is required), and the viscosity of the concentrate must be as low as possible (heat treatment of the concentrate should be minimized). Recently, a new process has been described, based on the fact that most of the lactose is crystallized in 3–4 h. In this process, the whey is concentrated to 53–55% TS, flash-cooled to about 30 °C, and seeded. The product is pumped to a conventional nonagitated tank, representing 2–3 h of production. The semicrystallized concentrate is pumped to a second flash cooler and cooled to 15 °C, and then to a second crystallization tank, where it is held ready for spray drying. Alternatively, a process similar to instantizing may be used, in which the surface of the partly dried whey powder particles is partially humidified prior to completion of the drying operation. This stage permits additional crystallization of the α-lactose during drying.

The market for permeate powders is not as yet well developed, probably because of difficulties in obtaining a consistent product, and difficulties encountered during drying caused by the high-lactose/low-protein content of the product. Worldwide, the

difficulties encountered in spray-drying permeate have led some companies to cease production of permeate powder, and to adopt perhaps less profitable alternative technologies. Research suggests that the drying properties of permeate may be considerably influenced by the pH and of course the crystallizing conditions. The development of successful means for the drying of permeate would be of particular value to the industry, as the production of permeate powder is a simpler option for many companies than, for example, the production of crystalline lactose. In response to this need, equipment supply companies are continuing to develop systems specifically for permeate drying.

Means for Increasing the Protein Content of the End Product

Whey solids contain about 11% protein. Many of the most popular methods of whey treatment aim to increase this level, with end products containing between 35% and virtually 100% protein. It should be noted that each of these methodologies results in a waste stream high in lactose, which will pose separate utilization or disposal problems.

Ultrafiltration Ultrafiltration is the most common method used by the dairy industry to produce a range of whey products with an increased protein content, known as whey protein concentrates (WPCs). Ultrafiltration relies on the passage of whey near a membrane with a pore size such that low-molecular-weight materials such as lactose and salts pass through the membrane, whereas higher-molecular-weight components, such as proteins, are retained. On ultrafiltration of whey, therefore, the solids content of the product retained by the ultrafiltration membrane (the retentate) is higher in protein and lower in lactose than the original whey, and the solids content of the product that passes through the membrane (the permeate) is high in lactose and ash, and has minimal protein content. WPCs are produced from a wide range of wheys, generally to protein contents of 35%, 50% and 75% (Table 1).

WPC containing 35% protein is often used as a skim milk powder replacer in applications where the specific functionality of skim milk powder is not important (a WPC of 35% protein content is generally significantly less expensive than skim milk powder). WPC with a protein content of 50% is not widely manufactured and generally is used for specific applications only. WPCs containing 75% protein can have very desirable functional properties, and these can be readily manipulated by modifying the manufacturing process. Such products often have excellent water-binding, gelation, and emulsifying properties, making them sought after by the food industry as functional ingredients.

Production of lactalbumin Whey proteins are heat-sensitive and can be precipitated by heat treatment under appropriate conditions of pH and ionic strength. This property is exploited in the manufacture of lactalbumin. (Note that lactalbumin, the product of heat precipitation of the proteins from whey, contains a mixture of denatured α-lactalbumin, β-lactoglobulin and other whey proteins. 'Lactalbumin' should not be confused with α-lactalbumin.) In the manufacture of lactalbumin, whey is heated to denature coagulate and precipitate the whey proteins; the sediment is recovered by settling and decantation (or centrifugation), washed to remove excess salts and lactose, and the product recovered by centrifugation or filtration prior to drying, grinding, and bagging. The heat treatment used in the manufacture of lactalbumin results in extensive denaturation of the whey proteins, resulting in a product of poor functionality. Therefore, lactalbumin finds its best applications in products where protein fortification is necessary, but it is not required to provide any functional properties.

Isolation and fractionation of protein In contrast to the precipitation of whey proteins by heat treatment in the manufacture of lactalbumin, protein isolation and fractionation methodologies aim to separate the proteins from whey in such a form that they remain, as far as possible, fully undenatured and thus retain their functionally. These products (protein concentrates and isolates) have a high protein content and can have exceptional functional properties of considerable value to the food industry.

Protein concentrates contain the whey proteins in about the same proportions as that in whey. (Note that, in this article, the term 'protein concentrates' is used for high-protein products containing the individual whey proteins in about the same ratio as that present in whey, the term 'whey protein concentrate' is used for such products manufactured by ultrafiltration, and the terms 'protein isolates' and 'protein fractions' are used to refer to high-protein products with a higher ratio of a particular protein than that present in whey.) Such protein concentrates are generally manufactured by the use of a nonspecific absorbent to bind the proteins in whey, followed by elution of the proteins by treatment of the absorbent with a specific eluent. Absorbents that have been commercially used include carboxy-methylcellulose and a range of mineral oxides. Although these absorbents are comparatively nonspecific, they can show a preference for binding particular proteins

under set conditions of pH, temperature, and ionic strength. Thus, these processes can be used to produce protein isolates, for example with a higher ratio of β-lactoglobulin to α-lactalbumin than that present in whey.

Protein fractionation technology is also developing, which relies on separation of α-lactalbumin from β-lactoglobulin on the basis of their different solubilities under specified conditions of pH, temperature, and ionic strength. It is therefore possible, for example, to separate by sedimentation most of the α-lactalbumin from whey by careful manipulation of processing conditions. Both the α-lactalbumin that has sedimented and the residual soluble protein (mostly β-lactoglobulin) are comparatively undenatured and thus retain their high functionality. The conditions employed in these processes are very mild and do not result in any denaturation of the whey proteins. With such processes, it is therefore possible to produce isolates rich in β-lactoglobulin (with an extremely high gel strength) and α-lactalbumin (a product that may have considerable potential in non-allergenic infant foods).

Lactose-processing Options

The options for treatment of whey involving lactose may be divided into three groups – those involving a fermentation step, those involving separation of the lactose and its utilization, and those involving enzymatic hydrolysis of the lactose to produce galactose and glucose.

Fermentation Many options for the fermentation of whey are described in the literature, including the production of biogas, biomass, ethanol, lactic acid, and citric acid. However, the dairy industry worldwide has not taken up such opportunities to any great extent.

Separation of lactose In many respects, this is a most attractive option, as it can be used also as a process for the treatment of waste streams from other whey treatment operations such as ultrafiltration. The manufacture of lactose (normally α-lactose hydrate) generally involves the removal of protein, concentration, refiltration, further concentration, induction of crystallization, and separation of crystals with a basket centrifuge.

The production of lactose in the major dairy countries is increasing rapidly – in the USA, production has tripled in the past 14 years, with exports doubling in the past 6 years, and in Australia, production has at least doubled. Similar increases in Europe have benn reported. Overall, the lactose market is holding steady through increased applications for the product, particularly in the confectionery field.

Hydrolysis of lactose The hydrolysis of lactose yields the sweet soluble sugars, glucose and galactose, thus increasing the applications of the product. Such hydrolysis can be carried out by treatment of whey with lactase (β-galactosidase) or by treatment of deproteinized whey at an elevated temperature and low pH. It should be noted that it is difficult to dry hydrolyzed wheys, because of the tendency of the monosaccharides formed by the hydrolysis to produce glasses on the surface of the drier.

It is often suggested that lactose-hydrolyzed products are attractive commercial options, first, because hydrolyzed products will be in demand by lactose-intolerant people, and second, the increased sweetness of the products makes them attractive to the general public. In fact, the demand by lactose-intolerant members of the community has not been significant, and the benefits of increased sweetness are of only marginal commercial value.

Hydrolysis of lactose may be carried out by a number of processes, including heat/acid treatment (for permeate only) and enzymic hydrolysis (for whey, permeate, and WPC). A number of hydrolyzed whey products are manufactured, using both immobilized and free enzyme technology. In Sweden, a beverage ('Nature's Wonder') is based on hydrolyzed whey; in Finland, hydrolyzed whey is used by bakeries and in a flavored whey beverage. In the UK, hydrolyzed whey has been used in confectionery products, generally to replace sweetened condensed milk. However, in spite of the apparent potential of these products, market development appears to be proceeding only slowly.

Changes in Mineral Composition

The mineral composition of whey, particularly casein whey, is such that it deleteriously influences the taste and applications of the product. Whole or partial demineralization of whey is therefore a popular option with manufacturers. In the past, this has been accomplished most often by treatment of whey by ion exchange (no preferential removal of ions) or electrodialysis (preferential removal of monovalent ions). However, these methods appear to be falling into disuse both because of their high cost and because of large volumes of intractable effluents that they produce.

More recently, an option for demineralization using 'open' reverse-osmosis membranes has been developed. This technique, known as ultra-osmosis, uses membranes that allow the passage of ions and

water, whilst retaining all other whey components, including lactose. Ultra-osmosis is rapidly gaining in application, in spite of the fact that its ability to reduce mineral content to much below 50% of original levels is limited. However, it does allow for preferential removal of monovalent ions, a considerable advantage.

Worldwide, demand for demineralized whey products is increasing rapidly, with emphasis on products containing reduced monovalents.

Applications

Whey solids may be used an ingredient in products such as calf milk replacers, infant formulae, whey cheese, beverages, baked goods, icecream and other dairy products, comminuted meat products, and imitation milk products. In most cases, the whey solids contribute little to the functionality of the product, offering only a comparatively low-cost source of protein, carbohydrate, and calcium.

Similarly, lactalbumin is used in foods where protein fortification is required, but additional functionality is not essential. Lactalbumin is commonly used in products such as baked goods and comminuted meat products.

WPCs are used where both protein fortification and functionality are required, although WPC of 35% protein content is generally used directly as a cost-effective skim milk powder replacer. WPC of 75% protein content, with its excellent gelation properties, is often used as a cost-effective egg white replacer.

The main market for demineralized wheys is in the formulation of cows' milk-based infant formulae with a composition closer to that of human milk. Demineralized wheys also may be used effectively as beverage ingredients, where the saltiness of the undemineralized product might normally preclude its use.

Lactose is used in sauces, instant drinks, and meat products, where its low sweetness and ability to enhance flavor are advantages. Lactose is also used extensively in the confectionery and baked goods industries. Highly purified lactose is also used in the pharmaceutical industry for tablet manufacture and as a substrate for the manufacture of penicillin and other fermented products.

Applications of hydrolyzed wheys include ingredients in foodstuffs, such as beverages, and other products, such as most animal foods, where it can be used as a humectant to replace the more expensive glucose commonly used.

Protein Concentrates and Fractions

J G Zadow, Mount Martha, Victoria, Australia

Introduction

Over the past 20 years, whey processing has been revolutionized by the development of methodologies for the manufacture of highly functional food products containing a higher proportion of protein than that found in whey. Functionality has been defined as 'any property of a food or food ingredient, except its nutritional ones, that affects its utilization.' The main functional properties of whey protein products used for food applications include solubility, whipping, flavor, water binding, thermal extrusion, viscosity, gelation, foam formation, and emulsification. The technology involved in the manufacture of functional whey-based ingredients generally involves either ultrafiltration or the selective separation of whey proteins (either by adsorption technology or by utilization of the different solubility characteristics of whey proteins under specified conditions of pH and temperature). This article will discuss the properties of the major proteins of whey, whey protein products

and methods for their manufacture, and the application of such products in the food industry.

Characteristics of Whey Proteins

Whey proteins are those which remain in solution after removal of the caseins from milk, either by treatment with chymosin or by acidification. The distribution of proteins in milk is shown in Table 1.

β-Lactoglobulin is the principal protein in whey, comprising about one-half of the total protein present. It occurs as a number of variants, and has a monomer molecular weight of about 18 000. It should be noted that β-lactoglobulin exists as a monomer only outside the pH range 3.5–7.5. Inside this range, it generally exists as a dimer although, under certain circumstances, some variants may form an octomer. β-Lactoglobulin is comparatively heat-sensitive and may be denatured by heat treatment much above 60 °C. α-Lactalbumin has a monomer molecular weight of about 14 000, and is somewhat more heat-resistant than is β-lactoglobulin. There are many other serum proteins (including immunoglobulins) in whey, most of which are readily heat-denaturable. For example, heat treatment of skim milk at 70 °C for 30 min denatures only 6% of the α-lactalbumin, but 32% of the β-lactoglobulin, and 89% of the immunoglobulins; cumulatively, such a heat treatment results in denaturation of about one-third of the total serum proteins. In whey, heat treatment is often carried at a pH quite removed from that of milk. It should be noted that the pH of heat treatment of whey has a considerable influence on the magnitude of the degree of denaturation of each of the whey proteins.

As globular proteins, both α-lactalbumin and β-lactoglobulin have the potential to be highly functional food ingredients. Unfortunately, many of the processes used for whey protein recovery result in their partial denaturation, which generally reduces the functionality of the product.

Table 1 Typical protein composition of milk

	g per 100 g milk

Major Products and Applications

Whey Protein Concentrates

Whey protein concentrates are manufactured by the ultrafiltration of whey. In this process, whey is passed against a semipermeable membrane, which selectively allows passage of low-molecular-weight materials such as water, ions, and lactose, whilst retaining higher-molecular-weight materials such as protein in the retentate. The retentate is then further concentrated by evaporation and spray-dried to yield whey protein concentrates (WPCs). WPCs are generally available commercially with a protein content of about 35, 50, or 75%. For the higher protein products a process known as diafiltration is employed, in which water is added to the retentate during manufacture to wash out more of the low-molecular-weight materials from the retentate.

The development of markets for WPCs has been slowed by the inconsistent quality and composition of the product, particularly during the early years of development. WPC 35% is often considered to be a skim milk powder analog, and for many skim milk powder applications, it may be utilized as a direct replacement. However, it is only in recent years, with improved product consistency and quality, that markets for this product have firmed. It should also be noted that this is not a particularly lucrative market for whey producers, as 35% WPC is generally priced at a significant discount to skim milk powder.

A WPC with a higher protein content, particularly the 75% product, is generally required by the end user to have defined and reproducible functionality. Again, however, inconsistent quality, due perhaps to a lack of understanding of processing conditions on functionality development, has slowed market acceptance. In some cases, however, supplies of 75% WPC have outstripped demand and this highly nutritional product has been sold for animal feed on the basis of its protein content.

A further problem with WPC development is the need to develop markets for the products of permeate processing. Whilst lactose markets are strong and continuing to increase, significant concerns about the ability of the industry to continue to cope with the increasing levels of permeate production worldwide remain.

There appears to be a slowing in the rate of installation of ultrafiltration membrane processing for the production of WPC by the industry. This is probably the result of a number of factors, including:

1. Such technology is only applicable to major whey producers, and many have already installed this technology (although some of these are reverting

to the production of whey powder for whey utilization).

2. The market response to the products has to date been disappointing. The early promise of extremely high returns for high-protein (>75% protein) WPC has often not been achieved, mostly because of inconsistent functionality of such products. However, there is the potential for good returns provided that quality and functionality can be maintained consistently. Products containing 35% protein have in general not proven particularly commercially attractive.
3. Adopting this technology does not solve any disposal problems – the permeate still requires processing or disposal. Further, given the fact that it is virtually free of protein, permeate is generally a less commercially attractive product to utilize than whey.

The inclusion of WPC into foodstuffs may confer a wide range of potential functionality. Important functional properties include solubility, foaming, gelation, emulsification, elasticity, viscosity, and organoleptic characteristics. It is possible, by manipulating compositional factors and processing conditions, to manufacture WPCs with a wide range of functionality, combining many of the above attributes. In general, WPCs of lower protein content have more limited functionality than those of higher protein content. In many cases, WPCs serve more than one functional purpose in foods. For example, as whey proteins remain soluble over a wide pH range, in particular near pH 4.5, they may be used in acidic drinks as protein fortifiers. WPCs can be used as water binders in products such as baked goods and processed meats. In such cases, processing temperature must be sufficiently high to denature the whey proteins, but not so high as to disrupt their water-binding properties. WPCs can also have excellent gelation characteristics, and can assist in the formation of heat-induced gels in meat products and baked goods. WPCs with good emulsification properties would find applications in products such as sausages, salad dressing, coffee whitener, and soup. WPCs may also have useful foaming properties, producing very stable foams on whipping. Applications for such products again vary depending on the functionality required in the end product, but would include desserts, cakes, and whipped products.

A major challenge to whey protein researchers and producers is to determine precisely the compositional and processing properties which influence the final functionality of WPC. It is well known that factors such as the source of whey, its protein content, the heat treatment applied to the whey or ultrafiltration retentate during manufacture, and the lipid content and mineral content of the product influence functionality, but detailed knowledge of mechanisms is far from complete. The manufacture of WPCs with such widely varying and yet specific functional properties certainly requires the careful control of manufacturing conditions. Currently, much ultrafiltration processing of whey is carried out on an *ad hoc* basis, with little understanding of the effects of individual processing parameters on the conformation or structure of the individual proteins, or on the functionality of the product. It should also be noted that the functionality of the whey products can be permanently impaired by the use of excessive temperatures or extremes of pH during processing.

Mineral composition is also an important factor determining whey protein functionality. Many of the functional properties of WPCs are considerably influenced by either demineralization or by the addition of calcium salts. Clearly, the manufacturing process used in the whey production process will influence the mineral content of the product, and thus its functionality.

Whey Protein Isolates

There have been some commercial developments recently in the manufacture of whey protein isolates. Generally these products are manufactured by the use of specific complexing agents which bind with the proteins, allowing their removal from the whey. The processes use absorbents such as carboxy-methylcellulose (such as in the Bi-Pro process), or inorganic oxides (such as with Spherosil reagents) or complex formation (with reagents such as polyphosphates). The end products may then be sold in the form of these complexes, or the proteins eluted and dried for sale as protein isolates. The products of these operations are highly functional, high-value-added whey protein fractions which have high specific functionality and generally sell for a high premium. Those products sold as complexes have less general applicability, and attract reduced profit margins. However, in spite of their availability, the market for these products has proved to be somewhat limited, and demand has not been as high as expected. It is believed that some difficulties have been experienced in insuring that the products of such processes have consistent functionality when utilized in foods.

Whey Protein Fractions

Whey proteins can be recovered as mixtures of the proteins in whey by use of the technologies outlined above. Commercially, ultrafiltration technology is dominant for such processes. However, WPCs

manufactured by ultrafiltration have not, in general, lived up to their promise of offering reliable highly functional cost-effective ingredients to the food industry. In particular, the functionality of WPCs is often poor and/or highly variable. Further, the functional properties of WPCs are often well below those expected from their protein composition. This may be due to mechanical or heat damage to the proteins during manufacture, or to the presence of other compounds in whey which inhibit the development of full functionality.

To overcome such difficulties, a number of alternative options for whey protein fractionation have been developed. These aim at the manufacture of protein fractions containing a higher proportion of a particular protein than that present in whey solids.

Ion exchange Ion exchange or adsorption was discussed briefly above as a means for the separation of proteins from whey. However, the adsorbents used can also selectively adsorb proteins from whey under specified conditions of pH and temperature. For example, under appropriate conditions, certain Spherosil adsorbents can selectively remove a significant proportion of the β-lactoglobulin from whey, leaving a fraction rich in α-lactalbumin as the effluent from the adsorption process.

Such processes generally use batch operation, involving adsorption, elution, and regeneration.

Ion depletion This technology relies on the fact that β-lactoglobulin is insoluble in solutions of low ionic strength, particularly in the vicinity of its isoelectric point. This principle has been used in a number of studies which have led to pilot-scale separation procedures. The products in general were substantially β-lactoglobulin, although other proteins were present. However, the yield of the process was poor, with only about 30% of the protein present in whey recovered as the precipitate.

Thermal separation A series of studies have recently shown that the solubility of α-lactalbumin decreases very markedly under certain conditions of pH, temperature (below that of denaturation), and ionic strength. These conditions have no effect on the solubility of β-lactoglobulin. Clearly, this difference in solubility characteristics may be exploited as a means of preparing whey protein fractions. Two processes based on this principle have reached the stage of near commercialization – one in France, the other in Australia. The major difference between the two is the starting material – the French process uses untreated whey while the Australian process uses whey concentrated to 12% solids by ultrafiltration. In the Australian process, the pH of the ultrafiltration retentate is adjusted to 4.2, and the process of aggregation initiated by heating of the mixture to 64 °C for 5 min. During this process, the α-lactalbumin aggregates into small particles. The product is then diluted with water to assist in the formation of larger aggregates, and the sediment (which is mostly α-lactalbumin) separated, for example, by centrifugation or microfiltration. The separated sludge is evaporated and dried, to yield a fraction rich in α-lactalbumin (α fraction). The supernatant is subjected to ultrafiltration and diafiltration (to assist in the removal of ash and lactose), and dried to yield a fraction rich in β-lactoglobulin (β fraction). The α fraction contains about 50% protein (mostly α-lactalbumin) and 40% lactose, while the β fraction contains about 75% protein (mostly β-lactoglobulin) and 15% lactose.

It is probable that the products from the French and Australian processes have similar functionality – in each case, the β fraction is low in lipid content. The β fraction has been shown to have excellent gelation characteristics (much greater than those shown by the best 75% WPC). Further, the gel strength exhibited by the β fraction can readily be manipulated by minor modifications to processing conditions. Clearly, this product has considerable potential as a highly functional food ingredient, with applications similar to those of egg white.

The α fraction contains most of the lipid and phospholipid in whey, and should be expected to show excellent emulsifying properties. A further application for the α fraction is in (humanized) infant foods. Although whey-based products are common components of infant foods, whey contains a significant amount of β-lactoglobulin, a protein which has no analog in human milk. On the other hand, human milk does contain an analog to bovine α-lactalbumin. Clearly, therefore, infant foods based on (β-lactoglobulin-free) α fraction may offer considerable advantages in reducing allergenic response.

An alternative thermal procedure is used in the manufacture of lactalbumin. In the manufacture of this product, whey is heated to denature, coagulate, and precipitate the whey proteins present, which are recovered by settling and decanting, or by centrifugation. The product (which should not be confused with α-lactalbumin) is generally virtually fully denatured, and comprises a mix of the heat-labile proteins present in whey. Given the fact the functionality is generally associated with proteins being present in a globular native state, it is not surprising that lactalbumin shows little functionality. However it finds specific applications in the food industry, particularly in biscuits and baked goods. Modified techniques for the preparation of lactalbumin, involving somewhat

less severe heat processing, have been reported, with indications that such products show markedly improved solubility and functionality.

Ferric chloride fractionation Techniques have been described in the literature for the treatment of partially demineralized whey with ferric chloride to precipitate β-lactoglobulin selectively as a ferric complex at near neutral pH. By contrast, at an acidic pH, almost all proteins except β-lactoglobulin are preferentially precipitated. In this case, the separated complex can be solubilized by a change in pH to near neutral, and the ferric ion separated by, for example, ultrafiltration. Such processes do not appear to be close to commercialization.

Removal of Lipid from Whey and Whey Protein Fractions

WPCs inevitably contain levels of residual lipid, in spite of attempts by producers to remove as much as possible As would be expected, levels of residual lipid increase with increasing protein concentration. Reports have suggested levels of about 2.1% fat in 35% WPC, 3.7% fat in 50% WPC, and 7.2% fat in 80% WPC. As can be seen in the higher protein content products, the level of lipid is quite significant. Removal of the lipid from whey results not only in an improvement in ultrafiltration flux, but also markedly improves product functionality. For example, higher levels of lipid have been shown to be detrimental to the foaming and flavor characteristics of WPC. Removal of lipids increases overrun whipping substantially, as well as increasing foam stability. Higher levels of lipid also inhibit the heat gelation properties of WPC.

The composition of the lipid fraction in WPC is not similar to that of bulk milk, being higher in phospholipid and milk fat globule membrane material.

Overall, therefore, the lipid fraction in whey is believed to inhibit much of the potential functionality of WPCs, and whey protein fractions. The lipid fraction in whey is also partly responsible for the fouling of the membranes on ultrafiltration processing of whey. Removal of the lipid fraction can thus improve processing efficiency (if ultrafiltration is employed) as well as product functionality.

Removal of such lipids from whey prior to ultrafiltration or fractionation can be achieved by microfiltration using membranes of an appropriate pore size to remove the comparatively large lipid-containing material. However, fouling of microfiltration membranes (presumably also by the lipid-containing fraction) in such processes has, as yet, mitigated against extensive commercial adoption of this approach. It is likely, however, that improvements in microfiltration membranes coupled with appropriate adjustment of processing conditions will result in increased commercialization of such processes in the near future.

The addition of calcium to aggregate lipoproteins in whey has also been proposed as an alternative to microfiltration for lipid removal. Whilst this process is technically effective, it may pose particular difficulties on scaling up to commercial operation.

A number of the whey fractionation processes previously outlined result in the preferential transfer of any lipid-containing portion of the whey into one particular fraction. For example, the lipid fraction in whey is preferentially found in the α fraction produced by the Australian process utilizing thermal aggregation. Such lipid material may be removed from whey fractions by, for example, microfiltration. This would result in a protein fraction with increased functionality, and a lipid fraction with excellent emulsification characteristics.

Summary of Whey Fractionation Methodologies

Of the various whey fractionation processes outlined, only the procedures based on adsorption/ion exchange involving the use of carboxymethylcellulose or Spherosil are in commercial operation, and these only in comparatively small-scale operations. The thermal procedures for whey fractionation are nearing commercialization. Of the remainder, the use of microfiltration to pretreat whey to remove lipid-containing material is likely to become further developed over the next few years. The remainder of the processes outlined seem unlikely to be of immediate commercial interest.

Functionality of Concentrates and Individual Whey Fractions

It is likely that whey protein fractions will have much greater and more reliable functionality than will WPCs, even WPCs containing 75% protein. Although the existing production of whey protein fractions is limited in the main to those from the Bi-Pro and Spherosil processes, and is of comparatively small tonnage, the ongoing development of the thermal aggregation processes will likely see the production of whey fractions increase sharply in the next few years. Already whey protein fractions attract much higher returns than WPCs and, with increased production, it is probable that increased applications will be identified, resulting in increased demand. Some products in which WPCs and whey fractions have been commercially utilized are listed in Table 2.

The individual proteins in whey can offer certain specific functional advantages. α-Lactalbumin is in demand for formulae which mimic human milk.

However, currently the product is very expensive, and some of the technologies available for production have not yet come on stream. β-Lactoglobulin has been shown to possess valuable functional properties, and this product has been developed in Australia as the basis of a solid fat-substitute, with initial development as an ingredient in reduced- or low-fat luncheon meats and salami. Lactoferrin is also a significant component in whey, and various technologies have been described for its isolation. However current medical/nutritional claims for the product still have to be fully verified, and existing production capacity probably exceeds market demand. This situation could, however, change dramatically if the benefits of the product are verified in clinical trials. Extracts containing growth factor from whey are also currently being commercially developed. An Australian consortium of private, university, and medical organizations is planning to undertake clinical trials to assess the benefits of whey growth factor in wound healing and repair, including application to ulcers, burns, and incision wounds.

Whey fractions and WPCs offer many valuable functional properties as food ingredients. They can modify some or all of the organoleptic, visual, hydration, surfactant, structural, textural, and rheological properties of the food, resulting in improved consumer acceptance of the product. It is probable that the further development of specialized whey fractions with reliable and well-defined functional properties will see a marked increase in the application of these products over the next few years. While the technology for the production of such concentrates and fractions is now well known, the commercial success of this technology will turn to a large extent on developing means for the utilization of the lactose-rich byproduct streams emanating from such processes.

Fermentation of Whey

J Mawson, Massey University, Palmerston North, New Zealand

Process Options – Economic Factors

An extensive range of products can be obtained from whey fermentation. However, although processes for the large-scale utilization of whey were first investigated in the 1930s and 1940s, the commercial realization of these technologies has been slow. The most important factors that impact upon the development of economically feasible whey fermentation processes are:

1. Volume of whey available: 6–9 and 25–30 l of whey are produced per kilogram of cheese or casein manufactured, respectively, but the volume available at individual processing sites can be quite variable. In countries where production efficiencies have driven centralization of dairy

processing, in excess of 2×10^6 l day^{-1} of whey may be produced at a given site; in other countries, factory production volumes may be less than 10^5 l day^{-1}.

2. Polluting capacity: the polluting load of whey is very high. The BOD_5 (biological oxygen demand) value of whole whey is typically 40–50 kg m^{-3} (35 kg m^{-3} for deproteinated whey), or about 100 times the strength of domestic sewage. Combined with the large volumes that can be produced and increasingly stringent legislation limiting discharges to the environment, effective treatment of whey poses a significant challenge. Aerobic treatment is expensive and alternative technologies are favored.
3. Microbial utilization: lactose is the principal carbon and energy source available for microbial growth but is utilized by a relatively narrow range of organisms, and in some cases not by those that would normally be selected for the commercial production of a given fermentation product. Furthermore, the natural concentration of lactose in whey of 4–5 wt% is low in comparison with traditional fermentation substrates such as molasses or sugar syrups. This presents two challenges: it may limit the product concentration that can be achieved in some fermentations, leading to high product recovery costs, and also precludes transportation of whey beyond the production site to centralized processing facilities unless the whey is first concentrated by evaporation or reverse osmosis.
4. Milk production: in some countries, milk production is seasonal and whey fermentation plants will be idle for part of the year unless other substrates can be processed during these periods.
5. Markets for whey fermentation products: the market for whey fermentation products is influenced by several factors. Some products may not have a significant local market and export costs may be high. Where markets exist, of most importance are competition from similar products produced from other sugar sources (e.g., corn syrups) and the demand for alternative whey products (e.g., whey powders, lactose).

As a consequence of these various constraints, the emphasis in whey fermentation has been largely on the production of commodity chemicals or biomass as a means of reducing the effluent load of large volumes of whey. Such products command low prices in competitive markets; recovery costs dominate the economics of the process and high fermentation productivity must be achieved. The economic return is necessarily limited, although this is offset by the low cost of the substrate. In some cases, a negative cost may be assigned to the whey in recognition of the expense of alternative disposal methods.

Those fermentation processes that have proved commercially successful have developed largely to service particular niches in local markets. These include the production of potable and industrial ethanol, yeast biomass products, methane for use as a fuel, some organic acids and their derivatives, and various whey beverages. These processes are summarized in Figure 1 and will be the major focus of this article. Briefer consideration will be given to several other fermentation products that have been extensively researched and offer potential for commercial production.

Ethanol

Whey distilleries are in operation in Ireland, New Zealand, and the US. A typical industrial process flowsheet is shown in Figure 2. Deproteinated cheese or casein whey serum is used as substrate and may be either concentrated by reverse osmosis or supplemented with other lactose-rich streams to increase the lactose concentration to 10–13 wt%. The fermentation employs strains of the yeast *Kluyveromyces marxianus* var. *marxianus* (synonyms: *K. fragilis, Saccharomyces fragilis*). The process may be operated under aseptic conditions using pasteurized whey, although this is not necessarily required provided that good serum handling methods are practiced. Fermentation temperature is commonly in the range of 24–34 °C. The pH is not controlled and falls to 4.0 or less during the fermentation, which may take 12–36 h, depending on the initial lactose and yeast concentrations. At least one distillery operates with continuous fermentation at an overall dilution rate of 0.07 h^{-1}. Typically, the fermenter vessels are of 120–250 m^3 total volume and some mixing is required to prevent supersaturation of CO_2 in the vessel. This may be achieved mechanically or by recovering and reinjecting CO_2. Almost complete utilization of lactose can be achieved (and is a necessary requirement for effective waste abatement) and the yield of ethanol is in the range of 75–85% of the theoretical value of 0.538 kg ethanol per kg lactose metabolized. This corresponds to an ethanol concentration of about 2 wt% for fermentation of natural whey or 5–6 wt% for concentrated whey streams.

The ethanol is recovered by distillation using conventional techniques. The process shown in Figure 2 incorporates two columns (stripping and rectifying 'beer' or boiling columns) for initial concentration and partial purification, an extractive distillation

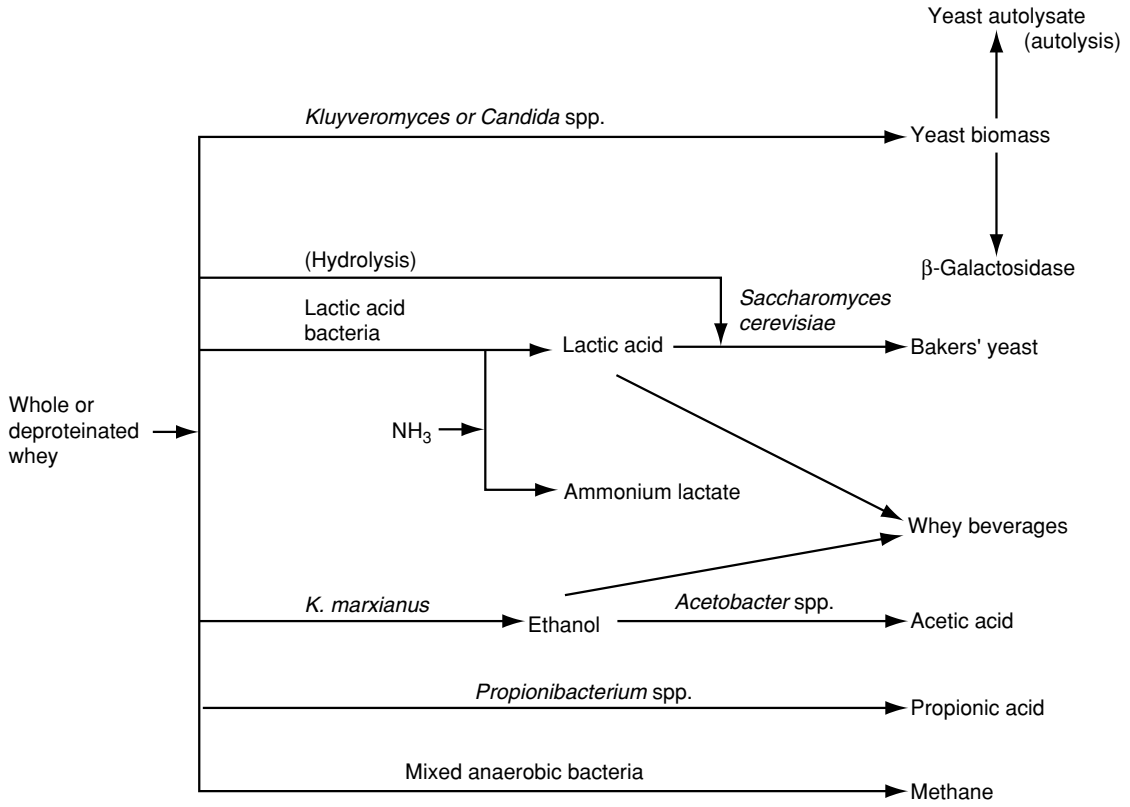

Figure 1 Major commercial products obtained by whey fermentation. Reproduced from Whey and Whey Powders: Fermentation of Whey, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

column using recycled hot water for removal of higher alcohols (fusel oils), and a rectifying column for final purification and concentration. For crude industrial or fuel alcohol, only the boiling columns and possibly a smaller side-draws purification column are required. For anhydrous ethanol production, additional azeotropic or extractive distillation columns, a zeolite molecular sieve, or a pervaporation membrane plant must be used.

Yeast Biomass

Single-cell Protein

Yeast biomass has been produced commercially by whey fermentation from the 1940s until the present. Strains of *K. marxianus* var. *lactis* or var. *marxianus* are those most commonly used, although other strains may be produced successfully. In some operations, ethanol is also obtained as a co-product by lowering the aeration rate during the fermentation.

The requirements of a suitable strain for biomass production are summarized as follows.

1. High specific growth rate and biomass yield to insure a high productivity
2. The strain must not be affected by whey proteins if these are present
3. The strain must be suited to continuous culture
4. The strain must be acid-resistant. (To control contamination, it is necessary to operate the process at low pH or to wash the yeast at frequent intervals with acid to remove contaminants)
5. Large cell size and uniform morphology to aid cell separation and concentration
6. Adequate protein content and acceptability in feeding trials

The Bel process (Figure 3), developed in France in the late 1950s, is a frequently cited example of this fermentation. Sweet cheese whey is first deproteinated and diluted to a lactose concentration of 20–25 kg m^{-3}. Whey is limiting in nitrogen sources for yeast growth, so ammonium salts are added to maintain a high nitrogen content and growth rate, and trace metals (Fe, Cu, Mn, Zn) may also be added. The culture has been shown to comprise three cooperating yeast species. The continuous fermentation is

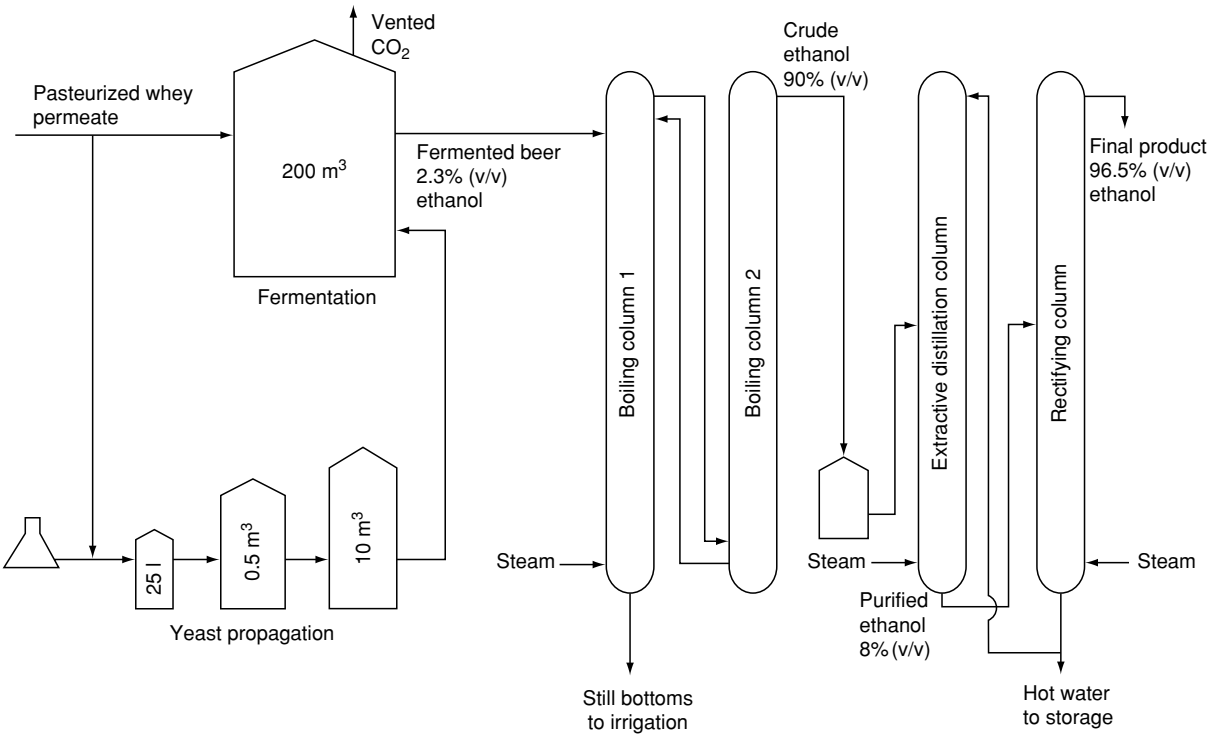

Figure 2 Typical process for production of ethanol from natural-strength whey permeate. Reproduced from Whey and Whey Powders: Fermentation of Whey, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

operated at a dilution rate of $0.33\,h^{-1}$ and a temperature of 38 °C. For a serum flow rate of 5–6 $m^3\,h^{-1}$, air is added at about $1800\,m^3\,h^{-1}$ and provides both the mixing and the aeration of the culture in an air-lift fermenter. The residual sugar level is about $1\,kg\,m^{-3}$, the biomass yield is 0.55–0.6 kg yeast (dry basis) per kg lactose metabolized, and the biomass productivity is approximately $4.5\,kg\,m^{-3}\,h^{-1}$. The yeast is separated and concentrated in a two-stage washing and centrifugation process, plasmolyzed to render the yeast protein more accessible, and dried.

The composition and uses of biomass produced from whey are similar to those of other food yeasts. The crude protein content is about 50 wt% on a dry basis and the only significant limitation is of the sulfur-containing amino acids. Overall, the protein value is similar to that of casein. Fermenting whole whey and recovering a product containing both the yeast biomass and the whey proteins may increase the food value of the yeast.

Bakers' Yeast

Two processes have been developed for the production of bakers' yeast to overcome the limitation of *Saccharomyces cerevisiae* not being able to utilize lactose. In the first, the lactose is hydrolyzed using β-galactosidase, and the glucose and galactose are consumed simultaneously by the yeast in fed-batch or continuous culture. The second process utilizes a two-stage fermentation system. In the initial stage, lactic acid bacteria convert lactose to lactate and this is consumed in the subsequent stage by the yeast. Although the bakers' yeast so produced appears comparable in quality to that from conventional processes, only very limited quantities are manufactured by these methods.

Products from Yeast Biomass

Yeast cells can be a useful source of several food additives or processing aids. Following cell growth and recovery, the biomass can be broken down mechanically or biologically to release cellular components which may be purified or transformed to yield high-value products. The major products that can be derived from biomass are yeast autolysate, flavour nucleotides, enzymes, and cell wall components such as glucan and mannan.

Autolysate and Flavor Nucleotides

Autolysis is a process of self-digestion mediated by degradative enzymes present within the cell. Elevated

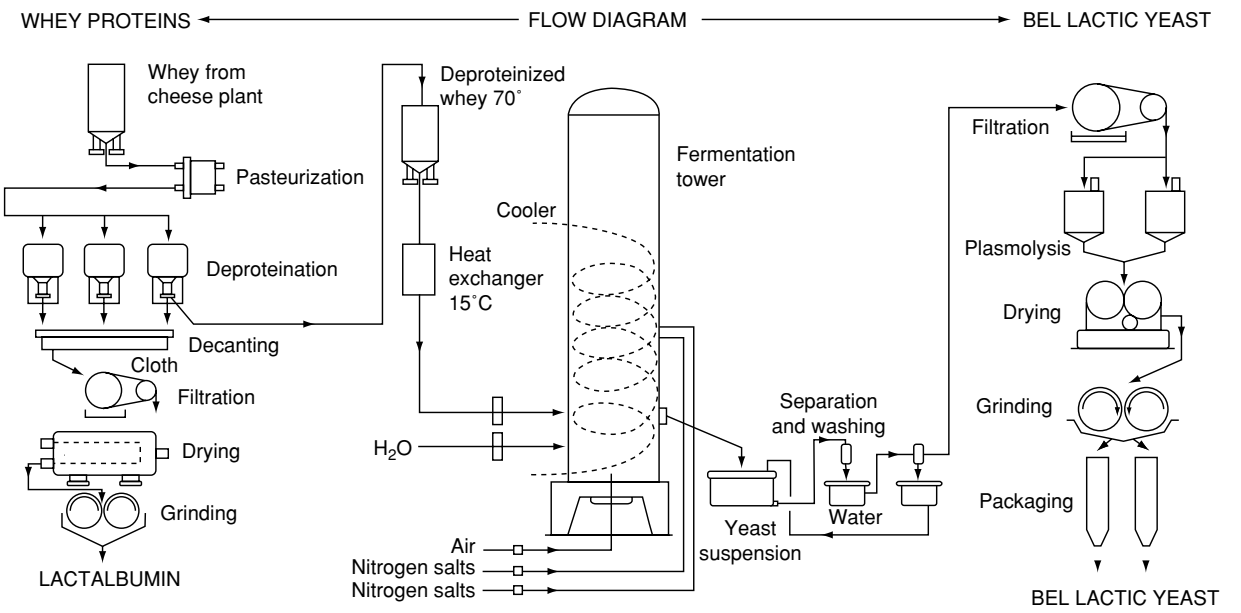

Figure 3 Fromageries Bel process for yeast production from deproteinated whey. Reproduced from Whey and Whey Powders: Fermentation of Whey, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

temperatures and the presence of NaCl enhance the rate of lysis during which protein is solubilized and cell wall polymers are broken down. Optimal conditions for autolysis of *Klyveromyces* strains are 50–55 °C, pH 5.1–6.5, and 8–12 h; addition of salt may not be necessary. Yeast nutrients are more readily available in autolysates than in intact cells and the autolysates find uses in foods, animal feeds, and microbial cultures, e.g., for enhancing the growth of dairy starter cultures.

RNA can be isolated from lysed cells and used to produce 5′-ribonucleotides which are important flavor enhancers in food systems.

β-Galactosidase

The enzyme β-galactosidase (EC 3.2.1.23), or lactase, can be produced from selected strains of *Kluyveromyces* spp. following growth on diluted whey. The enzyme is intracellular and is induced by lactose and galactose. One study showed that expressed levels may vary up to 60-fold between strains, but commercial yield data are not available. The optimum conditions for enzyme activity are pH 6–7 and 35–45 °C, and Mn^{2+} and Mg^{2+} are strong activators. β-Galactosidase may be used to hydrolyze lactose to overcome the problem of lactose intolerance and to generate syrups for food use which are sweeter than lactose and which do not crystallize as readily (hence reducing 'sandy' defects). Oligosaccharides, which have useful nutraceutical properties, are alternative and interesting byproducts of the hydrolysis process.

Organic Acid Fermentations

Lactic Acid and Ammonium Lactate

Whey has been a traditional feedstock for lactic acid production by fermentation, but the process struggles to be economic compared to the utilization of corn syrups. Lactic fermentations have typically been conducted in batch mode using homofermentative strains of *Lactobacillus* such as *L. delbrueckii* sbp. *bulgaricus*. Complex nutritional sources such as corn steep liquor, malt sprouts, and malt or yeast extracts may be supplemented. The pH is controlled in the range 5.5–6.5 by addition of $Ca(OH)_2$ or $CaCO_3$ and the optimum temperature is about 43 °C. The medium is usually pasteurized, but contamination is not usually a serious problem. For natural whey the fermentation will be complete in less than 24 h with a yield of 90–95%. The productivity of the fermentation is typically 1–3 kg m^3 h^{-1}.

Recovery and purification of lactate represents a major cost in the process and are complicated by the highly corrosive nature of the product. This requires all equipment to be 316 stainless steel or better and removal of metal ions introduced by corrosion may be required for some grades of product. In traditional processes, the fermentation liquor is initially heated

to 80–100 °C and the pH is raised above 10 to solubilize calcium lactate, kill all microorganisms, and precipitate calcium phosphate and proteins. The liquor is then decanted, filtered, and treated with carbon to increase the purity. Following evaporation under vacuum, a technical-grade lactic acid can be recovered by acidification with sulfuric acid, filtration of the precipitated $CaSO_4$, and further carbon and purification treatments. To obtain higher-grade products, calcium lactate crystals may be recovered following cooling of the liquor; these are then washed, redissolved, and carbon-treated in several cycles. Several alternative recovery processes are available, e.g., both solvent extraction and distillation of lactate esters are practiced commercially.

Lactic acid has attracted much recent interest as a base for the manufacture of biodegradable polylactate plastics. A large-scale pilot plant was commissioned in Wisconsin, US, but full-scale production did not proceed.

Ammonium lactate is produced by the addition of liquid ammonia to the fermentation broth. After completion of the fermentation, the broth is evaporated, neutralized by addition of further ammonia, and processed to a range of liquid or solid products. These are used as animal feeds and are especially suitable for ruminants. Ammonium lactate is superior to urea and similar to soybean meal in its nutritive value and digestibility.

Acetic Acid

Following the ethanol fermentation of whey, the alcohol can be further metabolized to acetic acid by *Acetobacter* spp. This process has been commercialized, most notably by Kraft, and the resulting whey vinegar may be used in salad dressings and other foods. The manufacturing process is assumed to be similar to that for conventional vinegar production. The production of acetic acid from whey as a base for synthesis of other chemicals has also been considered. Recent attention has focussed on production of acetate deicers as a possible market.

Propionic Acid

Propionic acid is added as a fungistatic agent to bread and bakery products and can be produced by whey fermentation using strains of *Propionibacterium freudenreichii* ssp. *shermanii*. Whole whey is typically used and the fermentation must proceed under sterile conditions at around 30 °C and pH 6.5–7.5. Nutritional supplements, such as yeast extract, considerably enhance propionate production and a typical yield of about 40% of the lactose fermented is achieved after 60–70 h. The culture fluid is spray-dried to obtain a powder containing both the acid and whey proteins.

Methane Fermentation

The microbial production of methane from whey offers the major benefits of an efficient waste treatment process coupled with the production of a z-convenient energy source that can be utilized on-site. The methane fermentation, or anaerobic digestion, requires a limited input of energy and nutrients and produces very little sludge for ultimate disposal in comparison to conventional aerobic treatment processes. A number of bioreactor (digester) configurations are available for the treatment of high-strength effluents such as whey. All of these rely on retaining the microorganisms mediating the fermentation in the digester, so that the hydraulic residence time of the waste stream can be very much less than the biological solids (or biomass) residence time. This separation is necessary as the cells grow only slowly, yet large volumes of waste must be processed daily.

Several large-scale whey or whey permeate digesters are in operation and many laboratory or pilot-scale trials have been reported for a variety of retained-cell systems. Mesophilic operation at 30–37 °C is favored. Overall COD (chemical oxygen demand) reductions of about 90% are possible for loading rates of up to $20\,kg\,m^{-3}\ day^{-1}$, although loading rates in large-scale operations are typically lower, at $1.5–10\,kg\,m^{-3}\ day^{-1}$. Gas production is about $35\,l^{-1}$ of whey processed and has a methane content of 55–65%. These figures are consistent with the theoretical yield of 350 litres CH_4 at standard temperature and pressure per kg COD removed.

Success has also been achieved with treatment of slops from whey distilleries by anaerobic digestion. The reduced strength of the slops from ethanol fermentation can promote more stable operation of the digester, although the total methane yield is less. However, regardless of the initial substrate, some aerobic polishing of the effluent is required before digester effluent can be discharged to natural waterways.

Fermented Whey Beverages

Whole or deproteinated whey can be fermented to produce a range of beverage products. The major advantages offered by whey as a substrate for beverage production are that whey drinks have a greater nutritive value and are more thirst-quenching than most soft drinks, and are less acidic than fruit juices. The marketing of these products generally emphasizes the health and nutritional benefits of the

Table 1 Production of a fermented-fruit whey drink from whey

Recipe	
Stabilizer	0·30%
Fruit concentrate	2–7%
Sour whey	85·7%
Sugar	6–10%
Flavor and color	As required, to 100%
Possible technical pH range	3·6–4·2
Method	
1. Coarse filtration of sour whey	
2. Disperse stabilizer in the sour whey, avoiding lumps	
3. Maintain gentle agitation for 30 min to allow the stabilizer to swell	
4. Heat to 85 °C and cool to incubation temperature (*c.* 42 °C)	
5. Inoculate with *Lactobacillus helveticus*	
6. Incubate to pH 4·0	
7. Cool	
8. Add fruit and sugar	
9. Check pH and adjust, if necessary, with 50% citric acid solution to pH 3·6–4·2	
10. Thermal treatment	
11. Place in chill	

beverage, especially if they still contain the whey proteins. A variety of whey drinks are available in many countries, although they are most popular in Europe.

Lactic or alcoholic fermentations can provide desirable properties in the beverage. Lactic fermentations use conventional starter organisms or probiotic strains and *Kluyveromyces* yeast strains are commonly used for the alcoholic fermentation. A combined lactic–ethanol fermentation may be conducted with a kefir-type culture, but whey health drinks usually have a low (< 1%) or negligible alcohol content. A typical recipe for preparation of a fermented-fruit whey beverage is outlined in Table 1. Whey 'wines' can be manufactured by fermentation of deproteinated wheys and can serve as a base for wine coolers.

Other Fermentation Products

Many alternative fermentation processes have been investigated for whey utilization. Possible products include mixed solvents (acetone, butanol, and ethanol), yeast oils and specialized lipids, glycerol, extracellular polysaccharides, other organic acids (citric, acrylic), vitamins, poly(β-hydroxybutyrate), amino acids, flavoring agents, pigments, and lantibiotics such as nisin. Of these, polysaccharides (xanthan gum) and flavoring agents (based on diacetyl) have been commercially produced in limited quantities, and the production of lantibiotics using lactic acid bacteria also appears feasible.

Principles of Dialysis

J J Roberts, University of Pretoria, Pretoria, South Africa
J F Mostert, ARC-Animal Nutrition and Animal Products Institute, Irene, South Africa

Background

Dialysis is the oldest, most natural, and flexible technique for separating components from a solution. Electrodialysis (ED), however, has been known and studied since the beginning of the twentieth century, but it was not until around the end of the 1940s that stable membranes of low electrical resistance were developed, allowing the commercial application of ED using membrane stacks with several membranes in series. The modern process of ED has been made possible by the development of highly selective membranes for anions and cations. Both processes may be used in conjunction with other

membrane-separation processes (osmosis, reverse osmosis, ultrafiltration, and microfiltration) in experimental and large-scale industrial applications. A major disadvantage is that an equilibrium is quickly reached. However, specific molecules may be completely separated, provided a high concentration gradient is maintained, and the permeate is constantly removed. (*See* **Membrane Techniques**: Principles of Reverse Osmosis; Applications of Reverse Osmosis; Principles of Ultrafiltration.)

Theory of Dialysis and Electrodialysis

Dialysis

Dialysis is a separation process whereby smaller molecules are segregated from larger molecules (macromolecules) in a solution by virtue of their different rates of diffusion through a specific membrane (or by nondiffusion, which is the criterion of the colloidal state and forms the basis of separation of colloidal materials from crystalloids). Alternatively, dialysis may be regarded as a membrane transport process in which solute molecules are exchanged between two liquids separated by a membrane. Hence, the primary driving force is the difference in concentration of the permeable species between the solution in the dialysis membrane system and that on the outside. The membrane might be natural, such as a pig bladder, or artificial (i.e., consisting of materials such as cellulose derivatives or collodion).

To illustrate the principles of dialysis, a test solution can be placed in a sack or bag that may consist of a membrane with, for example, a 24-nm pore diameter. The bag is closed/knotted and soaked in distilled water at a given temperature and for a given time; the bags are usually agitated. The small molecules diffuse out into the water, while the larger molecules remain in the solution in the bag. This method is commonly used to separate proteins from salt solutions. In addition, it is an indispensable technique in the recovery and purification of materials in food, chemical, biological, and pharmaceutical preparations.

Electrodialysis

ED is a unit operation that uses semipermeable membranes for the separation or concentration of electrically charged particles (ions) from nonionic particles or species in a solution. The key to the process is the use of ion-selective membranes. These membranes are ion-exchange resins cast in sheet form, which allow the passage of positively charged cations (e.g., sodium or potassium) or anions (e.g., chloride or phosphate). To achieve separation by means of ED, cation and anion membranes are alternated with plastic spacers in a stack configuration with the anode at the one end and the cathode at the other. Spacers are usually made of low-density polyethylene and arranged in the membrane stack so that all the mineralized streams are manifolded together, and all the concentrated streams are manifolded together. The spaces between the membranes represent the flow paths of the demineralized and concentrate streams. Hence, a repeating section, called a cell pair, consists of a cation transfer membrane, demineralized water flow spacer, anion transfer membrane, and concentrate water flow spacer. A typical membrane stack may have from 300 to 500 cell pairs.

A direct electric current (d.c.) (or an electrostatic potential or gradient) applied across the electrodes creates a driving force. This induces anions to migrate in the direction of the anode (+) and cations to move in the direction of the cathode (−). The ion-selective membranes form barriers to ions of opposite charge. The net result is that the anions attempting to migrate to the anode pass through the anion barrier or membrane but are stopped by the cation membrane. Likewise, cations trying to migrate to the cathode pass through the cation membrane but are stopped by the anion membrane. The overall effect is that the barriers form alternate compartments of ion-diluting cells and ion-concentrating cells. Therefore, ED relies primarily on voltage or electromotive force and the use of ion-selective membranes to effect separation between charged particles. Hence, on circulation of a specific liquid product or test solution through the diluting cells and a brine solution through the concentrating cells, free mineral ions leave the test solution and collect in the brine stream. The level of demineralization achieved depends upon the initial ash content, current density, and the duration of time the test solution is within the membrane cells.

Figure 1 shows a schematic diagram of a typical ED process for the demineralization of whey in an ED membrane stack. One stream enters the membrane stack and flows in parallel only through the demineralizing compartments, while a brine stream enters the membrane stack and flows in parallel only through the concentrating compartments. Note that the solutions flow across, not through, the membranes. When a d.c. voltage is applied across the electrodes, the electrical potential gradient created causes anions to move in the direction of the anode and cations to move in the direction of the cathode. The ion-selective membranes form barriers to ions of opposite charge. The result is that anions attempting to migrate to the anode pass through the anion membrane but are stopped by the cation membrane; cations trying to migrate to the cathode pass through the cation membrane but are stopped by the

anion membrane. Hence, the membranes form alternate compartments of ion-diluting cells and ion-concentrating cells. By circulating whey through the diluting cells and a brine solution through the concentrating cells, free mineral ions leave the whey and collect in the brine stream. The level of demineralization achieved depends on the initial ash content, current density, and duration of time the whey solution is within the membrane cells.

For a better comprehension of the process of ED dialysis (especially the efficiency of the mass-transfer reaction), the functioning of an electrolytic cell will be discussed briefly. A pair of electrodes as well as an electrolytic solution (i.e., a solution containing ions) are placed in such a cell. When a voltage is applied to the electrodes, a migration of cations and anions takes place. According to Faraday's law, the number of mass equivalents transported by this mechanism is directly proportional to the amount of electricity which passes through the cell. In mathematical terms, this can be expressed as follows:

$$\text{Current} \times \text{time} = F \times E\,(\text{equivalent mass transported}), \quad (1)$$

where E = number of moles × valency, and Faraday's constant $F = 96\,490$ A s per equivalent or 26.8 A h per equivalent.

Faraday's law states that if, for example, a current of 26.8 A is applied in an electrolytic cell for 1 h, it will transport one equivalent of matter from the solution to the electrodes. Hence,

$$i = FE(J_j Z_j) \quad (2)$$

where i = current density (A m^{-2}), J_j = molar flux of ion j (mol s^{-1} m^{-2}), and Z_j = valency of ion j.

Eqn (2), therefore, states that the total current in an electrolytic cell is equivalent to the sum of the current conveyed by each species in the cell.

Similarly, the amount of electricity necessary to produce separation by means of electrodialysis can be calculated by means of eqn (1). First, we must consider the cell efficiency coefficient (N_c), which accounts for the nonideality of the cell stack. This is due mainly to the presence of the selective membranes, but also to the loss of current through pipes and manifolds as well as the diffusion of electrolyte through the membranes. Thus, for a stack with n cell pairs:

$$n \times \text{current} \times \text{time} = FE\,(\text{equivalents removed})/N_c, \quad (3)$$

N_c can be expressed as the product of three efficiencies.

$$N_c = N_m \times N_l \times N_w \quad (4)$$

N_m accounts for the imperfection of the permselective membrane and is also called the Coulomb efficiency; N_l corresponds to the inefficiency due to current leakage through pipes and manifolds; N_w accounts for water transport, which always follows the migration of ions. The latter is also referred to as electroosmosis. For commercial equipment N_c is about 50%, and for laboratory equipment 90%. By manipulating eqn (3):

$$N_c = F(Q_{in}C_{in} - Q_{out}C_{out})/(In). \quad (5)$$

where Q_{in} = input flow ($m^3\,s^{-1}$); Q_{out} = output flow ($m^3\,s^{-1}$); C_{in} = input concentration (equivalents m^{-3}); C_{out} = output concentration (equivalents m^{-3}).

Owing to electroosmosis, Q_{in} and Q_{out} are generally different.

The energy consumed by an electrodialysis system may be computed from

$$E = RI^2t. \quad (6)$$

where E = electric energy (W s = J), R = total resistance of the system (ohm), I = electric current (A), and t = time (s). From eqn (3), the number of equivalents removed = ItN_c n/F. Hence from eqn (6) the energy per unit of equivalent removed is

$$e = RIF/N_c(\text{W s per equivalent}).$$

Types of Electrodialysis Membranes and Fouling Problems

The following types of membranes are used in ED:

- anion-permeable membranes (—NH_3^+) (A), which contain fixed cationic groups and repel cations;
- cation-permeable membranes (C), which contain fixed anionic groups (—SO_3^-) and repel anions; and
- nonselective membranes (N), which are permeable to both anions and cations.

Commercially available ED membranes are manufactured as heterogeneous and homogeneous membranes. The first type is made by mixing ion-exchange resins with a solution of polymeric materials, which is used as a thin coating material on a fine cloth or mesh as a mechanical reinforcement. Anionic or cationic membranes are obtained by using the corresponding ion-exchange resins. In homogenous membranes, the active cationic or anionic groups are induced or created in the polymeric material. Nonselective membranes are usually manufactured from cellulose. Pore sizes of the membranes are in the range 1–2 nm.

The desired characteristics of a good-quality membrane for electrodialysis include:

- good electrical conductivity;
- good mechanical strength;
- high ionic permselectivity;
- chemical stability;
- resistance to fouling by organic molecules;
- insolubility in aqueous solutions;
- resistance to chemical change in pH from 1 to 10;
- long life expectancy;
- impermeability to water under pressure;
- operation at temperatures in excess of 46 °C.

A major problem with ED is that of membrane polarization, also known as 'limiting current density.' Limiting current density is usually expressed as $(CD/N_d)_{lim}$, where CD = current density (the amount of current carried by a unit area of membrane surface), and N_d = normality of the demineralized outlet stream. This limit is a function of the fluid velocity in the flow path, the stream temperature, and the types of ions present. This condition may arise when too large a driving potential is applied to a system. The latter results in a rapid depletion of both anions and cations from the region immediately in contact with the membranes of the feed cell. Hence, ions are removed from the boundary layers through the membranes more rapidly than they can be replaced by diffusion from the bulk feed fluid, so that nothing remains to conduct the current. This polarization potential is a combination of applied voltage, diffusion characteristics of the ions, flow characteristics of the feed, and the ionic concentration of the feed. Note that polarization does not usually become significant at both membranes at the same time. Other typical problems with ED systems include current leakage, back diffusion, and membrane poisoning and fouling. Membrane poisoning is the result of ions passing into the membrane, attaching irreversibly, thereby obstructing the passage of following ions. In contrast, fouling is a surface phenomenon and is the result of the deposition on the surface of a fouling layer that forms a barrier to diffusion. These effects are largely eliminated in an electrodialysis reversal system.

Electrodialysis Reversal

The electrodialysis reversal (EDR) system is the first commercially available membrane process that is symmetrically reversible. This means that the direction of ion movement through the membranes and the

identity of the concentrating and demineralizing compartments are reversed at periodic intervals (e.g., every 20 min). To bring this about, the d.c. polarity is reversed. The mechanism of EDR differs from that of unidirectional ED in a very simple but profound way, and the advantages of EDR system are many. The process is more tolerant than other commercially available membrane processes of a wide range of troublesome organic, inorganic, colloidal, and biological contaminants. The single most important advantage of EDR is that any scale or film build-up, common in unidirectional processes such as electrodialysis and reverse osmosis, is limited. There is a tendency for constituents that are capable of forming slimes and precipitates to be deposited at the membrane/solution interface, and over a period of time, these deposits affect the membrane desalting/filtration performance. The self-cleaning characteristic of EDR systems is analogous to that of reversing heat exchangers used in the cryogenic industry for removal of carbon dioxide and water scale from low-temperature surfaces.

Transport Depletion

The fouling of anion exchange membranes by negatively charged organic collodial matter is a serious problem in conventional ED systems. This problem can be avoided by replacing anion membranes with nonselective (neutral) membranes, with the order of the membranes being –C–N–C–N–C–, so that concentration polarization is avoided.

Ion Substitution

Ion substitution is another variant of ED in which one species of ion is removed and substituted by another. Instead of the simple, alternating –anionic–cationic–anionic–(–A–C–A–)– membrane arrangement, the sequence –A–C–C–A– solution to be demineralized is fed into the C–C compartment.

Ion Replacement

Another modification of classical electrodialysis is ion replacement, where the membranes used are anionic or cationic only. In this application, the solutions are neither enriched nor depleted in ions; only an exchange in specific types of ions is accomplished.

Advantages of Electrodialysis

The many advantages of electrodialysis, e.g., in protein separations, include fast and controlled removal of salts, no product dilution, low membrane area requirements, negligible product adsorption, easy salt recovery in the same unit, and the use of lower concentrations of salting-out agents than are required by conventional direct addition processes.

Applications of Dialysis

J F Mostert and L Frylinck, ARC-Animal Nutrition and Animal Products Institute, Irene, South Africa

Introduction

The concentration, removal, or separation of components in aqueous mixtures by membrane techniques, e.g., dialysis and electrodialysis, have many applications in the processing of liquid foods and areas closely related to food.

Dialysis is a technique employing the difference in concentration as a driving force to separate large particles from small ones in a solution, for example, proteins from salts. The solution to be treated is placed on one side of a membrane, and a solvent (water) on the other side. The membrane has pores of a diameter that allows the small salt molecules to pass through, but is too small for the protein molecules to pass (**Figure 1**). A disadvantage of dialysis is that the rate of diffusion varies with the difference in concentration. Dialysis can, however, be speeded up if the solvent on the other side of the membrane is changed frequently.

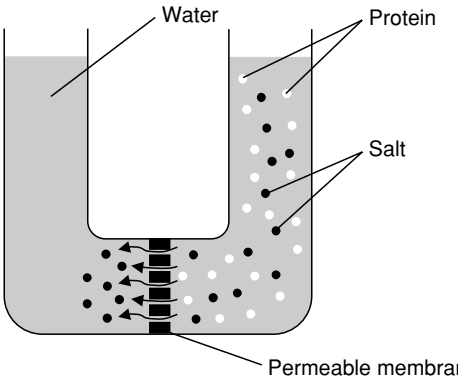

Figure 1 The separation of protein molecules from a salt solution, using a dialysis membrane. Reproduced from Bylund G (1995) The chemistry of milk. In: *Dairy Processing Handbook*, pp. 17. Lund, Sweden; Tetra Pak (Processing System Division), with permission.

Electrodialysis (ED), on the other hand, is defined as the transport of ions through nonselective semipermeable membranes under the driving force of a direct current and an applied potential. The membranes used have both anion and cation exchange functions, thus making the electrodialysis process capable of reducing the mineral content of a process liquid, e.g., whey or sea water. The most important use of ED is in the desalination of brackish water for the production of potable water as well as in the production of table salt from sea water. ED is a classic whey demineralization process with a well-proven technology and with a multitude of systems operating worldwide. Other important applications are found in the dairy, wine, and beverage industries. The integration of dialysis and ED in food-processing systems, together with new advances in fermentation systems, has a profound effect on new biotechnological applications for the manufacture of specialized and highly differentiated food products with enhanced functional properties.

Dialysis in the Dairy Industry

In the dairy industry ED is primarily used for the demineralization (desalting) of whey. Large volumes of whey are produced as a byproduct from cheesemaking and, to a lesser extent, from casein manufacture. For each tonne of cheese produced, about 8 tonnes of whey are left over, resulting in huge volumes. In the past whey has been returned to farmers for animal feeding, irrigation of lands and pastures, or discharged directly into rivers, waterways, or sewage systems. Considerable quantities of whey are still being discharged into the environment worldwide.

Whey is the liquid residue of cheese and casein production and is, to a certain extent, one of the biggest reservoirs of high-quality food protein not fully utilized in human consumption levels. The composition of whey will vary substantially depending on several factors, including the process involved in the production of whey. On average, whey contains about 65 g kg^{-1} of solids, comprising about 50 g lactose, 6 g protein, 6 g ash, 2 g nonprotein nitrogen, and 0.5 g fat. The whey protein fraction of bovine milk contains four main proteins: β-lactoglobulin (β-Lg, 50%), α-lactalbumin (α-La, 20%), blood serum albumin (10%), and immunoglobulins (lg, 10%; mainly lgG_1, with lesser amounts of lgG_2, lgA, and IgM). Wheys are broadly classified as 'sweet' wheys produced from rennet-coagulated cheeses and acid wheys, which have a similar composition but with a higher acidity and ash content.

The unique technological, nutritional, physiological, and even nutraceutical properties of whey proteins, together with the high disposal cost of dairy effluent, stimulated research in whey utilization within the food industry. Industrial whey processing began with fluid whey being concentrated and dried. New membrane techniques and processes revolutionized whey processing by providing breakthrough methods for the separation of dissolved or suspended solids, for the removal of water and, especially, for the combination of these. Nowadays demineralized whey powders, whey protein concentrates, whey protein isolates, individual proteins and derivates, as well as permeate products/lactose derivates are manufactured and are available on the market.

It is not easy, from an economic point of view, to process whey into products of higher commercial value. As whey has a fairly high salt content – about 8–12% calculated on dry weight – its usefulness as an ingredient in human foods is limited. By having the whey demineralized, various fields of application can, however, be found for whey, which is partially (25–30%) or highly (90–95%) demineralized. Partially demineralized whey concentrate can, for example, be used in the manufacture of icecream and bakery products or even in quarg, whereas highly demineralized whey concentrate or powder can be utilized in formulas for infants and also in a wide range of other products.

The two main methods used commercially for high-degree demineralization of whey, namely ion exchange and ED, result in products of somewhat different composition. The ion exchange process is relatively nonselective and removes both monovalent and polyvalent ions, whereas ED is more dependent on ionic mobility and tends preferentially to remove monovalent ions. Economically, only about 90% demineralization is possible with ED; 50–75% is regarded as being more viable from a practical and

economical point of view. The value of 90% is considered the practical limit of salt removal due to decreasing electrical conductivity with demineralization. ED is likely to have advantages for plants with high hourly utilization rates, for the manufacture of products that do not require high levels of demineralization, and where low-cost electricity is available. Based strictly on economics, the recent trend is towards combined ED ion exchange plants. The majority of ED plants use preconcentrated sweet whey as well as acid whey, skimmed milk, delactosed whey, milk, whey protein concentrate, and whey ultrafiltration (UF) permeates.

Whey produced by ED has a reduced mineral content and is rich in lactose and whey proteins, and contains appropriate low levels of essential minerals, which makes it an ideal ingredient for infant formulas. Raw whey is concentrated to 23–27% solids, and clarified before ED. Liquid or dried reduced-minerals whey could be used for blending infant formulas, but a high level of demineralization (90%) is required for sweet whey to be used in an infant formula. The use of reduced-minerals whey as an ingredient in infant formulas must be ranked as one of the major successes in terms of the valuable and profitable use of a byproduct. Reduced-minerals whey could be used in animal feeds, protein and citrus drinks, dry mixes, confectionery coatings, icecream, and bakery goods.

Although the trend has been towards the use of whey protein-based infant formulas, there is also a considerable percentage of infant formulas produced in which nonfat milk is used as the sole source or protein. These products tend to have higher ash contents, including higher levels of phosphorus, calcium, sodium, potassium, and chloride, than whey protein-based formulas. Other ED applications include the partial demineralization of whey protein concentrate, which is ideal for products that require a higher protein-to-lactose ratio; acid whey for mixing with sweet whey in the manufacture of whole whey powder; and of cottage cheese whey in order to reduce disposal problems.

ED is also used in various integrated membrane systems for specific purposes, e.g.:

- Nanofiltration/ED systems: nanofiltration is used to concentrate and partially demineralize whey prior to ED, which in turn completes demineralization to the desired level.
- UF/ED systems: UF allows molecules, such as sugars and salts, to pass through the membrane while protein molecules are retained. UF is used to produce whey protein concentrate (WPC) while ED demineralizes the WPC to produce a low-ash, high-protein ingredient for infant formulas.

Microbial Fermentation Systems

Membrane techniques are well established in fermentation processes and are increasingly used in integrated bioprocesses. Figures 2 and 3 give an indication of the possible implementation of an integrated bioprocess in the dairy industry using cheese whey/waste water as substrate for the production of lactic acid. Regarding the fermentation of concentrated substrates, one application for the ED technique during upstream processing may be a partial reduction of the salt content and to obtain osmotic pressure to their optimum values. A final microfiltration step can be incorporated to obtain a continuous

delivery of sterile substrate to the bioreactor. In continuous fermentation systems, membranes can be used for cell separation, retention of metabolic compounds, and recirculation. The reaction compounds are discharged from the membrane reactor with the permeate, which is then replaced by a new substrate solution. Owing to cell retention, cell density and, hence, substrate conversion velocity can be significantly enhanced.

The application of ED in downstream processing offers many economically competitive methods for the recovery of whey-based lactic acid:

- Continuous cell recycling with UF or microfiltration membranes followed by the removal of lactic acid by ED units.
- Acid recovery by means of ED with bipolar membranes (Figures 3 and 4). Bipolar membranes consist of cation and anion exchange layers arranged in parallel between two electrodes which enable the lactate salt to be split and electrically neutralized by H^+ ions and the corresponding alkali. The function of the bipolar membrane in the electrodialytic production of acids and bases from the corresponding salt solution is based on its capability for enhanced water dissociation under the influence of an electric potential gradient.

The combination of technologies and the demand for specialized products will in future lead to the next generation of highly differentiated whey protein-based products, with specific functionalities.

Other Applications of Dialysis

Dialysis and ED techniques are also applied in the demineralization of foods such as soy sauce, fruit juice, vinegar, hydrolyzed vegetable protein, sugars, and wine; deacidification of foods; purification of fermented products, hydrolysates, lipopolysaccharides, and protein fractions; as well as for the isolation of flavor substances and the production of enzymes. Other applications include the recovery of salts, acids, or alkali from industrial rinse waters as well as the purification of drinking water supplies, e.g., drinking water nitrate reduction.

Synopsis

Whiskies are distilled beverages which have been produced by the distillation of fermented cereals and have been matured in oak casks. They can be classified according to starting material, blending and country of origin. The major grains used in whisky production are maize, barley, wheat and rye. Amylase activity required for starch breakdown is obtained from malted barley, and some regulations permit the use of other enzymes. The yeast used for fermentation of the cereal extract is normally a specially developed strain of *Saccharomyces cerevisiae*. Distillation is in small pot stills or continuous column stills, followed by maturation normally for at least 3 years in oak casks.

Types of Product

Whiskies are distilled beverages that have been produced by the distillation of fermented cereals and have been matured in oak casks. They can be classified on the basis of the nature of the cereal, the manner in which the product is blended, if at all, and the country of origin. Although there is some evidence for a distillation-type process in ancient Egypt, the first reports of whisky production arise in Ireland in the twelfth century, and the first description of a whisky production process is found in Scottish records dating from 1494. The term 'whisky' is derived from the Gaelic '*uisge beathe*,' which means 'water of life.' Major countries of production are Scotland, the USA, Ireland, Canada, and Japan, while similar products are produced in many other countries including Brazil, Korea, and Spain.

Regulations in the European Union (EU) define whisky as a spirit produced by the distillation of a mash of cereals and matured for at least 3 years in wooden casks. There are limitations on the enzymes that can be used to hydrolyze starch to fermentable sugars and on the distillation strength, and yeast must be used for the fermentation. Within this definition, Scotch and Irish whiskies are further restricted. In practice, this provides for three distinct products: malt whisky, produced from 100% malted barley; grain whisky, produced from unmalted cereal grains; and the bulk of the whisky produced in Scotland, which is blended from 60–70% grain whisky and 30–40% malt whiskies. This blended whisky usually contains up to 40 individual malts that are blended to produce a consistent brand flavor, and every component of the blend must be matured for the minimum period, or the age specified on the bottle. Malt whiskies may contain either a blend of malt whiskies of a given minimum age or malt whisky from a single distillery. Scottish malts have a different character depending upon whether they are from the west coast, such as Campbeltown and the Islay region, which produce highly peated malts, or from the Highlands or the Lowlands. Irish whiskies have a similar flavor to Scotch but do not have a peaty character.

Whisky produced in the USA has evolved in a different legislative framework, allowing for a greater variety of distinctive products. The basic definition of US whiskey is that it is distilled from a fermented grain mash at less than 95% alcohol (190° US proof). Within this broad definition, there are two special categories, which are bottled as such or provide flavoring whiskies for blending. In the first group, the cereal content of the mash is restricted to not less than 51% of the named cereal (e.g., rye for rye whiskey, maize for Bourbon), the distillation must be at less than 80% alcohol, and maturation must be in new charred oak. Bourbon takes its name from Bourbon County in Kentucky. Corn whiskey must be from a mash of 80% maize, and matured in new uncharred or used oak. If matured for 2 or more years, these are 'straight whiskies.' They are to the blender the equivalent of the Scotch malts, and provide the majority of the flavor in a blend with lighter flavored grain spirits. US blenders are also permitted to use 'blending materials,' such as sherry or blending wine, at up to 2.5%. (*See* **Barrels**: Wines, Spirits, and

Other Beverages; **Sherry**: The Product and its Manufacture; **Wines**: Production of Table Wines.)

Canadian whisky production follows the same general practice as in Scotland and the USA. Canadian blends are light column still whiskies with normally 10–15% of heavier-bodied flavoring whiskies. Up to 9.09% (on the basis of absolute alcohol content) of 'flavorings' is permitted, which may include wines and sherries, rum, brandy, bourbon, or malt whisky. Maturation must be for not less than 3 years, and oak casks of 182 l (40 imperial gallons) are commonly used. The range in flavor required by the blender cannot be achieved by using the products of many different distilleries, but techniques such as variation of the composition of the mash (corn, wheat, rye or barley), cooking procedures, yeast strain, distillation procedure, barrel type, and maturation period can be used. Traditionally, pot stills were used but these have largely been phased out. (*See* **Brandy and Cognac**: Armagnac, Brandy, and Cognac and their Manufacture; **Rum**.)

Similar products are produced in many other countries and are subject to local regulations, which, while generally similar in principle to the EU definition, allow different extents of variation. In Brazil, regulations permit the addition of a proportion of agricultural alcohol to blended whisky, and in Japan, the locally produced spirit is frequently blended with imported Scottish malts. Spain is a substantial producer of whisky, which must meet the EU requirements. EU and USA regulations also include provision for grain spirits or grain brandies, which are essentially similar to whiskies but not matured. In other parts of Europe (e.g., Poland), 'whiskies' are produced that are essentially vodkas, matured briefly and flavored with wood extracts or other materials, and which may or may not meet regulations commonly accepted for whiskies.

Raw Materials

The major grains used in whisky production are maize (*Zea mays*), barley (*Hordeum polysticum*), wheat (*Triticum vulgare*), and rye (*Secale montanum*). These are the grains traditionally used for whisky, on the basis of a high fermentable starch content providing a good yield of alcohol. A typical composition of these grains is shown in Table 1. In Scotland and Ireland, all the amylase activity required for starch breakdown is obtained from malted barley, in the form of either a kilned malt, which is stored at a moisture content of 5%, or a green malt, which is prepared specifically on site as a source of enzyme activity for production of grain whisky. Some regulations also permit the use of other (normally microbial) enzymes during wort production. Cultivars are normally selected on the basis of extract and fermentability, corresponding to spirit yield, or enzyme activity in the case of malt for grain distilling. Enzyme activity should be considered under process conditions, as this will not be the same as activity measured under optimum laboratory conditions. Ethyl carbamate is an undesirable trace component in distilled beverages, and its content in malt whisky is largely determined by the cyanogenic precursor, epi-heterodendrin, in malt. Barley cultivars that do not contain the precursor are being developed. (*See* **Barley**; **Rye**; **Wheat**: Grain Structure of Wheat and Wheat-based Products.)

Water is required for mashing, cooling during distillation, dilution of the spirit before maturation, and blending. The quality of the product may be influenced by the nature of the water supplied, and many distilleries take their water supply from individual water courses or special wells. Soft water is normally used for malt distilleries, but some degree of hardness is preferred in grain distilleries since this has a stabilizing effect on the amylase enzymes. The water should be monitored for chemical and microbiological contamination and be free of decaying vegetable matter. The water used for dilution of the spirit must have a low calcium and iron content, and is normally demineralized, to minimize the risk of discoloration or precipitation occurring in the final product.

The yeast used for fermentation is normally a specially grown distilling yeast that has good physiological and microbiological properties for producing alcohol. However, some recycled brewer's yeast is commonly used in Scotland, and yeasts from previous distillery fermentations may be used in some Bourbon

processes, which may influence the range of flavor products in the wash. The main criterion for yeast strain selection is normally efficiency in converting fermentable sugars to ethanol. To a limited extent, strains may be selected to provide the required composition and flavor characteristics in the distillate, particularly the ester content, and yeast cultivation and storage conditions also affect its performance. Yeasts expressing glucoamylase activity have been developed.

Barrels used in whisky production are produced from either American white oak, *Quercus alba* and related species, or the Spanish oak, *Quercus robur*. Scotch whisky is traditionally matured in barrels which have previously been used for Bourbon maturation or sherry production. Spanish sherry production is carried out in barrels constructed from either Spanish or American white oak. Except where the regulations provide otherwise, barrels are commonly reused until they fail to provide a satisfactory maturation. Such barrels may be regenerated by scraping out the inner surface and charring the inside of the barrel, but this does not produce performance equivalent to a new barrel. During periods when sherry casks have been in short supply, barrels have also been wine treated or wine seasoned (filled with sherry for up to 6 months), and Madeira or port casks are also occasionally used. (*See* **Barrels:** Beer Making; **Sherry**: The Product and its Manufacture.)

Method of Manufacture

Malting and Mashing

The traditional method of production involves the production of wort from cereal grains using amylases from barley. These α- and β-amylases are produced by the barley during the malting process. Malting of barley is carried out by steeping the grain in water for 2–3 days and permitting the grain to germinate until the root is approximately one-third the length of the grain. When this stage is reached, the grain is dried down to a moisture level of 5% by kilning. The grain is then stored until immediately prior to use, when it is milled before being transferred to a mash tun. In Scotch whisky production, peated malt is prepared by drying the malt in the presence of smoke from a peat fire and is an important source of flavor compounds, normally assessed on the basis of the total phenols content of the malt (up to 50 p.p.m.), although other components may contribute to flavor. The nitrosamine contamination of malt has recently been of concern in Scotch whisky, arising from the use of natural gas in directly fired kilns. This can be controlled by the use of burners designed to reduce nitrogen oxides, by burning sulfur to add sulfur dioxide to the air stream, or by indirect firing. (*See* **Flavor (Flavour) Compounds**: Structures and Characteristics; **Phenolic Compounds**.)

Most of the breakdown of the starch occurs during the process of mashing, which is carried out in a mash tun. Barley grist can be mashed directly since it has a high amylase activity, whereas worts produced from maize and other cereals require the addition of malted barley as a source of enzymes. The process of mashing may be a simple batch process similar to the infusion mashing techniques used in brewing beer, in which the grist is mixed with water at 63–68 °C for 0.5–1.5 h before the wort is filtered off. However, in the production of grain whisky, an initial cooking stage, to gelatinize the starch of the nonbarley cereals, is required. The cooking may be carried out as a batch process at 120 °C for 1.5 h or, as is more usual in North America, as a continuous process. In either case, the mash is cooled to 60–65 °C before the addition of the malted barley. Careful control is required at this stage to prevent the solidification of the gelatinized starch. When a cooking stage is used, amylase activity is normally provided by adding 10–15% freshly malted barley (green malt) after the cooking stage (Figure 1). (*See* **Starch**: Structure, Properties, and Determination.)

During the malting stage, β-glucanase enzymes are also produced; these facilitate the breakdown of the endosperm cell walls and the release of starch and proteases. The latter are involved in the breakdown of some of the barley grain proteins to amino acids and peptides. These amino acids are an essential nitrogen source for the growth of the yeast. (*See* **Amino Acids**: Properties and Occurrence; **Peptides**.)

The mash is usually filtered prior to the fermentation to give a clear wort, but in some processes, a higher yield is obtained by fermenting the whole mash directly. The composition of a typical Scotch grain whisky wort is shown in Table 2. Refer to individual ingredients.

Fermentation

The wort, which is produced when the contents of the mash tun has been filtered, is then transferred to a fermentation vessel and fermented using one or more strains of the yeast *Saccharomyces cerevisiae* to give a wash containing approximately 7% ethanol and a large number of flavor compounds. When the wort is not boiled (as is the case in malt whisky production), it contains microorganisms and active amylases. It is cooled to 20–25 °C before inoculation with a strain of distilling yeast and, in some processes, secondary yeasts. Yeast growth occurs rapidly and is completed in the first 8–12 h. Ethanol production follows

growth initially, then continues in a linear manner until the metabolizable sugars have been consumed. During the growth period, wort sugars are rapidly metabolized, and the temperature may rise to 33 °C if it is not controlled. The pH drops from an initial value of 5.0–5.5 to 4.2–4.5 as a result of the production of organic acids, such as acetate, succinate, and pyruvate. A wide range of flavor compounds, such as higher alcohols, fatty acids, esters, and carbonyl compounds, are also produced throughout the fermentation; they pass through into the distillate and constitute an important part of the product. In contrast, glycerol, which is also produced, is nonvolatile and does not pass into the distillate; this represents an important loss of yield. At the end of the fermentation, usually between 48 and 72 h, death and autolysis of the yeast may occur. The fermentation is not a sterile process, so bacterial contamination can occur. Most of the bacteria that are introduced from the raw materials die during the early stages of the fermentation. However, lactobacilli can survive and grow with a concurrent formation of lactic acid during the later stages of the fermentation. There is some suggestion that limited growth of lactic acid bacteria is beneficial in flavor terms, but to prevent excessive growth and resulting yield losses, fermentation is normally completed in 40–48 h, rather than the longer times traditionally used. Heavy contamination by lactic acid bacteria can also result in a loss of yield and the production of acrid off-flavors. (*See* **Lactic Acid Bacteria**.)

Distillation

The fermented wash is then distilled either in a series of two or three pot stills (Figure 2), or in a series of column stills. The distillation process varies with the type of product and the country of origin. Historically, the first whisky processes used copper pot stills, and this type of process is still used for the production of malt whisky in Scotland, where two stills – the wash still and the spirit still – are used. In Ireland, a three-still process was typical. Pot stills have also been used in the USA and Canada, but grain spirit is normally produced by continuous distillation in column stills. Again, the first continuous process is associated with Scotch whisky production and the development of the Coffey or Patent still by Aeneas Coffey in 1830. The ethanol concentration of the

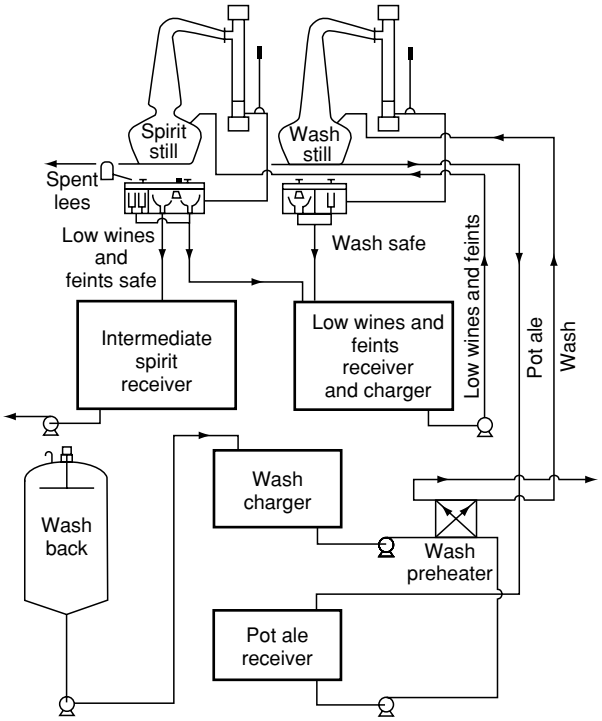

Figure 2 Typical malt distillery flow diagram. From Nicol D (1989) Batch distillation. In: Piggott JR, Sharpe R and Duncan REB (eds) *The Science and Technology of Whiskies*, pp. 118–149. Harlow, UK: Longman Scientific and Technical, with permission.

distillate determines the extent of impurities (congeners) present, a higher strength distillate being purer aqueous ethanol, and thus its strength of flavor.

In batch distillation processes, all the contents of the fermenter are transferred to the large wash still and boiled for 5–6 h to produce a distillate, low wines, which contains 20–25% (v/v) ethanol. This is transferred to the smaller low wines or spirit still where it is distilled to give a spirit containing around 70% (v/v) ethanol (Figure 3). The Coffey still consists of two columns, referred to as the 'analyzer' or 'beer column', and the 'rectifier column.' The wash is fed towards the top of the first column, and alcohol-free stillage is withdrawn at the bottom of the column; vapors are fed from the top to the base of the rectifying column (Figure 4). This produces a 190° US Proof spirit and is still used for the production of grain spirit in Scotland. In the USA, whisky production employs more complex distillation processes involving the use of up to five columns. The heat for most distillation processes is supplied as steam at the present time, although pot stills directly fired by solid fuel or gas are also in use. In addition to producing spirit, distillation processes produce a large quantity of stillage, which is processed into various by-products, such as dark grains and distiller's solubles.

Maturation

All whiskies are matured, and most legal definitions of whisky incorporate a minimum maturation period. The legal minimum varies from 1 year for some American grain whiskies to 3 years for Scotch, Irish, and Canadian whiskies. In effect, these are the minimum requirements, and most spirits are matured for longer periods. Branded products are generally matured for between 4 and 8 years, whereas single malts and premium straight whiskies are matured for 8 to more than 18 years. The process of maturation involves storing the raw spirit from the still, diluted to 50–80% ethanol, in barrels made from a limited range of oak woods. The type of cask used greatly affects the properties of the mature spirit. American straight whiskies (e.g., Bourbon) are matured in new charred American oak barrels that by law cannot be reused. Maturation in new charred casks is associated with an increase in color, solids, acids, esters, aldehydes, and tannins, together with increases in sugars, such as arabinose, glucose, and xylose. (*See* **Carbohydrates:** Classification and Properties; **Tannins and Polyphenols.**) New charred casks give a strong sweet, wood-derived flavor to the final product. The casks used for straight whisky maturation are American standard barrels (180 l) made from American white oak. 'White oak' is a cooperage trade classification used for at least 10 oak species, the principal species being *Quercus alba*.

Most other types of whisky are matured in barrels previously used either for maturation of Bourbon or in sherry production. Bourbon barrels may be used 'as is' or reassembled as hogsheads, with additional staves and new ends to increase capacity (250 l). Reuse of casks decreases the levels of wood components extracted during maturation and gives a much less intense wood-derived flavor. Sherry casks used for the maturation of some whiskies are generally butts or puncheons (480–520 l), which have been used for the fermentation and/or aging of various styles of sherry. Sherry casks can be either American or Spanish oak casks (predominantly *Quercus petraea* and *Quercus robur*). American oak is generally used for fino and amontillado sherries, whereas Spanish oak is used for oloroso sherry. For sherry casks, distillers will specify the species of oak, whether the cask is used for fermentation and the contact time with maturing sherry, as all are known to affect the final properties of the mature spirit. In all but Bourbon production, casks are reused until they are exhausted, i.e., fail to produce a satisfactory change in the spirit over an economical maturation period. The life of a cask can be extended by removal of the old char layer and refiring the cask. This regeneration

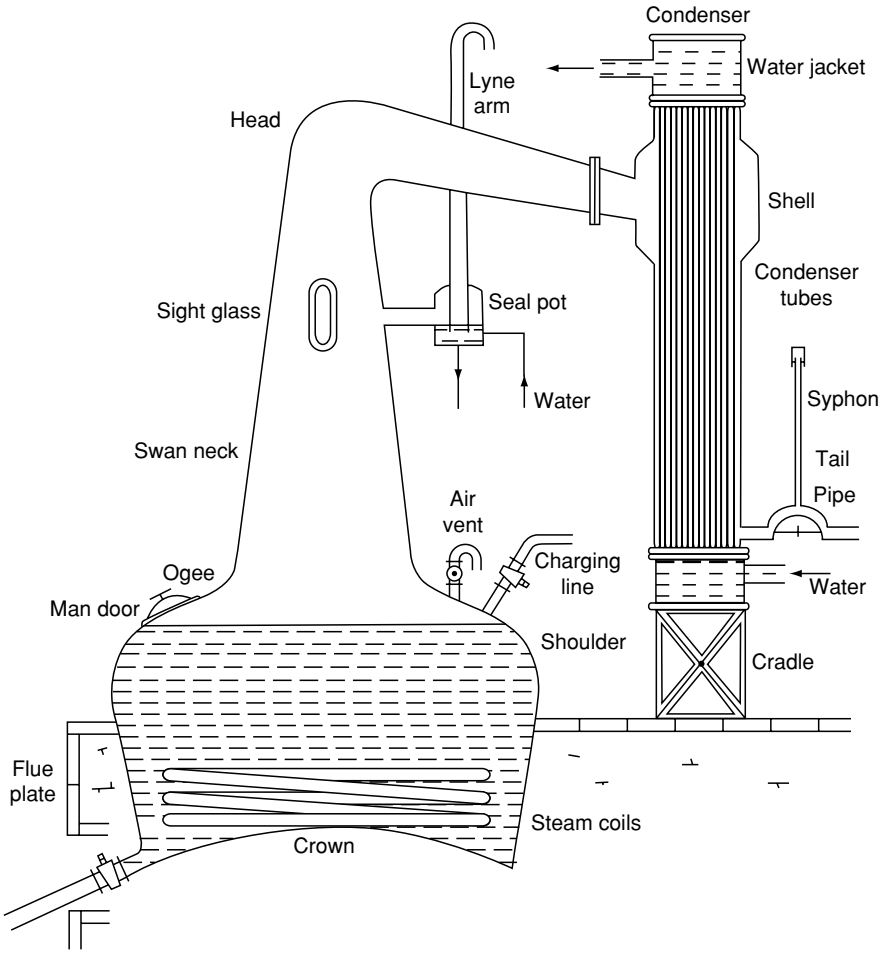

Figure 3 Plain wash still. From Nicol D (1989) Batch distillation. In: Piggott JR, Sharpe R and Duncan REB (eds) *The Science and Technology of Whiskies*, pp. 118–149. Harlow, UK: Longman Scientific and Technical, with permission.

increases the levels of wood polymer breakdown products extracted during subsequent maturation, but does not regenerate all wood constituents, and such casks give different sensory properties when compared with a new cask.

Maturing whisky was traditionally stored in stone-built warehouses located beside the distillery. Casks were stored in racks or in 'stows,' two or three high on the earth floor. Expansion in production resulted in much larger warehouses with steel racking, which allowed casks to be stored up to 12 high. The temperature and humidity within warehouses vary between different countries, and this can affect the way in which a spirit matures. In cool damp climates, such as Scotland and Ireland, more ethanol than water evaporates from the cask and consequently strength decreases during the maturation period. In warm dry climates, such as the USA, more water than ethanol evaporates and strength increases. During maturation, many of the chemical changes that occur are influenced by the storage conditions, particularly temperature. However though higher maturation temperatures have been shown to increase the rate of extraction of wood components, this does not generally correlate with improvements in sensory quality.

Blending to Bottling

All whiskies are to some extent blended. Even in the most tightly controlled environments, batch-to-batch variations can occur at any stage in the production process. Blending is used to produce a consistent product that has the distinctive flavors of that particular brand. For Bourbon and single malt production, variations are evened out to create the recognized brand from different batches of whisky. True blended whiskies consist of light bodied spirits mixed with a number of heavier bodied spirits in a wide range of proportions. 'Light-bodied spirits' are those distilled to high ethanol concentrations using continuous column stills and include Scotch grain and American light whiskies. 'Heavier bodied' whiskies are either

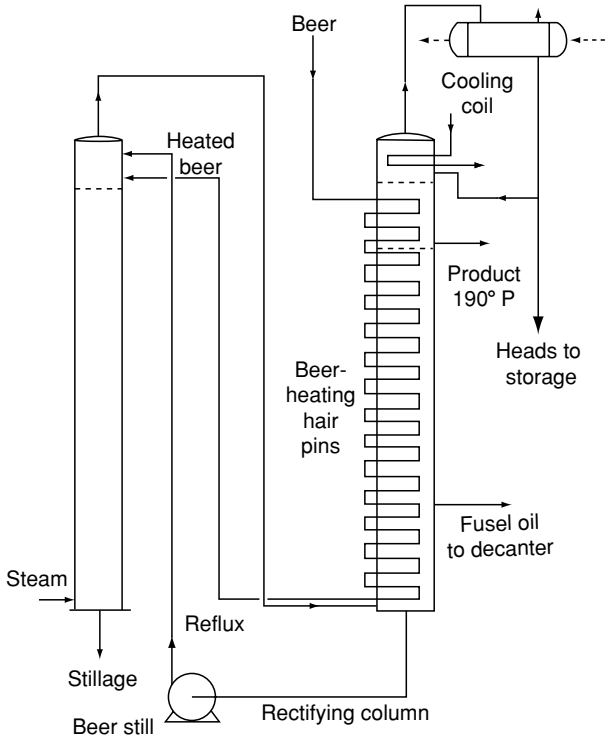

Figure 4 Coffey still. From Panek RJ and Boucher AR (1989) Continuous distillation. In: Piggott JR, Sharpe R and Duncan REB (eds) *The Science and Technology of Whiskies*, pp. 150–181. Harlow, UK: Longman Scientific and Technical, with permission.

batch pot still products or column still products distilled to lower ethanol concentrations. The nature and components of blends are determined by the traditions and regulations of the country of origin. In Scotland, there are a large number of distilleries, and blend recipes are complex with as many as 50 malt whiskies used. Purchasing or exchanging new whiskies by producers maintains the complexity of these blends. In North America, where there are fewer distilleries, and trading between competitors is uncommon, the variety of whiskies for blending can be increased by variations in mash bills, fermentation conditions, distillation parameters, maturation periods, and cask types.

The physical process of blending is, however, very similar. Approved whiskies are drained from casks into passivated steel troughs, which convey the whisky to a blending vat. Mixing uses mechanical agitators and compressed air. When the blend is correct, deproofing water is added to reduce the alcohol content to bottle strength. In Scotland, blending is sometimes followed by a further maturation or marrying period to allow integration of the individual components into the final product. An additional maturation or finishing period is also used for some single malts. This frequently employs a distinctive wood type, such as port casks, and is used to add complexity to a whisky or to increase the number of styles available from a single distillery.

Most whiskies are filtered prior to bottling to reduce the risk of haze formation during storage. In heavier bodied older whiskies and whiskies matured at high strengths, high-molecular-weight lipids and wood components slowly flocculate when the whisky is reduced to bottling strength. This is controlled by chill filtration, where whisky is cooled to between -10 and $10\,^{\circ}C$ for a specified period of time, and the problem compounds are removed by physical separation and adsorption by a filter. The conventional filter is a plate and frame filter with preformed pads of cellulose, or cellulose impregnated or precoated with diatomaceous earth. Operational parameters depend on the batch size, the nature of the product, and the filtration rate required.

Composition and Analysis of Whisky

J R Piggott, University of Strathclyde, Glasgow, UK
J M Conner, The Scotch Whisky Research Institute, Riccarton, Edinburgh, UK

Introduction

Whisky has traditionally been assessed by expert blenders with many years of experience, by comparison of samples with experience or a reference. Vocabularies of descriptive terms have been used, which have often been presented in the form of a 'flavor wheel.' With the advancement in chromatographic techniques and their coupling with mass spectrometry, the number of compounds identified in whisky has increased dramatically. They include alcohols, carboxylic acids, esters, aliphatic carbonyl compounds, heterocyclic sulfur compounds and aliphatic sulfides, heterocyclic nitrogen compounds, a wide range of simple phenolic compounds, phenolic aldehydes, and heterocyclic oxygen compounds.

Sensory Assessment

Whisky has traditionally been assessed by expert blenders with many years of experience and training within the industry. An experienced blender knows what flavors of distillate a still can produce, which are desirable, and how a whisky is likely to develop during maturation. The blender's task is then to identify faults and deviations from the expected path of maturation, and to select a specific maturation point at which a whisky can contribute to the blend. Blenders use a system of flavor description to assist their work, but their method of working is largely by comparison of samples with experience or a reference. Each sample is evaluated in terms of its similarity to an expected or acceptable product. (*See* **Sensory Evaluation**: Taste.)

Scotch grain whiskies are light-bodied continuous still spirits, largely regarded as providing a background for a blend. Malt whiskies provide the majority of the character of a particular blend, and, though the distilleries all produce slightly different whiskies, for convenience, they are divided into groups sharing common characteristics. The Highland malts, the most numerous, are further divided into first, second and third class. These are not intended to be quality evaluations, but are simply descriptive classes. The Lowland malts are not regarded as having a distinctive character, and thus can be used in relatively large quantities in blends. There are only two remaining Campbeltown distilleries, and this group has, as a result, declined in importance. The Islay whiskies tend to be full-flavored and are usually heavily peated, and thus have a significant impact on a blend even when used in small proportions. The Highland group contains most of the great whiskies, which have established reputations as single malts and for their value in blending. A wide range of flavors is available, and a skilled blender can make use of it to create a distinctive blend.

Formal methods of laboratory sensory analysis have also been used. Many companies use difference tests for quality-control monitoring, and the whisky industry seems to have been one of the first to adopt the duo–trio and triangle tests for such purposes. Over the past 25 years or so, there has also been an increasing interest in the assessment of whiskies by profiling or descriptive methods, largely for research into the origins and development of flavor in whiskies. Several broadly similar vocabularies of descriptive terms have been used. These vary mainly in the number of terms they include, and therefore in the detail with which they attempt to describe flavor. They have often been presented in the form of a 'flavor wheel,' with varying numbers of concentric tiers, which, while having no particular theoretical significance, provide a framework for communication and training (Figure 1).

The Chemistry of Flavor Compounds

With the advancement in chromatographic techniques and, in particular, their coupling with mass spectrometry, the number of compounds identified from whisky has increased dramatically. Particular use is made of gas chromatography with a number of detectors for the measurement of volatile organic compounds. Nonvolatile constituents may be measured as a whole spectrophotometrically, or individually by high-performance liquid chromatography. Problems arise, as compounds of sensory importance may be present at very low concentrations (nanograms per gram). Typical analyses of a Scotch malt whisky new distillate are shown in Table 1, and the major categories of compounds thought to be important in the development of flavor are discussed below. (*See* **Chromatography**: High-performance Liquid Chromatography; Gas Chromatography; **Flavor (Flavour) Compounds**: Structures and Characteristics; **Mass Spectrometry**: Principles and Instrumentation.)

Alcohols, Carboxylic Acids, and Esters

Aliphatic alcohols, acids, and esters are produced by the yeast during fermentation, though ester formation

may also occur during distillation and maturation. Saturated and unsaturated chains are found, ranging from one to 16 carbon atoms. Short-chain alcohols such as propanols, butanols, and pentanols are the most abundant. Nonaliphatic alcohols include 2-phenylethanol and 2,3-butanediol. The principal organic acid is acetic acid, accounting for between 50 and 90% of the total content of volatile acids. Octanoic, decanoic, and dodecanoic acids are quantitatively important, though lower-molecular-weight acids such as butanoic and pentanoic acids may have more sensory impact. The most abundant esters are the ethyl esters of the acids named, their concentrations reflecting the relative abundance of the acid. Any other combination of the acids and alcohols present may occur. After ethyl esters, the most abundant are acetate esters such as isoamyl acetate and phenylethyl acetate. The esters of hydroxy acids, such as lactic acid, and of dicarboxylic acids, such as succinic acid, can be distilled along with alcohol and steam and so occur in whisky.

Aliphatic Carbonyl Compounds

The majority of carbonyl compounds are produced by the metabolic actions of the yeast. However, their formation by oxidation of unsaturated fatty acids or Strecker degradations has been shown to occur at almost any stage of production. Acetaldehyde is the most common and is often used to determine total aldehydic content. Many other aldehydes, ketones, and acetals have also been identified. For aldehydes and ketones, aliphatic chain lengths, both saturated and unsaturated, range from two to 14 carbon atoms. Due to the high alcoholic strengths of the distillate,

aldehydes exist in equilibrium with the corresponding acetal and hemiacetal. The most frequently reported acetal is 1,1-diethoxyethane, though a range of aldehydes up to six carbon atoms have been shown to form acetals.

Sulfur and Nitrogen Compounds

Yeasts have the ability to utilize inorganic sulfur, sulfur-containing amino acids, and vitamins, and from these sources, volatile sulfur-containing compounds are produced. The range of compounds detected includes heterocycles, such as thiazoles and thiophenes, and aliphatic mono-, di-, and trisulfides. Formation of sulfur compounds has also been shown to occur during distillation, and concentrations are highest in new spirit. Wood extract and traces of elemental copper are important in the degradation of such compounds during maturation (Table 2). Heterocyclic nitrogen compounds such as pyrazines, pyrroles, and pyridines are formed via the Maillard reaction during cooking, mashing, distillation, and barrel charring. As they have relatively low odor thresholds, they may well make a contribution to the aroma of whisky. (*See* **Browning**: Nonenzymatic.)

Phenols

A wide range of phenolic compounds are found in whisky. Simple phenols such as phenol, the isomeric cresols, xylenols, ethyl phenols, and guaiacols arise through the thermal degradation of benzoic acid derivatives from malt and from peat smoke. Phenolic aldehydes such as vanillin, syringaldehyde, coniferaldehyde, and sinapaldehyde are formed from the breakdown of wood lignin during cask charring and maturation. Their corresponding acids and ethyl esters have also been detected. Polyphenols extracted from the wood include ethanol-soluble lignin and tannins derived from both gallic and ellagic acids. (*See* **Phenolic Compounds**; **Tannins and Polyphenols**.)

Heterocyclic Oxygen Compounds

The main types of these compounds found in whisky are furaldehydes and lactones. Furfural (2-furaldehyde) is formed from pentoses and 5-hydroxymethyl-2-furaldehyde from hexoses via the Maillard reaction during mashing, distillation, and cask charring. Lactones are formed by the dehydration of aliphatic hydroxy acids, and most are derivatives of 2(3H)-furanones. The most abundant of these are the *cis* and *trans* isomers of 5-butyl-4-methyldihydro-2(3H)-furanone, the oak or whisky lactones, which are formed and extracted from oak casks during maturation.

Variations with Processing

Though there are only four basic processes in whisky production; local, regional, and national variations in these processes are responsible for the large number of whiskies available. Each stage of production, from the production of a fermentable extract, through to fermentation, distillation, and maturation, can affect the character of the final product. However, each stage is interlinked, and identifying one, as the most important for a particular type of whisky, is often impossible.

Production of a Fermentable Extract

The cereal grains in common use are wheat, corn (maize), rye, and barley, though the choice of cereal is often legally restricted. Flavor differences between cereals arise from two quite separate sources. The choice of cereal can also indirectly affect the flavor of the final product. The composition of the fermentable extract varies with cereal used and can influence the metabolism of the yeast. Factors such as pH, amino acid concentration, and levels of insoluble material are known to affect the levels of fusel alcohols, acids, and esters produced, which may influence the flavor of the final product. Between cereals, differences also exist in the levels of precursors for a number of classes of flavor compounds. Examples are compounds formed by the chemical and enzymatic oxidation of fatty acids, the reaction of free amino acids and reducing sugars (Maillard reaction), and the thermal degradation of biosynthesized precursors like *S*-methylmethionine and benzoic acid derivatives. However, the breakdown of these compounds frequently occurs during fermentation and distillation and is affected by variations in these processes. Consequently, no flavors in the final product have been unequivocally linked to components of the original cereal.

Fermentation

Fermentation is responsible for the primary production of a large number of flavor compounds in whiskies. Factors that are known to alter the production of these compounds are the strain or mix of yeasts used, design and level of aeration in the fermenter, the duration of the fermentation, and the presence of contaminating bacteria. These factors alter according to distillery design and the raw materials employed and so may be important in producing regional and national differences in whiskies.

Distillation

In batch distillation using pot stills, the selection of the cut points in the still run has a marked influence on the flavor of the product. Generally, aldehyde and short-chain ester concentrations are determined by the primary cut from foreshots to spirit, while the concentration of fusel alcohols and acids is determined by the cut from spirit to feints. Other factors, which affect the physical process of separation during distillation, are still design parameters such as the still height, the angle and length of the lyne arm, and the type of condenser used. In addition, a number of chemical reactions can occur when the wash or low wines are heated for distillation. This is particularly true for batch distillation in pot stills where the heat impact is greater. Examples include the formation of sulfur compounds from sulfur-containing amino acids, the breakdown of unsaturated fatty acids to carbonyl compounds, and the dehydration of β-hydroxypropionaldehyde to acrolein. Copper catalyzes many of these reactions.

In continuous stills, congener concentrations are determined by the design, operation, and efficiency of the still. The range of reactions described for pot stills can still occur but becomes progressively less important as the distillate strength increases. Collection of spirit at high ethanol concentrations (> 90%) results in low levels of congeners in the spirit.

Maturation

During the maturation period, the new distillate becomes highly modified as a result of its contact with the cask (Figure 2). The composition of the cask wood has a major effect on the extent of this modification and varies with the species of oak used, the pretreatment applied to the wood, and the previous use of the cask. In general, American oak (*Quercus alba*) yields higher concentrations of vanillin and *cis* oak lactone, whereas Spanish oak (*Quercus robur*) gives higher concentrations of tannins. Charring increases the levels of lignin breakdown products and lactones extracted during maturation, whereas previous use of a cask greatly reduces the amount of extractable lignin breakdown products and lactones. The use of sherry casks results in raised levels of tannins and sugars. The cask is the major determinant of mature quality, but other factors such as filling proof, climate, and warehouse conditions also affect the course of maturation. Higher temperatures produce greater evaporation rates and also increase extract levels and some reaction rates, but do not necessarily produce a more mature product.

Correlation of Chemical Composition with Sensory Data

The flavor of whisky is dependent upon a complex mixture of components that originate from, and are modified by, different stages of production. Although improved analytical methods have revealed much about the chemistry of whisky, this has not resulted in a better understanding of the chemical basis of whisky flavor and quality. Frequently, chemical differences can be related to variation in production processes, but identifying the actual compounds responsible for the flavor differences has been much more elusive.

The extent to which volatile compounds from cereals survive fermentation, distillation, and maturation is the hardest to establish. Whisky prepared

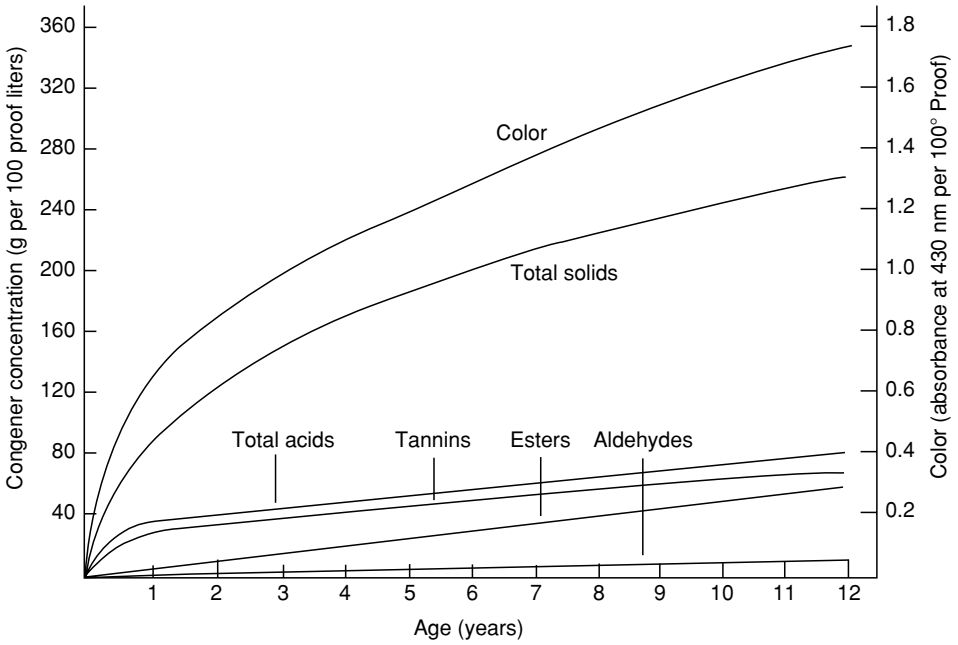

Figure 2 Congener changes during maturation of whisky. From Reazin GH (1981) Chemical mechanisms of whisky maturation. *American Journal of Enology and Viticulture* 32: 283, with permission.

from heavily peated malt retains a characteristic flavor that is strongly correlated with the total phenols content of the malt and of the whisky. However, the range and concentration of phenols present are greatly altered by mashing, fermentation, and distillation, and whether the phenols fully explain the 'peated' flavor is still uncertain. Likewise, some whiskies (especially Canadian) have a characteristic 'spicy' or 'minty' flavor, which is possibly related to the use of rye in the mash, but no compound has been identified as responsible.

Various flavors in new distillates have been correlated with sulfur compounds. Polysulfides are present in whisky at levels around and above their sensory thresholds (3–6 $ng\,g^{-1}$ for dimethyl trisulfide), and the data available suggest that these compounds are correlated with 'sulfury' and 'heavy' characters in fresh distillates. Other sulfur-containing compounds are thought to be important contributors to flavor, and their formation is dependent on the levels of precursors present in different cereals/cultivars. However, such compounds are frequently formed during fermentation and distillation and then degraded during maturation. Each stage has its own impact on the concentration in the final product, making it harder to establish their role in whisky flavor.

The products of fermentation and distillation make a substantial contribution to whisky flavor. However, these compounds, except when present in excess, appear to form what has been described as the 'integrated whisky complex,' and their individual contributions have not been determined. It does appear that relatively constant proportions of some of these compounds must be present for a recognizable 'whisky' character, though substantial changes can occur with only minor changes in flavor.

Compounds considered to be important in maturation are vanillin, eugenol, and *cis* oak lactone. These have been correlated to 'vanilla' and 'clove-like' flavors in some whiskies matured in new casks. However, cask reuse causes a general decrease in wood extractives, and their importance in whisky matured in refill casks is still uncertain.

Attempts to create a model of whisky flavor have been largely unsuccessful. Attempts were based on compositional analyses of the liquid. Research has since shown that there are complex relationships governing the release of flavor compounds from whiskies. Major factors identified include alcoholic strength and the nonvolatile content of the whisky matrix. Dilution of spirits for sensory assessment, to reduce the pungency of ethanol, can greatly alter the release of aroma compounds more soluble in ethanol than in water. Dilution also increases the capacity for matrix effects that suppress the release of ethyl esters and other aroma compounds. Matrix effects may occur through competition for release at the liquid surface or changes in solubility of flavor components. Changes in solubility can be related to the physical structuring of the ethanol–water

mixture. Differential scanning calorimetry, light scattering, and mass spectrometry have all demonstrated that physical changes occur during maturation, adding another layer of complexity to whisky flavor and reinforcing the uniqueness of each individual product.

WILD RICE

O W Archibold, University of Saskatchewan, Saskatoon, Canada

Background

Wild rice is an aquatic grass that grows naturally in shallow lakes and slow-moving rivers (**Figure 1**) in the Great Lakes region of North America. It is North America's only native cereal, and until very recently had not been improved by breeding and selection. Lake-grown wild rice is unique amongst commercial crops in that it is grown and harvested on water and, once established, will reseed itself indefinitely. Wild rice was an important staple of the indigenous peoples of the Great Lakes region and remains part of many legends and ceremonies. The range of the species was initially extended by the early European voyagers who took wild rice with them to establish food supplies along the waterways that they traveled. Recent commercial exploitation has greatly increased production and extended the crop well beyond its native range. Most of the wild rice is now produced in artificial paddies and combines have replaced the traditional hand-harvesting methods. Vigorous marketing and product development have created global markets for this highly nutritious crop.

Taxonomy and Tradition

The contemporary common name 'wild rice' applies to annual species of *Zizania*, emergent aquatic grasses, which are native to eastern and central North America. Four forms are generally recognized on the basis

Figure 1 Shallow bays supplied with nutrients from slow-moving streams provide the ideal wild rice habitat.

of morphology, range, and habitat. The exclusively riparian species *Z. aquatica* L. includes the variety *aquatica* (Hitch.) Fassett (southern wild rice) and the variety *brevis* (Fassett) Dore (estuarine wild rice). A second species, *Z. palustris* L. is comprised of the variety *palustris* Dore (northern wild rice) and the variety *interior* (Fassett) Dore (interior wild rice). *Zizania palustris* is the most widespread species; it is also the species of commercial value, owing to its large seed size. Northern and interior wild rice are found in the upper Mississippi–Great Lakes region, extending into the boreal forest. These two varieties are sympatric over much of their ranges, although a latitudinal gradation in dominance is acknowledged.

Wild rice grows naturally in shallow lakes and streams, and is a traditional crop of the native peoples of the upper midwestern USA and central Canada. The grain was a staple diet for these seminomadic peoples, and was a cherished resource that was vigorously guarded for food and trade. French explorers noted the resemblance of wild rice to tares, a troublesome weed of wheat, and during this period it was known as 'folle avoine.' Indeed, the scientific name chosen by Linnaeus comes from the Greek *zizanion* – a weed of Mediterranean grainfields. By the early nineteenth century, English-speaking explorers called the grain 'wild rice' or 'Indian rice' because its aquatic habitat reminded them of Asiatic white rice (*Oryza* spp.). Wild rice, and the French Canadian equivalent 'riz sauvage,' remain the common names for the species. By the end of the nineteenth century, non-Native Americans started to become interested in the potential of wild rice as a commodity, first as brokers assuming control of wild rice processing and sale, then as planters and farmers, ultimately gaining control of the industry. Records of treaty negotiations show repeatedly the attempts by native Americans to explain the importance of their natural resources. Various federal and state laws have been passed which recognize the traditional value of the crop, and specify the type of equipment that can be used and the amount of wild rice that can be collected. Consequently, most of the lake-grown wild rice in Minnesota and Wisconsin is under control of Native Americans. Legislation in Canada similarly provides for aboriginal involvement in wild rice production in the pristine northern lakes. However, increased commercial demand and high commodity prices in the late 1970s resulted in the rapid establishment of artificial paddies which now account for most of the production.

Life Cycle of Wild Rice

Wild rice is an annual plant that grows each year from seed and requires approximately 120 days to mature. Under natural conditions ripe seeds shatter into the lakes. The seeds do not germinate until they have been subjected to an afterripening period of several months at low temperatures. Dormancy is broken naturally during the long boreal winters while the seeds lie embedded in the mud beneath the frozen lake. Freezing does not harm the seeds and germination begins in late spring, when water temperatures rise to about 5 °C. For the first 3 or 4 weeks of growth the young plants are under water, then long, thin leaves reach the surface as the plant enters the floating-leaf stage. By the end of June the stem and leaves begin to emerge from the water and the plant enters the aerial-leaf stage. Additional stems (tillers) may arise from the lower part of the stem and increase the density of the stands.

Flowering commences in mid-July, with separate male and female florets forming a branching panicle up to 50 cm in length, although considerable variation in panicle size occurs within and between natural stands. The flowers mature from the top down. The female (grain-producing) flowers nearest the top are the first to bloom, and it can take several weeks for all of the flowers to mature. Wild rice is wind-pollinated. The female flowers remain receptive to pollen for only a few days and so receive pollen from the male flowers on other plants; this insures cross-pollination and high genetic diversity. The grains take 4–6 weeks to mature following pollination. During this time the maturing grain passes through the soft-textured milk and dough stages until it becomes firm and greenish-black in color within the encasing hull. The first seeds usually ripen by the end of August, and must be harvested quickly because they shatter readily. However, seeds will continue to ripen over a period of several weeks until the plant is killed by frost. Seed loss, even in harvested stands, is normally sufficient to maintain stands from year to year.

Environmental Conditions in Natural Stands

Wild rice growing in unmanaged habitats is sensitive to the vagaries of the weather. In the early stages of growth, water depth and wind are critical because the young plants can be drowned or uprooted by wave action. The ideal water depth is 75–100 cm. Mature grains can be lost under windy conditions, and in some areas the harvest period is often cut short because of frosts. Wild rice production is also influenced by numerous site-specific environmental factors. Wild rice does not grow well in acidic water that is low in essential nutrients; neither will it grow well in alkaline and saline water. Total alkalinity ranging from 40 to 80 mg l^{-1} and pH values ranging from

6.9 to 7.4 are considered optimal, although the relationship between sediment chemistry and wild rice production is tenuous. Wild rice will grow on a variety of sediments, but the most productive stands are typically associated with soft organic materials that are easily permeated by the coarse fibrous roots. The state of oxidation of the sediment is an important factor affecting production, and many lakes seeded to wild rice seem incapable of nurturing the crop when E_h (redox) values are below −200 mV.

Wild rice growing in lakes does not compete well with taller, emergent perennials such as spike-rush (*Eleocharis palustris*) and cattails (*Typha latifolia*), which renew growth early in the spring. Similarly, floating-leaved aquatics such as water lilies (*Nymphaea* spp. and *Nuphar* spp.) and bur reed (*Sparganium* spp.) can also be problematic. In paddies common water-plantain (*Alisma trivale*) and various aquatic grassy weeds are of concern as no herbicides have been cleared for their control. Intraspecific competition for light and nutrients can also occur in very dense stands of wild rice and some paddies are thinned to increase in production.

Lake-grown wild rice is relished as a food source by waterfowl, muskrats, beavers, and moose, while red wing blackbirds (*Agelaius phoeniceus*) and crayfish (*Orconectes virilis*) are pests in the paddies. Insect depradation and losses from fungal, bacterial, and viral diseases have also been reported. Most damage is attributed to the riceworm (*Apamea apamiformis*) which feeds on the developing grain and the rice stalk borer (*Chilo plejadelus*) which feeds on the lower stems, making them susceptible to breakage or causing incomplete development of the grain. Reduced yields are also attributed to leaf spot, smut, and similar microbial pathogens. Ergot has long been associated with wild rice.

Agronomic Development

The natural range of wild rice has been extended through deliberate introduction, but early expansion of the industry was hampered by unreliable yields from stands in natural lake environments. The first attempts to domesticate the crop began in the 1950s when wild rice was grown in Minnesota in dyked paddies where a water depth of about 30 cm could be maintained during the growing season. A further significant development occurred in 1968 when the nonshattering Johnson cultivar was introduced. In Minnesota this has largely been replaced by earlier-maturing cultivars such as K2, Voyager, and Franklin. Shattering resistance requires the crop to be harvested by specially modified combines and grain losses have been significantly reduced. The paddies are drained prior to harvest and must be reseeded to wild rice in much the same way as other grain crops.

Agrochemicals are also used to maximize paddy production. Ammonium phosphate or urea is commonly incorporated into the upper few centimeters of the soil during seedbed preparation together with phosphate and potash; nitrogen topdress applications may be desirable as the stem begins to elongate. Fungicides may also be needed. Weeds are usually controlled by water management, while pests, such as blackbirds and crayfish, may also need to be controlled. Such agronomic developments have reduced the problem of unpredictable yields, thereby facilitating expansion of commercial markets for wild rice.

By 1978 more than 4000 ha of paddies had been established in Minnesota, and production approached 1.0 million kg of processed wild rice compared to 0.46 million kg from lakes. This year is significant because in 1978 paddy wild rice cultivation commenced in California. By 1986 production in California exceeded 4 million kg (processed) compared to 2.3 million kg in Minnesota. Paddy acreage in Minnesota is now about 6500 ha compared to about 3200 ha in California, with combined production currently about 5.0 million kg; this accounts for more than 90% of the world's supply. Approximately 0.4 million kg is produced annually in Canada, mainly in Saskatchewan, Manitoba, and Ontario. The remainder comes mostly from Idaho, Wisconsin, and Oregon. Although trials have been conducted in Finland, at present wild rice is not grown commercially outside North America.

Harvest

In traditional harvests wild rice is collected by knocking the grain into canoes using two sticks. It is then dried in partial shade to avoid mildew, picked over to remove pieces of stem and leaves, then parched by smoke drying or scorching in kettles. Each kernel is enclosed by a hull comprised of a scabrous lemma and palea which is difficult to remove until it has been heated. Once detached from the seed by treading or threshing, the chaff is removed by tossing in the air with large winnowing trays. The kernels left in the tray are then ready for cooking or storage. The traditional stages of processing have been adopted by the commercial plants that handle the massive increase in yield harvested mechanically from the paddies. Dyked and ditched fields allow water levels to be closely regulated at all stages of production, and fertilizers and pesticides are applied as necessary to optimize yields. In August the paddies are drained to allow access by modified combine harvesters. After a period of drying to help

eliminate weeds, the soils are prepared for seeding the next year's crop. Paddies in Minnesota are planted in the fall and reflooded the following spring. In California the seed must be kept in cold storage to break dormancy prior to planting in the spring.

Lake-grown wild rice differs from other crops because it is grown and harvested on water. Unlike the nonshattering paddy cultivars, lake-grown plants must be harvested regularly to minimize grain losses. Wild rice kernels mature gradually, beginning in August and continuing for 15–30 days, depending on weather conditions. About 3–6% of the potential yield matures each day. Maximum production can therefore be achieved if harvesting is repeated regularly during the ripening stage. A wild rice plant can develop many stems, particularly in shallow-water sites. These tillers are capable of producing the same-quality grain as the main stem. However, tillers generally come into flower later than the main stems. Maximum yields can only be achieved if the area is harvested several times. Normally, harvesting is repeated every 4–7 days. Most of the lake-grown wild rice now comes from Canada and is harvested by propeller-driven airboats. The most widely used design consists of a blunt-bowed, flat-bottomed aluminum hull about 3.6 m long and 1.5 m wide fitted with a collecting tray, popularly known as a speedhead (Figure 2). The sides and rear of the speedhead frame are covered with window-screening material. The speedhead has no moving parts; the kernels are dislodged through the impact of the wild rice plants against the leading edge and they fall into the tray.

Processing and Grading

Freshly harvested wild rice for processing must be delivered to the plant as soon as possible. The grade and appearance of the finished product depend a great deal on how the wild rice is handled. Careful storage is important in that it helps begin the curing process. Not all of the wild rice is at the same stage of maturity, and it is necessary to pile it in windrows to allow it to cure. The windrows are watered regularly to prevent self-heating and drying. They must also be turned daily to prevent decay. It is during this 4–10-day period that the wild rice acquires its familiar black color and flavor, and the hulls also begin to loosen. When the grain is properly cured it passes into the parching ovens. Parching removes moisture from the kernels and toughens them so they will not break as easily. Smaller batch parchers will hold up to 275 kg of wild rice, and the drum is rotated to prevent the grain from burning. Larger processing plants use continuous-flow parching. It takes about 2 h for the grain to pass through the parcher at temperatures of 145 °C in these automated systems. Wild rice can be loaded into continuous-flow parchers at a rate of up to 400 kg h^{-1}.

Figure 2 Propeller-driven airboat used to harvest lake-grown wild rice.

The primary purpose of parching is to reduce the moisture content of the kernel to about 7% without fracturing. In addition, the hull is loosened, pigmentation of the pericarp is completed, and the flavor of the grain is brought out. Steam retention in closed parchers helps to give a glassy, translucent appearance to the grain by gelatinization of the starchy endosperm. After parching, leaf and stem fragments are removed by screening, and ferrous metals are trapped by magnets on the conveyors. The hot kernels immediately pass into the hulling machines where the dry hulls are removed. The kernels are dehulled by passing through a roll huller which consists of two closely spaced, rubber-faced rollers which rotate towards each other at different speeds. This strips the hulls off and makes the kernels look black and shiny. Some processing plants use a barrel huller in which rubber cogs rotate at high speed. The hulls and the kernels fall into an aspirator that sucks off the lighter chaff. Once the hulls are removed, the wild rice is cleaned by passing over vibrating screens to separate unhulled grain, stones, and other heavy materials. Once broken kernels have been sorted, the intact kernels are graded by size on a gravity table prior to inspection and packaging. Most plants use 45-kg sacks to bag the final product for storage.

Various grades of wild rice have been proposed by the Processors Committee of the International Wild Rice Association, mainly on the basis of size. The longest kernels command the highest market prices, as they are preferred by the gourmet culinary trade. For long-grain wild rice (grades 1 and 2), kernel length is greater than 1.03 cm, medium-grain wild rice (grade 3) is 0.79 cm, short-grain wild rice (grades

4 and 5) is 0.40 cm, with smaller kernels classed as small and broken wild rice (grades 6 and 7). These grades are further defined according to the percentages of kernels of each size. Long-grain wild rice requires a minimum of 85% long grains, and a maximum of 10% medium, 7% short, and 3% broken grains. Medium-grain wild rice contains a minimum of 80% medium grains and a maximum of 10% long grains, 10% short grains, and 7% broken; short-grain wild rice contains a minimum of 80% short grains, a maximum of 10% broken, 5% long, and 10% medium kernels. The average kernel weighs approximately 50 mg.

Four quality grades of wild rice are recognized – premium, choice, good, and standard – on the basis of foreign materials such as dust and chaff, unhulled grain, or weed seeds, damaged kernels, and percent moisture. Color, taste, and odor also affect product quality. Blackish-brown kernels are favored and quality is reduced if the thin bran peels off and exposes the white endosperm. The kernels also lose some of their color when some of the bran is removed through scarification. However, this is necessary to hasten cooking time and allows wild rice to be used in blended-rice products. Improperly processed rice which contains green kernels that have not been fully fermented or which lacks the preferred toasted flavor or has a musty odor is not acceptable. Moisture content is reduced to less than 7% during processing. This facilitates long-term storage, but stress cracks which develop due to excessive heat during parching make it susceptible to damage during subsequent handling.

Wild rice is considered a specialty by retailers and is often sold in regional airports and tourist resorts in attractive transparent packages or ornamental containers. Appearance is an important aspect of quality and customer appeal and broken kernels render the product less desirable. Lake-grown wild rice is normally larger than paddy-grown cultivars and so commands higher prices, but they are indistinguishable in terms of nutritional value.

Composition and Food Quality

In the traditional native diet, wild rice was more nutritious than other naturally available fruit, grain, or animal food sources. The wild rice kernel is similar in structure to other cereals. It consists of an embryo, a starchy endosperm, and an aleurone layer encased in a tough, impermeable pericarp. Wild rice has good nutritional value; it is rich in carbohydrates and high in protein and minerals, but low in fats and oils compared to other cereals. Starch accounts for approximately 75% of the dry weight of the kernels, protein averages about 13%, dietary fiber 7%, sugars 2%, minerals 2%, and oils and fats 1% (Table 1). Many amino acids are present at concentrations that are adequate to meet daily human requirements. Lysine, threonine, and methionine, important indicators of nutritional quality of cereals, are typically present at higher concentration in wild rice than in other grains (Table 2). Very little amino acid is lost in processing, whereas essential minerals (Table 3) are mainly present in the pericarp, and a considerable reduction occurs when wild rice is scarified or polished. Vitamin A is absent from processed wild rice, but it is a good source of dietary B-vitamins, especially niacin and thiamin (Table 4). Linoleic and linolenic acids are comparatively abundant and together make up about 70% of the total fatty acid content in wild rice. Although this is desirable from a nutritional standpoint, it can lead to problems of rancid odor if oxidation occurs because of improper storage. However, properly cured and stored wild rice remains wholesome for several years.

Wild rice has also attracted the interest of the food-processing industry because it contains the antioxidant phytate (myoinositol hexaphosphate). Additions of 15% by weight of cooked wild rice to beef patties has been shown to reduce rancidity by reducing the production of thiobarbituric reactive substances by as much as 50%. This has a significant potential in microwavable precooked meat products, especially as studies have shown consumer taste preferences for meat patties blended with wild rice. In addition, nutritive properties are enhanced, cholesterol and fat percentages are reduced, and cooking yields are augmented. Similar antioxidant properties were found with extracts from wild rice hulls; these are presently discarded at the processing plants. Wild rice starch has been shown to have a low degree of retrogradation and this may be useful in the paper, textile, and adhesive industries where changes in prepared batches of pastes are undesirable.

Table 1 Typical composition of wild rice and other cereals (g 100 g^{-1} of dry product)

	Wild rice	*Brown rice*	*Yellow corn*	*Hard wheat*	*Oat groat*
Starch	74.0	78.0	71.5	66.5	62.0

After Anderson RA (1976) Wild rice: nutritional review. *Cereal Chemistry* 53: 949–955, with permission.

Contamination of the wild rice habitat has prompted concern about elevated levels of toxic metals in the kernels which might pose a health hazard. Copper concentrations as high as 14.4 μg g^{-1} and lead and cadmium levels as high as 6.2 and 6.7 μg g^{-1} respectively have been reported in some samples of parched and dehulled wild rice. Locally elevated metal concentrations have been attributed to atmospheric deposition from smelters, and it has also been reported that lead derived from shotgun shells can be taken up by wild rice. Concentrations of lead (0.5–11.5 g 100 g^{-1} dry weight), cadmium (1.0–10.2 g 100 g^{-1} dry weight), and arsenic (0.6–14.2 g 100 g^{-1} dry weight) have been found in wild rice sold in the USA.

Concluding Remarks

Interest in wild rice from companies like Uncle Ben's and General Foods has spurred the development of the industry. Blended products containing 12–18% wild rice mixed with long-grain white or brown rice have increased on the supermarket shelves. The smaller grain sizes developed by breeders have eliminated the problems of lengthy cooking times and, coincidentally, increased the number of grains per package, thereby making it more attractive to consumers. With increasing acceptance of wild rice, a variety of products began to emerge, including stuffings, frozen casseroles, bread and pancake mixes, and puffed rice snacks, as well as a myriad of cookbooks and recipes. However, natural lake-grown wild rice continues to be the preferred choice of the gourmet and health-food markets. In an effort to maintain some control of the market, native growers were successful in getting legislation requiring that paddy-grown rice be so labeled, thus distinguishing it from the traditional product. Attempts by Native American organizations to compete or cooperate with the larger companies have not been overly successful. In effect, the white-monopolized industry has caused a reversion of wild rice to its traditional role as a subsistence item in the Native American economy.

WINES

Contents

Types of Table Wine

R S Jackson, Bic, QC, Canada

Background

Classification is a common human trait. Without it, precise language would be nonexistent. Unfortunately, the natural desire to group wines into logical categories is fraught with difficulty. Wine is an eclectic collection of grape-based beverages that reflects local conditions and grape cultivars, as well as adaptions to changes in cultural attitudes and technological advances over several millennia. There is no evolutionary progression to connect these diverse products. In the absence of an inherently rational basis for organizing wines, they have generally been grouped according to those features that tend to be relatively stable and easily detected (e.g., color, sparkle, alcohol content), or origin (e.g., geographic or varietal).

Classification based on these features has potential value because it supplies a crude idea of the sensory attributes of the wine. For example, red wines are typically more flavorful, drier, and astringent than white wines, which generally are milder tasting, and may come in sweet and semisweet styles (red wines seldom do). The obvious presence of an effervescence has become culturally associated with celebration. The mention of a particular grape cultivar or region can suggest, to those possessing sufficient experience, the likely presence of a particular set of flavor and taste characteristics.

The problem with empirical systems, such as those noted above, is that they depend heavily on experience most consumers lack. Although people readily distinguish color categories and may recognize geographic names, they seldom have a clear concept of their sensory significance. Despite the need for a clear, rational classification of table wines, the diversity of wine is too great to permit presentation of a readily understandable, coherent categorization. What is feasible is an organization based on those features that generate the diversity found in table wines.

The most critical element influencing the sensory features of a wine is the winemaker. Starting with red grapes, a winemaker can make an almost infinite spectrum of wines – from almost colorless, through pink, to light red, to dark red–purple, with equivalent variations in flavor intensity. In addition, the winemaker may direct production toward sparkling or sweet versions of any of the former styles, or choose to produce sherry- or port-like wines. Because the effect of the winemaker can be so marked, and unpredictable, it is typically neglected or submerged under regional or stylistic categories. This is possible because tradition, if not legal constraints, often limit winemaker freedom in the style(s) produced.

In Europe, most regions have tended to specialize in the production of one or very few wine styles, made from one or a few, typically indigenous, grape cultivars. This feature has permitted the association of

particular flavor traits with wines from particular regions. However, cultivars generally produce similar flavor attributes wherever they are grown. For example, 'Cabernet Sauvignon' and 'Chardonnay' often produce wines undistinguishable from those produced in their homelands of Bordeaux and Burgundy, respectively. Thus, the predictive value of varietal origin on sensory attributes depends more on the skill of the winemaker, and the maturity and health of the grapes, than geographic origin. Although winemaker skill is difficult to quantify, grape maturity and health are often quantified for consumers in vintage ranking. The central roles of grape variety and production style are outlined in Figure 1 and discussed below.

Varietal Origin

In a fundamental sense, wine taxonomy should be based on the cultivar or cultivars used in their production. Varietal origin sets the outer limits of the wine's sensory attributes. Unfortunately, most grape cultivars do not, or are not known to, possess a readily distinguishable varietal aroma. Thus, varietal origin is of significance only for those cultivars that possess unique aromatic potential. Several of the better known of these are briefly noted below.

Red Cultivars

'Cabernet Sauvignon' is the most well-known member of the Carmenet family of grape cultivars. Its renown comes from its involvement in most Bordeaux wines (and equivalents). Other members of the family include 'Merlot' and 'Malbec.' Their inclusion in Bordeaux blends moderates the tannin content donated primarily by 'Cabernet Sauvignon.' The tendency of 'Merlot' to mature more quickly has made it a popular substitute for 'Cabernet Sauvignon.' Under optimal conditions, 'Cabernet Sauvignon' yields a fragrant wine possessing a blackcurrant aroma. Under less favorable conditions, it generates a bell-pepper aroma. 'Cabernet Sauvignon' probably is the result of an accidental crossing between grapes related to, if not identical with, 'Cabernet Franc' and 'Sauvignon blanc.'

'Gamay noir à jus blanc' is the primary, white-juiced Gamay cultivar. Its reputation has risen in association with the increased popularity of Beaujolais wines. Crushed and fermented by standard procedures, 'Gamay' produces a light red wine with few distinctive characteristics. However, when processed by carbonic maceration, it yields a distinctively fruity wine. Most of these features come from the grape-berry fermentation phase of carbonic maceration.

'Nebbiolo' is generally acknowledged as producing the most highly regarded red wine in north-western Italy. With traditional vinification, it produces a wine high in acid and tannin content that requires years to mellow. The color has a tendency to oxidize rapidly. Common aroma descriptors include tar, violets, and truffles.

'Pinot noir' is the most famous Noirien grape variety. It is particularly environmentally sensitive, producing its 'typical' fragrance (beets, peppermint, or cherries) only occasionally. The cultivar exists as a varied collection of distinctive clones. Usually, the more prostrate, lower-yielding clones produce more flavorful wines. The upright, higher-yielding clones are more suited to the production of rosé and sparkling wines. The South African cultivar, 'Pinotage,' is a cross between 'Pinot noir' and 'Cinsaut.'

'Sangiovese' is an ancient cultivar consisting of many distinctive clones, grown extensively throughout central Italy. It is most well known for the light- to full-bodied wines from Chianti, but also produces many fine red wines elsewhere in Italy. Under optimal conditions, it yields a wine possessing an aroma reminiscent of cherries, violets, and licorice. 'Sangiovese' is also grown under local synonyms, such as 'Brunello' and 'Prugnolo,' used in producing Brunello di Montalcino and Vino Nobile di Montepulciano wines, respectively.

'Shiraz' ('Syrah' in France) has become famous for yielding a deep red tannic wine with long aging potential in Australia. This has helped 'Syrah' regain the prominence it once held in the Rhône Valley of France. Its wines are peppery with aspects reminiscent of violets, raspberries, and currants.

'Tempranillo' is probably the finest Spanish red-grape variety. Under favorable conditions, it yields a delicate, subtle wine that ages well. It is the most important red cultivar in Rioja. Outside Spain, it is primarily grown in Argentina. In California, it usually goes under the name 'Valdepeñas.' 'Tempranillo' generates an aroma distinguished by a complex, berry-jam fragrance, with nuances of citrus and incense.

'Zinfandel' is extensively grown in California. Its European counterpart is probably the Italian variety 'Primitivo,' or its Hungarian equivalent, 'Plavac.' 'Zinfandel' is used to produce a wide range of wines, from ports to light blush wines. In rosé versions, it shows a raspberry fragrance, whereas full-bodied red wines possess rich berry flavors.

White Cultivars

'Chardonnay' is the most famous white member of the Noirien family of cultivars. It not only produces

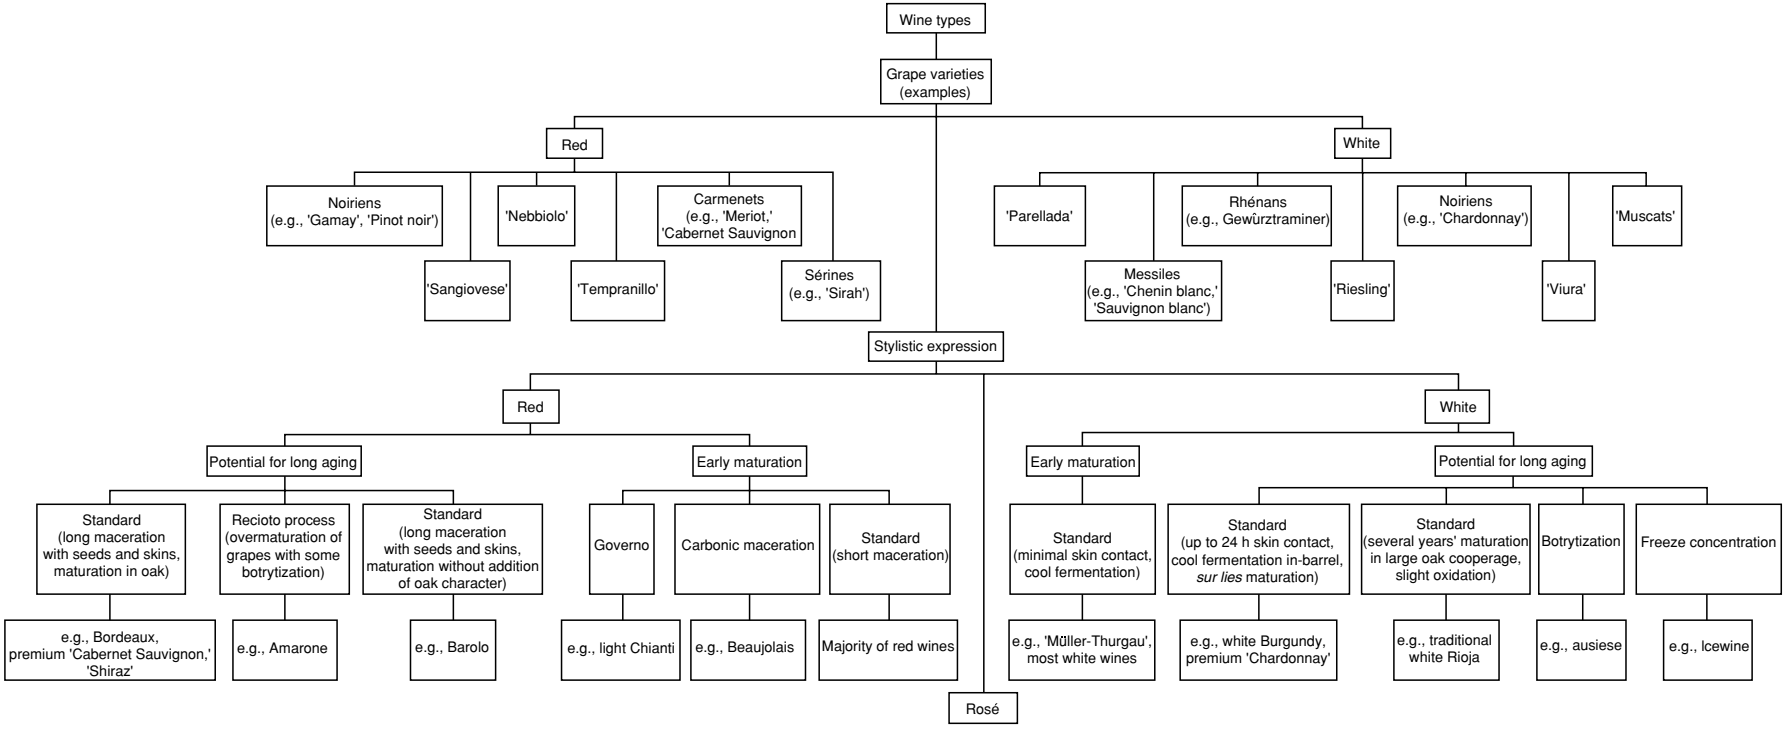

Figure 1 Major sources of the different types of table wine.

wines with an appealing fruit fragrance, but also tends to do well world-wide. In addition to producing fine table wines, it yields one of the finest sparkling wines (champagne). Under optimal conditions, the wine develops aspects reminiscent of various fruits, including apple, peach, and melon.

'Müller-Thurgau' is possibly the most well-known modern *V. vinifera* cultivar, constituting about 30% of German hectarage. It is most likely a crossing between 'Riesling' and 'Chasselas de Courtillier.' Its mild acidity, subtle fruity fragrance, and early maturity are ideal for producing light wines in cooler climates.

'Muscat blanc' is one of many members of the Muscat family of cultivars. Their aroma is so distinctive that it is described in terms of the cultivar name – muscaty. Because of the intense flavor, slight bitterness, and tendency to oxidize, Muscat grapes have been used most commonly in producing dessert wines. The reduced bitterness and lower oxidation susceptibility of the new Muscat cultivar, 'Symphony,' permit the production of dryer wines with a better aging potential. 'Moscato bianco' is the primary variety used in the flourishing sparkling wine industry in Asti, Italy.

'Parellada' is a variety distinctive to the Catalonian region of Spain. It produces an aroma that is apple- to citrus-like in character, occasionally showing hints of licorice or cinnamon.

'Pinot gris' and 'Pinot blanc' are color mutants of 'Pinot noir.' They are both cultivated throughout the cooler climatic regions of Europe for the production of dry, botrytized, and sparkling wines. 'Pinot gris' typically yields subtly fragrant wines with aspects of passion fruit, whereas 'Pinot blanc' is more fruity, with suggestions of hard cheese.

'Riesling' is without doubt Germany's most highly respected grape variety. It can produce fresh, aromatic, well-aged wines, which can vary from dry to sweet. Its complex floral aroma, commonly reminiscent of roses and pine, has made it acclaimed throughout central Europe and much of the world. Outside Germany, its largest plantings are in California and Australia.

'Sauvignon blanc' is one of the main white Carmenet varieties in Bordeaux, and the principal white cultivar in the upper Loire Valley. It has become popular in California and New Zealand in recent years. Often, its aroma shows elements of green peppers, as well as a herbaceous aspect, especially in cooler climates. Better clones possess a subtly floral character.

'Traminer' is a distinctively aromatic cultivar grown throughout the cooler regions of Europe and much of the world. Although possessing a rose blush in the skin, it produces a white wine. 'Traminer' is fermented to produce both dry and sweet styles, depending on regional preferences. Intensely fragrant ('Gewürztraminer') clones generally possess an aroma resembling lichi fruit.

'Viognier' has become popular in the USA and Australia, following its languishing in the Rhône Valley since the phylloxera epidemic of the late 1800s. The wine matures quickly and is characterized by the development a fragrant peach to apricot aroma.

'Viura' is the main white variety cultivated in Rioja. In cooler areas, it produces a fresh wine possessing a subtle floral aroma with aspects of citron. After extended aging in large wood cooperage, it develops a golden color and rich butterscotch to banana fragrance that characterizes the traditional white wines of Rioja.

Stylistic Origin

Although varietal attributes set the outer limits of a wine's characteristics, their expression may be influenced by growing conditions. Equally, the way in which varietal attributes exhibit themselves depends on grape health and maturity, how the grapes are transformed into wine, and how the wine is subsequently stored. Thus, after varietal origin, vintage conditions and production style are the most important features establishing the features that characterize the wine.

Because wine styles have arisen independently, there is no obvious or evolutionary logic by which wine can be classified. For simplicity, they can be organized temporally, relative to whether they occur before, during, or after grape fermentation.

Type Reflecting Procedures Before Fermentation

One of the oldest processes that may be involved in wine production is carbonic maceration. This occurs whenever whole grapes collect in large piles (in the absence of oxygen). Before the mid-1800s, carbonic maceration was involved in the production of essentially all wines. Inefficient manual crushing resulted in many whole grapes remaining after crushing. Thus, when yeast fermentation consumed the oxygen dissolved in the freed juice, whole grapes began a grape-cell fermentation (carbonic maceration). Carbonic maceration generates a unique set of aromatic compounds that give the wine a distinct, raspberry–kirsch fragrance. When the majority of the grapes undergo carbonic maceration, as in the production of Beaujolais wines, the fruity aromas generated often mask the presence of varietal aromas. Only as the wine ages, and grape-fermentation odors fade, may a varietal character express itself. Most Beaujolais wines do

not age well because the cultivar from which they are made ('Gamay noir') possesses little varietal aroma to replace the fading carbonic maceration fragrance.

Another, technique that can fundamentally modify a wine's sensory attributes is over-maturation. Over-maturation generally occurs by leaving the grapes on the vine past maturity (late-harvest). For white wines, it is used to produce a more flavorful, usually sweet wine. Its most classic expression is in the production of botrytized wines, such as the ausleses of Germany, the Tokaji of Hungary, and the Sauternes of France. During over-maturation, infection by the fungus *Botrytis cinerea* concentrates the juice, reducing the varietal aroma, and generating its own unique apricot, honey-like fragrance. Late-harvest wines not involving the intervention of *Botrytis cinerea* generally have only an enhanced over-matured varietal aroma. Ice wines (*eisweins*) are a distinctive category of late-harvest wines. They undergo a particularly long (up to several months) over-maturation on the vine, until frigid (−7 to −8 °C) conditions freeze the grapes. The grapes are harvested and crushed while frozen to extract only the highly concentrated juice (most of the water in the grapes remaining in the crusher as ice).

Although more commonly used in the production of white wines, over-maturation is occasionally employed in the making of particular red wines. For example, in the production of Chianti, a portion of the harvest may be set aside to slowly dry and over-mature. Most of the crop is crushed and fermented into wine following standard procedures. A month or so later, the over-matured portion of the crop is crushed, begins fermentation, and is added to the majority of the harvest that usually has just completed fermentation. The effect of the second fermentation is to produce a wine that is fruitier and matures earlier than otherwise. This process, called the *governo* process, is less popular than in the past because it does not promote aging potential – the touchstone of quality for most connoisseurs.

In Veneto and, to a lesser extent, in Lombardy, a technique called the *recioto* (*appassimento*) process involves the exclusive use of over-matured grapes. Especially selected mature clusters are laid on trays in thin layers, and the trays stacked in well-ventilated, unheated, storage sheds. The grapes are left to dry and over-mature slowly for several months. Frequently, a portion of the grapes undergo a slow transformation under the action of *Botrytis cinerea*. This results in a marked increase in the concentration of glycerol and sugars, as well as the oxidation of grape phenolics. The latter appears to generate several volatile phenols that give the wine its distinctive tulip–daffodil pungency. After several months, the grapes are crushed and fermented to produce dry, semisweet, or sparkling wines. The most commonly exported version is the dry Recioto della Valpolicella Amarone.

Type Reflecting Conditions Immediately Following Crushing

One of the most fundamental decisions in winemaking involves the conditions immediately following crushing. For white wines, the juice is separated from the seeds and skins shortly after crushing and before fermentation begins. In contrast, the juice is left in contact with the seeds and skins throughout most of the fermentation period for the production of red wine.

Separation of the juice from the seeds and skins, directly after crushing, limits the uptake of most grape flavorants (aroma), and yields an almost colorless wine. In contrast, leaving the juice in contact with the seeds and skins progressively permits the extraction of flavorants and colorants, notably from the skins. For white wines, skin contact (maceration) is short (often only a few hours) to minimize the uptake of bitter-tasting phenolics.

Type Reflecting Conditions During Fermentation

The duration of joint fermentation and maceration significantly affects a red wine's characteristics. Gently pressing to remove the seeds and skins immediately after crushing may result in the production of a white wine. Maceration with the skins for the first 24–48 h usually generates a rosé wine. Standard red wines typically undergo maceration for 4–5 days, during which fermentation becomes fully active. Depending on the efficiency of the juice–skin contact, moderate to long aging, deeply pigmented wines are produced. Traditionally, wines designed for long aging have been left on the seeds and skins for upwards of 2–3 weeks. This may generate flavorful wines, but prolonged maturation is required before their high tannin content 'softens.' Newer techniques optimize flavor and pigment uptake without the extraction of excessive amounts of bitter, astringent tannins. Most varietal flavors are dissolved from the skins within about 3–5 days, whereas tannins are removed more slowly.

Another condition that fundamentally affects the characteristics of a wine is fermentation temperature. White wines are typically fermented at cooler temperatures than red wines. Cool temperatures (about 15 °C) enhance the production and retention of 'fruit' esters synthesized by yeasts, giving the wine a fruity fragrance. This is particularly important for white wines produced from cultivars with little distinctive aroma. Wines from aromatically unique varieties may be fermented at somewhat higher temperatures to

accentuate the aroma versus general fruitiness. Red wines often are fermented at warm (about 22–25 °C) temperatures to facilitate yeast growth in the presence of grape phenolics, and to promote pigment and flavor extraction from the skins.

Several other fermentation conditions influence the stylistic expression of a wine. However, most are so extensively, but variably, used across varietal and regional styles as to negate their value in characterizing wine types. Examples are the use of different yeast strains, the employment of malolactic fermentation, and the use of in-barrel vs. tank fermentation.

Type Reflecting Conditions During Maturation

For the majority of wines designed for early consumption, maturation prior to bottling typically occurs in stainless steel tanks, or other inert cooperage. This avoids the uptake of additional tannins from wood cooperage that can require extensive aging to mellow. It also avoids the extraction of oak flavors that might mask the wine's mild fragrance.

Wines benefiting from extended aging, or possessing a distinct varietal aroma, are often aged in oak cooperage. For white wines, this is seldom more than for 6–12 months. This may or may not be combined with *sur lies* maturation (3–6 months' contact with the dead and dying yeast cells following the end of fermentation). The procedure is often thought to enhance the wine's flavor complexity. For red wines, maturation often occurs in new or used oak barrels (approximately 250-l capacity), for a period of up to 2 years. An older procedure, less commonly used today, is maturation in large (1000–10 000 l) oak tanks. The latter supplies less oak character to the wine, while providing slower but increased moderate oxidation. In-barrel maturation accentuates the varietal character of several major grape cultivars, such as 'Cabernet Sauvignon,' whereas tank maturation tends to moderate varietal distinctiveness.

Geographic Expression

Although it is often implied that geographic wine expressions are clearly recognizable, this is rarely the case. Even experienced wine tasters often fail to identify the varietal origin of wines, let alone their regional variations. If one knows that the wines come from a single region, are made from the same cultivars, and have been produced using similar techniques, it may be possible, under ideal conditions, to differentiate subregional expressions. However, if the varietal wines come from several different countries, it is unlikely that the individual geographic origins of the wines can be consistently recognizable. Even the more distinctive varietal feature of many New World wines is not dependable. Yearly variations in weather conditions can produce greater fluctuations in wine attributes than climatic differences between regions.

The prominence given to geographic origin in most wine classifications comes from the familiarity that consumers have, or can obtain, with regional names. As already noted, in several European regions, legislation limits the use of grape cultivars and wine production techniques. Although this helps maintain stylistic consistency, it limits innovation.

Appellation Control (AC) Laws

The frequent grouping of wine by geographic origin, and the economic value of clear distinction (if only by name), have combined to promote the establishment of appellation control laws. Although these laws vary considerably from country to country, and even from region to region, they always act as a certification of geographic origin. They may also stipulate varietal composition, conditions of grape culture, as well as fermentation and wine-processing procedures. Although important, what is of greater general interest is how these laws reflect cultural views on the origins of wine quality.

In most established European regions, it is often assumed that historically accepted practices and geographic features define wine quality. However, they have limited improvement, leading to less regulated regions rapidly reaching and surpassing the quality of established regions. Furthermore, weather conditions can be so variable as to nullify the law's attempt to 'guarantee' wine quality. Finally, in the absence of uniform yearly assessments of wine quality, AC laws effectively assure only geographic authenticity.

In Europe, appellation control laws fall into two philosophically different groups. One ascribes greatest importance to geographic features (e.g., France, Italy, and Spain), whereas the other accentuates the importance of grape maturity (e.g., Germany and Austria).

In the French version, regions are ranked relative to geography (incorporating traditional winemaking and grape-growing procedures). Regions are classed according to historic perceptions of their winemaking quality – premium (AC), superior (VDQS, vins délimités de qualité supérieure), good (vins de pays), and basic (vins de table). AC regions are often subdivided, with smaller regions viewed as producing more distinctive (and better) wines than those from larger regions. This subdivision on geographic origin may be taken down to single vineyards. In most cases, though, it goes down only to single parishes or townships. As the area becomes smaller, production regulations often become more precise and restrictive.

In addition to the classification of regions, individual vineyards (or wineries) may be hierarchically ordered. The most well-known example is the 1855 grouping of some Bordeaux vineyards. This arrangement is called the cru classé system. As in AC designations, the cru classé system is based on the historic potential of the vineyards to produce quality wine. Thus, yearly sensory assessments of wine quality are not considered necessary for use of the designations.

In Italy, most wines are classified heirarchically into DOCG (denominazione di origine controllata e garantita), DOC (denominazione di origine controllata), IGP (indicazione geografica tipica), and Vino da Tavola categories. One of the unique features of the Italian AC system is the potential pyramidal interconnection. Wine production exceeding the quantities stipulated in the regulations progressively demotes the wine to lower and lower categories. Use of the highest (DOCG) designation requires that the wine pass yearly governmental sensory evaluation tests.

In the Germanic concept of quality, greatest importance is placed on grape maturity. Thus, it has a prominent place, along with geographic origin, in the naming of wines. Correspondingly, annual achievement of a minimum score on a governmental sensory evaluation test is required before permission is granted to use any of the QbA (qualitätswein bestimmter anbaugebietes) or QmP (qualitätswein mit prädikat) quality designations. Historical reputation has no influence on the quality or geographic designations in the German system.

Most New World countries are developing AC regulations. In most instances, they do not have the same significance as their European equivalents. This results from the diversity of wine styles produced within the designated regions. Thus, New World appellation laws generally certify only geographic origin. This, however, achieves the primary advantage of appellation designations – nominal differentiation of regional wines in the marketplace.

Production of Table Wines

K Wucherpfennig, Baumann-Gonser-Foundation, Wiesbaden, Germany

Introduction

Wine is legally defined as the product that is recovered exclusively by complete or partial alcoholic fermentation of the fresh, treated grapes or the grape must. If alcohol is added to the wine, e.g., in the form of distillate of wine, dessert wine is obtained with an alcohol content between 15 and 22% by volume (sherry, port, etc.). If a second fermentation is carried out without the escape of the formed carbon dioxide, champagne or sekt is produced. If carbon dioxide is artificially introduced, pearl wine or simple sparkling wine is obtained. (*See* **Port**: The Product and its Manufacture; **Sherry**: The Product and its Manufacture; **Wines**: Production of Sparkling Wines.)

Wines, dessert wines, pearl wines, and sparkling wines can be further processed to vinous beverages. These are products in which the proportion of wine is in excess of 50%. The best known products of this group are the aromatized wines such as vermouth. (*See* **Vermouth**.)

If fruits or other sugar- or starch-containing raw materials are processed to alcoholic beverages, the end product is not wine within the meaning of the pertinent wine legislation, but a beverage similar to wine. These include the fruit wines, the main representative being cider.

Table, land, and quality wines made from grapes make up by far the largest category among the different sorts of wine. For this reason, the main focus will be on their method of production. The production of, for example, fruit wines is very similar, however.

Viticulture

The vine belongs to the genus *Vitis*, of which 50–60 species are known. One of these is the European vine, *Vitis vinifera*, from which a large number of varieties stem. Over the centuries, the variety best suited to the growing area has been selected, i.e., the variety that offers the highest quality together with adequate potential crop and resistance to diseases of the vine.

Vine Varieties

As the *Vitis vinifera* varieties used for the production of high-quality wines are susceptible to attack by the phylloxera, they can only be grown grafted on to the stock of American vine. World-wide, a group of 15 vine varieties has established itself for the production of red wines, and a group of 20 vine varieties has proved suitable for the production of white wines. Scientific breeding of vines has been practiced since 1900 with the aim of improving the performance of the vine with respect to yield and quality.

Methods of Cultivation

In the cultivation of vines, certain planting systems and forms of training are applied with a view to attaining regular and high-quality crops. It must be insured that the sprouting flower buds with two bunches per shoot on average are exposed to as much sun as possible, and that every shoot has about 10–15 leaves.

Maturity and Vintage

In the course of several growth stages, the setting gives rise to the grape consisting of the skin (exocarp), the pulp (mesocarp), and two to four seeds. The largest part of the berry is the succulent pulp. The grape increases most in weight during the final growth stage; sugar (glucose and fructose) is stored, and water is absorbed, while the concentration of total acid and malic acid decreases substantially. The grapes can be considered physiologically ripe when a sugar content of 75–80° Oechsle (18.20–20.47° Brix) is reached, corresponding to an alcohol content of 9% by volume. From this point onwards, the stems develop into mature cane, and nutritious matter from the soil and the sugar formed in the leaves can no longer penetrate into the grapes. If the grapes have reached the state of full ripeness and are not harvested immediately, their constituents are concentrated owing to evaporation of water. The grapes become overripe and soft, as a result of which the sugar content increases. Further concentration can take place if the grapes are attacked by the fungus, *Botrytis cinerea*. If this happens at an early stage, it causes 'grey rot,' which is responsible for a deterioration in quality; however, if the disease strikes at a late stage, the so-called 'noble rot' develops, which is desirable in special areas, e.g., for the production of Sauterne. (*See* **Ripening of Fruit**.)

Choosing the right time for harvesting is of particular significance, as the current consensus of opinion is that the volume of alcohol to be expected from the sugar content in the grapes determines the quality The more sugar the grapes contain when harvested, the higher the quality rating of the wine produced.

The vintage has been carried out manually for centuries. However, as an expense of work of 250 h ha^{-1} is required, there is an increasing tendency to use machines that straddle the rows of vines and shake off the bunches of grapes. The yield varies between 60 and 150 hl ha^{-1}, depending on the vine variety, climate, soil, and care.

Processing of White Wine

The flow chart of white wine processing is shown in Figure 1. After harvesting, the grapes should preferably be transported to the press room in an uncrushed state to prevent undesirable excessive extraction of tannins from the stems and seeds (1). There, they are weighed and crushed. The must weight is also determined at this point, which is an important criterion for the quality of the subsequent wine.

Pressing

The grapes are often stemmed (2) to produce wines with a low tannin content, although this is not absolutely essential. The crushed grapes are then transported direct into the press or into storage tanks or straining bins (3). (*See* **Tannins and Polyphenols**.)

The untreated or treated crushed grapes can be pressed in discontinuously operating horizontal presses. These comprise a perforated press cage in which one or two mechanically or hydraulically actuated pressure plates gradually reduce the space available to the crushed grapes, causing the must to be pressed through the fine slots (4).

In the recently introduced pneumatic presses, the crushed grapes are pressed by air pressure acting on a plastic membrane against a perforated metal plate and are, therefore, pressed extremely gently. Good must and wine qualities can be attained using continuous, large-diameter screw presses that rotate at a low speed.

Freshly pressed musts still contain insoluble parts of the cellular tissue, protein–tannin compounds, microorganisms, crystal compounds, e.g. tartar, dirt particles, and substances of an unknown nature that can adversely affect the quality of the wine. For this reason, they are preclarified by sedimentation, defecation, or centrifugation (6).

During the sedimentation, which takes about 10 h, pectolytic enzymes natural to the fruit degrade pectic substances and other cell wall components that would later stabilize the lees.

Amelioration of Alcohol Content and Regulation of Acidity

Freshly pressed musts frequently exhibit a disharmonious sugar–acid ratio. Musts from northern growing areas often have too much acid, and musts from more southern areas too little. Thus, during climatically unfavorable vintages, neither is likely to produce the required alcohol content. For this reason, the acid content must be regulated and the sugar content increased. To compensate for adding acid (tartaric or citric) to the wine, a deacidification process is normally carried out chemically using calcium carbonate, but treatment of the must is the preferred option. (*See* **Acids**: Natural Acids and Acidulants.)

To compensate for insuffiency of natural alcohol, it is permissible in most wine-growing countries to

add sugar (saccharose) to the crushed grapes, must, or wine (chaptalization). The sugar is intended exclusively for alcoholic fermentation and not as a sweetener.

Alcoholic Fermentation

The most important stage in wine processing is the alcoholic fermentation, i.e., the anaerobic degradation of sugar typical of yeasts, such as *Saccharomyces cerevisiae*.

Fermentation of grape must or crushed grapes is possible with the mixture of yeast strains that occur on the skins, or within damaged grapes. This is referred to as 'spontaneous fermentation.' In order to avoid the risks associated with this type of fermentation, yeast strains selected especially for their suitability for use in wine processing are used. The fermentable monosaccharides – glucose and fructose – which are present in a ratio of approximately 1:1, predominate. Saccharose (sucrose) added to low-sugar musts is likewise fermented owing to the high content of β-fructofuranosidase (invertase) in yeasts.

While the theoretical yield through fermentation of these hexoses amounts to 51.1% ethanol (by weight) and 48.9% CO_2 (by weight), the actual alcohol yield is only around 47%. Normally, 'spontaneous fermentation' can scarcely produce more than 17.5% by volume in a wine.

The large difference between the theoretical and practical yields of ethanol is attributable to loss of ethanol during fermentation, and the formation of fermentation byproducts. One of the most important fermentation byproducts is glycerol, which is a major contributory factor in forming the body of the wine. Although smaller in volume, the byproducts that react with sulfurous acid are equally important.

Heat is generated during fermentation of the must, and in the case of large must volumes, the must has to be cooled. Heating of the fermentation product accelerates the fermentation process up to a certain point. The fermentation activity of most yeast strains decreases at must temperatures in excess of 30 °C. Once fermentation has finished, the yeast settles on the tank bottom.

Malolactic Fermentation

After alcoholic fermentation and a storage time of several weeks, low-acidity wines with a pH above 3.3 often experience a decrease in the acid content. This is due not only to precipitation of the acid potassium salt of tartaric acid, but primarily to the action of lactic acid bacteria of the genera *Lactobacillus*, *Leuconostoc* or *Pediococcus*. This causes fermentation of the L-malic acid to L-lactic acid and carbon dioxide (8). (*See* **Lactic Acid Bacteria**.)

Since the malolactic fermentation usually takes place after the alcoholic fermentation, vigorous carbon dioxide production can stimulate a secondary fermentation. In France and Switzerland, this is consciously initiated and forced, while opinion is divided in other countries, especially in the case of white wine. By contrast, this 'second fermentation' is practically obligatory for red wines.

Processing of Rosé and Red Wine

The flow chart for rosé and red wine processing is shown in Figure 2. If red grapes are pressed in the same way as described for white wines, pale-pink musts are obtained from which rosé wines are produced (1, 2, 4). Although they are produced from red grapes, they are actually classified as white wines as regards their components and the technology applied.

As the pigments of red grapes are in the skin, the cells of the skin must be made permeable, which is achieved by fermenting or heating the crushed grapes (3, 6). (*See* **Colorants (Colourants)**: Properties and Determination of Natural Pigments.)

Fermentation on Skins

The classical process for the production of red wines is so-called 'fermentation on the skins' (6). The initial processing steps utilize the same methods and machines as in the production of white wine and comprise vintage, transport, grape receiving, stemming, and crushing (1, 2).

In fermentation on the skins, the red grapes are not pressed to must before the alcoholic fermentation. The crushed grapes are partially or completely fermented, in which process, the alcohol produced extracts the pigments (6).

The crushed grapes are usually left to ferment spontaneously with the natural mixture of yeast strains in a special fermentation tank. In the case of fermentation on the skins, the carbon dioxide bubbles convey the pulp and skin to the surface of the fermentation product, producing a so-called 'head' or 'cap,' which must be kept below the surface of the fermentation liquid. A number of methods can be employed to bring the skins in contact with the color-extracting liquid, such as the use of submerged caps, pumps, agitators, mechanical removal of the floating head by screw conveyors or rakes, or sudden decompression of the compressed carbon dioxide in the tank (6, 7).

Heating of Crushed Grapes

In the increasingly widespread new process for red wine production of heating the crushed grapes, the stemmed and crushed grapes are conveyed to the

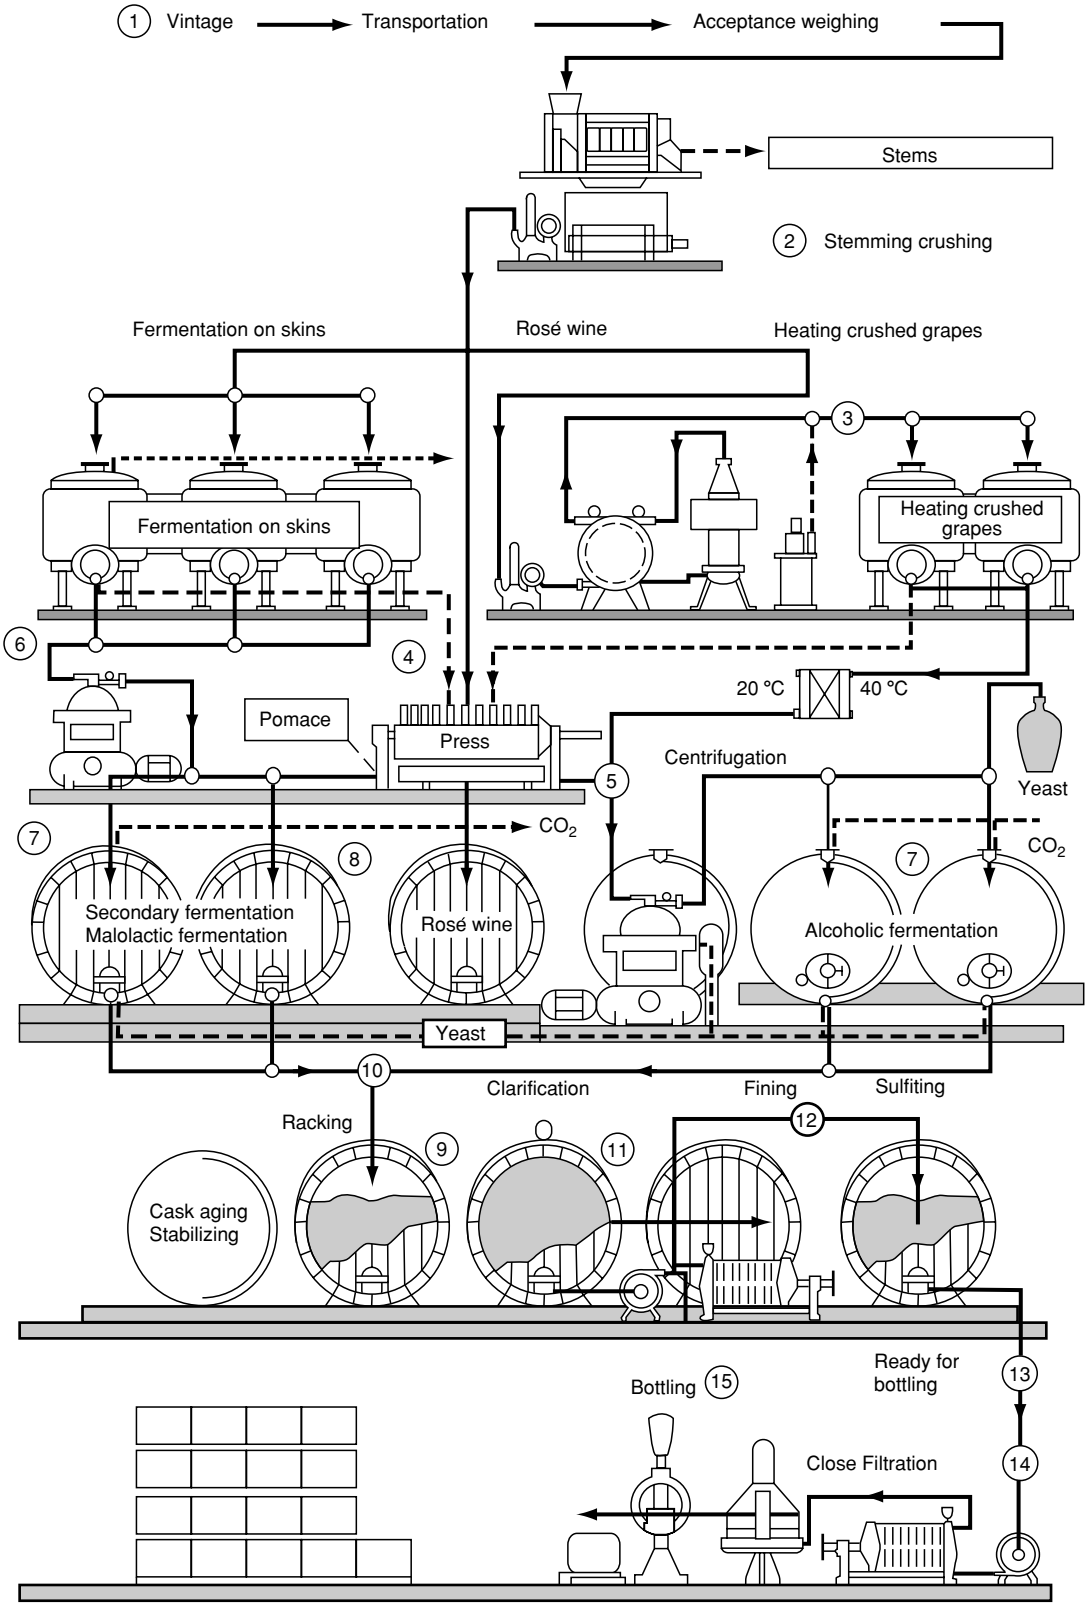

Figure 2 Flow sheet of processing rosé and red wines according to Troost G (1988) Technologie des Weines, 6th edn. Stuttgart: Eugen Ulmer. (1) Acceptance of grapes; (2) stemming, crushing; (3) heating crushed grapes; (4) pressing; (5) centrifugation; (6) fermentation on skins; (7) alcoholic fermentation; (8) malolactic fermentation; (9) clarification; (10) racking; (11) fining; (12) sulfiting: (13) ready for bottling; (14) sterilizing filter; (15) bottling.

heater by means of a smooth-action pump (3). In this process, which is also termed plasmolysis, the semipermeable, cytoplasmic membrane becomes permeable to the dissolved substances.

Heaters for crushed grapes consist of a system of tubes in a steam-heated room. It has been established that heating the crushed grapes to 45–55 °C is adequate to obtain dark-colored musts. Nowadays, it is common practice to heat the crushed grapes above the plasmolysis temperature to about 87 °C for a brief period in order to inactivate the enzymes inherent in the fruit, and to kill off the microorganisms. Subsequently, the crushed grapes are cooled to a moderate temperature.

The pretreated crushed grapes can now be conveyed directly into a press (4) or into a straining bin. After heating, processing is identical to that described for white wine. The use of selected yeasts for initiation of the fermentation process is strongly recommended.

After the alcoholic fermentation, the red wines are developed in the same way as white wines, but with the difference that the malic acid is degraded to lactic acid almost completely (8). This 'second fermentation' is brought about by the activity of lactic acid bacteria, but this frequently happens a number of months after the alcoholic fermentation.

Development

After fermentation of the must, which may have been ameliorated or whose acidity may have been adjusted, numerous processes take place in the young wine. It develops to a peak, termed maturity. This aging and finishing process takes place in a tank or in the bottle. If the maturity peak is exceeded, the wine becomes 'firne,' which can still be considered a positive quality characteristic. However, if this development continues, the wine will develop a rancid taste and become 'maderized' and oxidized – a sign of rapidly decreasing quality.

The finishing and aging processes can be influenced to a certain extent and for this reason one often talks of 'developing' the wine. This involves treating the wine with the aim of supporting the natural maturation and clarification processes, and to protect the wine from undesirable changes.

Racking

The first step in the development of wine in the cellar is racking (10, 10). By this is meant the separation of lees from the wine by decantation.

Despite racking, visible fine lees can still be suspended in the wine; in any case, the wine contains invisible colloidal dissolved substances. If the beverages are to be limpid and clear when bottled and sold, they must be clarified. This can be done by centrifugation or filtration. Before filtration, beverages are usually treated with fining agents, i.e., a portion of the substances to be separated out are flocculated, which improves the filtering efficiency. This treatment is denoted preclarification and fining of the wines (11, 11). (*See* **Filtration of Liquids**.)

Fining

The invisible particles present in the wine consist largely of polymeric carbohydrates, proteins accounting for 10–20%, and oxidized and condensed polyphenols making up the rest. All particles become electrically charged in solution; in wine, they normally carry a negative charge. If the negative charge of a wine is altered by adding particles with the opposite charge, particle repulsion is neutralized. Particles combine to form larger aggregates that sink to the bottom or float to the top, i.e., the particles are flocculated or coagulated. (*See* **Flocculation**.)

A number of organic and inorganic substances are available for treating the wine. With the exception of silica sol, the inorganic fining agents serve primarily to prevent turbidity and to eliminate nonbacterial disorders. In other words, their main function is to stabilize the wine. Today, fining is usually carried out with gelatine and silica sol, and bentonite is used for stabilization. Special effects can also be achieved with casein, isinglass, albumen, and tannin.

Sulfiting

Prior to filtration, the wines must be adjusted to a certain sulfurous acid concentration. Sulfur dioxide (SO_2) dissolves in wine to form an equilibrium mixture [1]:

$$SO_2 \rightleftharpoons HSO_3^- \rightleftharpoons SO_3^{2-} \qquad (1)$$

and it has been added to wines since time immemorial to improve the storage characteristics. It inhibits the growth of, or even kills, certain bacteria, and also prevents browning and oxidation reactions; certain substances are reduced, and taste is improved. This versatility makes sulfite indispensable in the cellar. (*See* **Preservation of Food**.)

One of the essential tasks of the 'free' SO_2 is to bond the small quantities of organoleptically perceivable acetaldehyde, thereby neutralizing its sensory characteristics. If free acetaldehyde is present in the wine, the wine creates a sensory impression that is

labelled rancid, 'maderized' and oxidized or 'sherry taste,' and avoidance of this defect is vital in white wines.

Sulfurous acid has no significance as a preservative in wine as the permissible maximum contents are too low.

Stabilization

Although fining and filtration are normally sufficient to obtain a limpid and clear wine, they can become turbid again after this treatment or can exhibit deposits. Colloidal proteins can alter and become insoluble. Wines containing thermolabile proteins are most frequently stabilized by treatment with minerals containing aluminum silicate. Bentonites are most suitable for this purpose. It is also possible that heavy-metal ions will cause discoloration or turbidity because they may either form insoluble colored compounds with the wine components or become insoluble and precipitate out. These phenomena are primarily caused by iron and copper ions.

In 1922, success was achieved in bonding the iron and precipitating it to a large extent by adding a precisely determined amount of potassium ferrocyanide (potassium hexacyanoferrate (II)). Subsequently, it was found that a series of other metal ions, such as those of copper, zinc, manganese, nickel, and silver, and the extremely toxic metal ions of lead and cadmium, could be precipitated out as ferrocyanide complexes. (*See* **Heavy Metal Toxicology**.)

After fining of the wines to protect them against changes, a further stabilization is normally required to inhibit crystalline precipitation. This is aimed chiefly at separating out potassium bitartrate together with calcium tartrate, i.e., the so-called cream of tartar. To prevent tartrate precipitation, it is usual to cool the wine down to a temperature of between +4 and 0 °C for a period of 4–10 days. After fining and stabilization, the wines must be completely clarified prior to bottling.

Whereas centrifugation is only suitable for separating out relatively coarse trub particles, filters can remove even particles down to the molecular range from the wine.

Three different types of filter are applied to wine filtration: the so-called precoat filter, in which the porous mass constantly reforms during filtration; the sheet filter, in which the porous mass is prepared beforehand and placed in the filter; and the membrane filter, which has a defined pore size. Purely mechanical clarification has a negligible effect on the chemical composition of white wines. However, the sensory properties are improved substantially.

Bottling

After development of the wine in the cellar, the wine must be 'bottle ripe', i.e., it must be physically, chemically, and biologically stable. White wines in particular should be optically clear as well as tasting fresh and elegant to meet the requirements of today's consumer. In the case of red wines, long aging in wooden casks is desirable (Bordeaux wines). (*See* **Barrels**: Wines, Spirits, and other Beverages.)

A bottling line consists of machines and equipment for cleaning the bottles, bottling, corking, capsuling, labelling, packing (in plastic cases or boxes) and palleting (15, 15). The most important feature of bottling of wine is the microbiological stabilization of the wine to ensure that the bottled wines do not become turbid due to the activity of microorganisms. In practice, this means cold-sterile or hot-sterile bottling of the wine.

Central to cold-sterile bottling is bacterial clarification of the wine by filtration with fine-pore filter sheets (sterilizing filters or germ-proof filters) or membranes (Figure 1 (14), Figure 2 (15)). The difficulties associated with cold-sterile bottling can be overcome by heating the wine. For an alcohol content of *c*. 10% by volume, a bottling temperature of 55 °C is adequate.

Classification

The composition and nature of a wine depend on the grape variety, the site and soil of the vineyard, the climate and growth conditions of the vine, and the state of the grapes. They are also greatly influenced by the must treatment, the yeast, and the treatment of the wine in the development stage. The quality of the wine generally depends on the amount of volatile compounds, such as ethanol and aromatic substances, and the content of nonvolatile compounds, which are classified under the heading 'extract.'

Wines can be classified, to a certain extent, by the analytical determination of individual components. In particular, it can be established whether the legally defined maximum and minimum limits have been adhered to. Adulteration by addition of nonpermissible substances such as acids can be detected. (*See* **Adulteration of Foods**: History and Occurrence.)

However, it is difficult to make an objective assessment of the quality of the wine with the aid of chemical analysis. Table 1 gives an overview of a number of important wine components.

Classification of a wine, therefore, necessitates a sensory evaluation as well as the results of chemical analysis. The current consensus is that analytical and sensory tests are equally important and complement

Table 1 Important components (g l^{-1}) of wines[a]

Alcohols	
Ethanol	
Table wines	50.0–110.0
Dessert wines	104.0–176.0

one another. In sensory evaluation of the quality of wine, color, odor, and flavor are evaluated.

Physiology and Toxicology

The value of a wine lies in the combination of sensory impressions such as odor and taste and the specific effect of the alcohol, which together make drinking in moderation a pleasurable experience. The predominant component is the ethanol, which enters the bloodstream relatively rapidly as it is easily absorbed by the mucous membranes in the mouth and stomach, but mainly in the small intestine.(*See* **Sensory Evaluation:** Sensory Characteristics of Human Foods.)

As is the case with all other aliphatic alcohols, ethanol affects the central nervous system, causing anesthesia and intoxication. It is degraded chiefly in the liver, where, in the first stage, acetaldehyde is formed by alcohol dehydrogenase, this is converted to acetic acid in the second stage by aldehyde hydrogenase and is metabolized to carbon dioxide and water in the citrate cycle. (*See* **Alcohol:** Metabolism, Beneficial Effects, and Toxicology.)

Sulfur dioxide is the only component with any toxicological significance that is used in the development of wine. Approximately 95% of the sulfite in the wine is absorbed by the body. It is oxidized to sulfate by the sulfitoxydase present to some degree in all body tissue. The latter is essential for the human body and is needed for the degradation of sulfur-bearing amino acids. The oxidation of sulfite to sulfate takes place with amazing speed. To date, it has not been possible to detect sulfurous acid in body fluids. The sulfate is discharged almost completely via the urine within 24 h, as has been demonstrated in tests using radioactively labeled sulfur. For this reason, there is, at present, no evidence that sulfurous acid poses a threat to health if it is added to wines in the legally permitted concentrations.

Production of Sparkling Wines

S Buxaderas and E López-Tamames, University of Barcelona, Barcelona, Spain

Background

Carbonic acid gas and the capacity to form bubbles are the characteristics that differentiate sparkling wines from other types of wines on the market. These wines are consumed for the most part in cocktails, aperitifs, and special occasions (weddings, baptisms, birthdays, etc.), probably because they are considered elegant wines. They are required to have a clear sparkle, a perfect tonality (especially white sparkling wines, the most popular kind), a harmonious bouquet, and a refined and attractive presence. These qualities can be achieved only with raw materials of the best quality and a meticulous elaboration, which explains their tendency to be on the expensive side.

Although sparkling wines are mostly consumed in social events, in the producing countries, different types of sparkling wines are prepared for other occasions. The *brut* type (dry or almost dry) may be drunk as a table wine, as an aperitif, or with fish, and also along with cheese. Others are dessert wines, such as the sparkling *Asti*, or appetizer wines, such as *Prosecco*.

Sparkling wines are gassy beverages in which the carbon dioxide is found in a state of oversaturation (generally, 4–6 bar at 20 °C). When the wine is poured into a glass, CO_2 is rapidly released as a result of the difference in pressure between the hermetically sealed bottle and atmospheric pressure. The effervescent CO_2 bubbles reach the wine surface forming, during the first seconds, a great volume of foam, which seconds later, is reduced to a foam collar. The endogenous or exogenous origin of the CO_2 allows these wines to be classified into two large groups: natural sparkling wines (those produced by the Champenoise, Charmat method (or similar methods), or the 'pearl' wines, which have a natural 'sparkle') (**Figure 1**), and those carbonated artificially (aerated sparkling wines).

In the first case, a dry wine to which sugar (saccharose or concentrated must) has been added is refermented or subjected to a second alcoholic fermentation either in a sealed bottled (as in the Champenoise method and other similar methods) or in pressurized tanks (as in the Charmat method). Other sparkling wines are processed by refermentation of a must partially fermented using their own sugar. In these products, the pressure of carbon dioxide forms effervescence, but it does not reach the values necessary to form foam. These wines can also be included within this group, since the CO_2 origin is endogenous. In the European Union (EEC regulation of the 1493/99), the denomination of sparkling wine is only applied to those wines that, when uncorked and poured into the glass, are able to form foam. This would explain why pearl wines, which do not reach the 3.5 bar of CO_2 pressure (measured at 20 °C), are not considered sparkling wines, but semisparkling wines. In the second case, gassy carbon dioxide of exogenous origin is added directly to a wine (aerated wines), thus creating the more modest types of sparkling wine.

Champenoise Method

The first historical information concerning the preparation of a sparkling wine dates back to the seventeenth century in France. At the end of that century, the abbot Dom Perignon (1638–1715) tried to rationalize the natural tendency of Champagne wines to sparkle lightly in the bottle. The Champenoise method, probably because of its geographical proximity, expanded to the north of Spain (Catalonia) around 1842 (Montferrant Cellar) and 1878 (Codorniu Cellar).

At present, within the European Union (EU), the Champagne region in France (located in the Epernay and Rheims area) is the only region that can use the denominations of the Champenoise method and Champagne for the production of sparkling wines. Other natural sparkling wines produced in other regions of France are known as *vins mousseux*. In Italy and Spain, the Champenoise method is designated classic (*metodo classico, Talento* wines, and *Spumanti Metodo Classico*) and traditional (*método tradicional, Cava* wines), respectively. These sparkling wines are considered to be of premium category

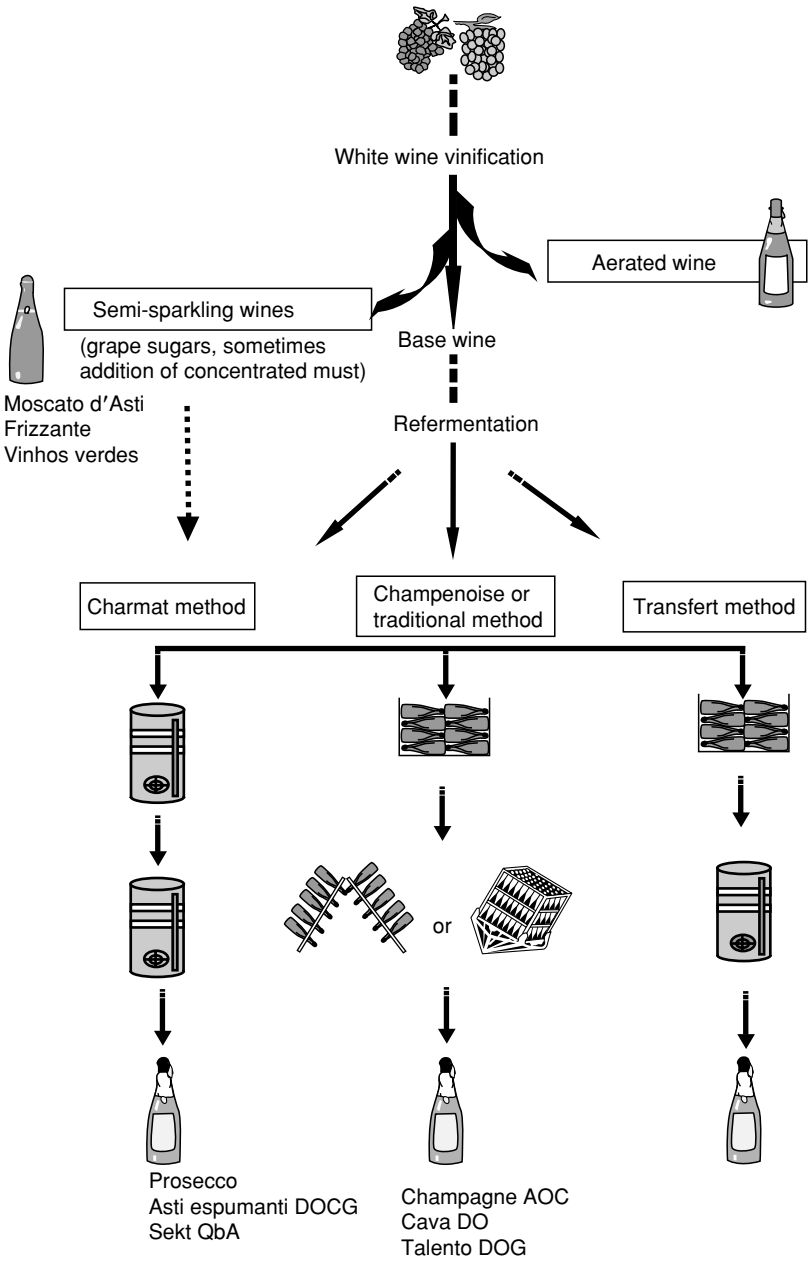

Figure 1 Process for making sparkling wines.

when their quality is guaranteed by a Certified Brand of Origin (CBO) (quality wines called *p.s.r.*, 'produced in specific regions,' according to the EU's terminology) (EEC regulations 823/87 and 2043/89). The regulations that entitle natural sparklers to receive a CBO are strict and establish the authorized grape varieties and their place of cultivation, the maximum yield per vineyard (kilograms of grapes per hectare), the viticulture, and the winemaking processes, sometimes to the point of specifying details such as the type of material to be used in ageing wine and the period of this ageing. In the USA, the denomination of Champagne for sparkling wines produced according to the method champenoise (or called 'fermented in the bottle') can appear on the label on the condition that the geographic place of its processing is mentioned (and thus labeled as Californian Champagne, New York Champagne, and so on).

In the Champenoise method, as well as in the classic and traditional methods, there are two production stages: preparation of the base wine (pressing of the grapes, clarification and fermentation of the must, and clarification and stabilizing of the wine)

and the sparkle stage (bottling and 'tirage' process, second fermentation, ageing of the wine on its lees, elimination of yeast or riddling, disgorging and addition of the 'expedition liqueur'). The differences detected among the Champagne sparkling wines, the Spumanti Metodo Classico, and the Cava are due to the different grape varieties used, the viticultural ecosystem of the geographic area, and the enological practices applied (type of pressing, blending (*coupage*) of the wines that will make up the base wine, yeast strains used for the first and second fermentation, period of contact with the yeast during maturation, etc.).

The French grape varieties Pinot noir, Pinot meunier, and Chardonnay are the main varieties used all over the world to produce natural sparkling wines (in Italy, England, USA, Australia, New Zealand, etc.). Sometimes, these wines are blended with wines from other varieties that may or may not be native to the area. In Italy, Pinot blanc is also used. In England, these varieties are blended with hybrid varieties (e.g., Bacchus, a cross between a Silvaner and Riesling hybrid with a Müller-Thurgau grape, and Kerner, a cross between Riesling and Schiave grossa grapes) and other English varieties (e.g., Schonburger). Spanish Cava is probably one of the few exceptions. The main grapes used are native varieties (Macabeo, Xarello, and Parellada) as a way of fostering Cava's distinctive sensory characteristics. Only the foreign variety of Chardonnay is allowed for white sparkling wines and the Pinot noir variety for Cava *rosé*.

Base Wine Preparation

This preparation involves off skin fermentation, but with certain peculiarities. Grapes are picked in 20–25-kg lugs (in Italy and Spain) or 35-kg lugs (in France) so that the grapes reach the winery uncrushed. It is better to avoid the release of phenolic compounds from the broken skins and the reactions of enzymatic oxidation. That is also why grapes are pressed gently with mechanical or pneumatic horizontal or lateral presses, which have replaced the old vertical basket presses. The free-running juice produced during the loading of the press and the grape juice, which is extracted with very gentle pressure, are used to produce the highest-quality natural sparkling wines, whereas the must obtained by increasing the pressure is used for lower-quality sparkling wines or other wines such as table wines The regulation of the Champagne Certified Brand of Origin (A.O.C., 'Appellation d'Origine Contrôlée)' and that of Cava (D.O., Denominación de Origen) requires a 66.6% must yield, which is slightly higher (max. 70%) for the Talento (D.O.C., 'Denominazione di origine controllata'). Approximately 2.7 l are obtained from 4 kg of grapes, constituting the free-running juice and the juice of the first press fraction.

The must is treated with sulfur dioxide to block polyphenol oxidase and prevent uncontrolled fermentation. Before alcoholic fermentation occurs, the must is racked by physical methods (sedimentation for 12–24 h, then filtration or centrifuging) and its acid and sugar levels corrected. The cold climate of the Champagne region and Germany is responsible for the high acid but low sugar levels, thus necessitating chaptalization (addition of sugars). Musts obtained in the Mediterranean climates of Italy, Greece, and Spain have sufficient quantities of sugar to ensure a minimum alcohol content of 9–9.5% of base wines, but it is often necessary to add tartaric and/or citric acid. Alcoholic fermentation is carried out at 16–20 °C so as to minimize the loss of aroma. Temperature control is facilitated when fermentation occurs in stainless steel tanks, which incorporate a refrigerating system (double jacket). Since fermentation may take several days to finalize, wine is devatted before fermentation is completed to prevent the appearance of mercaptan compounds resulting from prolonged contact with the lees. Dry wine, with a residual sugar content usually no higher than $1.5\,g\,l^{-1}$, is left to settle for several months (cloudy wines). During this time, it is clarified by sedimentation, and if this is not adequate, fining agents are employed (bentonite, gelatine, caseinates, etc.). Malolactic fermentation is favored only when the acidity is excessive (15 g of malic acid per liter). Malolactic fermentation should not occur in the bottle, since this would increase the CO_2 pressure, and colonies of lactic bacteria would form viscous lees attached to the inside of the bottle. Tartaric stabilizing involves precipitation of tartrate salts. Tartaric acid and its salts become less soluble in hydroalcoholic solution when sparkling wine is at a low temperature. To prevent tartaric crystals forming the tank temperature is reduced below 0 °C (−4 °C). Finally, a sterilizing filtration is carried out (base wine). Generally, the base wine is not a monovarietal wine. The blending, or *coupage*, among wines of different characteristics can be done in the tank for tartaric stabilization or before filtration to yield a base wine with more rounded sensory properties. It is permissible for some natural sparkling wine labels to indicate the proportion of monovarietal wines used in the preparation of the base wine (as in France, Italy, Germany, USA, and South Africa), but in other countries, such as Spain, Greece, and Argentina, the wine varieties may be mentioned, but not the proportions of the blend.

Fermentation and Aging in Bottle

The settling of the sparkle, or *prise de mousse* phase, starts with the 'tirage' process, when the wine is bottled, and the sugar and yeast solution are added. The 'tirage liqueur' is added to the base wine (55 ml of wine-liqueur mix per liter). The composition of this liqueur is: 1–2 million cells of yeast per milliliter, ≈ 500 g of saccharose per liter and 0.1–0.2 g of bentonite per liter to agglutinate the lees during riddling, and/or ammonium phosphate (50 ml hl^{-1}) and others compounds to stimulate yeast growth. The bottle glass is usually thick to withstand the CO_2 pressure generated by the second fermentation (5–6 bar at 20 °C before opening). The bottles are hermetically sealed with a cup-shaped plastic insert, known as a bidule, and a metal crown cap, and are stacked horizontally in bins or along cellar walls, at a temperature of 12–14 °C. The settling of the sparkle phase varies in duration; a minimum of 9 months for Cava and 15 months for Champagne and Spumanti Metodo Classico. This length of time is sufficient for the second alcoholic fermentation to take place and for the exchange of compounds between the yeasts and the wine. However, the ageing period for natural sparkling wines tends to be much longer. Yeast autolysis is believed to occur 9 months after the tirage. This enzymatic process implies the release of compounds from the cell walls followed by a progressive dissolution of the cytoplasmic compounds in wine. Between the 12th and 18th month, marked changes are detected in the wine composition (the content of polysaccharides, peptides, and free amino acids rises, and that of proteins falls). Undoubtedly, the special ageing of natural sparkling wines depends on this contact between the wine and the less of the second fermentation, but the reducing atmosphere created by the CO_2 also plays a part. The complex reactions that take place during the settling of the sparkling wine are still under study, but they are known to give rise to each wine's special and characteristic bouquet (matured aromas and flavors that supply the fruity, nutty, yeasty, and toasty notes). The most frequent ageing period is 2–3 years, although in some cases, it may be up to 6 years, but sparkling wines tend to lose their freshness if left to age excessively. When the wine has reached the desired ageing, the dead yeast cells have to be eliminated through the riddling (*remuage*) process. The sediment that has accumulated in the bottle on the side on which it has been lying is directed to the mouth of the bottle and is gathered in the bidule of the inverted bottle. In manual riddling, the bottles are placed in classical racks, called *pupitre*, at an angle of 25–30 ° from the ground. Bottles are progressively given an 1/8 twist, and their inclination is also increased, so that the sediments slide to the mouth of the bottle. At the end of the riddling operation, the bottle is neck down and the sediment is in the bidule, ready for disgorging. Classical hand riddling requires many specialized workers and lasts for 1, 2, or more months. This is why most wineries have replaced the racks with 500-bottle bins, which rest on an inverted octagonal pyramid. Each change of the octagonal face on which the bin is resting represents the 1/8 spin of the rack. At the same time, bascule guides increase the inclination of the bin until it is vertical. The most sophisticated riddling system has replaced the mechanical control of the bin movements on the octagonal base with automatic riddling machines. These modern systems take only 2–4 weeks to do all the riddling. There are also automatic racks (Pupi-matic) that continually shake and tilt 240 bottles. The process only lasts 10 days but requires more workhands to load and unload the rack than the bin system, whose unloading into the disgorging machine is mechanized. The bottles sitting in the neck-down position facilitate the disgorging process. The mouth of the bottles is plunged into a freezing solution of ethylene glycol (45%). When the crown cap is removed, the ice plug with the frozen sediment shoots out of the bottle due to the CO_2 pressure. Pressure loss is approximately 1 bar, and wine loss is 10–15 ml. The volume lost is restored by adding the filling solution or 'expedition liqueur'. This is made up by wine recovered from the disgorging, or an aged wine, to which sugar and sometimes liquor (e.g., Armagnac, brandy, or rum) or a fortified wine is generally added. Sparkling natural wines in the EU receive different appellations, depending on the amount of sugar added to the expedition liqueur: Brut nature < 3 g l^{-1} (only residual sugars), extra brut 0–6 g l^{-1}, brut < 15 g l^{-1}, extra dry 12–20 g l^{-1}, dry 17–35 g l^{-1}, medium dry 33–50 g l^{-1}, and sweet > 50 g l^{-1}. Sweetness tends to disguise some defects in the wine. Therefore, natural sparkling wines of premium quality are the brut nature and extra brut wines, which contain only the residual sugar of the second fermentation or have been sweetened only very slightly. For these natural sparkling wines, the raw material and the production process must be impeccable. The bottle used in the settling of the sparkle is the same bottle that reaches the consumer, corked, foiled, and duly labeled.

The Charmat or Granvas Method (or Bulk Method)

The basic difference in this method compared with the Champenoise method (fermentation in the bottle)

is that the second fermentation is carried out in a Charmat tank (a sealed tank that traps the carbon dioxide gas produced during the second fermentation). This is the main method used in the USA, Australia, and New Zealand) (Table 1). The period of time during which the wine is in contact with the lees of the fermentation distinguishes the short Charmat from the long Charmat. Young and fruity wines preferably should not lose these sensorial characteristics by ageing in contact with the yeasts. The organoleptic result of ageing on the lees reduces their value. This is the case with the Italian Asti and Prosecco. The production method most suitable for these is the short Charmat.

[a]Data provided by Freixenet, S.A. cellar.

Short Charmat Method

The base wine (monovarietal or *coupage*) ferments in a Charmat tank to which the 'tirage liqueur' (sugar, nutrients, and yeast) has been added. This liqueur has a similar saccharose concentration to that used in the Champenoise method, but less volume is added (44 ml instead of 55 ml of wine-liqueur mix per liter). Then, 10% of yeast-enriched wine is added to the sweetened base wine. The ideal temperature for fermentation is 12–13 °C. When the desired CO_2 pressure has been reached (approximately 4 bar), the temperature of the Charmat tank is reduced to 8 °C to arrest the fermentation (with 10% of residual sugars). The low temperature causes the suspended yeast to sink to the bottom. The next step is to transfer under pressure the partially decanted wine, already bubbly, to the Charmat tank where it will be cold stabilized. When the wine is transferred from one Charmat tank to another, it is filtered or centrifuged to separate it from the lees, thus ensuring minimal contact between the wine and the lees to prevent the yeast from absorbing bouquet notes. Filtration by counter-pressure uses a gas (usually carbon dioxide) to compensate the empty volume of the Charmat tank while it is being emptied of the wine. The gas that is introduced will be at least 1 bar higher than the pressure of the sparkling wine to ensure that it remains invariable. This is also why the gas introduced into the second Charmat tank, which will receive the sparkling wine through the filter or hermetic centrifuge, remains at the same pressure as that of the sparkling wine. The gas used most often is nitrogen, rather than compressed air or carbon dioxide. Compressed air is not favored because of the negative influence of oxygen on wine. In some countries, such as France, Italy, or Spain, the use of industrial carbon dioxide is forbidden in cellars that produce natural sparkling wines, and can be employed only by companies that produce artificially gasified sparkling wines. However, it is possible to use the carbon dioxide that is recovered from the alcoholic fermentation as a compensation gas. If necessary, tartaric cold-stabilizing (−4 °C) is carried out when it has not previously been applied to the base wine. The wine is then refrigerated at 0 °C to prevent liquid loss, especially between the bottling and corking process.

There are several sparkling wines of excellent quality that deserve special attention, such as the Moscato d'Asti (a semisparkling wine, according to the EU's denomination) and the Asti spumate (Asti DOGC: denominazione di origine controllata e garantita)

(Table 2). The Moscato d'Asti is thought to be originally from Piamonte in Italy, and as ancient as Champagne. There are dessert wines produced from muscat grapes (Moscato bianco) and with a low alcohol content (4.5–5.5%), which differ from the sparkling wines previously described in that the base wine is a must wine whose second fermentation is carried out using sugars from the grapes of origin. In the past, the artisan production of the Moscato d'Asti meant that alcoholic fermentation had to be arrested when the desired alcohol content, CO_2 pressure, and quantity of residual sugars had been reached. Successive filtrations and the elimination of nitrogenated compounds gradually diminished the fermentation process until the critical point was reached. This point was determined by the percentage of nitrogen present and the quantity of live cells that made the wine incapable of fermenting when exposed to low-temperature, alcoholic, and reducing (CO_2) conditions. At present, the procedure for producing Moscato d'Asti is essentially the same, but modern techniques are available to facilitate the process (temperature of $-3\,^{\circ}C$, sterilizing microfiltration, and the use of selected yeasts). The filtered must is left to lie at $0\,^{\circ}C$ for 12–15 months. During this time, as soon as incipient fermentation is detected, the must is filtered and refrigerated again to eliminate and deactivate any yeasts, and it reaches a maximum alcohol content of 1%. Once the ageing period has passed, selected yeast strains are added, and the must is left to ferment at a controlled temperature of 18–20 °C. When an alcohol content of 4.5–5% is reached, and approximately 80 g of residual sugars per liter are left over, fermentation is stopped by refrigeration at $-3\,^{\circ}C$, followed by microfiltration and bottling. In some cellars, the product may be pasteurized to ensure that a second fermentation does not reoccur. The difference between the Moscato d'Asti and the Asti spumante is the alcohol content and CO_2 pressure in the bottled product. Asti spumante ferments aged must wine with 1% alcohol in a Charmat tank until an alcohol content of 7.5–9% is reached. As for the pressure, once fermentation has started, CO_2 is released, but when the product approaches the 5% alcohol content, the Charmat tank valve is closed. The pressure in the tank will reach 6–7 bar at $20\,^{\circ}C$ so as to ensure a pressure of 3.5 bar once the product is bottled.

Long Charmat Method

This method is used to produce sparkling wines with organoleptic characteristics that are closer to those achieved by the Champenoise method, especially wines of the Pinot and Chardonnay varieties. This is because the period during which the wine remains in the Charmat tank of fermentation is prolonged for several months (minimum 6 months). Wine ageing in contact with the lees gives rise to the development of aromatic compounds typical of this special ageing process. Another difference with respect to the short Charmat is that the sugar added for the second fermentation should be the necessary one to obtain a dry sparkling wine with a pressure of around 6 bar. Once the 6-bar pressure (measured at $20\,^{\circ}C$) is reached, the wine is kept in contact with its lees for 9 or more months at room temperature and with intermittent riddling. The riddling is delayed 2 or 3 weeks before the end of the ageing period, and the wine is then decanted. The decanted wine is centrifuged, and at the exit, a dosage pump injects expedition liqueur suitable for the type of sparkling wine desired. Then, the centrifuged wine is filtered into the Charmat refrigeration tank. The refrigeration temperature

[a]A semisparkling wine.

depends, as for the short Charmat, on whether tartaric stabilization is needed. After bottling under pressure at a low temperature, the sparkling wine is left to age for a long period (7–14 months) in bins so as to acquire the premium organoleptic qualities, especially with wines of Pinot origin (such as the German dry sparkling wines). A typical example of this type of production is the German and Austrian natural sparkling wine known as *Sekt*. Even though this sparkling wine can be produced following the traditional method, Charmat method, or Transfer method, for the most part, the wine is produced using the long Charmat method (85%), only 7% by the transfer method, and 8% by the traditional method.

In some cellars, once fermentation is complete, yeast autolysis is accelerated by increasing the temperature in the Charmat tank to 42 °C for 72 h. The disadvantage is that the CO_2 pressure is doubled from 5 bar at 20 °C to 10 bar. Therefore, Charmat tanks resistant to 13 bar are used, even though the pressure in the interior is not allowed to exceed 8–9 bar because decompression is provoked. The temperature stimulates the activity of the proteolytic enzymes and the lysis phenomenon to improve similar organoleptic characteristics to those of sparkling wines fermented in the bottle. This shortens the long Charmat method, even though an aging period of several months is still recommended after bottling.

Transfer Method

This system, of Italian origin, obviates the need for the riddling and disgorging steps characteristic of the Champenoise, traditional, or classical methods. The term 'transfer' refers to transferring the wine, which has undergone a second fermentation in a bottle to a Charmat tank (**Figure 1**). Therefore, it can be considered an intermediate system between the Champenoise method and the Charmat method. The wine is left in the bottle with only a crown cap during a minimum of 9 months, sometimes more. It is then transferred under pressure with the lees to the Charmat tank. From this moment on, the process is exactly like that of the Charmat method. The drawback of this method is that it is as laborious as (if not more so) the Champenoise method (from bottle to tank to bottle), and that filtration is carried out on a product that contains a Champenoise bouquet, significantly reducing the sensorial qualities of the sparkling wine. This method is declining and has already been abandoned in Italy, but is still employed on a limited scale in some German, Austrian, Greek, Hungarian, American, and Argentinean companies. In the USA when the sparkling wine has been transferred to another bottle different to that used for fermentation, the label may mention that it has been 'fermented in bottle,' but not 'fermented in *this* bottle,' as in the case of sparkling wines produced by the method champenoise.

Dietary Importance

S S Percival and S L Talcott, University of Florida, Gainesville, FL, USA

Background

The health benefits ascribed to wine are associated with both moderate alcohol intake and the content of polyphenols that have antioxidant capability. This review will cover wine composition, epidemiological data, and experimental data related to beneficial effects of wine consumption. It is important to note that alcohol consumption and mortality follow a J-shaped curve (**Figure 1**); that is, if nondrinkers are assigned a relative risk of 1.0, then the odds ratio for relative risk of adverse health effects is lower for those

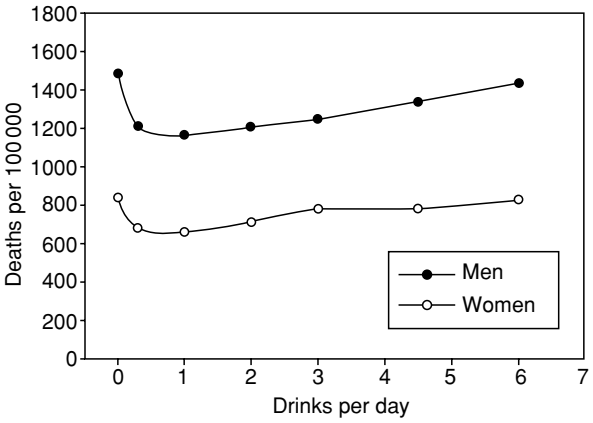

Figure 1 Rates of death from all causes.

consuming one to three drinks per day. When consumption is greater than three drinks per day, the odds ratio is greater than for nondrinkers. Thus, teetotalers and heavy drinkers have a greater risk of adverse effects and death than moderate consumers. Health benefits, accordingly, are manifested only in relation to a moderate consumption of wine, moderate in terms of quantity related to body size and therefore defined as two glasses (150 ml per glass or 5 oz per glass).

The grape species used in wine production is usually *Vitis vinifera*. When information is available, we will also include data related to the species *Vitis rotundifolia*, also known as the muscadine grape. This grape has a higher antioxidant profile and contains unique components and amounts compared with *Vitis vinifera*. Very few studies have been done with the *Vitis labrusca*, which is also known as the Concord grape.

Wine Composition

The phytochemical content of grapes of all species is linked to environmental conditions, but levels in wines are also influenced by viticultural practices, variety, and processing procedures (Table 1). In addition to ethanol, wine (especially red wine) contains a range of phytochemical compounds that confer health benefits for a variety of reasons that will be discussed. These include phenolic acids (*p*-coumaric, cinnamic, caffeic, gentisic, ferulic, and vanillic acids), trihydroxy stilbenes (resveratrol and polydatin), and flavonoids (anthocyanins, catechin, epicatechin, myricetin, kaempferol, and quercetin). An estimate of the different classes of compounds in wine follows (Table 2). Nonflavonoid compounds such as the hydroxy benzoic acids, hydroxycinnamic acids and stilbenes make up about 40% of the total

Table 1 Variability in total phenolics analyzed by different laboratories

	Investigator 1	*Investigator 2*	*Investigator 3*
Cabernet Sauvignon	1800	2600	821
Petite Syrah	3200	2266	
Muscadine			1269

phenolic acids and polyphenols. Flavonoids make up the remaining 60%. Hydroxybenzoic acids make up about 60% of the nonflavonoid fraction with gallic acid, about 120 mg l^{-1}, found in the highest quantity. Anthocyanins make up the largest portion of the flavonoids with the distribution as 50% anthocyanins, 30% flavanols such as catechin and epicatechin and 20% flavonols such as quercetin, myricetin, and kaempferol. Procyanidins are large complexes of epicatechin, catechin, and gallic acid. They comprise the largest fraction of the flavanols. A high level of flavonoids is found in the skin and seeds of the grape. Therefore, the longer the fermentation time with skin and seeds, the more flavonoids are extracted. Consequently, white wine has relatively low levels of flavonoids compared with red (Table 2).

V. rotundifolia, the muscadine, has approximately twice the polyphenolic content of the more commonly consumed *V. vinifera* and significantly more gallic acid and epicatechin (Table 3). *V. rotundifolia* has less catechin and procyanidin B3 than *V. vinifera*. Also, *V. rotundifolia* is found to have approximately 10 times more resveratrol than *V. vinifera*.

Muscadine grapes are similar to *V. vinifera* in that both contain high concentrations of neutral and acidic polyphenolic compounds. Neutral phenolics contain characteristic structural features that have been associated with radical scavenging abilities, including the number and location of hydroxyl groups, and the presence of a 2, 3 double bond. Additionally, these compounds have the ability to act synergistically with other antioxidant compounds or chelate metals that participate in free radical generation.

Epidemiological Evidence for Health Benefits of Red Wine

Epidemiological evidence that led to the suggestion that red wine confers benefits was first revealed in the Mediterranean population. Despite an intake of saturated fat about three times greater than Americans, the French population has only about one-third of the incidence of coronary disease. Consumption of red wine has been hypothesized to be the contributing factor in protection against cardiovascular disease

Table 2 Relative distribution of phenols and polyphenols in red and white wines

and is popularly known as the 'French Paradox.' The positive attributes of the Mediterranean diet, besides a moderate consumption of alcohol, mainly as wine, include: high monounsaturated to saturated fat ratio; high consumption of vegetables, fruits, legumes, and grains; moderate consumption of dairy, mostly as cheese; and low consumption of meat. The French population consumes less milk, and more garlic, cheese, fruits, vegetables, and wine. Therefore, this postulate, that red wine is the protective factor in these diets, cannot be wholly ascribed to the wine. Other dietary factors may play a considerable role.

Epidemiological data showing a relationship between chronic disease and red wine consumption are limited, but the data suggest a significant correlation between red wine and reducing the risk of heart disease. The fact that red wine is high in flavonoids and polyphenols and therefore antioxidants is often the reason why the consumption of red wine is thought to reduce the risk of disease.

Although benefits due to red wine consumption and heart disease are largely thought to be due to polyphenols, some studies suggest a benefit due to alcohol regardless of the form in which it was consumed. One study was not successful in showing a wine and heart disease correlation, but the consumption of wine by this particular population was very low.

Epidemiological evidence supporting a reduction in risk for certain cancers is strong for consumption of fruits and vegetables or for the consumption of green tea, yet data do not exist for red wine consumption. Some evidence exists from animal studies and will be discussed.

Relation to Diet

Bioavailability

Research on the absorption of polyphenolics from foods is limited, and yet it is the critical element in understanding health benefits conferred by red wine as well as by fruits, vegetables, and teas. Limited data are available on the bioavailability of bioactive compounds from red wine; however, anthocyanins have been detected in human plasma as well as in the urine of volunteers who drank red wine. Furthermore, anthocyanins have been detected in human and rat plasma as intact glycosides with no deglycosylation or further methylation or sulfation, although the level was less than 1% of the oral dose. A methylated form of a particular anthocyanin was detected in the liver of the animals. Catechin has been detected in

mouse plasma after consumption of a diet containing wine solids.

Colonic bacteria can metabolize polymeric procyanidins. An *in vitro* study showed that they were able to be completely degraded to low-molecular-weight aromatic compounds. These monomers may be easily absorbed in the large intestine and may therefore result in further beneficial effects.

Numerous studies indirectly assess bioavailability by measuring plasma antioxidant levels as an index of absorption and transport to the blood. Each day, 356 ml (12 oz) of red Muscadine wine (cv. Noble) were consumed for 4 days. The oxygen radical absorptive capacity (ORAC) in human plasma was increased by 10–15% (Figure 2). When the serum sample was deproteinized by acetone, the plasma ORAC values were lower but increased 21–33% over the 4 days. Mice consumed muscadine wine or Cabernet Sauvignon over 9 days as their sole source of fluid. Based on preconsumption levels, plasma ORAC levels rose by two-thirds in the case of the cabernet and doubled in the case of the muscadine (Figure 3). The results showed that the antioxidant capacity in plasma increased two- to three-fold with the consumption of the wines. The antioxidant capacity in this study was measured by DPPH (1, 1-diphenyl-2-picrylhydrazyl). This has been shown by others and confirms that the compounds that confer antioxidant activity are absorbed and transported to the plasma.

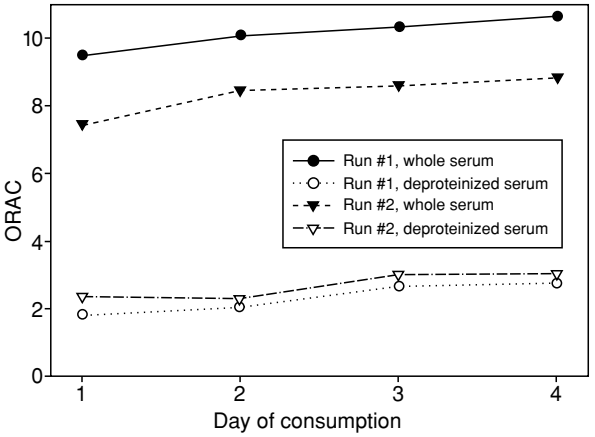

Figure 2 Human serum of oxygen radical absorptive capacity (ORAC) values after 9 days of consumption.

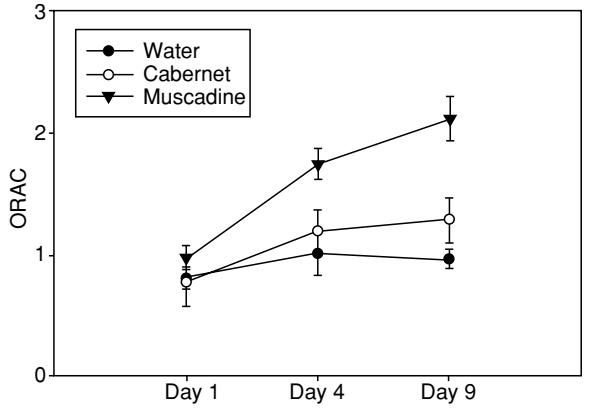

Figure 3 Mouse serum oxygen radical absorptive capacity (ORAC) values after 9 days of consumption.

Intake

The estimated intake of total polyphenols in the diet per day is 1 g. Although this value was derived over 25 years ago, it appears still to hold true. Wine composition is complex and variable. Because of the variability among grapes and wine, it would be difficult to estimate the consumption of polyphenols, even if consumption of the wine volumes were known. Teissedre, however, calculates the flavonoid consumption by the French population to be about 400 mg per day from red wine. In the USA, the consumption would probably be less.

Individual Components of Red Wine having Potential Benefits

The phenolic compounds in wine all have the potential to act as antioxidants. Because of structural differences, the phenolics vary in their relative activity.

Ellagic acid has been well studied as an isolated compound. Ellagic acid is an important phenolic compound found in many small fruits including cranberry, blackberry, blackcurrant, mayhaw, strawberry, and raspberry. Various reports have shown a positive effect for ellagic acid as a functional antimutagen, anticarcinogen, and inhibitor of various chemically induced cancers. Muscadine grapes have appreciable amounts of ellagic acid (10–25 mg l^{-1}) thought to be derived either directly from hydrolysis of ellagitannins or from dimerization of gallic acid.

Resveratrol is a phytoalexin that has been associated with anticancer, antiinflammatory, and antimutagenic activity. Resveratrol is found in the highest concentration in the skin and seeds, especially when the plant has been stressed. The content of resveratrol in the red wines from *V. vinifera* contains very little resveratrol, whereas it is found in higher concentrations in the muscadine wines. During processing, the longer the skins and seeds are fermented with the crushed grapes, the more resveratrol will be found in the wine. Resveratrol was first discovered in the *V. vinifera* grape species. It is synthesized by the leaf and skin in response to fungal infection. Thus, wine

derived from healthy plants has little to no resveratrol. Muscadine, however, has higher levels of resveratrol. The biological activities of resveratrol are numerous. It has been shown that resveratrol has antiinflammatory activity from its ability to inhibit eicosanoid production, antioxidant activity by scavenging radicals and chelating metals, and anticancer activity including antimutagenic, anticarcinogenic, and chemopreventative activity. Heart health benefits may be derived from its ability to inhibit platelet aggregation and induce vasorelaxation. Resveratrol has also been shown to have estrogenic activity.

Catechin and epicatechin are major components in red wine and are responsible for all the flavonoid content of white wine. These polyphenols are high-molecular-weight molecules with the ability to complex with other phenolic acids making a near endless array of procyanidins. They are also found in green tea and chocolate.

Health Benefits

Alcohol, Flavonoids, and Immunity

Ethanol is known to modify immune cell function detrimentally. In animals that drank 5% ethanol daily, there was a marked reduction in total splenocytes and total thymocytes, and an increase in T-cells relative to B-cells in the periphery. An increase in natural killer (NK) cytotoxic activity in both the spleen and the periphery was also found, but there was little change in NK cell number. We also found a modest, but significant, change in peripheral NK cell numbers.

Alcohol consumption for 2, 4, and 8 weeks was associated with a decrease in the number of NK cells in the spleen and periphery over time. The cytotoxic activity of peripheral and splenic NK cells was decreased modestly, in contrast to the aforementioned study.

The effect of alcohol on NK activity is one of the most controversial because of the variable results among laboratories. A reduction in the number of NK cells or their activity would have serious consequences in terms of host defense to viruses and tumors. Further research is needed to understand the role of both alcohol and wine polyphenolics on NK cell activity.

The detrimental effect of alcohol on immune function is thought to be due to free radical generation related to acetaldehyde. By extension, then, will the consumption of red wine reduce the detrimental effects of alcohol on immunity by virtue of its antioxidant polyphenolics? Consider, first, the data that show an effect of polyphenols on the modification of immune cell function. Although the studies showing modification of immune cell function have been largely done with isolated compounds, the research suggests that flavonoids can alter immunity.

Flavonoids have been studied in relation to NK cell function. A dose-dependent antitumor activity against solid tumors was exhibited using a type of flavone in mice. This was attributed to a stimulation of cytokine gene expression caused by the flavone. Specifically, mRNA for interferon α was upregulated. This was an *ex vivo* experiment, so it is not known if naturally occurring flavones show the same effect or if the food itself is potent enough to alter cytokine expression.

Flavonoids commonly found in red wine have been shown to be antiallergenic. Certain flavonoids were found to inhibit the stimulated release of mast cell, eosinophil, and basophil granular components, with quercetin being particularly active. Antiviral activity was demonstrated by the inhibition of viral infection of cells and inhibition of the replication of virus, once the cell was infected. Different flavonoids have different capabilities. Antiinflammatory activity was demonstrated by the inhibition of neutrophil activation via inhibition of the NADPH oxidase activity. Inhibition of phospholipase A_2 was also demonstrated, resulting in an inhibition of the release of arachidonic acid and reduced production of prostaglandins and leukotrienes. These activities have not been demonstrated in studies utilizing the wine itself.

A study was conducted in 4-week-old mice in which they consumed one of four beverages put into their drinking bottles as the only fluid available to them. They drank a Muscadine wine, a Cabernet Sauvignon wine, ethanol, or water for 8 weeks. The Muscadine, Cabernet, and ethanol were adjusted to 6% alcohol, and it was shown that the mice drank an equal volume of fluid without any differences in body weight or food consumption among the groups. The amount of wine or ethanol consumed by the mice was equivalent to two 178-ml (6-oz) glasses of wine for a human when based upon caloric consumption. This model utilized a moderate consumption of the food itself rather than isolated compounds or pharmacological doses.

Some aspects of immune function were impaired in the mice that consumed ethanol, but not in those that consumed wine. Ethanol consumption decreased the basal numbers of NK cells and T-lymphocytes. However, the mice that consumed the same amount of ethanol as wine had basal levels of NK cells and T-lymphocytes equal to the water-consuming controls.

Mice were stimulated with a low level of lipopolysaccharide (LPS) in order to induce an immune response. We asked, first, if ethanol would reduce

the response and, second, if the red wine would prevent the reduced response. In control mice, 24 h after injection of LPS, blood lymphocyte numbers were reduced due to emigration and turnover. However, in the mice that consumed ethanol, the T-lymphocyte numbers were the same before and after the LPS. The mice that consumed either of the red wines showed a normal emigration of T-lymphocytes after LPS injection.

NK cell numbers, however, increase after LPS, likely due to the reduced numbers of other lymphocytes from the blood and/or possibly due to the migration of NK cells from the bone marrow. The mice that consumed ethanol had the lowest increase in NK cell numbers, whereas the mice consuming the red wine had an increase equal to that of the animals that drank water. These data suggest an impaired immune response to the LPS when even a moderate amount of ethanol was consumed. The mice that consumed wine as their sole beverage responded identically to the mice that consumed water. Perhaps free radicals generated during alcohol metabolism damaged the immune response, but the polyphenolic compounds in the red wine prevented the damage. It was also hypothesized that another mechanism could be functioning, i.e., the alteration in the phase I and phase II enzymes involved in alcohol degradation.

Free radical damage due to ethanol consumption was not found in any of these groups. Liver and lymphocyte glutathione levels and thio barbituric acid-reacting substances (TBARS) were not significantly different among the groups, stimulated or nonstimulated. The data suggest that immunity can be compromised without any overt signs of free radical damage.

Cardiovascular Disease

The health benefits of red wine related to cardiovascular disease have been documented in epidemiological studies, as well as experimental animals and humans. An excellent review of this was presented by German and Walzem in the Annual Reviews of Nutrition (2000).

Research has shown that moderate alcohol intake, regardless of the type of beverage, lowers cardiovascular mortality risk. The mechanism is related to the elevations in high-density lipoprotein (HDL) cholesterol. The rise in HDL cholesterol accounts for nearly half of the reduction in risk for death due to heart disease. Ethanol also stimulates liver lipogenesis, resulting in increased plasma triglycerides, increased lipoprotein lipase, thereby increasing triglyceride-rich lipoproteins, and increased expression of ApoAI and ApoAII, which together have a net effect of increasing the production of HDL.

The other nonalcoholic components of wine have also been shown to modify physiological cardiovascular health. One of the initial factors related to plaque formation in heart disease is the oxidation of low-density lipoprotein (LDL). Once oxidized, the molecule is rapidly taken up by macrophages that then take on the appearance of 'foam cells.' These foam cells modify the endothelium and contribute to the formation of blockage. Many *ex vivo* studies have measured the oxidation rates of LDL in the presence of wine phenolics and shown it to be reduced. It is not clear how much or to what extent the LDL is protected *in vivo*.

In addition to the protection against LDL oxidation, the polyphenols and phenolic acids in wines affect endothelial cells, platelets, lymphocytes, and macrophages through changes in cell signaling. The phenolic compounds in wine, as well as the ethanol, have been shown to reduce platelet aggregation. In addition, phenolics and ethanol have both been shown to improve endothelial function, as measured by vasodilation, vasorelaxation, or cellular adhesion molecule expression. Again, the extent to which this happens *in vivo* is not known.

Cancer

One of the few studies that used wine itself in the experimental design showed a reduction in cancer frequency. Mice consumed commercial wines or 12% ethanol with or without ethyl carbamate at 10 or 20 mg per kilogram of body weight for 41 weeks. Liver and lung were examined, and the incidence of tumors (percentage of mice with tumors) and the frequency (number of tumors per tumor-bearing mouse) were evaluated. Although the incidence of liver tumors was not consistently affected by the treatments, the frequency of tumors was significantly less for the wine-drinking animals than for the water- or ethanol-drinking animals. Similar results were found for the incidence and frequency of lung adenomas.

Moderate wine consumption in humans was associated with protection against hydrogen peroxide-induced DNA damage, a preliminary event related to cancer. Four volunteers drank 300 ml (9 oz) of red or white wine. Blood samples were collected before drinking and 1, 3, 8, and 24 h after drinking. Hydrogen peroxide-induced micronucleated cell frequency was determined in fresh lymphocytes that were incubated in the donor's homologous serum. Less damage occurred when the lymphocytes were incubated with their respective plasma 1 h after consumption, but not before consumption or at 8 or 24 h, suggesting that the protective effects are transient due to turnover of the bioactive compounds.

HTLV-1 transgenic mice that develop clinical and pathological features resembling human neurofibromatoses were fed dehydrated and dealcoholized wine (wine solids). The wine solids diet contained 0.04% polyphenols. Mice were examined daily for tumors, and the endpoint was age of tumor onset (latency). The age at which the first tumor appeared in the control mice and that in the experimental mice were 71 ± 4 days and 102 ± 10 days, respectively in the first experiment and 63 ± 4 and 86 ± 6 days in the second. They calculated the wine solid concentration at approximately one-quarter of that of a human consumption of 1 g of polyphenols per day. Catechin was the major polyphenol measured in the wine.

Other Diseases

Many other chronic diseases exist that are thought to be due to free radical damage. For example, Parkinson's and Alzheimer's diseases, diabetes, arthritis, inflammatory disorders, radiation injury, reperfusion injury, and macular degeneration as a few examples are thought to result from the accumulated damage caused by free radicals. No data exist to suggest that red wine consumption will prevent or alter the course of these diseases.

Mechanisms

Antioxidation

The mechanisms by which the compounds in red wines are thought to provide benefits related to risk reduction of chronic disease are via the antioxidant capabilities of the polyphenolic compounds. In general, antioxidants work by different mechanisms. Firstly, a free radical is defined as a compound missing an electron. Polyphenols, and antioxidants in general, can donate electrons to the free radical to prevent the free radical from obtaining electrons from the lipids of cell membranes, proteins, or nucleic acids. Secondly, the phenolics in red wine, shown by *in vitro* studies, can chelate metals, particularly iron and copper, which participate in the generation of free radicals. Thirdly, the phenolics in red wine can spare or help in the regeneration of other antioxidants. Flavonoids have been shown to conserve endogenous vitamin E contained in the LDL molecule.

The relative strengths of the flavonoids in their ability to prevent free radical damage by any of the above mechanisms is dependent upon the system used to study it. Numerous systems exist, in both aqueous and hydrophobic phases. The radical generated in the procedure as well as the detection system are different and can result in different effects. Some generalizations of structural requirements can be drawn to signify relative strengths of the polyphenols. Conjugation between the A and B rings in the form of a 2,3 double bond, a 3′,4′ di-hydroxyl configuration of the B ring, a 3-hydroxyl group in the C ring, and a 5-hydroxyl group in the A ring is highly significant for the radical scavenging function. Glycosylation of the polyphenols as well as sulfation and methylation may result in changes to the relative antioxidant strength. As stated earlier, the absorption and relative bioavailability are factors in assessing relative antioxidant strength. Much is yet to be done to understand the structure–function relationship of the thousands of polyphenolic compounds. Although the mechanisms, components, and availability are not yet clear, consumption of red wine is known to increase the antioxidant capacity of the plasma.

Cell Signaling

Flavonoids and therefore, by extrapolation, bioactive red wine components produce other metabolic changes that could be interpreted as beneficial. Components found in red wine are known to inhibit the arachidonic acid cascade via inhibition of phospholipase A2, lipoxygenase, and cyclooxygenase, thus accounting for potential antiinflammatory activity. Growth inhibitory activity via, for example, p53, tyrosine kinase, or polyamine metabolism have been shown to result from bioactive compounds found in red wine. Very little work has been done *in vivo* or with the wine itself.

Microsomal Detoxification Enzymes

Changes in the levels of Phase I and Phase II microsomal detoxification enzymes are associated with both beneficial and harmful effects. Inhibition of the Phase I microsomal detoxification enzymes is associated with drug toxicity due to a reduction in drug metabolism. Activation of the phase I enzymes is associated with drug tolerance or the conversion of innocuous compounds to toxic or carcinogenic compounds. Induction of phase I enzymes has been associated with the promotion stage of carcinogenesis. Potential phase I enzymes that may be involved in carcinogenesis include cytochrome P450 2E1 (CYP2E1), CYP1A1, CYP1A2, and CYP3A4. Alcohol is known to induce CYP2E1.

Induction of phase II enzymes is associated with anti-initiation processes related to cancer. Enzymes such as glutathione *S*-transferase (GST), epoxide hydrolase, *N*-acetyltransferase, and quinone reductase have been linked to beneficial anticancer activities.

Different dietary agents result in distinct alterations in the expression in phase I and II enzymes. For example, butylated hydroxy toluene (BHT), ethoxyquin, indol-3-carbinol, and phenethyl isothiocyanate induced both the phase I and the phase II isozymes and are therefore referred to as bifunctional agents. Caffeic acid, garlic oil, and propyl gallate induced phase II enzymes, but not phase I. 4-Methyl catechol, α-tocopheral, and red wine decreased phase I and induced GST. The type of red wine used in this study was not defined. The ratio of the phase I/phase II is more important in understanding protection or toxicity as opposed to the levels of one or the other. If the relative increase in phase II enzymes is greater than the phase I enzymes, then the assumption is that it is overall protective. If phase I enzymes increase relatively greater than phase II, then the potential for damage, by free radicals or production of toxic compounds, is greater. Alcohol consumption is known to induce phase I CYP2E1, resulting in production of acetaldehyde. Acetaldehyde, whether generated by this mechanism or by alcohol dehydrogenase, is potentially damaging due to its participation in free radical generation.

In one of the few articles that used the wine itself, Chan *et al*. showed that red wine solids, but not white wine solids, inhibited CYP3A4. In the study by Percival and Sims, liver microsomal cytochrome CYP2E1 and GST were altered by wine consumption, and Muscadine wine resulted in different patterns relative to the Cabernet Sauvignon. The Muscadine wine reduced CYP2E1 about 80%, whereas the Cabernet had no effect. Although the GST activity was also reduced in the mice that drank Muscadine, the ratio between the two enzymes was increased threefold, suggesting a beneficial effect of the Muscadine wine. GST activity was no different in the ethanol group or the Cabernet group compared with the water-consuming group, suggesting that there are unique components in the Muscadine wine that resulted in the observed changes. Moreover, the mice that drank the Cabernet Sauvignon did not have an extensive change in the microsomal detoxification enzymes, signifying a unique response of the mice to the Muscadine wine.

Ellagic acid has been shown to increase phase II enzymes GST and quinone reductase in mice. It has also been shown to inhibit metabolic activation of carcinogens. For example, ellagic acid inhibits the conversion of polycylic aromatic hydrocarbons, nitroso compounds, and aflatoxin B1 into compounds that cause genetic damage. Ellagic acid was also shown to inhibit CYP1A1. The anticarcinogenic effectiveness of ellagic acid was due to several different structural aspects of the molecule.

Summary

Red wine consumption results in an increase in antioxidant levels in the blood. Data on benefits of the individual compounds are emerging, but the study of red wine itself is limited. Health benefits can be demonstrated in epidemiological and animal studies regarding heart disease, but information is less solid regarding cancer, and nonexistent for other disease. The data cannot be ascribed solely to the phytochemical content of the wine since moderate alcohol intake is known to have benefits, both physiologically and psychologically.

The mechanisms by which the phenolic/polyphenolic compounds confer benefits are via their antioxidant activity, intracellular signal modification, alterations in gene expression, and alterations in microsomal detoxification enzyme activity. Other functional modifications that occur due to phenolics/polyphenolics, such as antimutagenic, anticarcinogenic, or antiinflammatory activity are derived from one of these major mechanisms.

The contribution of red wine to health can only be understood in the context of the whole diet. In populations that consume limited amounts of fruits and vegetables, as in Denmark, the consumption of wine is likely a significant contributing factor of phenolics and other phytochemicals and therefore more likely to provide benefits. In other populations, such as those that consume a Mediterranean-style diet, red wine is less likely to contribute to the overall health and disease risk reduction due to the consumption of olive oil, fruits, and vegetables. Recommendations to consume red wine for its beneficial effects may be imprudent, due to the health problems associated with overuse. However, if a person drinks alcohol sensibly, red wine has an advantage due to its contents of beneficial compounds.

Wine Tasting

A C Noble, University of California, Davis, CA, USA

Introduction

The phrase 'wine tasting' is most frequently associated with subjective determination of quality of wine by experts at competitions or wine fairs. Increasingly often, consumers are learning about wine through tastings conducted by wine societies; similarly, wine bars offer the opportunity to taste single glasses of wines. Although wines are informally 'tasted' throughout all phases of wine-making, for example during aging in oak barrels, analytical sensory methods must be used to determine if wines differ in flavor or to measure the effects of a specific treatment. In this article, standardized wine terminology and objective sensory methods for evaluating wine flavor will be introduced and contrasted with more subjective quality evaluations. (*See* **Sensory Evaluation**: Sensory Characteristics of Human Foods.)

Quality Evaluation

Assessment of quality is made as a composite response to the sensory properties of wine based on expectations for a given wine type. These expectations are a function of previous experience with wines. Thus, while quality judgments are required for wine shows, for example, they are subjective. Responses vary among individuals because of different expectations and preferences. Therefore, the most experienced, skilled, and sensitive of wine judges will have differences of opinion about wine quality. Considerable experience with wines is required to make meaningful wine-quality evaluations; nearly all quality scorecards or schemes for awarding medals at competitions assume that the judges have a concept of the 'standard' for each wine type being judged. (*See* **Sensory Evaluation**: Practical Considerations; Food Acceptability and Sensory Evaluation.)

One of the most widely used scorecards is the Davis 20-point system (**Table 1**). For both systems, each factor is assessed separately and judged relative to an existing internal standard for the class of wine being evaluated. For example, for a young white Riesling, points are subtracted for a dark gold color which suggests excessive oxidation in this generally very light-colored variety, whereas a dark gold in an older white Riesling may be consistent with a wine of that age, so no points are subtracted.

These types of scorecard serve as a training device by forcing judges to examine the same factors, but experienced judges seldom rate each category independently, using the specific weighting assignments. Instead, the attributes are confounded; dark color in a young white Riesling influences the judge to look for and generally subtract points for an oxidized aroma and flavor by mouth. Most experienced assessors tend to evaluate color, aroma, taste, and flavor by mouth and come up with a final score using their own criteria. Further, differences in preferences result in greatly differing overall quality evaluations. Judges who like varietally distinct Sauvignon blanc or Cabernet Sauvignon wines (e.g., wines with intense asparagus or bell-pepper aromas) give high-quality ratings for these wines, whereas judges who dislike the intensely vegetative aromas rate the wines as being defective. (*See* **Sensory Evaluation**: Appearance; Aroma; Taste.)

Wine Terminology

An alternative and more analytical approach to wine tasting is descriptive analysis. This can be done

informally by recording specific terms to describe a wine. However, when naive wine drinkers first try to describe wine flavor, they usually find it difficult to name specific and familiar flavor notes. Standardized terminology for wine evaluation has been developed which facilitates development of precise descriptions. A standardized terminology using analytical terms for evaluation of table wines is presented in a hierarchical system in the wine aroma wheel (Figure 1). (A similar scheme for evaluation of sparkling wine aroma has also been developed.) The most general terms are located in the inner tier, with increasingly specific terms placed in the second and third tiers. In construction of this word list, subjective, hedonic terms, such as 'rich,' 'well-rounded,' 'harmonious,' 'elegant,' and 'austere,' which may have meaning to an individual or group of people but which cannot be readily defined or standardized, were specifically excluded. Terms are grouped by similarity of the aromas where possible. To define the terms, reference standards can be easily prepared (Table 2).

Descriptive Analysis

In contrast to quality ratings of wine experts, which provide an overall impression of their preferences but do not provide description of the flavor or reasons for the quality assignment, descriptive analysis provides specific information about the wines, which is figuratively a 'photograph of the flavor.' Analytical sensory evaluations, such as descriptive analysis, are conducted under controlled conditions which minimize bias. For example, to exclude the influence of color, tests are conducted under red lights or using black glasses. Tulip-shaped glasses are used for all evaluations of aroma. The optimum shape for increasing intensity has recently been demonstrated to be a tall glass with a wide bowl and narrow mouth. (*See* **Sensory Evaluation**.)

In descriptive analysis, initially analytical descriptive terms or attributes, such as those in the wine aroma wheel, are identified which are necessary to describe and differentiate the wines. For each attribute, reference standards are provided which define the specific aroma or taste characteristics and provide a common point of reference for communication. Even if descriptive analysis is done informally by consumers, profiles of wine flavors can be developed which permit specific comparisons of the differences among wines. More formally, data obtained using trained judges under controlled conditions provide precise information about wine flavor. Judges are trained extensively in the use of these terms in discussion sessions and in formal scoring tests, with reference standards available to define each attribute clearly. The intensity of each term is then rated in each of the wines and the data are analyzed statistically to confirm that the judges are consistent and reproducible and to determine whether differences among wines are statistically significant. (*See* **Sensory Evaluation**: Sensory Rating and Scoring Methods.)

The information provided by this type of analysis can be illustrated briefly, first, by examination of results from a descriptive analysis of Napa Valley Cabernet Sauvignon wines made from vineyards with different soils. Trained judges rated flavor by mouth and aroma attributes using the reference standards described in **Table 3**. How soil type may have influenced wine sensory properties is seen in Figure 2 for two wines which were produced at the

[a]Explained in detail in Amerine MA and Roessler EB (1983) *Wines, Their Sensory Evaluation*. San Francisco: W.H. Freeman.
17–20, superior wines: must have some outstanding characteristic and no marked defect; 13–16: standard wines with neither an outstanding character nor defect; 9–12, wines of commercial acceptability but with a noticeable defect; 5–8, wines of below commercial acceptability; 1–4, completely spoiled wines.

Table 2 Composition of typical aroma reference standards

Term	*Composition*
Berry	1 blackberry, 15 g raspberries, 10 g strawberry jam, 10 g raspberry jam in 3 ml base wine
Vanilla	0.1 ml vanilla extract in 25 ml base wine
Butterscotch	0.2–0.3 ml butter extract in 25 ml base wine
Vegetative	0.2 ml asparagus brine, 0.4 ml black olive brine, 1.5 ml green-bean brine in 25 ml base wine
Bell pepper	0.1 g fresh bell pepper in 25 ml base wine
Cloves	3 whole cloves in 25 ml base wine
Soy	0.4 ml soya sauce in 2.5 ml base wine
Mint	Piece of eucalyptus leaf and 0.05 ml mint eucalyptus extract in 25 ml base wine

Base wine was a neutral, low-intensity red wine.
Data from Spears TA (1990) Evaluation of the effects of soil and other geographic parameters on the composition and flavour of Cabernet Sauvignon wines from the Napa Valley. Unpublished. MSc Thesis, University of California, Davis.

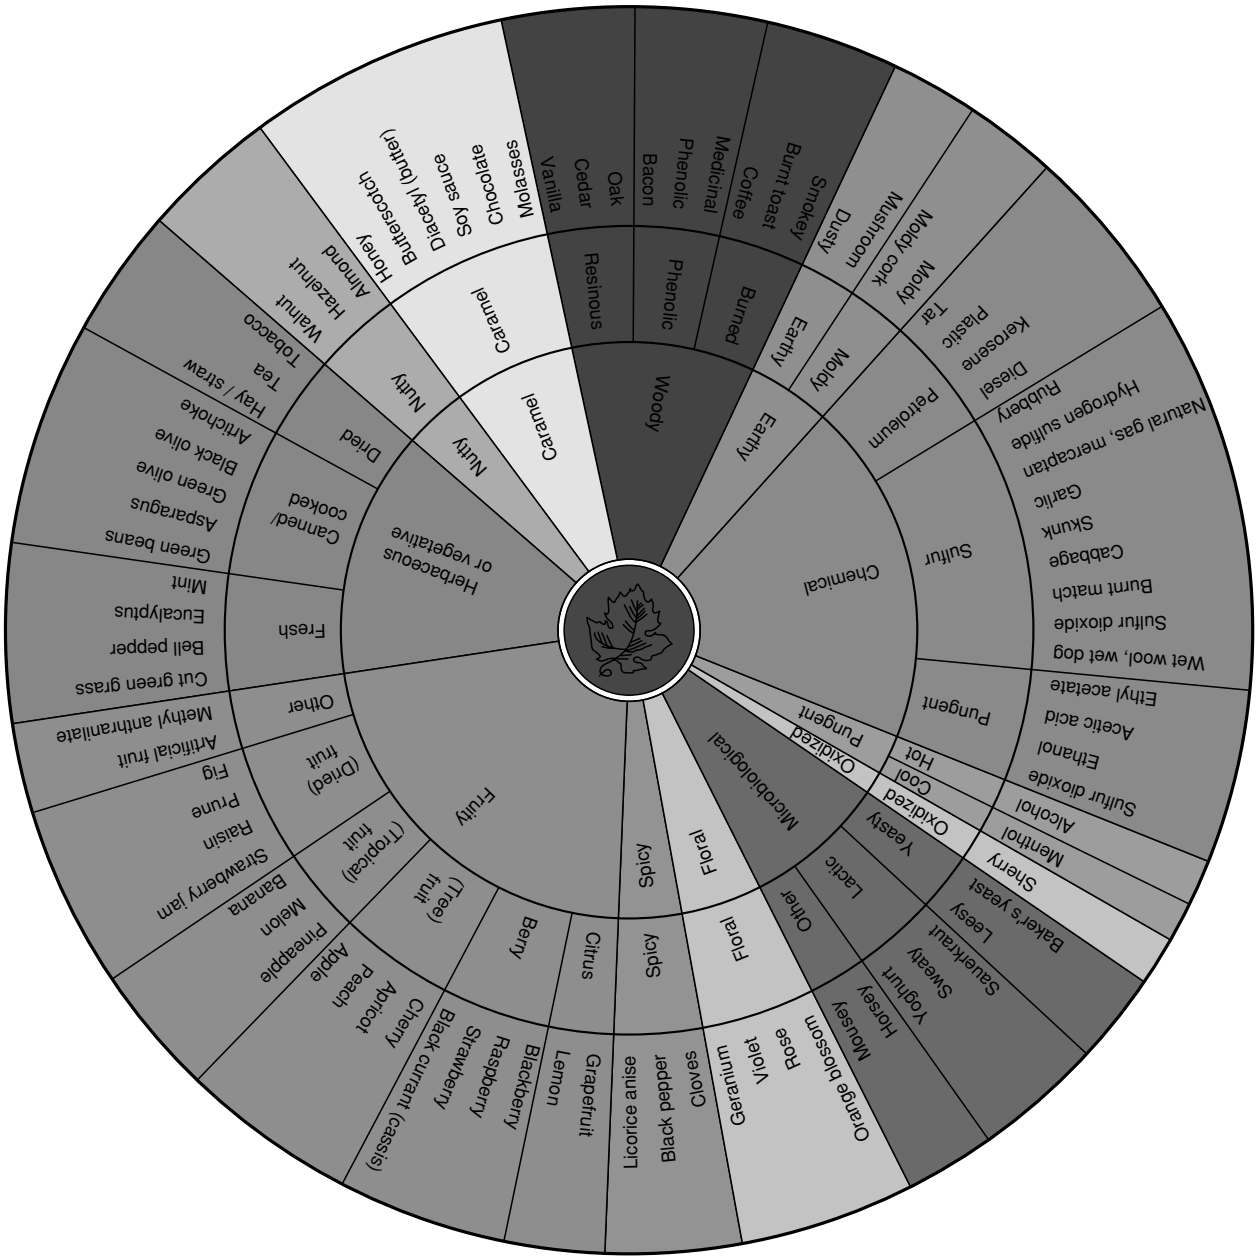

Figure 1 Wine aroma wheel. Standardized terminology showing most general terms (first tier) to most specific ones (inner tier). Copyright 1990, AC Noble, www.winearomawheel.com.

same winery from vines grown in very different soil types. In this polar coordinate graph, the center of the figure represents low intensity with the distance from the center to the intensity rating corresponding to the relative intensity of each wine for the attribute. By connecting the mean ratings, the profiles of wines are shown.

Wine 12 is characterized by a fruity (berry) aroma and flavor by mouth and is high in intensity of vanilla and butterscotch aromas. In contrast, wine 13 is low in these notes, and high in bell pepper, soy, and vegetative aromas and in vegetative flavor. Soil at site 12 is young, shallow, sandy, and nutrient-poor with a low water-holding capacity, whereas at site 13 there is a deep, clay-rich, older soil which is high in nutrients with a high water-holding capacity. Using a multivariate statistical method, the soil data were related to the sensory descriptive analyses for these sites and wines, demonstrating an association between wines with higher intensity of vegetative aroma and flavor by mouth and soils with higher water-holding capacity. Conversely, fruitier wines, high in berry aroma and flavor, were associated with older, gravelly soils with poor water-holding capacity.

As a second illustration of the application of descriptive analysis, 58 Chardonnay wines spanning three vintages were evaluated by descriptive analysis in 1985. For clarity, mean values for only two vintages are plotted in Figure 3. The younger wines from the 1983 vintage are higher in fruity (peach, citrus, and floral) aromas. The older wines from the 1981 vintage are lower in these fruity characteristics but higher in vanilla and bell-pepper aromas. Previously, it was claimed that younger wines were fruitier than older wines, but this study was the first quantitative evaluation to substantiate informal observations. More recently it was demonstrated that storage at high temperatures can decrease the fruitiness of white wines in less than 15 days. The intensity of citrus, floral, and green apple aromas decreased by 50% in Chardonnay wines stored at 40 °C for 15 days. After 30 days, the fruity notes were almost absent, while tea/tobacco, honey, and vanilla were the dominant aroma characteristics (Figure 4).

The 1981, 1982, and 1983 Chardonnays were also scored for quality by expert judges using the Davis 20-point scorecard (Table 1). No significant differences in quality scores were found across the 58 wines, but quality ratings for the vintages were statistically significantly different, although they were too small to be meaningful. (The oldest vintage was scored 14.80, and the youngest vintage the lowest, 14.08.) From examination of the aroma profiles of these vintages in Figure 3, it can be seen that higher-quality ratings were assigned to the older wines which were higher in vanilla (from oak aging) and lower in fruity notes which decreased over time because of chemical changes, such as hydrolysis of fruity esters to odorless or nonfruity compounds. Whether these differences in flavor resulted in the higher-quality ratings for the older wines, or factors such as the

greater complexity of older wines influenced the experts, can only be speculated upon. However, this example illustrates the greater information provided by wine descriptive analysis than that provided by quality scores. (*See* **Sensory Evaluation:** Descriptive Analysis.)

Time–Intensity Evaluation

When wine is tasted, the flavor by mouth often lingers. To measure aftertaste, the method of time–intensity evaluation in which judges rate intensity continuously is useful. When a wine is sweetened, the fruitiness is perceived to increase. As shown in Figure 5, as the concentration of sugar was increased from 1% to 3%, the fruity flavor by mouth became more intense and lasted longer. Time–intensity analysis is useful for characterizing the temporal profiles of bitterness and astringency. Both are very persistent and increase in intensity upon repeated sips. For example, astringency intensity was rated continuously, while the tasters took four sips of the same wine at 25-s intervals. The average time–intensity curve shown in Figure 6 illustrates the build-up of astringency when red wine is sipped rapidly.

WORLD HEALTH ORGANIZATION

J Akré, World Health Organization, Geneva, Switzerland

The Birth of the World Health Organization

The World Health Organization (WHO; Figure 1) is the culmination of efforts at international health cooperation that began 150 years ago. Although people have exchanged remedies and diseases for many thousands of years, only recently has thought been given to ways of working together to promote health that could go beyond purely parochial concerns. Early attempts at international cooperation in health were limited to small groups of countries, which discussed a few obviously contagious diseases such as cholera and smallpox, and strategies such as quarantine to keep them at bay. Although 11 international sanitary conferences were held in Europe between 1851 and 1903, it was not until 1907 that a world-wide international institution – the Office International d'Hygiène Publique – was founded to prepare and administer international sanitary conventions and to provide national health administrations an opportunity for regular contact and discussion.

The terrible epidemics that raged in Europe at the end of World War I, coupled with the mass movement of liberated prisoners of war, constituted a menace of such magnitude as to require coordinated international effort. The League of Red Cross Societies, created in 1919, attempted the task but quickly realized that intergovernmental action was essential to cope with a problem of such magnitude. As the charter of the Office International d'Hygiène Publique did not give enough power for action in individual countries, provision for necessary measures had to be made by the League of Nations, then in the process of creation.

The Geneva-based League, during its short and unhappy history between the two world wars, had been the first to invoke international health cooperation to deal with many kinds of health problems. In the same period, the Pan American Sanitary Organization, originally established in 1902, continued to work in its own geographic sphere. (In 1958, it became the Pan American Health Organization, which also serves as WHO's Regional Office for the Americas.)

In 1945, the United Nations (UN) Conference on International Organization, meeting in San Francisco, unanimously approved a proposal by Brazil and China to establish an autonomous international health organization within the UN system. The following year, a conference held in New York set up an interim commission and approved the *Constitution of the World Health Organization*, which came into force on 7 April 1948. Since then, 7 April is celebrated every year as World Health Day, when attention all around the globe is focused on a theme of major international public health importance.

The Task Entrusted to WHO

The agreed policy of WHO is a structured effort by all countries to bring health within the reach of everyone. The Organization's objective is the attainment by all peoples of the highest possible level of health. Health, as defined in WHO's Constitution, is a state of complete physical, mental, and social well-being, and not merely the absence of disease or infirmity. It is seen as a shared responsibility, calling for a high degree of self-reliance from the individual, the family, the community, and the nation as a whole. Because the determinants of health are so broad, the efforts of the health sector must be supported and augmented by those of many other sectors, including agriculture, water and sanitation, finance, communications, planning, and education. In carrying out its activities, the WHO Secretariat focuses on six core functions:

- Articulating consistent, ethical, and evidence-based policy and advocacy positions.

Figure 1 The WHO emblem.

- Managing information by assessing trends and comparing performance; setting the agenda for, and stimulating, research and development.
- Catalyzing change through technical and policy support, in ways that stimulate cooperation and action and help to build sustainable national and intercountry capacity.
- Negotiating and sustaining national and global partnerships.
- Setting, validating, monitoring, and promoting implementation of norms and standards.
- Stimulating development and testing of new technologies, tools, and guidelines for disease control, risk reduction, health care management, and service delivery.

WHO also proposes conventions, agreements, and regulations, and makes recommendations about international nomenclature of diseases, causes of death, and public health practices. It develops, establishes, and promotes international standards concerning foods and biological, pharmaceutical, and similar substances.

Structure and Management

WHO is a UN specialized agency, as provided for in the *Charter of the United Nations*. A goal-oriented organization with policies, programs, and budget defined through well-developed mechanisms, WHO consists of three constituent bodies.

The *World Health Assembly*, which is the highest decision-making body, is held in May of each year, and is attended by delegations from WHO's 191 Member States and two Associate Members. Its main function is to determine the policies of the Organization; it also appoints the Director-General and reviews and approves the budget.

The *Executive Board*, comprising 32 members designated by Member States, meets twice a year. It functions as the executive organ of the Assembly, prepares the agenda for each session, and submits to it a general program of work. The Assembly elects countries entitled to designate members of the Executive Board, and one-third of the membership is renewed annually.

The *Secretariat* is headed by the Director-General who, as the chief technical and administrative officer of the Organization, is appointed for a 5-year term by the World Health Assembly on the nomination of the Executive Board. Dr Gro Harlem Brundtland (Norway) took office on 21 July 1998. Past Directors-General have been Dr Brock Chisholm (Canada, 1948–1953), Dr Marcolino Candau (Brazil, 1953–1973), Dr Halfdan Mahler (Denmark, 1973–1988), and Dr Hiroshi Nakajima (Japan, 1988–1998).

In general, all technical activities that are of universal applicability – such as biological standardization, the overall assessment of the efficacy of methods and materials, and promoting the control of diseases – are led from *headquarters* in Geneva, Switzerland (Figure 2). WHO's decentralized structure enables it to respond directly to the needs of its membership, upon request, through its six regions – Africa, the Americas, South-east Asia, the Eastern Mediterranean,

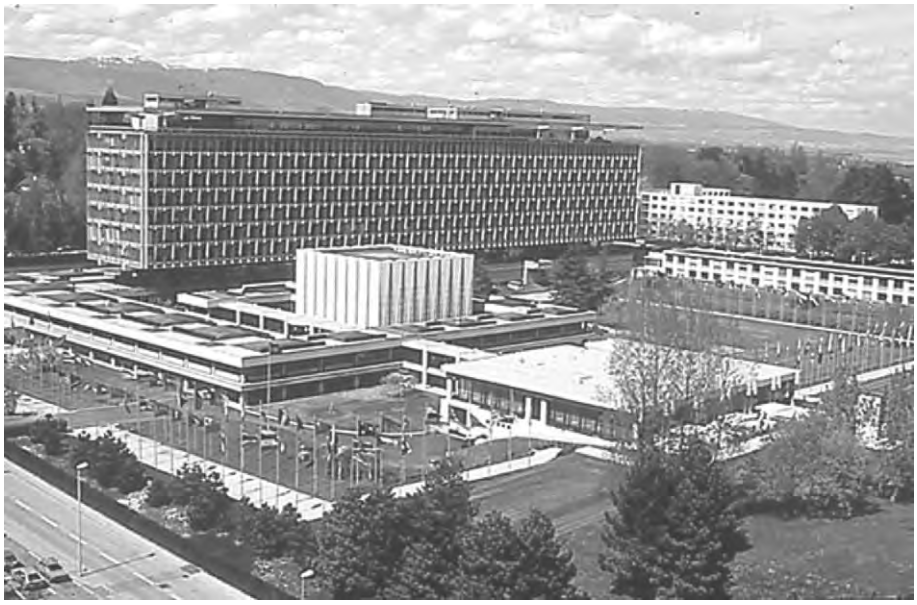

Figure 2 General view of the WHO headquarters in Geneva, Switzerland (photograph by J. Germain, WHO).

Europe, and the Western Pacific – each consisting of a *regional committee* and a *regional office* (Figure 3). The regional offices, with their own directors, are responsible for formulating policies of a regional character and for monitoring regional activities. In many countries, there is a resident WHO representative, who is the main intermediary for WHO support, and who participates, with the government, in planning and managing national health programs.

Some 27% of WHO's approximately 4300 staff members work in countries all over the world, either in field programs or as WHO representatives; 44% are in the regional offices, and 29% at headquarters.

The WHO's standard-setting functions include preparation and updating of the *International Classification of Diseases*, assignment of generic names for pharmaceuticals, and development of the authoritative scientific knowledge base – methodologies, standards, norms and criteria, and guidelines and strategies – for preventing, detecting and managing the major forms of malnutrition. Since 1957, evaluation of the safety for human consumption of selected food additives and contaminants in food and establishment of acceptable daily intakes for these substances has been the focus of the Joint FAO (Food and Agriculture Organization of the United Nations)/WHO Expert Committee on Food Additives. The committee's reports, as well as those of a similar FAO/WHO group responsible for evaluating the safety of pesticide residues, are used in formulating national food legislation intended to protect consumers from hazardous additives or contaminants and by the Codex Alimentarius Commission – another joint FAO/WHO body – in establishing international food standards. Food legislation is one of the many topics covered by WHO's *International Digest of Health Legislation* database.

Apart from its regular budget, WHO receives voluntary contributions from both governmental and nongovernmental sources. The regular and projected extra-budgetary figures for the biennium 2002–2003 are US$855.6 million and US$1.380 billion, respectively. Voluntary contributions include subaccounts for purposes such as developing a new international growth reference based on an international sample

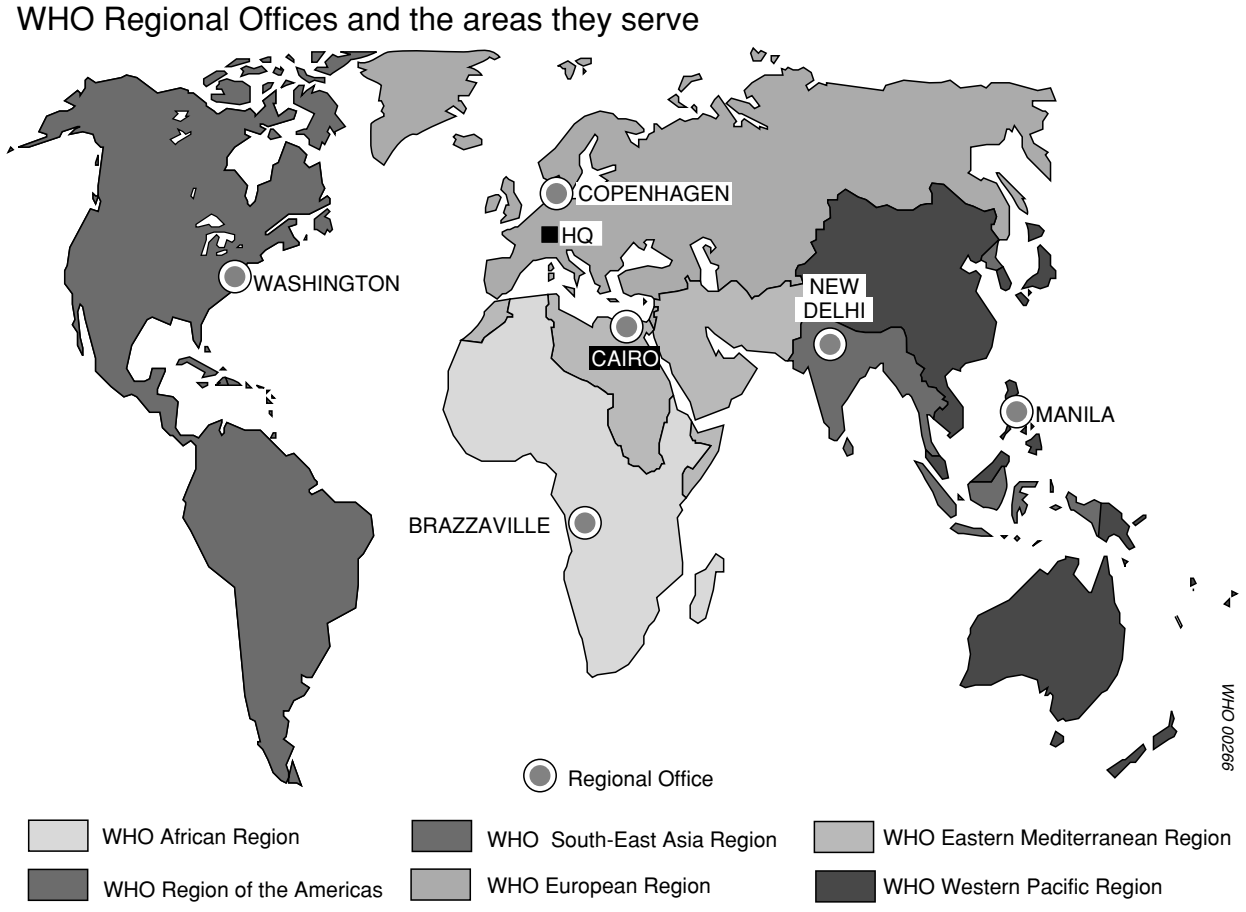

Figure 3 WHO regional offices and the areas they serve.

of breastfed infants from healthy populations with unconstrained growth; fostering health research; improving community water supply; expanding immunization; eradicating polio; preventing and controlling HIV/AIDS, diarrheal disease and yaws; preparing a credible emergency health response to disasters and natural catastrophes; and responding to new and re-emerging diseases, e.g., viral hemorrhaghic fevers like Ebola, and tuberculosis (see below concerning public–private partnerships).

Working Together for Better Health

From its beginning, WHO set out to work not through its small staff alone but with and through others. Many thousands of individual researchers and scientists, including Nobel laureates, have put their talents at the Organization's disposal – and their number continues to grow. The same is true of the nearly 1200 leading health-related institutions around the world that have been officially designated as WHO collaborating centers in a wide range of disciplines.

WHO was also mandated to work with other agencies within the UN family of organizations. Nutrition work, for example, quite naturally came to involve FAO, as did work against animal diseases and, as mentioned above, in the area of food additives, pesticide residues, and contaminants. WHO cosponsored, with FAO, the International Conference on Nutrition (Rome, 1992) when 159 governments reached a new global consensus on the nature of malnutrition and its multiple causes, and on the urgent action required to prevent, reduce, and ultimately eliminate malnutrition. Programs aimed at educating teachers on how to deal with mentally retarded children came within the purview of the United Nations Educational, Scientific and Cultural Organization (UNESCO). Occupational health was a shared activity with the International Labour Organization. Drug dependence and abuse called for collaboration with the United Nations Division of Narcotic Drugs. WHO, together with the United Nations Children's Fund (UNICEF), the United Nations Development Programme, the United Nations Population Fund, UNESCO and the World Bank, was a founding cosponsor of UNAIDS, the global effort to control the spread of HIV/AIDS.

One of WHO's closest partners has been UNICEF, with which, for example, the early yaws and malaria campaigns were carried out, and it prepared the International Code of Marketing of Breast-milk Substitutes (1981). In 1991, the two agencies jointly launched the Baby-friendly Hospital Initiative to promote breastfeeding, and they continue to collaborate in the development of a global strategy for infant and young child feeding.

Collaboration was also initiated with professional, charitable, and other nongovernmental organizations (NGOs) pursuing aims consonant with those of WHO. By the end of the first decade, WHO had established official relations with 40 such bodies, ranging from the International Council of Nurses to the International Commission on Radiation Units and Measurements, and from the World Federation for Mental Health to the International Leprosy Association. Work of vital importance has been made possible through the enthusiasm of these and other valuable organizations – for example, the Bill and Melinda Gates Foundation – which have in turn benefited from the moral support and the technical information provided by WHO.

Collaboration continues unabated; examples include cancer pain relief with the International Association for the Study of Pain, efforts to insure safe blood and plasma supplies undertaken with, among other groups, the International Federation of Red Cross and Red Crescent Societies, and support for polio eradication provided through Rotary International. The success of these joint ventures is illustrated by the ever-lengthening list of NGOs admitted into official relations with WHO, which now numbers 192 with the recent acceptance of Timor-Leste.

To further its mission and policies, WHO also regularly interacts with commercial enterprises, including through participation in alliances and other relationships, exchange of information, product research and development aimed at improving health, generation of cash and in-kind donations to WHO, and advocacy for health. While stressing the need to be fully transparent and to avoid conflict of interest arising in any relationship – work with the private sector to achieve health outcomes is governed by formal guidelines – the Executive Board has encouraged new forms of partnerships and other relationships in order to advance WHO's health agenda. A number of groundbreaking public–private partnerships – WHO, government agencies, NGOs, and the pharmaceutical industry – have been recently developed to tackle several particularly challenging diseases, including leprosy, malaria, and trachoma.

World Health in the Twenty-first Century

Using pragmatic tools in pursuit of its visionary goal, WHO strives to respond to its constitutional mandate through its evolving program of activities. These are based on the needs and priorities determined by Member States themselves through the World Health Assembly and the Executive Board. Changes in program emphasis occur in response to altered political, social, economic, and environmental realities.

For example, in 1977, the World Health Assembly decided that the major social goal of governments and WHO should be the attainment by all people of the world by the year 2000 of a level of health that would permit them to lead a socially and economically productive life. This was the birth of the Health for All movement, which was followed, in 1981, with the adoption of the Global Strategy for Health for All. In 1994, WHO's Member States, while acknowledging that significant global changes had occurred since the adoption of the goal of Health for All, called for a renewal of the strategy to meet challenges, exploit opportunities, and overcome obstacles at the dawn of the twenty-first century.

Respecting the new issues and priorities of the times for WHO means grappling with the multiple consequences for health and nutritional status of accelerating social and demographic changes, including population growth, ageing, international movements of migrants and refugees, and complex emergencies resulting from natural and ecological disasters, wars, civil disturbances, and serious disease outbreaks. It calls for dealing creatively with the impact of indebtedness, incurred over time, that has led many countries to reduce public spending in health services, which are often regarded as being only an expenditure rather than an investment in human potential. There continues to be a massive gap between the resources needed to help poor communities tackle different causes of illness – malnutrition, malaria, tuberculosis, and HIV/AIDS being among the most urgent examples – and the funding and human capacity currently available to them.

WHO must also face up to threats to human health that respect no national boundaries, such as uncontrolled dumping of toxic wastes and pollution of land, water and air, and prodigious consumption and mismanagement of natural resources. The globalization of infectious diseases is not a new phenomenon. However, increased population movements; growth in international trade in food and biological products; social and environmental developments linked with urbanization; deforestation and climate change; and modification of food-processing methods, distribution, and consumer habits have reaffirmed that infectious disease events in one country are potentially a concern for the entire world. The solution of these problems hinges, to a large extent, on the degree to which WHO is able to harness the interdependence of nations and peoples as a positive force for conciliating between competing present and future needs.

Maintaining that health should be seen as central for development and to the quality of human life, WHO seeks to achieve a dynamic yet harmonious balance between health in terms of consumption and health as an investment in human capital with dividends earned in the future. The Organization's history has been one of adaptation to evolving circumstances, giving priority first to one health problem, then to another, and it continues to adjust its priorities to meet the world's ever-changing health requirements. At the same time, WHO is being asked to respond to unprecedented requests for support in addressing the problems brought about by dramatically declining resources, political upheaval, war and civil strife, together with the pandemic of AIDS, epidemics of cholera and bovine spongiform encephalopathy (and its human form, Variant Creutzfeldt–Jakob Disease), environmental degradation, as well as natural disasters such as earthquakes, floods and drought. In 2001, WHO opened an office in Lyon (France) to help with the technical training of specialists from all over the world who work to control epidemics. WHO's Tobacco Free Initiative was created to focus international attention, resources and action on the global tobacco pandemic that kills four million people a year today. WHO is leading the way with the Framework Convention on Tobacco Control – the world's first multilaterally negotiated rules devoted entirely to a major health issue – which will be ready for signature no later than 2003.

In this light, and as a reflection of the decisions taken during the World Health Assembly, the Executive Board, and the regional committees, WHO has designated its priorities for the start of the twenty-first century. These include an approach that focuses particularly on links between health and poverty reduction; a greater role in establishing consensus on health policies, strategies and standards; more effective action to improve health and decrease inequities in health outcomes; and an organizational culture that encourages strategic thinking, global influence, prompt action, creative networking, and innovation. To pursue these ends, the work of WHO has four strategic directions:

- reducing excess mortality, morbidity, and disability, especially in poor and marginalized populations;
- promoting healthy lifestyles and reducing factors of risk to human health that arise from economic, social, and behavioral causes;
- developing health systems that equitably improve health outcomes, respond to people's legitimate demands, and are financially fair;
- developing an enabling policy and institutional environment in the health sector and promoting an effective health dimension to social, economic, environmental, and development policy.

The Foundation of Nutritional Well-being

Nutrition is a cornerstone of health and development; it affects and defines the health of all people, rich and poor. It is a fundamental pillar of human life, health, and development across the entire life span and an essential foundation for human and national development. From the earliest stages of fetal development, at birth, through infancy, childhood, adolescence, and on into adulthood and old age, proper food and good nutrition are essential for survival, physical growth, mental development, performance and productivity, health, and well-being. Conversely, malnutrition spells increased vulnerability to disease and premature death.

Malnutrition means 'badly nourished,' but it is far more than just a reflection of what people eat, or fail to eat. Clinically, malnutrition is the result of inappropriate intake and absorption of protein, energy, and micronutrients, whether too little or too much, and by frequent infections or disease. Nutritional status is the result of the complex interaction between the food we eat, our overall state of health, and the social and physical environment in which we live – in short, food, health and caring, the three 'pillars of well-being.' Good health is as essential to nutritional well-being as good nutrition is crucial for maintaining healthy growth and development. Preventing infection and managing infectious diseases – minimizing their incidence, duration, and severity – are essential for optimizing nutrition.

The fundamental WHO goal of Health for All – that people everywhere have the opportunity to reach and maintain the highest attainable level of health – is impossible in the presence of hunger, starvation, and malnutrition, which remain among the most devastating problems facing the majority of the world's poor and needy and continue to dominate the health of the world's poorest nations. Indeed, poverty, inequality, and underdevelopment will not be truly resolved until both malnutrition and ill-health are effectively addressed.

Malnutrition: Casting Long Shadows

Nearly 30% of the world's population, especially in low-income countries, bears the triple burden of poverty, malnutrition, and ill-health, which stalk one another in a vicious circle. From a human-development perspective, poverty compromises health and nutritional status, and undermines socioeconomic development. In a world that has both the resources and knowledge to end this catastrophe, the situation is a continuing travesty of justice and an abrogation of the fundamental human right to adequate food and nutrition, and to be free from hunger and malnutrition. In addition to suffering from one or more of the multiple forms of malnutrition, 800 million people – many of whom depend on food aid for their survival – are threatened by food insecurity. Malnutrition kills, maims, cripples, and blinds on a massive scale world-wide; and it is both a major cause and effect – as well as a key indicator – of poverty and underdevelopment.

The point here is as simple to state as it is complex to remedy – proper nutrition is a prerequisite both for insuring good health and for reducing poverty. Where hunger and malnutrition prevail, unnecessarily high levels of morbidity and mortality, and unacceptable levels of economic and social deprivation are sure to be found. Thus, for example:

- *Poverty* underlies most of the world's *malnutrition*, with attendant inadequate and insecure food supply, inappropriate feeding practices and care, nutritional emergencies, and widespread infection and infestation that are compounded by lack of health services.
- *Nutritional status*, determined using nutritional indices, is a reliable and easily measurable objective indicator of poverty and progress achieved in national development.
- *Maternal malnutrition* remains a major factor for the 30 million infants born each year (23.8% of all births) with *intrauterine growth retardation* leading to retarded physical, mental, and intellectual growth, and heightened risk of infectious diseases and death.
- *Protein–energy malnutrition* affects more than a quarter of the world's children – 26.7% (150 million) underweight and almost 30% (161 million) stunted – of which 70% are in Asia, over 25% in Africa, and 4% in Latin America and the Caribbean.
- *Malnutrition* contributes to 60% of the 10.9 million *deaths* each year among children under five in developing countries. Well over two-thirds of these deaths, which are often associated with poor feeding practices, occur during the first year of life.
- Some 740 million children and adults in 130 countries are affected by *iodine deficiency disorders*, still the greatest single cause of preventable brain damage to the fetus, infant, and young child.
- *Vitamin A deficiency* affects more than 250 million preschool children in 118 countries, mainly in Africa and South-east Asia, causing blindness and increased risk of infection and death.
- Vast problems of *iron* and *folate deficiency*, resulting in anemia, affect more than 60% of

women of childbearing age in developing countries, and millions of young children.
- *Noncommunicable diseases* contribute to approximately 60% of deaths in the world and 43% of the global burden of disease. About half of these deaths are attributable to *cardiovascular diseases*.
- Major natural and human-induced *emergencies* of all types are increasing in number and intensity, further compromising the care and feeding of vulnerable populations, including refugees and internally displaced persons who currently number more than 40 million (including 5.5 million under-five children).

Responding to the Challenge of the Twenty-first Century – A Two-Pronged Approach

To promote healthy nutrition for all people, it is necessary to take simultaneous action on two different, if overlapping, fronts. On the one hand, many less-favored nations remain handicapped by a formidable array of development constraints, including rapidly increasing population, unproductive agriculture, environmental degradation, limited health service coverage, and war and civil strife. Among the most visible – and tragic – consequences are the many millions of wasted and stunted children who do not have enough protein and energy in their diets, who suffer from cretinism and other permanent brain damage because their diets and those of their parents are deficient in iodine, or who go blind or even die for lack of vitamin A. It is in just such environments that diarrheal disease, frequently compounded by seasonal or chronic food shortages, take their heaviest toll in terms of malnutrition, ill-health, and premature death.

On the other hand, there has been a significant drop in recent years in the prevalence of infectious diseases, while food availability and the quality of diets have improved for population groups all over the world. The result in many countries has been a sharp reduction in infant and child mortality and longer adult life expectancy. These and related factors have paved the way for a dramatic expansion of a different type of nutrition crisis – diet-related chronic disorders are now flourishing where, not so long ago, infectious diseases were seen as the greatest menace to health. Chronic disorders are fast becoming major killers, and their prevalence is especially high in rapidly industrializing low- and middle-income countries among the urban poor who pursue the unhealthy dietary habits and lifestyles that, until recently, were considered the province of more affluent groups.

The rapidly increasing burden of noncommunicable diseases is a key determinant of global public health. On the basis of current estimates, deaths from noncommunicable diseases are expected to account for 73% of deaths and 60% of the disease burden by the year 2020. Already 79% of deaths attributed to noncommunicable diseases occur in developing countries, where most people affected by these diseases are between 45 and 65 years old. In China and India alone, the burden of cardiovascular disease is greater than that in the industrialized countries as a whole. One of the main objectives of WHO's global strategy for the prevention and control of noncommunicable diseases is to reduce the level of exposure to the major risk factors, namely, tobacco use, unhealthy diet, and physical inactivity, which should be tackled in an integrated manner.

WHO is committed to reducing malnutrition's global burden and its associated morbidity and mortality. The overall aim of its work in nutrition is to promote healthy nutrition and appropriate feeding for all population groups based on sound scientific evidence. WHO seeks to prevent, reduce, and eliminate malnutrition world-wide, thereby promoting sustainable health and well-being, accelerating poverty reduction, and enhancing human and national development. Within this context, WHO's seven priority action areas are:

- *protein–energy malnutrition* – assessment, monitoring/management, prevention, and reduction;
- *micronutrient malnutrition:*
  - Elimination of vitamin A deficiency and iodine deficiency disorders;
  - Significant reduction of iron deficiency anemia;
- *obesity* and other *diet-related diseases* – epidemiology, prevention and management;
- *national nutrition policies and programs* – development and implementation;
- *infant and young child feeding* – appropriate breastfeeding and complementary feeding;
- *nutrition in emergencies* – preparedness and response;
- *food aid for development* – guidance for food-assisted development activities.

Against this backdrop, WHO strives to:

- strengthen the technical capabilities of its Member States for assessing and coping with malnutrition;
- develop authoritative standards, norms, criteria, methodologies, guidelines and strategies for preventing, detecting, and managing all major forms of malnutrition;
- promote the health and nutrition benefits, for food-insecure populations, of food-assisted development and emergency activities;

- monitor, evaluate, and report on the world's major forms of malnutrition and progress achieved in combating them.

Given malnutrition's multicausal nature and multisectoral dimensions, WHO collaborates extensively with many multilateral (United Nations) and bilateral (national) development agencies (see examples above), and international scientific advisory bodies and NGOs. A world-wide network of 28 distinguished collaborating centers in nutrition also undertake a wide range of nutrition training and research activities.

In view of nutrition's foundational importance for health and development, WHO focuses on priority issues in basic nutritional science, nutritional care throughout the life span from infancy to old age, and nutrition policies and programs for sustainable development. Today's most urgent priority in tackling these vast nutritional challenges is for WHO to focus its combined normative and collaborative strength, particularly through its technical outreach in regions and countries, to strengthen the ability of all its 191 Member States to effectively prevent, control, reduce, and, ultimately, eliminate malnutrition in all its forms.

WORLD TRADE ORGANIZATION

S D Kalyankar and S P Kalyankar, Marathwada Agricultural University, Parbhani, Maharashtra, India
C D Khedkar and A S Khojare, College of Dairy Technology, Warud (Pusad), Maharashtra, India

Emergence of WTO

As per the proposal made by the USA, the world economy organized around the International Monetary Fund and International Bank for Reconstruction and Development. In 1947, the General Agreement on Tariffs and Trade (GATT) was created and signed by 23 countries on 30 October at the Palais des Nations in Geneva and came into force in 1948 with its first meeting at Havana, Cuba. Thereafter, GATT completed seven rounds. The eighth round, the largest trade round (1986–1993), was known as the Uruguay Round (UR). The UR proposals had covered agriculture in a comprehensive manner for the first time, since the creation of GATT in 1947. The problems of stagnation in agricultural trade were presented in the UR at Punda del est in 1986 and articulated in the Dunkel proposals in December 1991. The Dunkel proposals were eventually ratified, and these form part of the rules of the World Trade Organization (WTO).

Objectives

WTO is an international body dealing with the rules of the international trade. The basis for the organization are the agreements and negotiations signed by the bulk of the world's trading nations, which are essentially contracts, binding governments to keep their trade policies within agreed limits. It aims to facilitate trade flow as freely as possible, as long as there are no undesirable side-effects, and serves as a forum for trade negotiations and as a dispute settlement body. It encourages countries to enter into free trade gradually through negotiation by promoting fair competitions and trade without discrimination.

Structure

Membership

WTO currently has 132 member countries. Thirty-two countries are currently negotiating for accession. These include China and the Russian Federation, and a number of developing countries.

Decision-making System

WTO has a three-tier system of decision-making. The decisions are made at three levels: ministerial conference, general council and other councils, and heads of delegations.

The top-level decision-making body is the ministerial conference, which meets at least once in a year and can make decisions on all matters under any of the multilateral trade agreements. WTO has organized two ministerial conferences: Singapore (1996) and Geneva (1998).

In the intervening period between two conferences, the general council acts on behalf of the ministerial conference and carries out the day-to-day work of WTO. The general council of WTO, together with other councils for trade in goods, trade in services, and intellectual property, performs WTO functions. These councils are responsible for implementing WTO agreements in their respective areas of specialization.

The third tier of decision-making system is at the heads of delegation level. This is most effective in overcoming inherent impediments for reaching consensus on trade-related issues. This level is usually represented by different sets of people, depending on the need of the nation and their expertise and experience. The usual process is to hold a meeting of about 40 countries, which are most interested in a particular issue. Such meetings are termed 'green room meetings'. An example of the success of such a meeting is the market access negotiation. In the last 5 years of the operations of WTO, its growing importance and membership have proved to be effective in this new millennium, and will grow further with changing requirements. The WTO structure and decision-making process is adequately equipped to face future challenges.

Agreements

These rules are contained in the following legal instruments.

- Annex 1A. Multilateral Agreement on Trade in Goods.
- Annex 1B. General Agreement on Trade in Services and Annexes.
- Annex 1C. Agreement on Trade-related Aspects of Intellectual Property Rights.
- Annex 2. Understanding the Rules and Procedures Governing the Settlement of Dispute
- Annex 3. Trade policy Review Mechanism.
- Annex 4. Plurilateral Trade Agreement.

Member countries are under an obligation to ensure that their national legislation, regulations,

and procedures are in full conformity with the provisions of these agreements. The harmonized rules stipulate that there should be no unnecessary barriers to trade and that a country's exports are not disrupted by the sudden imposition of higher tarrifs or other barriers to trade.

Annex 1A. Multilateral Agreement on Trade in Goods

1. Agreement on Agriculture;
2. Agreement on application of sanitary and phytosanitary measures;
3. Agreement on technical barriers to trade;
4. Agreement on textiles and clothing;
5. Agreement on TRIMS;
6. Agreement on the implementation of Article VI of GATT 1994;
7. Agreement on preshipment inspection;
8. Agreement on rules of origin;
9. Agreement on import licensing procedures;
10. Agreement on subsidies and countervailing measures;
11. Agreement on safeguards.

Agreement on Agriculture (AOA)

AOA is a set of rules governing international agriculture policy development to liberalize agricultural trade and reduce the existing distortions in the sector, if any. The agreement itself has concessions and commitments of members regarding market access – removing various trade restrictions confronting exports, domestic support programs, and tackling the problem of making exports artificially competitive. The reform program requires that countries that have applied quantitative restrictions to import be permitted to add to existing import tariffs on the prices of imported products. This process has come to be known as 'tariffication.' Under the reform program, the countries, which granted subsidies to their farmers will have agreed to reduce by agreed percentages domestic subsidies that distort trade and export subsidies.

General Agreement on Trade in Services (GATS)

Services cover a wide range of economic activities from banking, insurance, and telecommunications to recreation, cultural, and sporting services. One of the main characteristics of services is that they are intangible and invisible. These characteristics influence the modes in which international trade transactions in goods and services take place. While international trade in goods involves the physical movement of goods from one country to another, relatively few service transactions involve cross-border movements.

Trade in services is growing and accounts at present for over 20% of international trade. GATS has created a framework for bringing this trade under international discipline. Its provisions apply to all modes of supply of service in international trade, viz.:

- cross-border trade in services;
- establishment of a commercial presence in foreign country;
- temporary movement of natural persons to another country to provide services there; and
- movement of consumers to the country of importation.

The agreement consists of a framework text, which lays down a set of general principles for measures affecting trade in services. The annexes applicable to specific sectors complement the text.

Agreement on Trade-related Aspects of Intellectual Property Rights (TRIPS)

Intellectual property right is the legally enforceable power to exclude others from using the information created or to set the terms on which it can be used. The objective of the agreement on TRIPS is to give adequate and effective protection to the intellectual property rights to reward creativity and inventiveness. TRIPS sets out minimum protection to be given to each category of intellectual property in the national laws of each WTO member. It lays down procedures and remedies to be provided by each country for intellectual rights enforcement. The agreement on TRIPS lays down minimum standards of protection that countries must provide for intellectual property rights. One of the other important features of the agreement is that it also requires countries to ensure effective enforcement of these rights. Its rules apply to:

- copyright and related rights;
- trademarks;
- patents;
- geographical indications;
- industrial designs;
- layout designs of integrated circuits; and
- undisclosed information.

Y

YEASTS

T Deák, Szent István University, Budapest, Hungary

Introduction

Humans have consumed cereals since prehistoric times. In Mesopotamia, baked pastes of ground grain were consumed, while, in Egypt, leavened bread was prepared. For thousands of years, humans were unaware of the existence of yeasts but were able to use them not only for breadmaking but also for brewing. The fundamental role of yeasts and bacteria in fermentation processes was only discovered in the last century by Pasteur. Soon after this, Hansen established the use of pure cultures for brewing and baking. Until that time, bakers used spent brewer's yeast for leavening, or seeded the fresh dough with a small part of already leavened dough. The commercial production of yeast for baking purposes started after about 1850, and since then, yeast technology has grown into a highly productive and economic industry. 'Yeast' in this article refers solely to the species *Saccharomyces cerevisiae*.

The Organism

Baker's yeast is a biotype of *S. cerevisiae* that can metabolize sugars both aerobically, producing the end products carbon dioxide and water, and anaerobically, producing ethanol and carbon dioxide. Thus, baker's yeast can be propagated in large quantities under aerobic conditions, and the cell mass added to dough can produce carbon dioxide under various conditions to leaven bakery products. These are the fundamental properties of baker's yeast that render it indispensable to the production of bread. Through this century-old application, many specific requirements have been imposed by the producer and the user, and strains have been selected with improved properties to meet these requirements. The strains used today are able to reproduce rapidly under strong aeration and limited nutrient supply. The yeast cells show remarkable tolerance to various storage conditions, and survive drying. Baker's yeast possesses strong fermentative activity and flavor development in various conditions of processing.

Production

There are at least four major steps in the manufacture of baker's yeast: preparation, fermentation, separation, and packaging (Figure 1).

Preparation

The manufacture of baker's yeast starts in two separate areas: in the laboratory with the propagation of a pure yeast culture, and in the factory with the preparation of the fermenters and the nutrient medium.

In the laboratory, where pure stock cultures are maintained, a small flask of sterile fresh culture is prepared after one or more subcultivations. This sample is then inoculated into the first pure culture tank. Two or three tanks of increasing capacity from 50 to 400 l may be applied. The yeast produced in an earlier stage is used to seed the next stage, while transfer is made under sterile conditions. In these early stages of propagation, the main concern is to maintain purity. The pure culture fermenters are fed with sterile molasses medium supplemented with the necessary growth factors, but aeration with filtered air is not at full capacity in the first batch fermentation.

Before the First World War, grain mash was used for the commercial propagation of yeast. During the war, shortages of grain led to its replacement by molasses, a relatively cheap byproduct of cane and beet-sugar production. Since then, molasses has become the traditional source of carbon and energy for yeast growth. It is usually fortified with a source of nitrogen, minerals and growth factors. Nitrogen is added in the form of ammonia, its salts, or urea; phosphorus is supplied in the form of phosphoric acid or ammonium phosphate. Depending on the

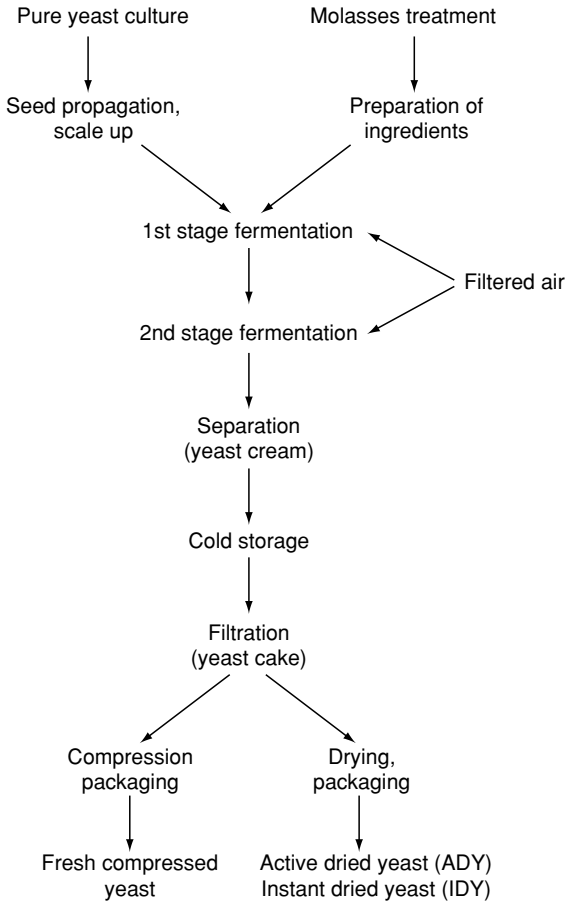

Figure 1 Flow chart for the production of baker's yeast.

composition of the raw molasses, certain growth factors, most frequently biotin, are also added to the wort. The concentrated molasses is diluted, purified, supplemented with other nutrients, and sterilized before use.

Fermentation

Baker's yeast is usually produced in a multiple-stage process. During scale-up, strong aeration and incremental feeding are introduced. Full-scale fermentation is conducted in large (100 m^3 or larger) tanks. There is a great variation in the size and shape of fermenters. However, in their design, an important requirement is to insure maximum aeration, because it is the oxygen transfer that is usually the rate-limiting factor in yeast propagation. Mechanical and sparger aeration systems are generally used. During the aerobic growth of yeast, a considerable amount of heat is liberated, and an efficient cooling system is also an integral part of the fermenter. The strict demands for hygiene determine the overall construction of the fermenter and the materials used therein. Facilities for cleaning in place are always integrated.

After cleaning and disinfection, the fermenter is fed with water, in which the pure seed yeast is suspended, then mixed with wort, and the propagation starts with vigorous aeration. Baker's yeast 'fermentation' is a typical fed-batch process in that, after commencing the propagation, nutrients are fed incrementally, maintaining at all times a very low sugar concentration at full aeration. The protocols for nutrient feed rate, temperature, pH, and aeration are specifically set up and strictly controlled to optimize yield, productivity, and product quality. Special attention is paid to prevent underaeration, which leads to excessive alcohol formation and a decrease in productivity. Instrumental process control and automation are necessary to produce baker's yeast economically. Adequate sensors and computer applications now make it possible to control the most sophisticated fermenter systems. Baker's yeast producers, however, have to consider the baking quality (stability and activity) of the product, which can be attained at the cost of productivity. As a satisfactory compromise, at the final stage of fermentation, nutrient feeding is stopped, and aeration is continued for about an hour. During this ripening period, the properties of baker's yeast are improved. Nitrogen starvation increases stability, but fermentative activity decreases. At the end of a typical fermentation, the yeast solid content may vary between 3 and 8%, which means a yield of about 20 000–30 000 kg of fresh yeast in one batch propagation at 28–30 °C for 12–18 h.

Efforts to introduce continuous fermentations on a commercial scale have remained unsuccessful. Although continuous systems can be maintained at a maximum yield, a good product quality can be achieved only with propagation regimes that do not easily lend themselves to continuous culture. Moreover, the problem of preventing contamination raises the cost and makes the process economically unfeasible.

Separation and Filtration

At the end of each fed-batch propagation period, the yeast cells are recovered from the spent medium by centrifugation. Water wash is applied between two passages through centrifugal separators. A yeast cream is obtained with 18–20% dry weight, which can be stored in agitated tanks at 2–4 °C for a few days without any loss of quality.

The yeast cream is further concentrated by filtration on rotary vacuum filters or filter presses. Filtration yields a yeast cake of about 27–30% dry matter content. (*See* **Filtration of Liquids**.)

Packaging

After filtration, the yeast cake is mixed with oils, emulsifiers, and a small amount of water, then compressed and extruded into blocks, or granulated for bulk distribution. The oil and emulsifiers improve product appearance and aid the formation of blocks (extrusion, cutting). (*See* **Emulsifiers**: Uses in Processed Foods.)

The Product

Compressed Yeast

This is the form of baker's yeast produced by the process outlined above. Compressed yeast is the traditional form of baker's yeast, which is available to wholesale bakers in 0.5–2.0-kg blocks, while smaller (10–50 g) blocks are prepared for households. Compressed yeast wrapped with waxed paper and stored at 4 °C keeps for a few weeks. A granulated pressed cake form of the same product packed in 10–20-kg bags can also be prepared for large-scale bakeries.

Compressed yeast cells are alive. They use their reserve carbohydrates (glycogen, trehalose) for energy to survive. Storage under refrigeration retards metabolism, and wrapping inhibits drying out. Under improper storage conditions, deterioration processes (autofermentation, autolysis) may start, resulting in heat build-up and loss of yeast activity.

Dried Yeast

In a dried form, baker's yeast possesses a longer shelf-life than compressed yeast. Dried yeast retains stability even when stored at room temperature. It offers benefits by reducing the cost of refrigeration, transport and storage, but drying increases the expenses of the manufacturer. The disadvantage for the user arising from the lower activity of heat-stressed cells is compensated by the ready availability of dried yeast. In all, there is an increasing preference and a growing share in the market for dried yeast. There are two forms of dried yeast. The first, introduced about 50 years ago, active dried yeast (ADY) needs to be rehydrated in warm water before use. Developed only in the last decade, instant dried yeast (IDY) does not require rehydration and can be mixed directly with flour in making dough. The early procedures of yeast propagation for drying are basically similar to those of the traditional baker's yeast fermentation. However, specific yeast strains selected to withstand drying stresses are used, and the final stages of propagation are set in order to increase yeast resistance to drying. The feeding schedule and maturation period are controlled to produce yeast with lower protein but higher trehalose and lipid contents.

Preparation of the yeast for drying begins with extrusion of the compressed yeast cake into slender strands (1–3-mm diameter) that are cut into short pieces. These particles are dried in a hot air current; the early procedure of tunnel drying has been mostly replaced by tumble or rotating driers and, increasingly, by fluidized bed driers. Only the latter are suitable for the production of IDY. Airlift driers employ a blast of hot air at a velocity sufficient to suspend the yeast particles in a fluidized bed. Air temperatures of 160 °C can be used for quick drying but, after loss of the free cell water content (at about 35% moisture), temperatures should not exceed 40 °C in order to minimize cell-membrane damage and reduction of enzyme activity. Cells are rapidly killed at temperatures exceeding 50 °C. (*See* **Drying**: Spray Drying.)

The moisture content of ADY ranges from 6 to 8%, whereas that of IDY is only between 4 and 6%. ADY possesses only one-third to one-half of the leavening activity of fresh compressed yeast (Table 1). The instant drying procedure allows the production of yeast with a leavening activity comparable with that of compressed yeast.

ADY can be stored without refrigeration. During storage, ADY loses its activity by 1% per month if packed under vacuum or under nitrogen. On storage in air at ambient temperature, the loss of activity is faster. In order to restore activity, rehydration of ADY should be carried out by adding warm (40 °C) water to the yeast in a 4:1 ratio. During rehydration, 20–30% leakage of intracellular materials occurs, which leads to a loss of fermentation activity. A

Table 1 Main characteristics of commercial baker's yeast products

Product	*Form*	*Method of drying*	*Dry (%)*	*Protein (%)*[a]	*Gas production (%)*[b]
Compressed yeast	Blocks or granules	None	30	52	100
Active dried yeast	Irregular spheres	Drum	94	40	45
	Irregular particles	Belt	94	40	40
Instant dried yeast	Short rods	Fluidized bed	96	48	80

[a]Nitrogen × 6.5.
[b]Related to the activity of compressed yeast.

further disadvantage of this leaching is that it releases reducing substances, such as glutathione, which may cause slackening in the dough.

IDY particles are highly porous and easy to rehydrate. This allows immediate use without prior rehydration. However, air may also access the cells, resulting in rapid oxidation and loss of activity. Hence, IDY must be packed under vacuum or in a nitrogen atmosphere, and must be used within a few days after opening the package.

Addition of a variety of agents to the yeast cake prior to drying can improve activity and stability of dried yeast. Emulsifiers (e.g., 1% sorbitan esters) facilitate rehydration of IDY, and antioxidants (e.g., 0.1% butylated hydroxyanisole) increase the stability of ADY. (*See* **Antioxidants**: Synthetic Antioxidants.)

Applications

The application of baker's yeast is indispensable to the production of leavened baked products, such as breads, rolls, pastries, doughnuts, etc. Recipes and technologies for these products vary world-wide, but the essence of the process is the same, in that after mixing flour, water, yeast, salt, and optional ingredients, the dough undergoes panary fermentation before baking. The primary role of baker's yeast in the baking industry will be illustrated using as an example the predominant product, white bread.

Breadmaking

Conventional breadmaking technology involves sponge dough. This dough comprises about two-thirds of the total flour mixed with water, salt, and yeast, and is left for a fermentation period of 4–5 h. The sponge is then added to the balance of flour, water, and all remaining ingredients and thoroughly mixed mechanically until it is transformed into a smooth dough. The characteristic rheological properties of the dough are due to the structure of gluten, a cross-linked network formed from wheat proteins and lipids. This allows the elasticity of dough to retain gas evolved by yeast and thus to leaven. (*See* **Wheat**.)

The dough undergoes a series of mechanical operations (divided into pieces, rounded, and moulded) while being allowed to rest between these procedures for short periods. During these proofing periods, fermentation proceeds, and leavening continues. After the final proof, loaves are placed into a hot oven for baking. Within the loaf, gas expands, steam and alcohol evaporate to form holes in the coagulated matrix of gluten, and the characteristic structure of the crumb sets. While the temperature in the center of the loaf remains below 100 °C, the surface reaches 140 °C, to form a hard, brown-colored crust. The baked bread is left to cool before the finishing operations (slicing, wrapping) and distribution. (*See* **Bread**: Breadmaking Processes.)

The conventional sponge dough technology requires about 8 h to finish, and several alternative methods have been developed to shorten this period (Table 2). In the straight dough method, all the ingredients are mixed at the start, and one bulk fermentation period of 2–4 h is allowed for leavening. In the short-time dough process, only 15–30 min are allotted for the dough to rest, and intense mechanical working brings about the structure of the dough. Time is also saved by the continuous mix processes, in which a ferment or brew is first prepared from yeast with little or no flour (liquid ferment), and after about 2 h of fermentation, the dough is mechanically developed in a continuous mixer. Bulk fermentation of the dough can be replaced by intense mechanical working and/or the addition of chemical improvers in other process variants. Improvements in equipment design have brought about savings in labor, better control and automation, effective sanitation, and greater processing flexibility of breadmaking technology.

Role of Yeast

Yeast plays three major functions in the dough: leavening, maturing, and flavor development.

Leavening The increase of dough volume is due to the production of carbon dioxide during yeast fermentation of the carbohydrates available in the flour. Dry flour contains approximately 1–8% fermentable sugars (glucose, fructose, sucrose), whereas maltose is produced from starch granules by wheat amylases after wetting the flour. (*See* **Flour**: Dietary Importance.)

Yeast has to adapt to the mostly anaerobic environment in the dough as well as to the fermentation of maltose after depletion of available free sugars. Yeast also has to tolerate a certain degree of osmotic pressure exerted by salt (and sugars, if added). The concentration of solutes is higher at the first stage of dough preparation when only half of the regular water is added. In certain formulae, sucrose or high-fructose syrup is used to sweeten the dough. Increasing the osmotic stress not only reduces the fermentation rate but also induces glycerol production.

Maturation To some extent, both yeast itself and its fermentation activity play important roles in developing the texture of the dough, called maturation. This involves complex changes, including

Table 2 Schematic comparison of breadmaking processes

the mechanical forces of mixing leading to gluten formation. Carbon dioxide developed during yeast fermentation would not produce gas cells without the ability of viscoelastic gluten films to retain the gas. In fact, it is the air bubbles preformed in the dough during mixing into which the carbon dioxide diffuses. The rheological properties of the dough are influenced by the fermentation products (ethanol, pH decrease) in a way not yet clearly understood. Reduced compound (e.g., glutathione) liberated from yeast cells may split the disulfide bonds between gluten molecules, leading to the cleavage of the gluten structure.

Taste and Flavor The characteristic and appealing bread aroma would not develop without yeast. It is difficult to characterize the complex nature of bread aroma and to determine the precise role of yeast fermentation in its development. More than 200 volatile compounds have been identified by gas chromatography, and many of these organic esters and acids, alcohols, and carbonyl compounds are formed as byproducts of yeast fermentation. Other compounds, such as amino acids, originate from the yeast cells. In addition to fermentation, bread aroma is determined by the process of baking, which leads to crust browning. This is a Maillard-type reaction, and its extent is influenced by the fermentation products of yeast and its cell constituents. (*See* **Browning**: Nonenzymatic; **Flavor (Flavour) Compounds**: Structures and Characteristics.)

Sour Dough

Before baker's yeast was available commercially, part of leavened dough was added as an inoculum to the fresh dough. Acidification normally took place in this old dough, hence the name: sour dough. In recent years, consumption of sour-dough breads has greatly increased. The use of sour dough is necessary for the development of characteristic properties of rye breads. Sour doughs contain both heterofermentative lactic acid bacteria and yeasts, and the mixed population usually comprises several different species of both groups. Unlike baker's yeast consisting overwhelmingly of a single yeast species, *S. cerevisiae*, even commercial sour-dough starters are not made of defined pure cultures. *Lactobacillus brevis* and *L. sanfrancisco* are characteristic lactic acid bacteria in sour dough, whereas *Candida milleri* and *S. exiguus* are the predominant yeast species.

Yeast Starter Cultures

While about 1.5 million tons of baker's yeast are produced annually throughout the world, the estimated production of yeast starter cultures is less then 1000 tons, although these are made commercially in many countries. Wine starter cultures are used to initiate the fermentation of must instead of a natural (spontaneous) process. The use of yeast starter cultures in wine-making has increased strongly over the last decade. Freeze-dried or active dry yeast starters are made of selected strains of various useful

technological properties, such as a tolerance of high concentrations of ethanol, sugar, and sulfur dioxide, low temperature, etc. Their use is also advantageous in sparkling-wine production.

The use of dried yeast in breweries is not common, although it may offer advantages such as yeast availability, flexibility, and cost-effectiveness in particular for producing specialty beers in small quantities.

Future Developments

Although baker's yeast is one of the oldest biotechnological products that is used in large quantities and has been the subject of basic biochemical and genetic studies, there have remained a number of unresolved questions about its physiology relevant to production and application.

The carbohydrate metabolism of *S. cerevisiae* is under strict regulation, and it has been long recognized that a high sugar concentration triggers alcoholic fermentation, even under fully aerobic conditions (the so-called 'Pasteur effect'). Hence, baker's yeast is produced with strong aeration and limited sugar addition in a fed-batch process. However, cultures adapted to these conditions are required to perform leavening in drastically different conditions prevailing in the dough, i.e., anaerobically and with sugars in excess. Moreover, when glucose and fructose present initially are exhausted, yeast cells have to adapt the metabolism of maltose originating from flour starch. Hence, baker's yeast with a good leavening capacity should have a high glycolytic activity, a high potential of maltose fermentation, and an ability to synthesize enzymes under anaerobic conditions to adapt rapidly to changing substrates. In attempts to improve these characteristics, overexpression of certain glycolytic enzymes, modulation of the balance between glycolysis and gluconeogenesis, and induction or derepression of maltose utilization enzymes have been targeted using genetic transformants, producing mutants and constructing hybrids. Recombinant DNA technology provides further ways to enhance biomass yield on molasses and alternative carbon sources. Molasses contains raffinose, of which only the fructose part can be utilized by baker's yeast. Brewer's yeast, a close relative, produces melibiase, permitting complete fermentation of the trisaccharide. Baking yeast strains with this ability have been constructed, resulting in an increase in biomass yield up to 8%. A genetically modified baker's yeast, developed at Gist-Brocades (Delft, The Netherlands) in 1990, was the first to be approved for use. Currently, strains constructed by intraspecific hybridization and gene transfer are not regarded as true genetically modified organisms (GMOs); nevertheless, commercial use of genetically manipulated yeast, or any other organisms, raises issues of safety, regulation, and labelling by authorities and receives serious concern from the public. To date, successful strategies of genetic engineering to introduce foreign genes into *S. cerevisiae* enabling the utilization of alternative carbon sources have remained at laboratory scale.

Recombinant DNA techniques have been applied to incorporate and express amylase genes from bacilli, molds, and different yeast species into baker's yeast, enabling starch hydrolysis. *S. cerevisiae* strains have also been created that are able to utilize lactose, pentoses from hemicellulose, and even cellulose. Whey, which is rich in lactose, would be a good alternative carbon source, but baker's yeast lacks the necessary enzymes to utilize lactose. Laboratory strains of *S. cerevisiae* have been constructed by both interspecies protoplast fusion with the yeast *Kluyveromyces lactis* and genetic transformation of genes from the bacterium *Escherichia coli* or the mold *Aspergillus niger.*

The keeping quality of baker's yeast is a complex property that is not well characterized in terms of physiology and biochemistry. Factors influencing cryoresistance, osmotolerance, and tolerance to drying have a great impact on the loss of leavening performance of ADY in frozen doughs and sweet doughs. In this respect, the cryoprotective effect of trehalose, the osmoprotective role of glycerol, and the stress tolerance attributed to membrane composition have received most attention. Molecular genetic studies have allowed a deeper insight into the regulation of trehalose, glycerol, and phospholipid metabolism, the knowledge on which strategies to improve keeping quality of baker's yeast can be based. Conditions of yeast propagation and storage have been optimized to produce yeast cells with higher contents of trehalose, phospholipids, unsaturated fatty acids, and ergosterol. Glycerol accumulation has been achieved in genetically altered strains.

Strain development by recombinant DNA technology may have a further impact on the application of baker's yeast. The supplementation of bread doughs with enzymes has increased greatly and has become a standard practice in breadmaking. The use of amylases, often together with protease, lipase, lipoxi genase or other enzymes, improves the functional properties of dough, decreases the mixing time, and contributes to flavor development. These commercial enzymes are produced with filamentous fungi or bacilli, and may contain impurities adversely affecting bread quality or acting as allergens. Possibilities exist to genetically engineer baker's yeast

secreting one or more enzyme additives during the process of breadmaking. Success achieved with laboratory strains may be impractical, however, at the industrial level. Moreover, the approval for commercial use of genetically manipulated yeast expressing heterologous proteins is still problematic and has met with public resistance. Nevertheless, taking measures to prevent any possibility of harmful consequence of genetic manipulation, recombinant strains will have an important role in future developments in the production and application of baker's yeast.

YERSINIA ENTEROCOLITICA

Contents

Properties and Occurrence

G Zurera Cosano and R M García Gimeno, University of Cordoba, Cordoba, Spain

Background

The genus *Yersinia* comprises 11 species, of which three (*Yersinia enterocolitica*, *Yersinia pseudotuberculosis*, and *Yersinia pestis*) have clearly been shown to cause human disease. *Y. pseudotuberculosis* is associated with mesenteric adenitis, and *Y. pestis* is responsible for the bubonic plague. The remaining eight species (*Y. frederiksenii, Y. intermedia, Y. kristensenii, Y. mollareti, Y. bercovierii, Y. rohdei, Y. ruckeri*, and *Y. aldovae*) are sometimes referred to as *Yersinia enterocolitica*-like and have not yet been clearly shown to cause human disease and are easily distinguished from *Y. enterocolitica* by their biochemical characteristics. *Y. enterocolitica* is classified in the family Enterobacteriaceae. It is a small (1–3.5 μm × 0.5–1.3 μm), ovoid, sometimes rod-shaped, Gram-negative bacterium and facultative anaerobe. It grows within a wide range of temperatures, from −1 to 40 °C, achieving optimum growth at around 29 °C. It is nonmotile at 37 °C, but is motile and produces peritrichous flagella when it is grown at less than 30 °C. It produces colonies of 1.0 mm or less on nutrient agar. It is oxidase-negative and ferments glucose with little or no gas. It lacks phenylalanine deaminase and is urease-positive. *Y. enterocolitica* produce gastroenteritis (yersiniosis), and the symptoms include severe abdominal pain, suggesting an

appendicitis-like attack, diarrhea (lasting several weeks), fever, rash, nausea, headache, and vomiting. The minimum infectious dose is unknown. Illness onset is usually between 24 and 48 h after intake, although the incubation period can be as long as 11 days.

Y. enterocolitica is widely distributed in the environment, in lakes and stream waters, which are sources of the organisms to warm-blooded animals. Animals from which *Y. enterocolitica* has been isolated include cats, birds, dogs, guinea-pigs, rats, horses, chickens, cattle, swine, lambs, and fish. Certain biotypes and serogroups are associated with a specific host. A principal source or reservoir of virulent *Y. enterocolitica* are pigs. Virulent strains of *Y. enterocolitica* often reside in the oral cavity and the gastrointestinal tract of pigs. Serogroups 0:3 and 0:9 are mainly associated with pork tongues and tonsillar area. Despite this, it has been shown that pork meat has accidentally been a vehicle for yersiniosis.

There are four serogroups of *Y. enterocolitica* associated with pathogenicity: 0:3, 0:5, 0:8, and 0:9. The genes encoding for invasion of mammalian cells are located on the chromosome, while a 40–50-MDa plasmid encodes most of the other virulence-associated phenotypes. The 40–50-MDa plasmid is present in almost all pathogenic *Yersinia* species, and the plasmids appear to be homologous. Although heat-stable enterotoxin has been isolated from most clinical isolates, it is uncertain whether this toxin plays a role in the pathogenicity of the organism.

Y. enterocolitica have been detected in a wide variety of processed foods, particularly pasteurized milk, dairy products, vacuum-packaged meats, seafood, vegetables, and many ready-to-use foods. Incidence varies between countries. The most common *Y. enterocolitica* serogroups in human infections are 0:3, 0.5, 27, 0:8, and 0:9. In Europe, Africa, and Japan, serogroups 0:3 and 0:9 are the most common. These serogroups are prevalent in Denmark, Belgium, and Sweden, and are a significant cause of gastrointestinal illnesses in those countries.

Growth Requirements

Temperature

Y. enterocolitica is a psychrotroph and can grow at temperatures as low as 0 °C and as high as 44 °C, the optimum range being 22–29 °C. For biochemical reactions, the optimum temperature is about 28 °C in pure culture, but it is a poor competitor at this temperature. Multiplication can occur between −2 and 0 °C, but growth is very slow. At 3 °C, it takes 200 h to increase 2 logarithmic cycles in culture medium. Growth at 0–2 °C in milk after 20 days has been observed. Generation times at 4 °C appear to be strain-dependent, varying between 16 and 26 h in pasteurized milk, and growth is preceded by an extended lag time of up to 40 h. Increases in levels of up to 5 log increments in 10–14 days have been recorded in a variety of artificially contaminated cooked foods stored at 4 °C. Growth at 0–1 °C on pork and chicken has been observed and on raw beef kept for 10 days at 0–1 °C. Growth is slightly slower in the presence of competitor organisms but at 4 °C competes better against other psychrotrophic bacteria. In milk at 4 °C, *Y. enterocolitica* grow and reach numbers of up to 10^7 CFU ml^{-1} in 7 days, and compete well with the background flora.

pH

The pH range for growth is 4.6–9.0, with an optimum pH of 7.0–8.0. The minimum pH at which growth can occur varies between strains and also depends on storage temperature and the acidulant used. The following values have been found for six strains of *Y. enterocolitica* with the pH adjusted with HCl and incubated for 21 days: 4.42–4.80 at 4 °C; 4.36–4.83 at 7 °C; 4.26–4.50 at 10 °C and 4.18–4.36 at 20 °C. Growth inhibition at low pH is greater at 4 °C than at 20 °C, and the use of organic acids raises the minimum pH for growth. When organic acids are used to adjust pH, the order of their effectiveness is acetic > lactic > citric. Acetic acid is the most inhibitory organic acid commonly used in food, preventing growth below 5.7 at 4 °C and 5.1 at 20 °C. It has also been shown that tolerance to high pH values is dependent on temperature and on the medium used. Growth has been demonstrated at pH 9.5 at 10 °C but not at 6 °C. Under the same pH and temperature conditions, the inhibitory effects of acids are quite different. At a high pH (5.8), the order of inhibition of *Y. enterocolitica* 0:9 at 4 °C is formic acid > acetic acid > propionic acid > lactic acid, whereas at a lower pH (4.2) the order is formic acid > lactic acid > acetic acid > propionic acid. The mechanisms of the interaction of these acids inside bacterial cells differ under aerobic and anaerobic conditions. While the inhibitory effect of lactic acid is enhanced under anaerobic conditions, the acetic and formic acids are less effective.

Heat Tolerance

According to available data, the heat resistance of *Y. enterocolitica* seems to vary widely among different strains. Strains of *Y. enterocolitica* are not particularly heat-resistant. Sublethal injury to

Y. enterocolitica cells has been reported after heat treatment at 47 °C for more than 12 min. However, the magnitude of the effect depends on growth temperature. In the range of 4–20 °C, the growth temperature does not influence heat resistance at 54–66 °C for *Y. enterocolitica*. However, when cells are grown at 37 °C, heat resistance increases fourfold. The heat resistance of *Y. enterocolitica* is also influenced by the pH of the heating medium. The pH of maximum heat resistance in citrate phosphate buffer is pH 7 for cells grown at 37 °C but pH 5 for those grown at 4 °C. In both, the magnitude of the pH effect on heat resistance is constant at all heating temperatures. Different studies have been carried out in milk as pasteurization and thermalization are achieved effectively when the inoculum does not exceed 10^8 CFU ml^{-1}.

Freezing

Refrigeration reduces the multiplication capacity of *Y. enterocolitica* but does not inhibit it completely. Growth at low temperatures depends on other factors, mainly on pH. Good growth has been observed at 4 °C, when the pH is neutral, but very little growth has been detected at a slightly acidic pH (5.4). The ability of *Y. enterocolitica* to withstand freezing has been shown: cultures of *Y. enterocolitica* can survive for several weeks at −20 °C without any reduction in the number of viable cells. Also, in studies with frozen foods, 3–4 logarithmic reductions have been found to occur after 4 weeks of storage at −18 °C. Despite this, *Y. enterocolitica* has been isolated from a wide range of frozen foods.

Irradiation

The ability of *Y. enterocolitica* to survive γ-radiation depends on the food composition/treatment and the presence of preservatives. As *Y. enterocolitica* is more radiosensitive than other common foodborne pathogens such as *Salmonella* and *Listeria*, it can be completely eliminated at a dose range of 3–4 kGy. With low numbers of *Y. enterocolitica* (D_{10} values between 0.25 and 0.30 kGy), a contamination of up to 10^3–10^4 CFU g^{-1} can be positively controlled by a 1–1.5-kGy dose. Thus, the average dose of 1 kGy recommended by the FDA appears to be adequate for eliminating *Yersinia*. While irradiation even at 6 kGy fails to prevent survival in raw pork, the bacterium is completely suppressed in cooked ham and salami treated with lower doses of radiation. Faster recovery of radiation-injured cells in raw meat than in cured meat with spices or in cooked ham demonstrates that *Y. enterocolitica* in irradiated products can be inhibited by using combination processes including irradiation.

Preservatives and Packaging

The behavior of *Y. enterocolitica* in response to various preservatives depends on the temperature and level of the chemical, pH, and amount of sodium chloride present. At low pHs and temperatures, potassium sorbate is very effective against *Y. enterocolitica*. In contrast, other preservatives such as sodium phosphite and sodium hypophosphite are inhibitory at relatively high pH values. Packaging containing high levels of carbon dioxide is very effective at delaying growth and can cause complete inhibition. *Y. enterocolitica* can survive sodium chloride concentrations of 6–7% at specific temperature and pH levels. Although 7% NaCl is inhibitory at 3 °C, growth occurs with 5% NaCl. Other preservatives such as potassium sorbate, sodium hypophosphite, sodium phosphite, and curing salt delay or inhibit the growth of this microorganism.

Predictive Modeling

Predictive models are used to describe the behavior of microorganisms under different conditions such as temperature, pH, water activity, oxidation–reduction potential, and additives. They may be applied in various ways to ensure the microbial safety and quality. The main objective is to describe mathematically the growth or inactivation of microorganisms in food under prescribed food conditions.

Several models charting the growth and survival of *Yersinia enterocolitica* have been developed by studying the effect of different factors, such as: pH (4–8.5); organic acids (acetic, lactic, sulfuric, and citric acid); temperature (0–42 °C); NaCl concentration (0–10.5%); sodium nitrite (0–200 p.p.m.), strain with and without plasmids related to virulence agents, and mild heat treatment (50–60 °C). These models have been validated in different foods such as pâté, packed cold smoked salmon, UHT milk, yogurt, mayonnaise, meat and meat products, eggs, fish, and tofu; in general, predictive models overstimate growth rate values on the fail-safe side, i.e., the prediction always describes faster growth rates than the values observed in real foods.

Epidemiological and Clinical Features

From an epidemiological standpoint, *Y. enterocolitica* is widespread in nature, occurring in the gastrointestinal tract of an array of animal hosts, including mammals, avian species, and cold-blooded species, and is occasionally isolated in humans. Of all sources, swine appear to be the major source of strains

pathogenic for humans. Several outbreaks have been reported where infection has been associated with contact with pigs, and indirect contact with contaminated pork products and other foods (Table 1). Some outbreaks in families were attributed to exposure to cats and dogs. On rare occasions, it can be transmitted as a result of the bacterium passing from stools or soiled fingers of one person to the mouth of another person. This may happen when basic hygiene and handwashing habits are inadequate.

In general, sporadic or food-related outbreaks are more frequent in regions where pigs are the carriers of this microorganism. Seasonality seems to play a role in the incidence of this microorganism in focal geographical areas, with a higher frequency noted during cooler periods of the year.

Children are infected more often than adults, and confirmed cases or *Y. enterocolitica* in humans correspond to 1 in 100 000 persons per year. In the USA, it is estimated to cause 3000–20 000 cases each year. Most recently, it has been shown that humans can be asymptomatic, since clinically normal blood donors have supplied *Yersinia enterocolitica*-infected blood resulting in fatal septicemia in transfused patients. Nevertheless, 90% of cases originate from food.

Human clinical infections with *Y. enterocolitica* occur most frequently after the intake of food or water contaminated with this pathogen. The infectious dose estimated to be sufficient to cause human illness is approximately 10^7 cells, but consumer susceptibility will vary according to individual levels of immunocompetence, age, and general health. After intake, the bacteria pass through the stomach, colonize the epithelial cell surface of the small intestinal mucosa, and cause diarrhea, possibly by producing the enterotoxin YST. This microorganism can also invade epithelial cells, attach to M cells, and penetrate Peyer's patches, where it multiplies with the help of several surface components that enable it to resist phagocytosis and survive complement-mediated killing. The invasion process and virulence factor production are complex processes that are thermoregulated by both plasmid and chromosomally encoded information. Continued proliferation of bacteria results in inflammation leading to the formation of local microabscesses and ulceration of the overlying epithelium. In a relatively short period, ingested *Y. enterocolitica* reach the terminal ileum, spread to the mesenteric lymph nodes, and enter the blood stream.

From a clinical standpoint, *Y. enterocolitica* is a common human pathogen that causes a variety

of intestinal and extraintestinal syndromes, with varying degrees of severity, ranging from mild gastroenteritis to mesenteric lymphadenitis (often confused with appendicitis), and septicemia. Infections caused by this microorganism may also reveal postinfectious immunological sequelae, including erythema nodosum, arthritis, miocarditis, and glomerulonephritis.

Occurrence in Foods

Foods analyzed for *Y. enterocolitica* show that the distribution of this microorganism is fairly extensive; it has been isolated in beef, lamb, pork, oysters, shrimp, crabs, and water. The vast majority of these isolates are avirulent, and virulent strains seldom occur in any of these foods. Studies have examined the fecal droppings of rats near slaughterhouses and have found that the rats carried virulent *Y. enterocolitica* probably picked up from the pork that was being processed at the slaughterhouses.

The 68% positive samples of porcine tongues taken from freshly slaughtered animals have been isolated, and these represent six serogroups, 0:8 being the most common and 0:6, 30 the second most common, followed by other serogroups including 0:3, 0:13, 7, 0:18, and 0:46. Several studies performed in Brazil have reported positive isolations of *Yersinia enterocolitica* from raw milk (16.8%), pasteurized milk (1.7%), raw beef (80%) and chicken (60%), ground beef, liver, and pork (20%). In one study performed in the USA, after examining 100 milk samples, 12 raw samples and one pasteurized sample yielded *Yersinia enterocolitica*. Another study of this product in France reported that 81% of raw milk samples were positive, the predominant serovar being 0:5 (Table 2).

Outbreaks of yersiniosis have been reported in which chocolate, coleslaw, tofu, bean sprout, pasteurized milk, and pork chitterlings have been singled out as vehicles (Table 1). One of the first and most important outbreaks occurred in the USA, where 220 schoolchildren were taken ill; it was confirmed that *Y. enterocolitica* had caused the problem and that chocolate milk was the vehicle of infection. This milk was prepared at a small dairy by means of vat pasteurization; the chocolate was added after pasteurization and mixed with a paddle; hence, there was plenty of potential postprocessing contamination. In another case, the vehicle of transmission was tofu (soyabean curd) that had been packaged in untreated spring water contaminated with *Y. enterocolitica*.

Both virulent and avirulent strains of *Y. enterocolitica* have been isolated from a variety of dairy products. Three milkborne outbreaks occurred in the USA, two attributable to serogroup 0:8 and one to serogroup 0:13a, 13b. In 1982, there was an outbreak linked to pasteurized milk; 170 cases were confirmed, although epidemiological studies revealed that more than 1000 people were infected. The strain was also isolated from the plastic carrying cases used to carry the milk after bottling. In this case, outdated milk had been brought to a pig farm in carrying cases. The cases were placed in mud and manure, the milk poured into troughs for the pigs, and the carrying cases brought back to the plant and superficially washed. Although it was confirmed that the pigs were the source of infection, it was impossible to determine exactly how the microorganism had reached the milk from the carrying cases.

Prevention of Food Contamination

Food-related toxic infections caused by *Yersinia enterocolitica* seem to be related to foods in cold storage. In this situation, it is difficult to define preventive measures (repeated washing of vegetables, mainly in collective restaurants, strengthening of the cold chain, etc.) that enable the spread of this food-related infection to be restricted. These limitations to prevention highlight the importance of monitoring human infections (networks of expert doctors, control laboratories, and reference laboratories for studying strains). The prevention of foodborne disease depends on careful food production, handling of raw products, and preparation of finished foods. Hazards can be introduced at any point from farm to table. Monitoring and control technologies systematically applied to food production by the HACCP are highly effective for preventing foodborne illness.

Primary control of the microorganism would require changes to current slaughtering practice. The 'bagging technique' – the method of enclosing the anus and rectum of pigs in a plastic bag during slaughter – has been introduced in several slaughterhouses, mainly in Norway, and it has been shown that this effectively reduced carcass contamination by *Yersinia enterocolitica*. The removal of the head, tongue, and pharynx at an early stage of slaughter and improvements in the way in which intestines are removed would also help to prevent carcass contamination. Additional practices, such as the exclusion of tonsillar tissue from sale or the scalding of tongue and head meat prior to the dispatch of products may also be necessary.

[t]From Darbas H, Riviere M and Obertic J (1985) *Yersinia* in refrigerated vegetables. *Science Aliments* 5: 81–84.

Although normal detergents and disinfectants used in the food industry are effective for eliminating *Yersinia enterocolitica*, their effect is reduced if fatty residues are present. The regular use of steam cleaning instead of cleaning with hot water at 85 °C has been used successfully at a milk pasteurization plant.

Handlers of meal are the last critical control point before foods reach the table. Therefore, several practical food-handling precautions could reduce the risk of contamination of food by this microorganism. Cross-contamination of foods can be avoided by separating cooked and raw food and also by washing food handlers' hands, cutting boards, and contaminated surfaces. Practical recommendations can be followed by consumers, such as avoiding the consumption of raw or undercooked pork, raw milk, or related byproducts, and washing hands carefully before eating, preparing food after contact with animals, and after handling raw meat. After handling raw chitterlings, it is recommended that hands and fingernails be cleaned thoroughly with soap and water before touching children or their toys, bottles, or pacifiers.

Detection and Treatment

A Ramesh, B P Padmapriya, S Bharathi and M C Varadaraj, Central Food Technological Research Institute, Mysore, India

Background

Yersinia enterocolitica is an invasive enteropathogen prevalent in the environment and often isolated from soil, water, food, and clinical sources. The serotypes of *Y. enterocolitica* associated with disease in humans are O:3, O:9, O:8, and O:5, 27, and all harbor a 70–75-kb virulence plasmid. The bacterium has been recognized as a significant foodborne pathogen owing to its ability to survive in both vacuum-packed and refrigerated food samples. Thus, in the light of food hygiene and public health, it is imperative to develop rapid methods of detecting *Y. enterocolitica*. Various methods consisting of conventional cultural methods, detection of virulence plasmid, immunological methods, and rapid nucleic acid-based techniques have been described for the detection and identification of *Y. enterocolitica*. In an infection, the principal clinical feature in humans is abdominal pain and diarrhea accompanied by fever. Reactive arthritis and erythema nodosum have also been reported as common complications. Several cases of diarrhea resulting from *Y. enterocolitica* infection resolve on their own, thus avoiding the need for an antibiotic treatment. However, in the case of a severe infection, antibiotics are administered. The following section describes the methods of detection and treatment of *Y. enterocolitica*.

Detection of *Yersinia enterocolitica*

The common food samples associated with *Y. enterocolitica* infection are pork, milk and milk products, and raw vegetables. The detection of pathogenic strains of *Y. enterocolitica* from food samples and clinical specimens is mainly based on the isolation of the bacterium. A scheme of the different detection methods followed for *Y. enterocolitica* is shown in **Figure 1**.

Conventional Methods of Detection

Yersinia enterocolitica is a Gram-negative rod or ovoid, facultatively anaerobic, oxidase-negative, catalase-positive nonsporulating motile bacterium. The isolation of this bacterium from food samples is difficult, because it is present in low numbers and is slow growing compared to other coexisting members

of the enterobacteriaceae present in the background microflora. This underscores the need for a selective enrichment technique to facilitate the isolation of the bacterium. A basic isolation scheme involves preenrichment in a highly nutritious, well-buffered medium containing peptone, yeast extract, and mineral salts at temperatures ranging from 4 to 37 °C over 1–9 days. The salient features of the various types of enrichment procedures are indicated in Table 1.

Selective enrichment media like bile oxalate sorbose (BOS) broth, and phosphate buffer saline (PBS) supplemented with sorbitol and bile salts with a postenrichment alkali treatment has been widely used to enrich *Y. enterocolitica* from food samples. This method is simple, sensitive, and rapid, eliminating a large number of contaminating non-*Yersinia* species. *Y. enterocolitica* is also a psychrotroph, capable of growing under refrigerated conditions. Hence, cold enrichment can increase the isolation rate of the bacterium. Irgasan–ticarcillin–chlorate (ITC) enrichment has been shown to be more efficient in isolating pathogenic bioserotype from pork. The enriched culture is plated on to the selective media cefsulodin–irgasan–novabiocin

(CIN) agar and incubated for 24–48 h at 32–37 °C to obtain characteristic colonies with a deep red center (like a bull's eye) with an entire edge and a transparent border measuring 0.5–1.0 mm in diameter. Suspected *Yersinia* colonies from CIN plates are selected and suspended individually in trypticase soya broth (TSB) for further characterization through diagnostic biochemical tests, as indicated in Table 2. *Yersinia enterocolitica* has been essentially classified into six biogroups, i.e., 1A, 1B, 2, 3, 4, and 5. Biotype 6 is rare.

Current methods based on selective enrichment merely detect the presence of *Y. enterocolitica*, and these methods fail to recover all pathogenic bioserotypes. Further improvements in the specific detection of the bacteria can be achieved through immunological and nucleic acid-based methods.

Immunological Detection of *Y. enterocolitica*

Immunological methods have been reported since the early detection of *Y. enterocolitica* as an advancement over conventional microbiological tests. The methods that have been widely accepted include agglutination tests and immunoassay.

Agglutination tests Latex slide agglutination and tube agglutination (Widal) tests are commonly used and form the basis for many commercially available kits for the rapid detection of *Y. enterocolitica* O:3 and O:9 antibodies in the serum. Latex of 0.9 μm particle size was coated with specific antibodies raised against serotypes O:3, O:5, O:6, O:8, and O:9 of *Y. enterocolitica*. The latex reagents specifically detected the O-antigen of *Y. enterocolitica*, with no cross-reactivity between the serotypes. Alcohol-treated bacterial cells are used as antigens in some cases, and an agglutination titer of 640 or a fourfold or greater increase in the titer is an indication of recent or actual infection. Commercial kits are available to detect O:3 and O:9 antigens of *Y. enterocolitica* individually or in combination, using the latex agglutination method.

Immunoassays The lack of sensitivity and specificity of the agglutination tests hinders their application as a routine detection method. However, immunoassays like surface adhesion immunofluorescence (SAIF) technique, enzyme immunoassay (EIA), immunoblot, and enzyme-linked immunosorbent assay (ELISA) can alleviate this problem. SAIF has been used to detect *Y. enterocolitica* in broth and enriched meat cultures, with a polycarbonate membrane to trap the cells on the surface of the membrane prior to detection by immunofluorescence.

EIA was developed for the detection of *Yersinia* immunoglobulin (Ig) complexes of known Ig class. Immune complexes are attached to polystyrene microtiter plates by rabbit antihuman immunoglobulins. Detection of *Y. enterocolitica* O:3 antigens was demonstrated using Fab fragments of alkaline phosphatase-conjugate antibody against the same serotype. Methods to differentiate serological responses to *Y. enterocolitica* O:9 from responses to *Brucella* have been very successful. However, immunoblots

Modified from Bottone EJ (1999) *Yersinia enterocolitica*: overview and epidemiological correlates. *Microbes and Infection* 1: 323–333; Wauters G (1981) Antigens of *Yersinia enterocolitica*. In: Bottone EJ (ed.), pp. 41–53. Boca Raton, FL: CRC Press.

and ELISA targeting the *Yersinia* outer membrane proteins (YOPs) are more sensitive and specific than other serological tests for yersiniosis.

Monoclonal antibodies specific for the lipopolysaccharide (LPS) O antigens of *Y. enterocolitica* serotype O:3 can be used for the detection of *Y. enterocolitica* in colony immunoblots. This method has been shown to be sensitive in detecting a single colony of *Y. enterocolitica* in the presence of 3.1×10^8 heterologous organisms. Besides, the assay was specific with no significant cross-reactivity against any related serotypes. An immunoblot kit called *recom* Blot *Yersinia* IgG and *recom* Blot IgM/IgA has been developed and provides recombinant *Yersinia* antigens in a test strip format to detect IgG, IgM, or IgA antibodies directed against *Y. enterocolitica* and *Y. pseudotuberculosis*.

ELISAs using either purified lipopolysaccharide or formalinized whole cells expressing virulence plasmid-coded surface antigen (pYV^+ cells) can be performed to detect *Y. enterocolitica*. It has been shown that ELISA can specifically detect pYV antibodies in sera, cross-adsorbed to formalinized pYV-cured *Y. enterocolitica* O:3 cells prior to the assay. The serological response against YOPs using AB-ELISA was used to detect the O:9 serotype of *Y. enterocolitica*. In order to avoid interference by *Y. enterocolitica* O:9 LPS with YOPs in serological analysis, an antigenic preparation of YOPs was obtained from *Y. enterocolitica* O:7. There is a high degree of homology between YOPs of different *Yersinia* species and an absence of cross-reactivity between *Y. enterocolitica* O:7 LPS and *Y. enterocolitica* O:9 LPS. The commercially available *Y. enterocolitica* ELISA kit provides a high diagnostic sensitivity capable of differentiating IgG from IgA and IgM.

Although a host of immunological methods are available to detect *Y. enterocolitica* for clinical applications, the use of these assays in a food system is comparatively limited. An immunomagnetic separation technique has been shown as an efficient device to sequester *Y. enterocolitica* in food samples and facilitate its sensitive detection. The major factors limiting the use of immunological techniques for the detection of *Y. enterocolitica* in food systems are the cross-reactivity with the background microflora present in food samples and the inhibitors present in the food matrix itself.

Detection of Virulent Plasmid-bearing (pYV^+) Strains

The pathogenic strains of *Y. enterocolitica* are characterized by the presence of a 70–75-kb plasmid which encodes for a number of virulence factors manifested as conspicuous colony morphology, autoagglutination, dye binding capacity, and low calcium response. Plasmid-mediated phenotypic expression has been used to detect virulent strains and to discern them from avirulent plasmid-less strains. In a calcium-deficient medium like the brain–heart infusion agarose (BHO) calcium response of virulent strain was tested. At 37 °C, plasmid-bearing virulent cells (pYV^+) appear as pin-point colonies 0.36 mm in diameter, whereas avirulent cells (pYV^-) form distinctly larger colonies. The CIN agar medium incorporated with crystal violet can distinguish between pathogenic and nonpathogenic strains. At 32 °C, the colony morphology appears similar for both the strains. However it has been demonstrated that at 37 °C, plasmid-bearing pathogenic strains appear as densely stained microcolonies compared to the nonpathogenic strains. Direct detection of a plasmid-bearing virulent strain of *Y. enterocolitica* has been carried out in artificially contaminated food samples like pork chops, ground pork, cheese, and zucchini. Enriched samples plated on BHO incorporated with Congo red and incubated at 37 °C form red pin-point colonies as a manifestation of plasmid-mediated dye binding and a low calcium response. Thus, the Congo red binding technique is suitable for direct detection and isolation of pathogenic *Y. enterocolitica* using a single medium.

Detection by Nucleic Acid Probes

The physiological traits encoded by the virulent plasmid are only expressed at 37 °C, which also favors plasmid loss accompanied by elimination of virulent traits. Thus, the instability of the plasmid limits its use as a tool for detecting virulent *Y. enterocolitica* in clinical and food samples. The emergence of nucleic acid probes has provided an efficient tool to detect genes in *Y. enterocolitica* that encode specific pathogenic traits. Such gene probes can be used in colony- or dot-blot hybridization to directly detect *Y. enterocolitica* in the presence of high background microflora. Additionally, these probes can be evaluated as a substitute to tissue culture-based assay to ascertain the invasive phenotype of pathogenic strains.

The target regions in a probe-based diagnostic assay can be unique sequences within chromosomal DNA, ribosomal RNA, or plasmid DNA. The ribosomal RNA is widely preferred as a target gene owing to its ubiquity and relatively high copy number, which enhances the assay sensitivity. The GENE-TRAK colorimetric hybridization assay for *Y. enterocolitica* has been developed, employing probes directed against specific signature sequences of 16 s rRNA. This assay has been shown to be a convenient alternative to conventional microbiological procedures, yielding presumptive results in a significantly shorter time.

However, this method lacks the discriminatory power to differentiate virulent from avirulent strains.

Probes targeting virulence plasmid genes can be employed to specifically detect pathogenic *Y. enterocolitica* serogroups and distinguish them from environmental *Yersinia* species, which are frequently encountered in food samples. A synthetic radioactively labeled 19-mer oligonucleotide probe based on the plasmid-encoded *Yersinia* adhesin A (*Yad* A) gene has been used in colony hybridization to detect pathogenic *Y. enterocolitica* in pork samples. The probe demonstrates a superior estimation of virulent strains in the samples than conventional methods. Polymerase chain reaction (PCR)-generated nonradioactive probes are safe, inexpensive, and shelf-stable, and can be used in the detection of the organism. In colony hybridization, the DIG (digoxigenin)-labeled PCR-generated *Vir* F and *Yad* A amplicons are able to detect pathogenic *Y. enterocolitica* in artifically contaminated food samples and indicate equivalence with the PCR assay and phenotypic test for pathogenicity.

Spontaneous loss of plasmids in *Y. enterocolitica* during *in-vitro* replication is frequently encountered either in the environment or in the laboratory. This fosters the need to develop probes targeting the chromosomally encoded virulence factors like the attachment invasion locus (*Ail*) and the heat-stable enterotoxin (*Yst*). The gene coding for the attachment invasion locus (*Ail*) has been found uniquely in pathogenic strains of *Y. enterocolitica*, whereas the invasion (*Inv*) gene in all *Yersinia* spp. DIG-labeled *Inv* and *Ail* probes has been used to differentiate pathogenic from nonpathogenic strains. A PCR-amplified DIG-labeled *Yst* probe has been used in colony hybridization to detect and differentiate between pathogenic and nonpathogenic strains in naturally and artificially contaminated pork and milk samples following enrichment in ITC enrichment broth. The hybridization results are concordant with those from biochemical and serological tests, and a detection limit of 10 colony-forming units (CFU) ml^{-1} in the original sample has been achieved. The use of a multiplex riboprobe can be adopted as a comprehensive strategy to detect multiple targets, thus enhancing assay sensitivity and ensuring detection of virulent *Y. enterocolitica* irrespective of plasmid loss.

Detection by Polymerase Chain Reaction

The use of gene probe-based hybridization assays to detect *Y. enterocolitica* is limited by the lack of sensitivity. PCR allows rapid and selective identification of *Y. enterocolitica* and fulfils the criteria for specificity and sensitivity. The *Yad* A gene located on the virulence plasmid (pYV) encoding for an outer membrane polymeric protein has been used as a target to detect the presence of pathogenic *Y. enterocolitica* in retailed pig tongue and minced meat. However, loss of pYV is frequently encountered under certain conditions of handling, especially in food samples. This leads to the possibility of false-negative results. The chromosomally encoded attachment invasion locus (*Ail*) is characteristically associated with virulence and can be an appropriate target to detect pathogenic *Y. enterocolitica*. *Ail*-specific primers have been used in PCR to identify virulent strains in blood, and the levels of sensitivity achieved indicate the potential of PCR in the diagnosis of transmission-related bacteremia caused by *Y. enterocolitica*. A two-step PCR targeting the *Ail* gene has been employed to detect pathogenic strains in environmental water, and the results have demonstrated a superior specificity and sensitivity over cultural methods.

A PCR method based on the targeting of the *rfb* C gene involved in the biosynthesis of the O side chain of *Y. enterocolitica* O:3 has enabled the detection and differentiation between pathogenic strain of *Y. enterocolitica* of serotype O:3 and *Y. pseudotuberculosis* and other pathogenic *Y. enterocolitica*. PCR enables reliable and sensitive detection when applied to pure cultures, but its efficiency is markedly curtailed when applied to food and clinical samples. This is mainly due to the potential inhibitors or high levels of background microflora present in such samples. Therefore, adequate sample preparation is required to either eliminate such inhibitors or concentrate target cells to yield satisfactory detection levels. Selective enrichment followed by buoyant density gradient centrifugation provides an efficient sample preparation method prior to PCR. This treatment method has facilitated the detection of 10 CFU ml^{-1} of the bacterium in pork using a multiplex PCR simultaneously targeting the plasmid-borne *Yad* A gene and the *Yersinia*-specific 16S rRNA region. Immunomagnetic separation (IMS) of the target cells from meat samples has enabled a nested PCR assay to detect 10–30 CFU g^{-1} meat in the presence of 10^6-fold excess background microflora. Thus, IMS provides an efficient way of excluding the PCR inhibitors from the sample and has the potential to be exploited for automation.

Methods for detecting virulent *Y. enterocolitica* based on PCR involve gel electrophoresis for product analysis and the use of ethidium bromide to stain the gels, which is hazardous and impractical for routine analysis in food monitoring laboratories. The fluorogenic 5′ nuclease assay is an attractive option for rapid detection of virulent *Y. enterocolitica*. The assay exploits the 5′–3′ nuclease activity of *Taq* DNA polymerase and releases a probe with a fluorescent reporter dye and a quencher, which hybridizes to

an internal fragment of the target gene. With increasing cycles of PCR amplification, the fluorescent signal increases proportionately. A 5′ nuclease assay targeting the *Yst* gene has been shown to be highly specific in detecting virulent *Y. enterocolitica*. This assay has allowed a sensitive detection of $\geq 10^2$ CFU ml^{-1} in pure culture and $\geq 10\,CFU\,g^{-1}$ in spiked ground pork. The 5′ nuclease assay developed for detecting virulent strains has also been shown to yield a better estimation of contamination of pork and other processed meat and a better detection level than the 'gold standard' recommended by the US FDA in the Bacteriological Analytical Manual for the detection of pathogenic *Y. enterocolitica*. The assay is rapid and quantitative, can be performed for a number of samples at a time, and is suitable for application as an automated high-throughput detection system.

Conventional PCR-based assays fail to discriminate between viable and nonviable cells. However, a reverse-transcriptase 5′ nuclease assay targeting a specific gene transcript can be potentially exploited for the specific detection of viable *Y. enterocolitica*. PCR–ELISA is another alternative to circumvent electrophoretic analysis of PCR products and reduce the post-PCR analysis time. Essentially, a biotinylated capture probe is employed to immobilize the labeled PCR products on to microtiter plates. This colorimetric assay performed in the microtiter format is amicable to automation, can be applied to a large number of samples simultaneously, and allows the PCR product to be quantified directly. A PCR–ELISA adopted for detecting virulent strains has demonstrated a high specificity and sensitivity comparable to gel electrophoresis in detecting 6 CFU of the bacterium per PCR reaction. For the detection of *Y. enterocolitica*, the BAC *Screen* and BAC *Ident* kits are available commercially for conventional PCR and agarose gel detection and the LightCycler and ABI Prism PCR systems, respectively.

Random-amplified polymorphic DNA (RAPD) analysis is the amplification of random DNA segments with single primers of arbitrary nucleotide sequence. The difference in banding pattern allows strains belonging to the same species to be identified. Arbitrary primers used in RAPD have been shown to differentiate pathogenic and nonpathogenic strains and their serotypes. RAPD can also reveal coinfection with more than one strain of *Y. enterocolitica*, indicating the potential of this technique to detect strain variations in epidemiological studies.

Treatment of *Yersinia enterocolitica*

Yersinia enterocolitica is significantly implicated in foodborne illness leading to yersiniosis, arthritis, or even septicemia in children. In the majority of cases, patients recover without any treatment. Uncomplicated enterocolitis is a self-limiting disease. However, in older children, certain complications like pseudoappendicular syndrome, mesentric adenitis, ileitis, and extramesentric complications can be prevented by administering antibiotics, like cotrimoxazole. Uncomplicated gastroenteritis is often treated with norfloxacin, ciprofloxacin, or ciprofloxacin/doxycycline.

Regardless of the age, any patient with culture-proven septicemia should be treated. Treatment may shorten both the duration of the disease and the shedding of the bacterium. Aminoglycosides, in combination with third-generation cephalosporins, quinolones, or rifampin and trimethoprim-sulfamethoxazole, are effective against septicemia. No controlled clinical trials have demonstrated the efficacy of treatment, although septicemic patients should receive ampicillin and tetracycline because severe infection has a higher mortality (around 50%) rate.

Systemic infections, extraintestinal fecal infections, and diseases in immunocompromised children have been treated with cotrimoxazole (bactrim, septra, sulfatrim), cefotaxime (cloforan), and for a long time gentamycin (garamycin), which was later found as a failed drug. For cotrimoxazole, the recommended dosage is $160\,mg\,day^{-1}$ PO bid in adults weighing $>40\,kg$. The pediatric prescribed dosage is $8–10\,mg\,kg^{-1}\,day^{-1}$ PO divided bid. Dose-related complications include renal or hepatic impairment, crystaluria, stone formation, and possible hemolysis in glucose-6-phosphate dehydrogenase deficiency. Cefotaxime (claforan) is recommended in an adult dosage of $1–2\,g\,day^{-1}$ divided $q^{6–8\,h}$ intravenously/intramuscularly (IV/IM). Children are injected IV/IM with $150–180\,mg\,kg^{-1}\,day^{-1}$ divided $q^{6–8\,h}$. In patients with meningitis, $300\,mg\,kg^{-1}\,day^{-1}$ IV/IM divided $q^{6–8\,h}$ is recommended. Hypersensitivity to cephalosporin antibiotics has been documented. A dosage of $100\,mg\,kg^{-1}\,day^{-1}$ ciprofloxacin started early in the infection is an effective antibiotic treatment recommended in *Yersinia*-triggered reactive arthritis. However, antibiotic treatment has no effect on fully developed arthritis.

The agents traditionally used to treat human infections including cotrimoxazole, doxycycline, and chloramphenicol may remain the drugs of first choice. Very high failure rates of β-lactams like amoxycillin with or without clavulanate, benzylpenicillin, erythromycin, clindamycin, and first-generation cephalosporins have been observed. Ninety-nine per cent of all *Yersinia* strains have been found to be resistant to amoxycillin. Variations in minimum inhibitory concentrations (MICs) of different biovars are shown in Table 3.

This implies a complex regulation of β-lactamases in *Y. enterocolitica*. Some β-lactamases are prevalent and significantly expressed in specific biovars. Biovar 1A, 1B 2, 3, and 4 and serotypes O:3; O:5, 27; O:6, 30; O:7, 8; O:8, and O:9 are all found to be susceptible to most of the cephalosporins, aminoglycosides, quinolones, cotrimoxazole, doxycycline, piperacillin, tazobactam, and imipenem and highly resistant to cefazolins, amoxycillin, coamoxyclov, and macrolides. In clinical trials, cotrimoxazole and doxycycline have been found to be effective to an extent of 70–75%, whereas cefurozine, ceftazidine, cefaparazone, piperacillin, and gentamycin failed in seven of the eight courses.

Hygienic practices avoiding close contact with infected persons can prevent transmission of yersiniosis, thus obviating the need for drugs. Extreme care needs to be taken while handling natural warm-blooded reservoirs like pigs. Infection of *Y. enterocolitica* starts with the spread of the bacterium from the intestinal contents of the host carrier to the carcass and body parts. Virulent *Y. enterocolitica* serogroup O:3 has been isolated from various surfaces in slaughter houses. Stringent measures must be taken to prevent *Y. enterocolitica* contamination during slaughter with potential growth during subsequent storage and refrigeration. To prevent the initial colonization of *Y. enterocolitica* in reservoirs, application of vaccines or even feeding with an avirulent biotype 1A *Y. enterocolitica* capable of producing an *in-vivo* antagonistic substance (bacteriocin) against virulent *Y. enterocolitica* may be employed.

Research has focused on the development of vaccines and has shown a positive application when tested in mice. Intranasal immunization with *Y. enterocolitica* O:8 extracellular extracts have been shown to induce local and systemic immunity and subsequent protection against nasal infection. Efforts have also been made to design a rational live vaccine by mutating virulence-associated genes like *Yersinia* adhesion A (*Yad* A), Mn-cofactored superoxide dismutase. It has been found that the mutants are able to colonize Peyer's patches for at least 12 days, resulting in the induction of significant antibody titers against *Yersinia* outer-membrane proteins and in priming of *Yersinia* antigen specific $CD4^+$ Th1 cell isolates from spleen. A high level of attenuation does not diminish the immunogenic properties of the mutant strains.

In many experimental cases, oral vaccination is less successful as the colonization of *Y. enterocolitica* is inhibited in the gut. Vaccination has been shown to be more efficient by parenteral immunization than by oral route. Research has also paved the way for designing subunit vaccines using microbial heat-shock protein as a candidate and also interleukin-12 as an efficient alternative adjuvant to immunostimulating complexes for the induction of protective $CD4^+$ Th1-cell-dependent immune responses against bacterial pathogens.

Table 3 Antibiogram of *Yersinia enterocolitica*

Type	*Response*	*Antibiotic*	*MIC (mg l^{-1})*

Biovar 5	IS	Amoxycillin/clavulanate	
	S	Fosfomycin	1–32

IS, intermediate sensitivity; R, resistant; S, sensitive.

Concluding Remarks

Yersinia enterocolitica remains in the limelight as a prototype to study bacterial invasion and associated pathogenesis. Armed with an array of temperature-inducible, plasmid, and chromosomal-encoded virulence factors, and capable of being transmitted through food, water, and blood transfusions, *Y. enterocolitica* has instigated significant public health concerns. Consequently, extensive research is being carried out to detect its presence in food products and blood meant for human transfusion. Elegant detection techniques have been devised, embracing inputs from immunological and nucleic acid-based techniques. Antibiotic therapy has been adopted for effective treatment in patients with active infection and immunocompromised individuals.

YOGURT

Contents

The Product and its Manufacture

N Shah, Victoria University of Technology, Victoria, Australia

Introduction

At the beginning of this century, Nobel Laureate, Elie Metchnikoff, at the Pasteur Institute, linked health and longevity to the ingestion of bacteria present in fermented foods such as yogurt. This observation provided a major boost to the manufacture and consumption of yogurt and other fermented milk products.

Although no records are available to trace the origin of yogurt, it is believed that fermentation was the first technique employed by humans to preserve foods. The word 'yogurt' was derived from the Turkish word 'Jugurt.' Yogurt is defined as 'a product resulting from milk by fermentation with a mixed starter culture consisting of *Streptococcus*

thermophilus and *Lactobacillus delbrueckii* ssp. *bulgaricus*.' However, in some countries, including Australia, other suitable lactic acid bacteria are permitted for use as starter cultures. As a result, some yogurt manufacturers use *Lactobacillus helveticus* and *Lactobacillus jugurti* for yogurt manufacture. The first US Federal Standards of Identity for yogurt were published in 1981. The standard does not permit the use of culture organisms other than *Lb. delbrueckii* ssp. *bulgaricus* and *Sc. thermophilus* for making yogurt, and the titratable acidity must be at least 0.9%, expressed as lactic acid.

Yogurts differ according to their chemical composition, method of production, flavour used and the nature of postincubation processing. Based on the fat content, there are three main types of yogurt: full-fat yogurt, reduced-fat yogurt, and low-fat yogurt (Table 1).

On the basis of the method of production and the physical structure of the coagulum, yogurts are classified as either set or stirred. Set yogurt is the product formed when the fermentation of milk is carried out in a retail container, and the yogurt produced is in a continuous semisolid mass. In contrast, stirred yogurt results when the coagulum is produced from milk, and the gel structure is broken before cooling and packaging. Fluid yogurt can be considered as stirred yogurt of low viscosity.

On the basis of flavorings, yogurts are divided into three categories. Plain or natural yogurt is the traditional product, which has a typical sharp 'nutty' flavor. Fruit yogurts are made by addition of fruits, usually in the form of fruit preserves, puree or jam. Flavored yogurts are prepared from plain or natural yogurt by adding sugar and/or other sweetening agents, flavorings and colorings.

The method of yogurt production has changed very little over the years. However, some newer varieties have been added including frozen-, concentrated-, dried-, and pasteurized yogurt. Postincubation processing of yogurt may lead to pasteurized/UHT yogurt, concentrated yogurt, frozen yogurt, and dried yogurt. Pasteurized/UHT yogurt is prepared by heat- treating yogurt after incubation. Heat treatment destroys yogurt starter bacteria and reduces the levels of volatile compounds associated with the flavor of yogurt. In some countries, such as Australia, heat treatment after production to inactivate the starter culture is not permitted. In other countries, such as the USA and several countries in Europe, heat treatment is permitted; however, auxiliary labeling 'heat-treated after culturing' is required if yogurts are heat-treated after culturing. Frozen yogurt resembles ice cream, and the chemical composition and manufacturing details up to the freezing stage are similar to those of yogurt. Frozen yogurt can be either soft or hard. Dried yogurt can be produced by sun-drying, spray-drying or freeze-drying of yogurt. The drying process transforms the junket into powder. Drying also causes loss of some flavor compounds and destruction of the starter culture. Another type of yogurt, which may find favor among diet-conscious consumers is low-calorie yogurt, in which intense sweeteners are used, and the viscosity of the product is improved by the addition of stabilizers and thickening agents such as carrageenan and/or gelatin.

In the Middle East, concentrated yogurt is prepared by adding wheat flour or parboiled wheat, and the yogurt–wheat mixture is shaped into rolls and sun-dried. The product is popularly known as 'kishk.' In some countries, such as India, Nepal, and Bangladesh, yogurt is made in earthenware pots, and because of evaporation of moisture through the pores of the earthenware pots, the product becomes concentrated.

Table 1 Compositional standards for yogurt

	Full-fat yogurt	*Reduced-fat yogurt*	*Low-fat yogurt*
Fat (%)	≥3.0%	0.5–2	≤0.5
Milk solids not fat (%)	≥8.25	≥8.25	≥8.25
Titratable acidity (%)	≥0.9	> 0.9	> 0.9
pH	≤4.5	≤4.5	≤4.5

Processing and Manufacture of Yogurt

Preparation of Mix

A flow diagram for making yogurt is shown in Figure 1. Traditionally, yogurt is manufactured from milk, which has been concentrated by boiling to increase the viscosity of the product. Nowadays, milk is fortified with nonfat dry milk for the same purpose. The level of fortification varies from as little as 1% to as much as 6%. However, the generally recommended level of fortification is around 3–4%. This increases the total solids level in yogurt mix to 15–17%.

Ultrafiltration and reverse osmosis may also be used to achieve a higher solids content in order to improve the viscosity of the product. Milk concentrated by ultrafiltration to 18–20% total solids has been reported to produce good-quality yogurt. The viscosity of yogurt is almost wholly dependent on the protein content of milk. Hence, a high protein concentration is essential for the production of viscous yogurt. Casein is the major contributor of viscosity

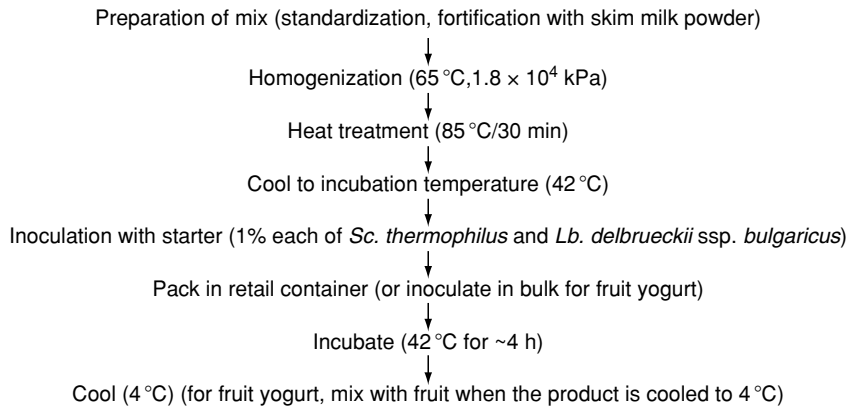

Figure 1 Flow diagram for yogurt manufacture.

followed by fat and whey proteins. Stabilizers can also influence the consistency of yogurt. In practice, gelatin, starch, vegetable gums, carrageenan, and pectin are used most widely as stabilizers for yogurt. The best yogurt texture is achieved by using gelatin at 0.3–0.8%. Good yogurt can be made without the use of added stabilizers, but yogurt without a stabilizer is more vulnerable to a number of stress factors than one that has not been stabilized. When properly chosen and used, stabilizers play an important role in improving the body, texture, mouth feel, and appearance of yogurt. The fat content may vary from 0.5 to 3.5%. Milk fat also tends to 'mask' the acid flavor of yogurt. Obviously, when milk fat is incorporated into the mix formulation, homogenization becomes important for the overall texture quality of yogurt.

Sweeteners are added to plain yogurts, generally with fruits. Addition of sugar is a method of cutting the sharpness of yogurt flavor. An appropriate level of sugar should be used to mask the full degree of acidity, but enough sugar should remain in the product after fermentation for a desirable acid–sugar blend. Up to 10% sucrose is usually used when fruit is added to yogurt. According to Ravula and Shah, a mix containing 4% or more sucrose, may reduce acid production and lower cell counts of both microbial species when incorporated in the mix prior to fermentation. Nonnutritive or intense sweeteners such as aspartame (NutraSweet) may find favor among diet conscious consumers. Since aspartame is approximately 200 times sweeter than sucrose, only a small amount is required for desirable sweetness. Because of this, yogurts containing intense sweeteners require a bulking agent such as polydextrose.

As yogurt mix is prepared, particular attention should be given to blending, homogenization, and heat treatment of the mix. The blending and homogenization steps are important to the uniformity of ingredient distribution. Homogenization is usually carried out before heat treatment, but in some cases, it may take place after the heat treatment.

Homogenization

Homogenization is the typical industrial process used to effect stabilization of the lipid phase against separation by gravity. The specific gravity of milk fat is 0.9, whereas that of skim milk is 1.036. Fat, being lighter, tends to separate from the serum or skim milk if left undisturbed. The diameter of the fat globules in milk ranges from 1 to 15 μm, with an average of 3–4 μm. Homogenization reduces the average diameter of fat globules to 1 or 2 μm. As a result, the fat globules do not cream during the incubation of yogurt. Because of the size reduction, there is usually a four-to sixfold increase in the surface area.

The fat-globule membrane protects the fat globules from lipase. Upon homogenization, the fat-globule membrane is destroyed, and the fat globule is vulnerable to attack by lipase, which is naturally present in milk. Because of this, the milk is pasteurized to inactivate lipase before homogenization. If the milk is to be homogenized before pasteurization, the milk must be pasteurized immediately to prevent lipolysis.

Since the efficiency of homogenization is much better at higher temperatures, the mix is warmed to around 65 °C to liquefy fat and then forced at high pressure (1.8×10^4 kPa) through a small orifice to reduce the size of the fat globules.

Heat Treatment

Yogurt mixes are heated to a high temperature, typically 85 °C for 30 min. Such a high heat treatment has many objectives: (1) to destroy all pathogenic bacteria, (2) to inactivate all the enzymes that may be

present in milk, including lipase, (3) to destroy most of the spoilage-causing bacteria, including thermodurics, and, most importantly, (4) to denature whey proteins, β-lactoglobulin and α-lactalbumin. This heat treatment denatures more than 90% of the β-lactoglobulin compared with 60% of the α-lactoglobulin. A complex is formed between κ-casein and denatured β-lactoglobulin, which increases the hydrophilic properties of the casein, reduces the propensity of the gel to syneresis, and facilitates the formation of a stable coagulum. The hydration effect of the protein is maximal when milk is heated at 85 °C but decreases as the temperature is raised above 85 °C. A higher heat treatment decreases the hydrophilic properties of the β-lactoglobulin–κ-casein complex. As a result, syneresis occurs, and the structure of the yogurt gel becomes weak and fragile.

After heat treatment and complex formation between β-lactoglobulin and κ-casein, the heated milk forms a smooth gel-like structure when the pH drops during fermentation to 4.6, which is the isoelectric point of casein (the pH at which casein proteins carry no electrical charge).

Inoculation and Incubation

After pasteurization, the mix is cooled to 45 °C and inoculated at a level that varies from 0.5 to 5%. The former level (0.5–1%) may be susceptible to growth conditions and a longer incubation time. The maximum amount recommended is 5%. This level will cause very rapid acid production, but leads to defects in aroma, and a large amount of culture must be prepared. The optimum level is 2%, 1% each of *Lb. delbrueckii* ssp. *bulgaricus* and *Sc. thermophilus*.

Lb. delbrueckii ssp. *bulgaricus* hydrolyzes milk proteins, the caseins, thus releasing essential amino acids, including valine, which stimulate the growth of *Sc. thermophilus*. Initially, *Sc. thermophilus* grows rapidly, reducing the pH to around 5.4, which stimulates the growth of *Lb. delbrueckii* ssp. *bulgaricus*, which is acid-tolerant and produces large amounts of lactic acid, which reduces the pH. *Sc. thermophilus* uses oxygen during its growth, which makes oxidation–reduction potential more favorable for *Lb. delbrueckii* ssp. *bulgaricus*; it also produces formic acid, which stimulates the growth of the lactobacillus.

The starter bacterial cells are distributed in the inoculated mix by stirring for 10–15 minutes after the addition of the cultures. This is followed by dispensing the mixes into consumer-sized containers and incubating at 42 °C for approximately 4 h until the pH decreases to 4.5. For the manufacture of stirred yogurt, the inoculated mix is incubated in bulk, and when the pH reaches the desired value, the yogurt is stirred, cooled, mixed with various flavorings, if required, and filled into retail containers.

The incubation temperature of 42 °C is optimal for the associated growth; the optimum temperature of the growth of *Sc. thermophilus* alone is 37 °C, and that for *Lb. delbrueckii* ssp. *bulgaricus* is 45 °C. Incubation temperatures above 42 °C will promote the growth of the *Lactobacillus*, whereas an incubation temperature of less than 42 °C will favor the growth of *Sc. thermophilus*, and lack of flavor results due to the poor growth of *Lb. delbrueckii* ssp. *bulgaricus*. Deviation in either direction will lead to a disturbance in the ratio of lactobacilli to streptococci. The ratio of lactobacilli and streptococci in natural yogurt for optimum flavor should be 1:1. By using monocultures, this ratio of 1:1 can be maintained easily by adjusting the inoculum level of both *Lb. delbrueckii* ssp. *bulgaricus* and *Sc. thermophilus*.

When a 2% inoculum is used at an incubation temperature of 42 °C, the milk will coagulate, and a firm gel will form in 3.5–4 h, and the pH will decrease to 4.4–4.5. When frozen concentrated cultures are used, an incubation period of 5–8 h may be required. Similarly, freeze-dried cultures may require longer times than fresh and active cultures.

A new trend in yogurt making is to incubate the yogurt mix at a significantly lower temperature than normal for a longer period. One of the advantages is that products require less starter cultures and shorter cooling times. An incubation temperature of 30 °C with 0.25% starter culture may take 12–14 h. If the incubation temperature is too low, the growth of yogurt starter may be affected adversely.

The final acidity of yogurt is 0.9–1%. The US standard requires a titratable acidity of 0.9% or higher, whereas the Australian standard requires a pH of 4.5 or lower. According to IDF, the minimum acidity of yogurt should be 0.7%.

The yogurt cultures produce acetaldehyde, which gives natural yogurt its typical flavor that resembles that of green apples. Other volatile compounds include acetic acid and diacetyl.

Cooling

Once the desired acidity has been reached, the product is cooled to <10 °C as quickly as possible. In the case of stirred yogurt, in one-phase cooling, the product is cooled from the incubation temperature to <10 °C prior to the addition of flavoring material and filling. In two-phase cooling, the temperature of the product is reduced to 15–20 °C during the first phase cooling before addition of flavoring materials and filling of containers followed by the second stage

cooling to <10 °C in a cold store. Yogurt quality may be improved by packaging at 24 °C followed by final cooling of the product in the container. To maximize the effect, the second stage of cooling should be carried out as slowly as possible over a 12-h period.

The viscosity of yogurt improves during storage for 1–2 days. During the first 24–48 h of cold storage, an improvement in the physical characteristics of the coagulum is observed, mainly hydration and/or stabilization of casein micelles. Proper hydration is required to avoid syneresis. It is therefore important to delay the sale or distribution of yogurt for 24–48 h.

During cold storage, it is important to minimize rough mechanical handling of the packaged yogurt, and to maintain the temperature of <5 °C. During transport, especially in summer, shaking of yogurt can lead to a reduction in viscosity and syneresis.

Flavored yogurts

Flavored yogurts are prepared by adding flavorings to plain yogurt. Sundae-style yogurt is prepared by layering 15–18% of total weight of yogurt with fruit purée or syrup on the bottom of the containers and then filling the containers with warm inoculated mix, followed by sealing the containers and incubation. The fruit in the product may be mixed with the yogurt gel by consumers before eating.

Swiss or stirred-style yogurts are prepared by blending fruit purée, sucrose, or glucose into bulk prepared fresh plain yogurt. Since the coagulum is broken during blending, plain yogurt is usually prepared with a higher level of stabilizer (0.7%) than normal (0.3%). The product after mixing with fruit is chilled to 4 °C.

Frozen yogurt

Frozen yogurt is a fermented milk or yogurt mix containing a typical yogurt flavor and has been subjected to fermentation by the two yogurt bacteria to a pH of 4.5 or lower or a titratable acidity of 0.9% or higher, expressed as lactic acid. Frozen yogurts, frozen flavored yogurt desserts, yogurt frozen on a stick, or frozen fermented dairy desserts are relatively new products that were developed in the 1960s. Frozen yogurts are prepared in a similar fashion as icecream, and therefore are made most conveniently in icecream factories.

Low-lactose Yogurt

Lactose malabsorbers do not produce sufficient lactase (β-D-galactosidase) and thus cannot hydrolyze the ingested lactose completely. In addition to the gastrointestinal discomfort, such as stomach upset and diarrhea brought about by ingestion of milk by these individuals, a general impairment in the normal digestion process has been observed.

Low-lactose or lactose-free milk for lactose sensitive individuals can be prepared either by the physical removal of lactose by ultrafiltration or by hydrolysis of lactose into the corresponding monosaccharides, glucose, and galactose.

Lactose can be hydrolyzed using strong mineral acid or enzymes. The enzyme β-galactosidase (β-D-galactoside galactohydrolase, EC 3.2.1.23), commonly called lactase, catalyzes the hydrolysis of the β-1 → 4-galactosidic linkage present in lactose. Lactase has been isolated commercially from the fungi, *Aspergillus niger*, *A. oryzae*, and *A. flavus*, or the yeast *Saccharomyces lactis* or from the bacterium *Escherichia coli*. Yogurt bacteria (*Lb. delbrueckii* ssp. *bulgaricus* and *Sc. thermophilus*) possess the highest amount of β-galactosidase activity among the lactic acid bacteria.

β-Galactosidase from *Saccharomyces* (known as neutral lactase) has an optimum activity at pH 6.8–7.0, is stable in the pH range of 6.0–8.5, and works best at 35 °C. It is suitable for treating milk (pH 6.6) or sweet whey (pH 6.2), but the lack of stability below pH 6.0 precludes its use for treating acid whey (pH 4.5). *A. niger* lactase (also known as acid lactase), with a pH optimum of 4.0–4.5, good stability over a wide range of pH (3.0–7.0), and an optimum temperature of 55 °C, is suitable for the modification of acid whey.

Low-lactose yogurt is then produced by the use of low-lactose milk during processing.

Heated or Pasteurized Yogurt

Even though natural yogurt is held at 4 °C, the titratable acidity increases due to residual activity of the starter bacteria. This process is referred in the industry as 'post-acidification,' as a result of which the product becomes too tart. Without heat treatment, the shelf-life of yogurt is 4–5 weeks at 4 °C. Heating destroys most of the starter bacteria and yeast and molds, and if post-processing contamination is avoided, the shelf-life of the product can be extended to 8 weeks. No postacidification occurs in heated yogurt. Heated or pasteurized yogurt can be prepared by heat-treating yogurt in the package at about 55 °C for 30 min, followed by cooling. The main problems associated with pasteurized yogurt are loss of flavor and syneresis. Stabilizers can be used to overcome the latter problem.

Controversies still exist regarding the heat treatment of yogurt after fermentation as heat-treated yogurt contains very few or no viable yogurt bacteria. It also raises questions about the definition of yogurt,

which must contain an abundant viable count of *Sc. thermophilus* and *Lb. delbrueckii* ssp. *bulgaricus*. Yogurt is considered to be an excellent nutritional food, and consumers ingest several million live cells through a typical serving of yogurt.

Prebiotics, Probiotics, and Synbiotics

The term 'probiotic' is derived from two Greek words meaning 'for life.' Probiotic organisms and substances produced by these organisms contribute to the microbial balance in the intestines. The generally accepted definition of probiotics is that 'they are live microbial food or feed supplements that provide a beneficial effect on hosts (human or animal) by improving the microbial balance in the intestine.' The intake of these bacteria is reported to help restore the balance in the intestinal microflora, which may have been lost due to stress, antibiotic use, or illness. The major strains of bacteria used in probiotics, *Lb. acidophilus* and *Bifidobacterium* spp., are dominant organisms of human large intestines. These microorganisms are claimed to inhibit the growth of pathogenic organisms through the production of organic acids and bacteriocins. Other benefits include reduction in lactose malabsorption, suppression of potentially harmful enzymes, increased immune response due to increased production of secretory immunoglobulins A, reduction in serum cholesterol, and antimutagenic effects.

The beneficial effects of the presence of bifidobacteria in the gastrointestinal tract are dependent on their viability and metabolic activity. The growth of bifidobacteria is dependent on the presence of complex carbohydrates such as oligosaccharides and other substrates such as *N*-acetyl glucosamine and lactulose. These carbohydrates that stimulate the growth of bifidobacteria are known as 'bifidogenic factors.' Some oligosaccharides, due to their chemical structure, are resistant to digestive enzymes and therefore pass into the large intestine, where they become available for fermentation by bifidobacteria.

Compounds that are either partially degraded or not degraded by the host and are preferentially utilized by bifidobacteria as carbon and energy sources are defined as 'prebiotics.' Some of the bifidogenic factors that are of commercial significance include fructo-oligosaccharides, lactose derivatives (such as lactulose, galacto-oligosaccharides), isomalto-oligosaccharides, xylo-oligosaccharides, gluco-oligosaccharides and soybean oligosaccharides. Resistant starch and nonstarch polysaccharides are classified as colonic foods but not as prebiotics because they are not metabolized by certain beneficial bacteria. Oligosaccharides have been recognized for their health benefits in Japan, and many products containing oligosaccharides were developed during the 1990s. Products that contain both prebiotics and probiotics are referred to as 'synbiotics.' An example of synbiotic includes SymBalance yogurt, which contains inulin as prebiotic and *Lb. reuteri*, *Lb. acidophilus*, and *Lb. casei* as probiotics.

It is not clear how probiotics work. Acidification of the gut is claimed to be one of the mechanisms. Breast-fed infants have a much higher percentage of *Bifidobacterium bifidum* than formula-fed infants. The intestinal microflora of the latter group is more like that of adults; it is a mixed microflora, including coliform bacteria. Bifidobacteria produce acetic acid, butyric acid, lactic acid, and pyruvic acid. The lactic acid and acetic acid account for more than 90% of organic acids produced. It is widely accepted that because of acid production by *Lb. acidophilus* and bifidobacteria, the enteropathogenic bacteria are unable to grow. The growth of clostridia and *E. coli*, when cocultured with bifidobacteria, has been found to be inhibited, even at a neutral pH, suggesting that acid production may not be solely responsible for inhibition. Metabolites produced by bifidobacteria may be partly responsible for the inhibition of pathogens.

Acidophilus and Bifidus Yogurt (AB Yogurt)

Lb. acidophilus and bifidobacteria are normal inhabitants of the intestine of many animals including man. *Lb. acidophilus* is Gram positive and rod-shaped, while bifidobacteria are Gram-positive rods of variable morphology that show branching and pleomorphism. Bifidobacteria were first isolated by Tissier at the Pasteur Institute, Paris, France, and predominate the gut flora in breast-fed infants.

Yogurt containing *Lb. acidophilus* and bifidobacteria has gained popularity in many countries, including Japan, France, Germany, Canada, Australia, and USA, and more than 70 products containing *Lb. acidophilus* and bifidobacteria, including sour cream, buttermilk, yogurt, milk powder, and frozen desserts, are produced world-wide. It is estimated that about 11% of all yogurt sold in France now contains *Lb. acidophilus* and *Bifidobacterium* spp. In 1978, the Yakult Co. launched a Bifidus fluid yogurt named Milmil™, which contains *Bifidobacterium breve*, *B. bifidum* and *Lb. acidophilus*. More than 54 different types of milk products containing *Lb. acidophilus* and *Bifidobacterium bifidum* are marketed in Japan.

Lb. acidophilus and *Bifidobacterium* spp. are difficult to propagate because of their specific nutritional requirements. Bifidobacteria are not as acid-tolerant as *Lb. acidophilus*, and the growth of

Bifidobacterium species is significantly retarded below pH 4.0. *Lb. acidophilus* and *Bifidobacterium* spp. are slow acid producers; the slow growth rate of these organisms can be compensated by adding a higher level of inoculum, such as 5 or 10%. Yogurt bacteria are usually added to carry out fermentation. If pure cultures of *Lb. acidophilus* and/or *Bifidobacterium* spp. are used, the time required to reduce the pH of milk to 4.5 could be as long as 18–24 h at 37 °C. When yogurt bacteria (*Lb. delbruecckii* ssp. *bulgaricus* and *Sc. thermophilus*) and AB (*Lb. acidophilus* and *Bifidobacterium* spp.) cultures are used, the incubation time is about 4 h.

Recent Advances in Probiotic Yogurt

The most commonly used species in commercial probiotic products are *Lb. acidophilus*, *Lb. casei*, *Lactobacillus* GG (a close relative of *Lb. casei* subgroup *rhamnosus*, ATCC 53103), *B. bifidum*, *B. longum*, *B. breve*, and *B. infantis*. Additional blends are also being investigated, such as *Lb. reuteri*, *Lb. plantarum*, and *Lb. casei*.

In Australia and Europe, yogurt containing *Lb. acidophilus* and *Bifidobacterium* spp. is referred to as AB yogurt. The recent trend is to incorporate *Lb. casei* in addition to *Lb. acidophilus* and *Bifidobacterium* spp, and such products are known as 'ABC yogurt.'

A wide variety of probiotic cultured products are now available world-wide such as Nu-Trish a/B, USA (acidophilus + bifidus), AB-yogurt, Denmark (acidophilus + bifidobacteria + yogurt culture), Miru-Miru, Japan (*Lb. acidophilus* + *Lb. casei* + *B. breve*), Bifighurt (*B. longum* + *Sc. thermophilus*). Products that contain both prebiotics and probiotics include SymBalance yogurt (*Lb. reuteri* + *Lb. acidophilus* + *Lb. casei* + bifidobacteria, inulin) produced in Switzerland and Fysiq (*Lb. acidophilus* + Raftiline brand prebiotic).

Several probiotic products contain both yogurt bacteria and one or more types of probiotic bacteria. Because of sensitivity to acid, *Lb. acidophilus* and *Bifidobacterium* spp. in yogurt begin to die within a few days after manufacture because of acid produced during manufacture and storage. In order to provide health benefits, the suggested level for probiotic bacteria is 10^6 cfu per gram of a product. However, studies have shown a low viability of probiotics in market preparations. Many yogurt manufacturers use a starter culture devoid of *Lb. delbrueckii* ssp. *bulgaricus* but a combination of *Lb. acidophilus*, bifidobacteria and *Sc. thermophilus* (known as 'ABT') as starter cultures to overcome the postacidification problem. However, the use of ABT starter culture increases incubation time significantly as *Sc. thermophilus* is the main organism responsible for fermentation in ABT starter cultures, and this organism is less proteolytic than *Lb. delbrueckii* ssp. *bulgaricus*. Bifidobacteria are anaerobic and are fastidious organisms, requiring specific growth factors and prefering a low oxidation–reduction potential for growth.

Cysteine is usually incorporated in the media used for selective enumeration of bifidobacteria. Cysteine is an essential growth factor for bifidobacteria and also reduces the oxidation–reduction potential for optimum growth of anaerobic bifidobacteria. Dave and Shah have shown a better viability of bifidobacteria, in yogurt made from ABT starter cultures, with an additional source of nitrogen, such as acid casein hydrolysate, than with lowering the oxidation–reduction potential with cysteine. These authors have also shown that incorporation of cysteine (at $> 250\,mg\,l^{-1}$) to lower the redox potential affected the growth of *Sc. thermophilus*, as this organism is considered aerobic. Since *Sc. thermophilus* is the sole fermenting organism in ABT starter cultures, the incubation time increased significantly.

The viability of bifidobacteria in yogurt made with starter cultures containing both yogurt bacteria was not affected as much, as *Lb. delbrueckii* ssp. *bulgaricus* is proteolytic and provides peptides and amino acids for the growth of bifidobacteria.

Yogurt-based Products

A Y Tamime, Ayr, UK

Introduction

The transformation of milk into yogurt, with a starter culture composed of *Streptococcus thermophilus* and *Lactobacillus delbrueckii* ssp. *bulgaricus*, can easily extend the shelf-life of milk from a few days to about 3 weeks. However, the starter cultures employed in the manufacture of biofermented milks including yogurt-related products have been reviewed recently. (*See* **Yogurt**: The Product and its Manufacture.) The main organisms belong to the following genera: *Lactobacillus*, *Bifidobacterium*, *Enterococcus*, and *Pediococcus*. The application of the different preservation techniques known to humans for thousands of years could extend the shelf-life of yogurt to a few months, or even indefinitely. Examples of such postfermentation processes include heating, concentration, freezing, and/or drying, but it is evident that such treatments will alter the characteristics of the end product. Some of these processes are still carried out using traditional methods, but limited data are available in the literature; however, some of these processes have been mechanized and developed by industrial organizations, and as a consequence, sometechnical data are somewhat limited. (*See* **Starter Cultures**.)

Methods of Manufacture

Pasteurization

Traditionally, natural yogurt in rural areas in the Middle East is heated gently for a few hours over low fires using a special wood, and the product is known as 'laban mudakhan' or 'smoked yoghurt.' The application of heat inactivates the starter culture organisms and their enzymes, as well as other contaminants, e.g., undesirable bacteria, yeasts, and molds. The use of such methods enables the nomads in that region to extend the shelf-life of yogurt for a few weeks, or until they reach a market to sell their product. Alternatively, the hot yogurt is placed in a clean jar and covered with a layer of olive oil or tallow, so that the 'smoked yogurt' is preserved over the winter months.

In mechanized plants, natural/plain, fruit, flavored, or drinking yogurts are subjected to heat treatment after the fermentation stage to prolong the shelf-life of the product. The time–temperature relationships, which are used to achieve this objective, are dependent on: (1) the level of acidity, (2) the method of heating and packaging, and (3) the storage conditions. Set-type yogurt is heated between 60 and 85 °C for up to 50 min, and in some instances, the heating is carried out under a pressure of about 0.2 MPa. The other types of yogurt are pasteurized/ultrahigh temperature (UHT), which is heated at 65 to >100 °C for up to 50 s. In general, the heating and packaging methods can be divided into the categories of pasteurized/UHT yogurts given in **Table 1**. (*See* **Heat Treatment**: Ultrahigh Temperature (UHT) Treatments.)

Postfermentation heating of yogurt causes the separation of the aqueous phase from the suspended casein particles. This is mainly due to the

phenomenon of aggregation/dehydration of the caseins caused by heating at the isoelectric point (pH 4.6). Certain hydrocolloids (e.g., pectins, alginate, carboxymethyl cellulose, or prophylene glycol) are negatively charged, and, when added to yogurt before the heat treatment stage, they interact with the positive charges of the casein below its isoelectric point, and the separation of the two phases in the product is avoided. (*See* **Casein and Caseinates**: Methods of Manufacture.)

Concentration

Concentrated or strained yogurt is a popular product in the Middle East region. The product is known as labneh, labaneh, or lebneh (in most Arab countries), mast or mastou (in Iraq), leben zeer (in Egypt), tan or than (in Armenia), Greek yogurt or Greek-style yogurt (in the UK), stragisto or tzatziki (in Greece), torba or suzme (in Turkey), basa or zimne (in the Balkans), and yogurt cheese (in some parts of the world). Other closely related products, which are produced in different countries and using mesophilic, thermophilic, and/or lactose-fermenting yeast starter cultures, are ymer (in Denmark), chakka and shirkhand (in India) and skyr (in Iceland).

The traditional and rural method of production consists of straining cold and unsweetened natural/plain yogurt using a cloth bag, animal skin, or earthenware vessel. The method, in comparison with large, factory-scale operations, is slow, labor-intensive, unhygienic, and cumbersome, and gives low yields due to the residues left in the bag. Typical compositional standards for labneh (e.g., in Saudi Arabia and Lebanon) range between 22 and 26 g 100 g^{-1} total solids and 7 and 10 g 100 g^{-1} fat, respectively.

The factory-scale production of concentrated or strained yogurt includes the methods described below.

Traditional Process

The cold natural/plain yogurt is stirred and emptied into cloth bags of about 25 kg. The bags are stacked on top of each other in a vertical press that is located in a refrigerated room. Pressure is applied in order to assist in whey drainage for a duation of 12–18 h. On the following day, the concentrated product is emptied into a mixing bowl to obtain a uniform texture prior to packaging. Alternatively, long, horizontal filter cloths can be used; the long sides are supported on poles and gently oscillated up and down, while slight lateral pressure is applied. This method of processing is known as the modified 'Berge' system, and was developed in France in the mid-1960s for the production of fresh curd cheese.

The application of more pressure and a longer dewheying stage will yield a product that contains $\geq$ 30 g 100 g^{-1} total solids, and is known as 'yogurt cheese.' This highly concentrated product can be shaped into balls by hand, placed in a jar, and preserved in oil. In Lebanon, mainly goat's milk is used for the production of yogurt cheese, which is known locally as 'labneh anbaris.' Herbs and spices are added to the curd after concentration, and before it is shaped into balls; the product is referred to as 'shanklish' (in the Lebanon).

Table 1 Categories of pasteurized/UHT yogurts

Temperature	*Packaging*	*Shelf-life/storage*
Pasteurization (low)	Hot	2–3 weeks/cold
Pasteurization (high)	Cold/aseptic	1–2 months/cold
UHT	Hot/aseptic	Several months/ambient

Mechanical Separators

The production of strained yogurt by centrifugation of heated yogurt has been used successfully in experimental trials and commercially in different countries; concentration is achieved using a nozzle or Quarg separator. Skimmed milk should be used for the manufacture of the yogurt, and the fermented milk is stirred vigorously, heated to about 60 °C, cooled to about 40 °C and concentrated to 18 g 100 g^{-1} total solids, cooled to about 12 °C, blended with cream, and finally packaged. If whole milk is used instead, the nozzles of the separator will clog. However, recent developments in the design of the centrifugal separators have made it feasible to use fermented whole milk for the production of strained yogurt.

After acidification (i.e., pH 4.6–4.8), the fermented milk is heated to 60 °C to inactivate the culture and control the level of acidity, and then deaerated for 15–20 min to assist the separation of whey in the separator. A centrifugal pump transports the fermented milk through a switchable double strainer to break up any lumps before it enters the separator. The concentrated product leaving the separator is blended with cream and seasoning (e.g., salt, herbs or fruit flavors – optional), cooled, and packaged. A typical chemical composition for strained yoghurt is 24 g 100 g^{-1} total solids and 9.6 g 100 g^{-1} fat (about 40% fat-in-dry-matter); the composition of the whey is 6.1 g 100 g^{-1} total solids, consisting mainly of lactose and minerals, but also about 0.5 g 100 g^{-1} fat. Capacities of such separators are up to 6.5 tonnes h^{-1}, depending on the composition of the milk used and the acidity of the fermented milk prior to concentration.

Ultrafiltration (UF)

Two different systems of UF have been used for the production of strained yogurt. Firstly, the standardized milk is concentrated by UF to the desired solids content before homogenization, heat treatment, and fermentation, and secondly, the warm yogurt (about 45 °C) is concentrated by UF. (*See* **Filtration of Liquids.**)

In the former system of production, the UF retentate is fermented in the retail container – as with the manufacture of natural set yogurt – and the firmness of the product is much greater than that of products made using the traditional (cloth bag) method or by the UF of warm yogurt. However, when the product is broken and smoothed by passing it through a lactic curd homogenizer, the strained yogurt showed signs of whey syneresis, and an excessive reduction in its firmness is observed. These faults are not evident in the other types of strained yogurt, and the product should be processed differently in order to overcome such faults.

The quality of strained yogurt made by UF of warm yogurt closely resembles the traditional product in terms of elasticity, firmness, and structure. The stages of manufacture consist of: (1) production of yogurt from whole milk, (2) UF of yogurt at 35–45 °C using batch or multistage systems, (3) partial cooling to 20 °C, fruit blending (optional), and packaging, and (4) cooling in the retail container to < 10 °C. No fat losses are observed in the permeates, and the solids content consists almost exclusively of lactose, organic acids, minerals and *very* slight losses of low-molecular-weight nonprotein nitrogen.

A wide range of UF plants are available on the market that can be used for the production of strained yogurt on a large scale. A typical example is illustrated in Figure 1, and according to the supplier, the manufacturing process is as follows. The standardized milk (e.g., 12.4 g 100 g^{-1} total solids and 3.5 g 100 g^{-1} fat) is preheated to 60 °C, homogenized at 14.7 MPa, heated in a plate heat exchanger (PHE) to 95 °C for 5 min in a holding tank before cooling to 40–45 °C in the regeneration section of the PHE. After the fermentation period, the warm yogurt is heated at 58–60 °C for 3 min in the PHE, cooled to 40 °C, concentrated in a two- to four-stage UF plant, cooled in a plate cooler to about 20 °C, and finally packaged. The degree of concentration of yogurt using a four-stage UF plant, for example, could be adjusted to give 14, 16, 19, and 22 g 100 g^{-1} total solids, respectively.

Product Formulation

It is feasible to manufacture strained yogurt from recombined dairy ingredients. The process involves reconstitution of powder(s) (whole, skimmed milk, retentate, and/or caseinate) in water and blending it with anhydrous milk fat/butter oil, stabilizer (e.g., Cremodan Mousse 31 (Danisco Ingredients (UK) Ltd.)), and salt (optional). The recombined milk is

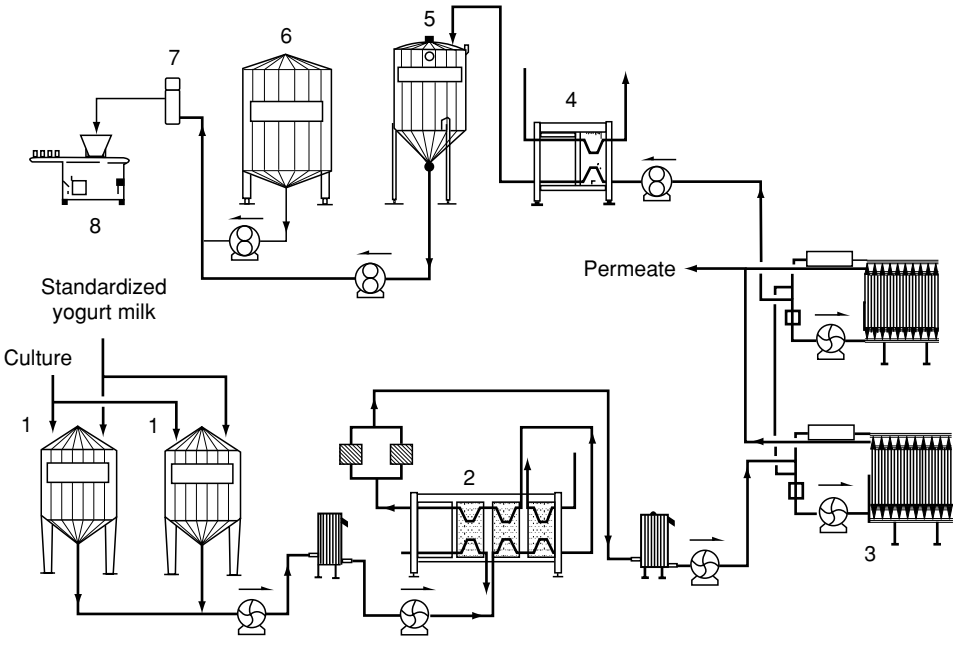

Figure 1 Simplified flow chart for the manufacture of strained yogurt by UF: 1, fermentation tanks; 2, plate heat exchanger; 3, two- to four-stage UF plant; 4, plate cooler; 5, buffer tank; 6, fruit tank (optional); 7, in-line mixer; 8, packaging machine. handled and processed in a similar way to the production of yogurt. After the fermentation stage, the product is precooled to about 20 °C and packaged, and the final cooling to 5 °C takes place in the cold store. Typical compositions of full- and low-fat strained yogurts are given in Table 2. (*See* **Recombined and Filled Milks.**)

At present, there are no compositional standards for this product in the UK. However, Table 3 illustrates the variation in the chemical composition of leading brands of strained yogurt that are marketed in the UK.

Freezing

Frozen yogurt resembles icecream, in that the fresh stirred yogurt is stabilized, fortified with fruit base (syrup or pieces), whipped, and frozen. In general, the product is classified into three main categories: soft, hard, or mousse. The recommended ratio of yogurt to fruit base for the manufacture of soft and hard frozen yogurts is 80:20 and 65:35, respectively. The outlet freezer temperature of these two products is −6 °C, and the storage temperature for soft and hard frozen yogurts is −6 °C and −25 °C, respectively. Although air is normally used at the whipping/freezing stage, a longer-shelf-life product can be achieved by using nitrogen rather than air.

The chemical composition of frozen yogurt may differ from one manufacturer to another, or between countries. This product is very popular in the USA, and the variation in the chemical composition of a number of commercial samples is shown in Table 4.

Drying

The objective of manufacturing powdered yogurt is to produce a product that is stable during prolonged storage and readily utilizable. The stages of manufacture depend on the method of drying used.

Traditionally, natural/plain yogurt or, in some instances, strained yogurt is mixed with 'burghol or bourghoul' (i.e., parboiled cracked wheat) in a ratio of 4:1. The mixture is kneaded daily for around a week, salted, passed through a meat mincer, shaped into rolls, and placed in the sun to dry. The dried product is called 'kishk', and it is either sold as rolls or ground into flour. Kishk as a dish is prepared by rehydrating the dried product with water and then simmering the mix gently over a fire. The product is rather thick, similar to porridge. Chopped onions, coriander, and/or tomatoes can be added to the reconstituted 'kishk,' and such a dish is normally consumed with bread. (*See* **Fermented Milks**: Types of Fermented Milks.)

Other types of dried, fermented dairy product are known in the Arabian peninsula as 'oggtt' or 'maddeer' or 'buqle'. The desert dwellers allow goat's or camel's milk to sour naturally, churn it to make butter, and then boil the buttermilk until it thickens. When cooled, the concentrated buttermilk is shaped into small cakes and left in the sun to dry.

At present, powdered yogurt, which is sometimes known as dried or instant yogurt, is manufactured in relatively small quantities using normal driers. Some of the manufacturing techniques have been patented, and the dried product is aimed towards the do-it-yourself consumer market, the baby food manufacturers, and the food/baking industries.

Table 4 Range of composition (g 100 g^{-1}) of commercial frozen yogurts sold in the US market

Yogurt presents no difficulties when spray dried, but some precautionary measures that should be considered included the following: firstly, the concentration stage, before drying, should be carried out at a low temperature (about 50–60 °C) to minimize scorching on to the surfaces of the evaporator, or discoloration of the final powder, and secondly, the processing conditions must be moderate in order to ensure a high viable cell count of starter culture organisms in the dried product. The acidified product is concentrated using an ordinary evaporator to 25–36 g 100 g^{-1} solids at 57–58 °C. The concentrated buttermilk, which is highly viscous, is pumped to the spray drier at 43 °C and dried using an inlet air drying temperature between 175 and 190 °C. The moisture content in the dried product is around 4 g 100 g^{-1}, and the tapped bulk density is 0.77–0.83 g cm^{-3}. (*See* **Drying**: Spray Drying.)

According to APV Nordic A/S, which is one of the leading drier manufacturers, yogurt can be dried in a three-stage drying plant, and an illustration is shown in Figure 2. The yogurt is concentrated to 35 g 100 g^{-1} total solids, preheated, and nozzle atomized into the drying chamber. The inlet and outlet air

Data compiled from Tamime AY and Robinson RK (1999) *Yoghurt Science and Technology*, 2nd edn. Cambridge: Woodhead, with permission.

drying temperatures are 160 and 65 °C, respectively. The partially dried yogurt particles fall down on to the integrated fluid bed drier in the bottom of the drying chamber. Such particles form a fluidized layer, which is further dried.

Finally, the powder is transferred to an external fluid bed drier for final drying and cooling. The spent drying air from both the drying chamber andthe external fluid bed is drawn through cyclone(s) to separate the very fine powder particles (fines) from the air. The fines are fed back to the external fluid bed drier, where they are mixed with the bulk of the powder. During drying, the maximum temperature of the powder is 55 °C and that of the product outlet, 25 °C. Such powder contains $2\,g\,100\,g^{-1}$ moisture and has a tapped bulk density of $0.5\,g\,cm^{-3}$.

It is evident that dried-yogurt products (traditional or industrial) are available to consumers in rural or industrialized countries, and Table 5 illustrates some typical compositional analyses. Note that some products contain low quantities of fat, which indicate that: (1) skimmed milk has been used rather than full-fat milk, or (2) in some traditional dried products, the fermented milk is first churned to make butter, and then the buttermilk is dried for preservation purposes.

Dietary Importance

J Buttriss, British Nutrition Foundation, London, UK

Introduction

Yogurt is a fermented milk product and as such is a means of preserving the nutrients in milk. A wide variety of yogurts are now available around the world, ranging from very-low-fat fruit yogurts to Greek-style yogurt with a fat content around 8 g per 100 g. Yogurt can be made from cows', ewes', goats', or buffalo's milk. This article reviews the nutritional composition of a range of yogurts, provides data on yogurt consumption around the world and discusses the importance of yogurt for different population groups. (*See* **Buffalo**: Milk; **Milk**: Dietary Importance; **Sheep**: Milk.)

Since yogurt is derived from milk, it provides protein, calcium, and other minerals, and a range of vitamins (**Table 1**). Levels of some vitamins, such as vitamin B_1 and pantothenic acid, are reduced as they are utilized by the bacterial culture used to produce the yogurt. However, folic acid levels are typically higher than in milk since folic acid is produced by the bacteria. Refer to individual nutrients.

Some people have speculated that the bioavailability of some minerals in yogurt is enhanced, but research to support this claim is inconclusive. (*See* **Bioavailability of Nutrients**.)

Sugar and Artificial Sweeteners

Reflected in the calorific content, yogurts with a range of sugar contents are now available. In plain yogurt, it is lactose, naturally present in yogurt, that provides the sweetness. But in other forms, sugar is added either as sucrose or as fructose and glucose from fruit. In 'diet' or 'very-low-fat' yogurt, artificial sweeteners are often used to reduce the calorie content. (*See* **Carbohydrates**: Sensory Properties; **Sweeteners**: Intensive.)

Trends in Yogurt Consumption

Yogurt and other cultured milk products have traditionally been popular dietary items in Eastern Europe. Popularity in the UK has increased considerably in the past 25 years: consumption

increased 10-fold from 0.4 kg per person per year in 1966 to 4.1 kg per person per year in 1989, according to the *International Dairy Federation (IDF) Annual Statistics*. By 1996, the per capita consumption reached 6.18 kg. Much of this increase has been due to the introduction in the UK of flavoured and fruit yogurts.

The UK's National Food Survey for 1998 indicated that yogurt consumption is 109 ml per person per week. Comparable consumption levels for fromage frais and other dairy desserts are 16 and 27 ml, respectively. In this data set, yogurt is responsible for 72% of the market for these three types of products.

Table 2 shows the consumption of yogurt, fromage frais, and, for comparison, dairy desserts, in a selection of countries. Again, yogurt represents about 72% of the market.

Importance of Yogurt for Different Population Groups

Yogurt and Health

Apart from its contribution to nutrient needs, the perception of yogurt as a 'healthy' food has been augmented by claims of health benefits attributed to specific live bacteria present in some yogurts, in particular *Lactobacillus acidophilus* and bifidobacteria. Both of these types of bacteria are to be found in the human gastrointestinal tract, especially in breast-fed infants, and it has been suggested that these microorganisms may be able to colonize the gut when consumed in yogurt, and protect against pathogens. It has also been speculated that they may be of benefit in a number of intestinal disorders, including

those precipitated by antibiotic treatment or by diseases such as cancer and liver or kidney disease. Claims have been made that specific bacteria used in the production of a certain brand of yogurt (no longer on the market) have the potential to reduce blood levels of low-density lipoproteins (LDL). On the basis of existing research it is not possible to substantiate these various claims, although evidence is increasing, and inconsistencies in the findings may in part be explained by differences in strain and species of bacterial cultures, and differences in experimental design.

There is, however, a substantial body of evidence to indicate that fermented dairy products such as yogurt are well tolerated by individuals who are lactose-intolerant. It has been suggested that this is because of the bacterial enzyme, β-galactosidase (produced by the culture) in 'live' yogurt. This enzyme, which is able to digest lactose to glucose and galactose, is intracellular and hence is thought to survive gastric digestion. However, as lactose maldigesters tolerate yogurts with varying β-galactosidase activities equally well, it would seem that other factors may also be important, including the rate of gastrointestinal transit of yogurt.

Intake of the types of lactic acid-producing organisms found in yogurt has also been postulated to prevent or inhibit intestinal growth of a variety of foodborne, disease-causing organisms. Most of the evidence supporting a role for cultured dairy products, or the bacteria used to make them, in controlling intestinal pathogens comes from experimental animal and *in vitro* studies. Findings are inconsistent, but various mechanisms have been proposed to explain reported protective effects. For example, the ability of lactic acid cultures to lower intestinal pH favors growth of lactic acid bacteria but provides a hostile environment for pathogens. It has also been suggested that lactic acid bacteria may produce bacteriocins, peptides with a direct antibiotic effect.

In summary, while a fairly clear case has been made for tolerance of yogurt by lactose maldigesters unable to tolerate milk, the potential benefit of yogurt (or specific types of yogurt) in protecting against pathogens, in recolonizing the gut after illness, or in lowering LDL cholesterol concentrations in the blood needs further investigation.

Importance of Zinc in Human Biology

Zinc is the 23rd most abundant element on the Earth's crust. Among the transition elements, zinc is the second in abundance in eukaryotic cells. In mammals, zinc is found, on average, at a concentration of 0.02 mM in the extracellular space and 1 mM in the intracellular space. The total amount of zinc in the body of an adult ranges from 1.5 g (female) to 2.5 g (male). The distribution of zinc in the organism of a man is detailed in Table 1.

The essentiality of zinc for growth for lower forms of life was discovered in 1869 by Raulin studying the effects of zinc on *Aspergillus niger*. Todd documented the essentiality of zinc for rats in 1934. Today, the requirement of zinc for the growth and replication of all cells is recognized. Zinc is required for virtually all aspects of cell metabolism, i.e., DNA synthesis, DNA transcription, translation of mRNA into proteins, and structure and stabilization of translated proteins. Thus, at a whole organism level, zinc is necessary not only for growth but also for development and highly relevant functions, such as immunity, tissue repair, vitamin A metabolism, protection against oxidative damage, neuropsychological functions, apoptosis, cellular signaling, and hormone action, among others. (*See* **Zinc**: Physiology.)

Prior to 1963, zinc deficiency in humans was unrecognized. Today, as a result of remarkable advances in the area of zinc metabolism, we know that mild zinc deficiency is a widespread condition, probably as prevalent as iron deficiency. This has led to the suggestion that zinc should be added to iron, iodine, and vitamin A, to the group of the micronutrients with the highest risk of suboptimal nutrition in the world.

Severe human zinc deficiency is now a rare condition. It has been reported mainly in patients with acrodermatitis enteropathica and in patients receiving total parenteral nutrition without added zinc. Clinical manifestations include growth retardation, delayed sexual maturation, alopecia, epithelial lesions, immune deficiencies, hypogeusia, hyposmia, delayed wound healing, altered appetite, and night blindness. Mild zinc deficiency is much more difficult to characterize, and much information has been obtained from zinc supplementation studies in populations around the world. Growth retardation has been the most extensively studied feature, and immunological alterations, neuropsychological manifestations, and increased morbidity have also been reported. (*See* **Zinc**: Deficiency.)

In order to understand why zinc is crucial for life and the importance of achieving a normal nutritional status regarding this mineral, it is necessary to analyze the biochemical characteristics of this ion.

General Properties

Zinc is a IIB element with a complete d subshell and two additional s electrons. It is a small ion, with a radius of 0.65 Å and an oxidation state of +2. It has five stable isotopes and several radioactive isotopes with variable half-lives, some of which are shown in Table 2.

Zinc is a ubiquitous element and is mainly found in intracellular space (extracellular/intracellular ratio 1:50). The concentration of free zinc ions varies from

Table 1 Distribution of zinc in the human body

	Total Zn (g)	*Percentage*
Skeletal muscle	1.53	57
Bone	0.77	29

^{70}Zn	0.62	^{71m}Zn	3.97 h
		^{72}Zn	46.5 h

$\leq 10^{-9}$ M in the cytoplasm of many cells to $\geq 10^{-3}$ M in vesicles. Zinc has a highly concentrated charge and a small size, and a modest binding capacity to anions such as carboxylate and phosphate. Like others ions, zinc has a high affinity for electrons. It is a strong Lewis acid and can bind strongly to donors such as thiolates and amines.

Zinc is a flexible atom that is able to adopt four, five, and six coordinated geometries. It has a distinctive ability to form stable complexes with several molecules. Zn readily complexes amino acids, peptides, proteins, and nucleotides, and has an affinity for thiol and hydroxy groups and for ligands containing electron–rich nitrogen as a donor. For instance, zinc is often found in internal cross-links of intracellular proteins, where it apparently functions in a similar way to the disulfide bridges of extracellular proteins. Disulfide bridges are unstable to reduction in the intracellular environment. Zinc does not show any changes in its oxidation state, and this is an important advantage in reactions in which redox activities may represent a risk for oxidative damage.

Table 3 lists the important properties of zinc in a biological context.

Link Between Properties and Major Roles

The exceptional ability of the zinc atom to participate in strong but readily exchangeable ligand binding, the flexibility of its coordination geometry and its stable oxidation state are extremely useful in biological systems. In other words, zinc is important for its ubiquity and versatility. These characteristics mostly explain the importance of zinc involvement in biological functions.

Table 3 Importance of zinc in biology

1. High availability
2. Strongly retained
3. Fast ligand exchange
4. No redox reaction
5. Flexible coordination geometry
6. Good electron acceptor or Lewis acid
7. Supplies hard base, hydroxide

Modified from Williams RJP (1989) An introduction to the biochemistry of zinc. In: Mills CF (ed.) *Zinc in Human Biology*, pp. 15–31. London: Springer-Verlag.

The biological functions of zinc can be classified into three main categories: catalytic, structural, and regulatory. Although there are good examples for each of these, this should be considered only as a rough classification, because there is often some degree of overlap.

Catalytic

The catalytic role of zinc is related to the requirement of zinc by more than 200 enzymes. Zinc metalloenzymes are found in all six enzyme classes: oxidoreductases, transferases, hydrolases, lyases, isomerases, and ligases. Zinc metalloenzymes are involved in nucleic acid, protein, carbohydrate, lipid, and vitamin metabolism.

A combination of properties of zinc accounts for its utility in zinc metalloenzymes. Zn as a Lewis acid is able to accept a pair of electrons, and it does not participate directly in redox reactions. This is highly valuable in reactions such as proteolysis and the hydration of carbon dioxide. As result of having filled the d-shell orbitals, no specific geometry is more stable than any other, although the binding geometry observed most frequently is tetrahedral, with the metal ion coordinating three or four protein side-chains. This flexibility is widely used by zinc metalloenzymes during catalysis. Another important characteristic is its rapid ligand exchange.

Zinc present in enzymes plays distinct roles, from catalytic or cocatalytic to structural. It is not uncommon to observe mixed functions.

Catalytic Zinc is located in the active site interacting directly with the molecule involved in the reaction. Zinc has a highly localized charge and electron affinity, so it is a very effective attacking element. The

most frequently observed ligand in the active site of zinc metalloenzymes is histidine, followed by glutamic acid, aspartic acid, and cysteine. These ligands account for three or four ligands that can be incorporated with at least one water molecule. The zinc-bound water is a critical component for the catalytic site. It can be ionized to zinc bound hydroxide, polarized by a general base to generate a nucleophile for catalysis, or displaced by the substrate. Thus, a given substrate binds directly to Zn and may displace the metal-bound H_2O molecule. Zinc in this case would act as a Lewis acid polarizing the bound substrate facilitating the nucleophilic attack. This mechanism is observed in aldolases and peptidases. Alternatively, zinc may not bind to the substrate but mediate its function through the metal-bound water molecule. In this case, zinc lowers the pK_a of the bound water molecule. The resultant metal-bound hydroxide ion is the direct agent attacking the substrate. Examples of enzymes in which zinc plays catalytic roles are carbonic anhydrase (EC 4.2.1.1) and carboxypeptidase A (EC 3.4.17.1).

Because of the mechanisms of action and the characteristics of the substrates of zinc metalloenzymes, these enzymes are used in nature preferably for acting on small substrates that cannot be handled by organic groups in a multipoint attachment or when a chemically less specific but very rapid attack is needed.

Cocatalytic This term refers to the participation of more than one metal ion in the catalysis, i.e., the situation in which there are several metal ions bound in proximity to each other, and although all ions play crucial roles in the catalysis, only one is involved directly in the attack. Examples of this group are alkaline phosphatase, which has two zinc atoms and one magnesium atom per mole (EC 3.1.3.1), phospholipase C, which has three zinc atoms per mole (EC 3.1.4.3), and leucine aminopeptidase, which contains two Zn ions per mole (EC 3.4.11.1).

Structural In its structural role, zinc is coordinated with four amino acid chains, usually in a tetrahedral geometry. Cysteine is the most frequently observed ligand, followed by histidine and aspartate. In this situation, zinc atoms contribute to the stabilization of the tertiary or quaternary structure of the protein but do not participate in the catalysis. One such example is the enzyme aspartate carbamyl transferase (EC 2.1.3.2), which has six zinc atoms per mole. These atoms are found in the R subunits tetrahedrally bound by four cysteine thiolates, stabilizing the quaternary structure of the protein.

Structural

The structural role of zinc is related to the participation of zinc in specific cellular or subcellular components. It is an important component in proteins involved in gene regulation and as part of cellular membranes.

Zinc and gene expression Important cellular processes such as transcription, RNA processing, and replication are regulated by protein–DNA and protein–protein interactions. A significant number of such regulatory proteins present domains (or motifs) that are involved in binding to the DNA molecule. A major breakthrough was the identification of such motifs as zinc-containing structures generically termed 'zinc fingers.'

Zinc fingers are usually formed by zinc and cysteine and histidine residues. Tetrahedral coordination of zinc to thio-sulfur of cysteine residues and imidazole–nitrogen of histidine stabilizes the segment in a structure that resembles a finger. In this structure, the zinc atom does not interact directly with the DNA: it acts as a type of scaffolding that confers the required conformation to the overall structure, enabling the DNA-binding domain to bind DNA. Site-specific binding of Zn finger domains to DNA is one of the mechanisms by which proteins modulate gene expression. Zinc finger proteins contain one or more zinc finger domains and include transcription factors, hormone receptors, DNA-repair enzymes, products of oncogenesis, and tumor suppressor genes. Genes encoding zinc finger proteins could amount to as much as 1% of the human genome.

The first transcription factor to be identified as a zinc finger-containing protein was TFIIIA in 1985. TFIIIA is required for the correct initiation of transcription of *Xenopus laevis* 5S RNA genes by RNA polymerase III. The structure of TFIIIA encompasses zinc bound to two cysteine and two histidine residues. This is referred as the classic zinc finger DNA-binding motif.

The steroid (glucocorticoid and estrogen) receptors are members of the multigene family, which also includes receptors for thyroid hormone, retinoic acid, and vitamin D. The steroid hormone receptor has two zinc-finger loops. Steroid hormone receptors are ligand-inducible transcription enhancers that bind specifically to short DNA sequences or hormone response elements and regulate a number of genes. The steroid hormones induce gene expression by binding to receptor proteins in the cytoplasm, causing these proteins to enter the nucleus, bind to DNA, and activate transcription of certain genes.

Other zinc finger-containing proteins are: transcription factor Sp1, NGFI-A/EGR/Krox 24/Zif 268

family, GATA-1, GAL4, the so-called RING-finger proteins (*R*eally *I*nteresting *N*ew *G*ene), and p53. p53 zinc-binding proteins seem to play important roles in the development/suppression of cancer. p53 seems to be involved in the induction of cell-cycle arrest upon identification of increased genomic DNA damage. About 50% of human cancers may involve a p53 dysfunction.

Zinc and membranes Zinc is a structural component of cellular and subcellular membranes. Although its specific roles are only partially known, a number of studies have demonstrated alterations when zinc is reduced in these structures. These include changes in protein structure and lipid concentration, increased red cell fragility and abnormal platelet aggregation, and reduced activities of selected enzymes, such as Ca-ATPase, 5′ nucleotidase and alkaline phosphatase.

Under physiological conditions the major role of zinc is not to be a membrane stabilizer, as previously considered, but a permissive factor for cell signaling. Zn acts by binding to, and maintaining, the tertiary or quaternary structure of several key proteins involved in signal transduction. A crucial feature in zinc deficiency is a defect in calcium channels function, specifically a reduced calcium uptake as result of an abnormal sulfhydril redox state in the membrane channel protein.

Regulatory

Zinc is involved in regulatory functions. One remarkable example is the regulation of the protein metallothionein (MT). MT is a small metal-binding protein characterized by a high cysteine content and a high affinity for heavy metals. There are four isoforms of MT. The functional significance of MTs is not well understood. It is a rather nonspecific metal-buffering ligand to retain or deliver metal ions. Among the proposed roles for MT are: metal donation to target apometallothioneins such as zinc fingers proteins and enzymes, metal detoxification, and protection against oxidative damage. It can also act as a short-term storage reservoir for the metals.

The transcription of MT genes can be activated, among others, by a number of metals, including zinc, copper, and cadmium. Zn is the most important in eukaryotic cells. The regulation of MT gene expression by zinc and other metals occurs via the interaction of the metals with multiple *cis*-acting DNA elements called metal response elements located in the MT gene promoters.

Another regulatory function of zinc is that related to the modulation of the gene-directed cell death process, or apoptosis. A number of studies have demonstrated the importance of maintaining an intracellular pool of zinc atoms to regulate this process. *In vitro* studies have shown that apoptosis is induced when cells are cultured in a zinc-free medium or when zinc is depleted by membrane-permeant zinc chelators. The exact mechanism by which Zn ions intervenes in preventing or reducing apoptosis is not completely understood. Zinc may interact with one or more participants of the apoptosis process. Thus, initial studies have proposed that zinc inhibits the activity of the Ca–Mg-dependent endonuclease, whereas others have proposed that zinc might block the mechanism by which the inactive procaspase-3 is activated. Zinc is a selective inhibitor of caspase 6, which promotes activation of caspase-3. It has also been proposed that zinc may participate through its antioxidant roles.

A series of recent reports have documented the participation of zinc in a variety of signal-related functions. Thus, β-2 adrenergic receptors are allosterically modulated by zinc. Zinc has been shown to increase the excitability of dopaminergic neurons in rat substantia nigra, to modulate signals from red- and short wavelength-sensitive cones to horizontal cells in carp retina, and to induce the stimulation of the c-Jun N-terminal kinase signaling pathway through phosphoinositide 3-kinase. Some observations in cultured cells have suggested the existence of a zinc-sensing receptor that triggers the release of intracellular Ca^{2+} and regulates ion transport.

Zinc Determination

Compared with other essential or toxic trace elements, such as selenium or arsenic, zinc does not present any major problems for its determination in a wide variety of matrices, and consequently, a large number of methods are used for its quantification. A detailed discussion of the basis, advantages, and limitations of each methodology is beyond the scope of this chapter, but there is abundant literature elsewhere on specific issues relating to zinc.

Principal Methods to Determine Zinc in Biological and Environmental Samples

The methods used to determine zinc are based on several physical, chemical, and nuclear characteristics of the atoms, including zinc. Some of the methods used to determine zinc are listed in Table 4.

Atomic absorption and atomic emission spectrometry are based on the property of the atoms to absorb or emit light energy during energy transition from ground states to excited states or during decay. By far the most commonly used method to determine zinc is atomic absorption spectrometry (AAS). For zinc, the analysis is usually conducted using a

Table 4 Methods to determine zinc in biological and environmental samples

Flame atomic absorption spectrometry

Photon activation analysis
Instrumental neutron activation analysis
Inductively coupled plasma mass spectrometry

wavelength of 213.9 nm. This method provides accurate and precise results, and the cost of the equipment and maintenance are low compared with most of the other techniques. The detection limit in its flame mode is about 100 $\mu g\,l^{-1}$ (or 100 p.p.b.). This detection limit is greatly improved, more than 200 times, when used with the graphite furnace. The significant improvement in sensitivity is also accompanied by a higher degree of interferences, mainly matrix effects. Similarly, the sensitivity of atomic emission spectrometry is improved when inductively coupled plasma is used. Unlike flame atomic absorption spectrometry (FAAS) or graphite furnace atomic absorption spectrometry, inductively coupled plasma-atomic emission spectrometry provides the capacity for performing multielemental analyses. Potentiometric methods, such as differential pulse anodic stripping voltammetry have shown analytical performances comparable with FAAS in simple matrices. The main advantage of potentiometric methods is the simplicity of the equipment and lower costs. It has been suggested as a candidate for routine clinical chemistry.

The group of nuclear analytical methods suitable for zinc determination includes a number of methods, such as: energy-dispersive X-ray fluorescence, total reflection X-ray fluorescence, proton-induced X-ray emission (PIXE), photon activation analysis, and instrumental neutron activation analysis (INAA), among others. These methods have detection limits in the range of p.p.b. to p.p.t. Some of them are based on the excitation of characteristic X-rays in a sample by electromagnetic radiation from an X-ray tube or radioactive source (X-ray fluorescence methods) or by accelerated charged particles (PIXE). Photon-activated analysis is based on photon emission after irradiation. INAA is a multielemental method that has been widely used for zinc and other trace element analysis. It is based on the measurement of the γ radiation produced after irradiation. For zinc, the reaction is ^{64}Zn (n, γ) ^{65}Zn. Gamma radiation from the long-lived nuclide ^{65}Zn is usually measured 15 days after irradiation.

Inductively coupled plasma mass spectrometry (ICP-MS) has shown remarkable advances in sensitivity and reliability for mineral analysis. The regular equipment is an ICP-quadrupole mass spectrometer, which has a detection limit in the range of p.p.t. with concomitant high precision and accuracy. This is a versatile technique that can be coupled to chromatography systems for other applications such as high-performance liquid chromatography–ICP-MS. New versions of high-performance ICP-MS include ICP magnetic sector-MS and ICP ion trap-MS. These are intended to reach detection limits in the low p.p.t.–p.p.q. range. ICP-MS can determine not only the total element concentration but also its individual stable isotopes.

The use of stable isotopes has proven to be a powerful tool in the field of zinc nutrition and zinc metabolism. Because they do not emit radiation, they can be safely used as tracers in any age/physiological condition group. This requires techniques with the capacity for performing highly accurate and precise determination of isotope ratios. Among the methods suitable for stable isotope determinations are: neutron activation analysis, electron ionization-mass spectrometry, gas chromatography-mass spectrometry, fast atom bombardment-mass spectrometry, thermal ionization mass spectrometry (TIMS), and ICP-MS. Of these, TIMS and ICP-MS are recognized as the techniques with the best results in terms of accuracy, precision, and sensitivity.

Regardless of the method used to determine zinc, an appropriate quality assessment of the procedures should be conducted, considering both precision and bias evaluation. The former is conducted through repetitive measurements and internal test samples, and the latter is accomplished through a series of actions such as the use of different operators or equipments, use of reference materials, participation in intercomparison rounds, external audits, etc.

The determination of zinc in biological samples can serve several purposes. One of the most commonly used applications has been the assessment of zinc status. Thus, zinc has been determined in: plasma, serum, hair, skin, semen, sweat, saliva, urine, neutrophils, lymphocytes, platelets, erythrocytes, and erythrocyte membranes. Although the determinations of zinc in these fluids or tissues have been conducted appropriately from an analytical point of view, they have shown limitations as indicators of zinc nutriture. These limitations also extend to other methods such as the activity of several zinc enzymes, including alkaline phosphatase (EC 3.1.3.1), α-D-mannosidase (EC 3.2.1.24),

5′ nucleotidase (EC 3.1.3.5), angiotensin-1-converting enzyme (EC 3.4.15.1), and several functional tests. (*See* **Nutritional Assessment:** Biochemical Tests for Vitamins and Minerals.)

Background

It was first established in 1869 by Raulin that zinc was essential for the growth of bread mold. In the twentieth century, it was discovered that zinc was essential for the growth of rats and to prevent the parakeratitis dermatological condition of swine. The essentiality of zinc, and its requirements, has been established in species from the protozoa, *Euglena gracilis*, to the steelhead trout. Most recently, the critical role that nutrition plays in the nutrition of the retrovirus of AIDS has been revealed. This article considers three topics: the normal metabolism of zinc by the body; aberrations of its metabolism; the physiological and biochemical functions of zinc for the organism. Emphasis will be placed on zinc in human nutrition.

Normal Metabolism of Zinc

Absorption of Zinc

Mechanisms of normal absorption Zinc is not absorbed in the esophagus or stomach but can be taken up along all parts of the small intestine (duodenum, jejunum, and ileum) with varying efficiencies and, to some extent, in the large bowel. The form of zinc in the diet, soluble in beverages or bound in food matrices, may determine the part of the alimentary tract in which the zinc is absorbed. In healthy humans, the fractional absorption of isotopically labeled oral zinc ranges from 40 to 70% from aqueous solutions and 2 to 40% in the presence of various foods and meals.

The cellular mechanisms and kinetics of zinc absorption have been studied extensively. It is likely that zinc, freed from food, is complexed to some small molecules as it approaches the brush border. Uptake across the mucosal membrane can be by a simple diffusion (nonsaturable) mechanism of low permeability and dependent upon the concentration gradient between lumen and blood, taking a paracellular pathway after membrane transport or by a carrier-mediated and energy-dependent (saturable) mechanism, which is most important at low intraluminal concentrations.

Once within the cell, an element of zinc has a multitude of possible designations. It can become part of the zinc nutrition of the enterocyte, itself; it can remain in the cell, eventually being bound to metallothionein (MT), a 6000–7000-Da peptide, with 61 amino acid residues, and then lost back into the lumen of the intestine when the cell is desquamated; or it can pass on to the serosal surface of the cell, possibly bound to intracellular ligands or binding proteins to be released into the body. The level of preexisting MT in the cell has been thought to regulate the amount of zinc available for exit into the bloodstream, but microvesicles may participate in the transport of the zinc that is eventually taken up by the circulation. The final exit step of zinc into the body may be energy-dependent, coupled to basal membrane adenosine triphosphate.

Zinc absorption appears to be homeostatically regulated, in so far as uptake is reduced in sufficiency

or excess, whereas in deficiency, the uptake is enhanced. In zinc-depleted subjects, more than 90% of a highly available dose can be absorbed. The amount that passes through the enterocyte by diffusion is related to the mucosal–serosal gradient and is unrelated to the zinc status of the host. It is the carrier-mediated active absorption that is responsive to underlying zinc nutrition. In animal experiments and human experience, zinc absorption from the diet has been shown to increase during both pregnancy and lactation.

The more zinc there is available to the intestine in a meal, the lower is its fractional absorption. However, the amount of zinc that reenters the intestinal lumen is now recognized to be a dynamic function of the quantity of the mineral absorbed from the diet. (*See* **Lactation**: Physiology; Human Milk: Composition and Nutritional Value.)

Bioavailability of zinc from the diet Bioavailability strictly refers to both the uptake and metabolic utilization of a nutrient. Since different valence states or chemical species are not an issue with zinc, the biological availability of zinc relates exclusively to the efficiency of its absorption. (*See* **Bioavailability of Nutrients**.)

In theory, zinc must be either in soluble form or bound to soluble, absorbable species to be absorbed by the intestine. The efficiency of mastication and gastric and pancreatic protease digestion of food determines the extraction of zinc from its food matrices. Once liberated and dissolved, the zinc ion needs to remain in solution and proceed in its transit through or around the enterocytes.

Substances that influence intestinal permeability to zinc are also mediators of bioavailability. A series of dietary substances influence the bioavailability of zinc, either by chelating or binding zinc or by competitively inhibiting its absorption. Two common components of whole-grain cereals – phytic acid and dietary fibre – are the most important substances that interfere with zinc absorption. Polyphenolic substances (tannins) in tea and coffee and oxalic acid of green leafy herbs are also inhibitors. Calcium and dietary nonheme iron are two inorganic elements that interfere with zinc uptake by direct competition. (*See* **Dietary Fiber**: Effects of Fiber on Absorption; **Phytic Acid**: Nutritional Impact.)

Alternatively, a series of compounds have been suggested as *enhancers* or *promoters* of zinc absorption, including amino acids, sugars, picolinic acid, citric acid, and prostaglandins. Only the first two classes of compound are likely to be of physiological significance. Red wine has been shown to enhance zinc balance under metabolic conditions. Ascorbic acid and lactose have a *neutral* influence on zinc bioavailability.

It should be remembered that bioavailability refers to a fractional efficiency of uptake, and the *total amount* of zinc ingested is a codeterminant of how much net nutrient will be absorbed. If the zinc intake is high in a diet of poor zinc bioavailability, the amount absorbed may still be sufficient to support true nutritional requirements.

Enteropancreatic circulation With each meal, a large volume of bile, pancreatic juice, and salivary, gastric, and intestinal secretions are secreted into the intestinal lumen, with pancreatic juice being the richest in the metal. Within the lumen, the endogenous zinc forms a common pool with that from oral intake. Some of the pancreatic zinc is not recovered and passes into the stools, but a substantial part is reabsorbed and becomes part of internal metabolism once more. This constitutes an enteropancreatic circulation for endogenous zinc. By virtue of this 'double jeopardy' of zinc to dietary inhibitors, the body can be more rapidly depleted of this nutrient than of most others.

Net daily zinc metabolic balance In growing individuals, more zinc should be taken in than excreted *on average* on any given day. Adults with a normal total body content of zinc should be in essentially zero balance, with the amount absorbed equal to the amount lost by all routes (see below). In pregnancy and lactation, the products of conception and the daily secretion of milk represent additional depots for newly absorbed zinc. In 1973, an expert committee of the WHO first used a factorial approach to estimate the amount of zinc that must be absorbed daily to account for deposition for growth and losses from the body in infants, children, and adolescents, and to account for losses in adults. This amount of zinc is often referred to as the 'true zinc requirement,' to distinguish it from the daily dietary *intake* requirement, and the daily dietary *allowance*. Estimations of the amount of *dietary* zinc to be absorbed daily have been refined by subsequent consultancies, the most recent being from the World Health Organization and the International Atomic Energy Agency in 1996 and from the US Food and Nutrition Board in their *Dietary Reference Intakes* process in 2001. For infants aged 6–12 months, it is 0.8 mg; for children aged 6–10 years, 1.1 mg; for men over 18 years, 1.4 mg; and for women over 18 years, 1.0 mg. During pregnancy, absorption daily from zinc in the diet should be 1.5 mg, rising to 1.8 mg during the first 6 months of lactation, and declining to 1.4 mg during the duration of the period of breast-feeding. Of

course, the amount of zinc reabsorbed from the endogenous sources of the mineral that enters intestinal lumen as part of pancreatic, biliary, and intestinal secretions with meals is at least equivalent to the dietary requirement. So, a rough calculation of the daily net absorptive demand across the intestine would involve a doubling of the aforementioned age- and physiology-specific values. (*See* **Dietary Requirements of Adults**.)

Distribution and Transport of Zinc

Distribution of zinc The total body content of zinc in normal individuals has been measured by isotopic dilution studies and ranges from 1.5 to 2.5 g. It is higher in men than in women and decreases with increasing age in adults. At the tissue level, the content of zinc is heterogeneous, ranging from 20 to 200 $\mu g\,g^{-1}$ in most tissues, and up to 600–800 $\mu g\,dl^{-1}$ in pancreas, gonads, and retina. Within the cell, zinc is ubiquitous but compartmentalized, being found in nuclear, mitochondrial, and cytosolic fractions.

The two major depots for zinc in the body are skeletal muscle and the skeleton, which contains, respectively, 57 and 29% of the zinc in an individual. Skin and liver share an additional 10%. The percentage of the total body content of zinc in the 7-l volume of peripheral circulation is less than 0.1%.

The uptake of newly absorbed zinc is greatest in the liver. Structural tissues, such as bone and skin, and functional tissues, such as kidney, thymus, pancreas, and gonads, have high rates of uptake, which implies high rates of intracellular turnover.

Transport of zinc Zinc that passes through and around the enteral cell, from the intestinal lumen, enters the capillary circulation of the gut and returns by the mesenteric and portal circulation to the liver. Some of the zinc is taken up by hepatic cells, and the remainder passes into the systemic circulation.

Since zinc would be filtered and lost by the kidney were it not bound to large, nonfilterable molecules or to reabsorbed species, it circulates in bound states in the systemic circulation. Forty per cent of zinc is a covalently linked component of α_2-macroglobulin, and most of the remainder is loosely bound to serum albumin. A small fraction is chelated to serum free amino acids or small peptides. About 3–5 mg of newly absorbed zinc and additional quantities moving from one site to another pass through the circulation daily; the flux of the transport pool is rapid. Hormones (glucocorticoids, glucagon catecholamines) and monokines (interleukin-1, tumor necrosis factor) modify zinc uptake and turnover in peripheral tissues. Whether or not a peripheral cell zinc receptor exists for the capture of the nutrient from the systemic bloodstream has not been determined.

In reproductive biology, two additional aspects of zinc transport – transplacental and mammary gland transport – are important in normal metabolism. Zinc can move bidirectionally from the maternal circulation to the fetus, and from the fetus to the mother, but the net flux is toward the fetus. The flux is rapid, and the size of the transfer is proportional to the mass of the fetus, increasing with advancing gestation. Some 75% of the zinc in amniotic fluid is bound to albumin. The exact mechanism for transfer of zinc from plasma to mammary gland, and within the gland into the breast milk, is poorly understood. The concentration of zinc decreases progressively with duration of lactation. A multinational study of seven countries, conducted by the International Atomic Energy Agency, showed that zinc concentrations in breast milk vary from nation to nation, and within countries from rural to urban dwellers. However, in experimental studies, high oral doses of zinc did not modify the zinc content of healthy mothers.

Retention and Excretion of Zinc

Zinc storage and retention Despite the relatively large amount of zinc in the body, and its ubiquitous distribution, most is either in active functions in metabolism or in nonretrievable deposits in bone, muscle, and integument. There is a consensus that if any metabolic storage pool of zinc exists to act as a reserve against nutritional compromise, it is small in relation to the total body content of the mineral. It is now postulated that the mobile exchangeable zinc pool constitutes about 10% of the total body zinc, i.e., is 150–250 mg. Thus, a cumulative deficit of 100–200 mg, i.e., the obligatory losses of 20–40 days, could be critical.

In tissues with active uptake and turnover of zinc, such as liver, kidney, pancreas, and gut, the metal-binding protein MT is prominent, and its synthesis is regulated and responsive to zinc availability. MT expresses its high affinity for divalent cations and is related to the 20 sulfur-containing cysteine residues. It is believed to constitute a cytosolic storage pool or buffer to regulate concentrations of free ions within the cytoplasm. It has a rapid turnover of 20 h and is subject to regulation or influence by a number of hormones and pathological conditions.

Zinc excretion A number of routes are available for zinc excretion from the body. In the zinc-adequate state, the excretion is proportional to the total body burden of the nutrient. Some pathways for zinc excretion are not regulated. Among these are those

via the integumentary tissues, i.e., the growing out of hair, the desquamation of skin, and sweating.

The major route for excretion of the zinc of the active metabolic pool is into the fecal stream from pancreatic and intestinal secretions. Low zinc status produces conservation of zinc, whereas zinc excess leads to enhanced fecal excretion. Adults chronically consuming 10–15 mg of dietary zinc excrete about 500 μg of zinc in the urine daily. With severe zinc restriction, the renal excretion in 24 h is reduced to 200 μg. When zinc is perfused parenterally or consumed orally in pharmacological amounts, a manifold increase in renal excretion is observed.

Pathophysiological Metabolism of Zinc

Several conditions can produce a pathophysiological metabolism of zinc. Its malabsorption is produced in short-gut or pancreatic insufficiency. Diarrheal disease, protein-losing (exudative) enteropathy, and enterocutaneous fistulas produce a wasting of endogenous zinc into the stools. Excessive renal losses are seen in primary renal disease, in certain endocrinopathies such as diabetes mellitus, with infection and stress, and with severe exercise.

Infection and stress induce a cascade of hormonal responses including the secretion of glucocorticoid and catecholamine hormones and the peptides from circulating monocytes and fixed macrophages (cytokines), which produce an internal redistribution of zinc with redirection of the mineral to the liver and the bone marrow. A primary effect of the hormones and cytokines may be to induce the synthesis of MT, which captures and holds zinc in the cells. A teleological explanation of this filtering of zinc from blood to liver and bone marrow would be to facilitate the hepatic synthesis of acute-phase protein and the proliferation of new lymphocytes or neutrophils.

Physiological, Metabolic, and Biochemical Functions of Zinc

Physiology at the System Level

Below is a comprehensive listing of the physiological and metabolic functions of mammalian organisms, including humans, that are dependent on zinc. The inference of their dependence is based primarily on zinc-restriction experiments in laboratory animals and livestock, along with some zinc-deprivation experiments in humans, in which the performance is altered with decreasing zinc status.

- growth of cells;
- replication of cells;
- antioxidant (antifree radical) protection;
- regulation of neurotransmission;
- insulin and leptin metabolism;
- sexual maturation;
- spermatogenesis;
- oogenesis;
- cellular apoptosis;
- dark adaptation or scotopic vision;
- cellular immunity;
- humoral immunity;
- appetite regulation;
- taste acuity;
- olfactory acuity;
- cognitive function.

Biochemistry at the Cellular and Molecular Level

Zinc is a unique element among the traditional metals in so far as it exists exclusively in the divalent oxidation state and has no redox potential. Its coordination chemistry is alternatively tetrahedral (four ligands) or trigonal bipyramidal (five ligands) geometry, coordinated by the negative charges of a sulfur of cysteine, a nitrogen of histidine, or an oxygen from aspartate and glutamate in various combinations. Within the organized complexes, the protein at the center exerts an intense positive charge. Zinc in proteins can participate directly in catalytic reactions or maintain stability and structure conformation of proteins.

Zinc metalloenzymes A zinc metalloenzyme is an enzyme that has a specific requirement for zinc as a cofactor or as an integral, coordinated firmly complexed moiety within the structure of the protein. In the latter circumstances, the zinc ion(s) can participate at the active site of the enzyme in its catalytic activity in either the 4- or 5-coordination configurations in association with a molecule of water. The transformation of water by the dense charge and acid–base equilibrium provides the energy for the catalytic properties. Alternatively, complexed zinc can serve a role in stabilizing the conformation of the protein. A selected number of the estimated 300 enzymes in nature that have been confirmed as zinc metalloenzymes are listed below:

- aldolase (fructose 1, 6-biphosphatase);
- alcohol dehydrogenase;
- alkaline phosphatase;
- carbonic anhydrase;
- carboxypeptidase A;
- carboxypeptidase B;
- collagenase;
- δ-aminolaevulinate dehydratase;
- deoxynucleotidyl transferase;
- DNA polymerase;
- enkephalinase;

- glutamic acid dehydrogenase;
- lactic dehydrogenase;
- malic acid dehydrogenase;
- pyruvate carboxylase;
- nucleoside phosphorylase;
- reverse transcriptase;
- DNA polymerase I;
- RNA polymerases I, II, and III;
- thermolysin;
- zinc–copper superoxide dismutase.

Zinc metalloenzymes are not restricted to mammalian enzymes: some examples are found in plants, bacteria, and viruses. Some of the pathogenesis of zinc deficiency can be attributed to defects in the reactions catalyzed by zinc metalloenzymes. For example, the impaired dark adaptation and night blindness of zinc deficiency have been attributed to a defective functioning of the alcohol dehydrogenase (retinol dehydrogenase), found in the retina, that is responsible for the conversion of retinol to retinaldehyde for the regeneration of the visual pigment, rhodopsin, in the rods of the retina. (*See* **Coenzymes**.)

Other putative cellular and molecular roles of zinc The other generic manner in which zinc, possibly in a freely exchangeable, ionic form within the cell, is in the stabilization of membranes, of membrane–protein associations, and of macromolecular structures. The association of protein kinase C with cell membranes, for example, depends on zinc.

Zinc has long been known to stabilize polyribosomes, and this is one of the putative roles of the nutrient in protein synthesis. More recently, a role for zinc, tightly complexed to amino acids in chains of peptides within the chromatin proteins of the nucleus of the cell, has been shown for expression of genetic information. A series of 'zinc finger' proteins have been characterized. The name derives from the rigid projection of a loop of protein (a finger), stabilized by the zinc in tetrahedral coordination with four amino acids; the most common motif is one coordinated with two cysteine and two histidine residues. Over 2000 different domains of these zinc finger proteins for regulating the expression of specific genes along the chromosomes, allowing a determined amount of the genetic code to be translated to its complementary messenger RNA, have been identified in the last decade. Functions of enzymes that do not contain zinc themselves may be impaired in zinc deficiency because of a defect in a zinc finger protein that governs its translation in the nuclear reserves of genetic information.

A specific form of transcriptional regulation is known as the metal regulating element, which is involved in the regulation of MT synthesis presumably in response to the cellular levels of zinc that exist. Hence, the amount of zinc entering the cell influences an MT transcription factor associated with this MRE in the chromosome coding for MT and accounts for the up- or downregulation.

Two levels of zinc's participation in genetic expression, i.e., in zinc finger transcription regulators and in polyribosome, may also help to support the theory, proposed by Mills, that increased protein degradation is a generic consequence of zinc deficiency, one that explains the defects in growth and the rapidity of the onset of manifestations after restriction of dietary zinc.

Tissue cells are constantly dividing, but the net cell mass of an organ remains constant. Apoptosis is the process of genetically programmed death of cells by which certain cells within the tissue 'commit suicide' to maintain the balance of mass and structure. Each cell has this potential in a series of 'procapase' protease proenzymes that can become activated to produce a cascade effect leading to nuclear involution, cytosolic dissolution, and loss of attachment. Zinc is among the dietary constituents involved in this process. A decrease in intracellular zinc concentration precedes the physiological and anatomical cellular changes of apoptosis.

Finally, the molecular basis of zinc's role in immune protection has not been elucidated. Its roles in cell proliferation and thymic function are basic but combined with regulation of cytokine production, modulation of apoptosis, and a function of induced metallothionein as a scavenger of harmful free radicals in the cell cytoplasm.

Deficiency

N W Solomons, CeSSIAM, Guatemala City, Guatemala

Background

Zinc is an essential nutrient for all living species. Human zinc deficiency was first described in patients as a secondary consequence of alcoholic cirrhosis in 1956. In 1961, human zinc deficiency was first described on a *dietary* basis in rural, Iranian children. Since then, clinical zinc deficiency has been described in all age groups from breast-fed infants to the very elderly. For both the clinical nutrition of hospitalized patients and the public health at the community level, human zinc deficiency has emerged as a relevant concern over the past three decades.

Mechanisms for the Pathogenesis of Zinc Deficiency

Only a very small 'exchangeable zinc pool,' sufficient for a few days' nutrition, exists in human body, and the major deposits of the metal in bone or muscle cannot be readily mobilized for nutritional purposes. Zinc in excess of short-term metabolic needs is either excluded from absorption or excreted by the kidneys or via the alimentary tract. The human organism lives with a perpetually marginal zinc nutriture by evolutionary design and is dependent upon regular dietary replenishment.

Certain extrinsic conditions and intrinsic situations can place an individual at increased risk of zinc depletion. Victor Herbert developed a conceptual framework for understanding the genesis of deficiencies of any nutrient based on six mechanisms that operate alone, or in combination, to contribute to the development of deficiency; these include: decreased intake, decreased absorption, increased destruction, increased excretion, decreased utilization, and increased requirements. With the exception of destruction, which is not relevant to inorganic nutrients, this scheme provides a focus for understanding the ways in which human zinc deficiency can occur.

With respect to zinc, primary deficiencies arise when the supply to the body, either by an oral/enteral (dietary) route or by parenteral nutrition, is insufficient to match losses and/or meet demands for growth. Selection of a zinc-poor diet, be it for cultural, socioeconomic or eating-disorder motives, can produce deficiency. When a patient is dependent on intravenous nutrition, improper formulation of the nutrient fluids can precipitate a primary deficiency. Impaired absorption of zinc results from digestive difficulties that impede its release from foods, interference with its mobility or solubility that inhibit its absorption, or intestinal membrane pathologies that impair its uptake. Increased zinc losses from the body can occur as a result of a hemorrhagia, superficial losses, excessive diuresis, or gastrointestinal tract wastage into stool. Decreased utilization can occur in inflammation, infection, and metabolic disorders. Thermal burns, catch-up growth, multiple pregnancies (twinning, triplets), lactation, and rampant malignancies are conditions that place additional demands on the supply of zinc. These factors can operate alone or in various combinations. In the case of an inflammatory bowel disease such as severe Crohn's enteritis, one might see the combination of: (1) reduced intake owing to anorexia; (2) impaired absorption owing to mucosal damage; (3) increased losses through bleeding and protein-losing enteropathy; and (4) impaired utilization owing to activation of the acute-phase response. Increased requirements for zinc might even occur in this disease if an adolescent patient develops a remission leading to rapid compensatory growth and sexual development after a period of growth arrest. (*See* **Bioavailability of Nutrients**.)

Once the body pool of zinc has contracted beyond a critical level, however, the exact molecular basis of the pathogenesis of zinc deficiency is poorly understood. Michael Golden has classified the deficiency of zinc as a type II nutritional deficiency, similar to deficiencies of the intracellular nutrients nitrogen, phosphorus, magnesium, and potassium, in which there is conservation of tissue concentrations at the expense of growth and development. This is especially true of zinc deficiency in experimental animals, in which restriction of the nutrient produces marked anorexia, immediate cessation of growth and reproductive capacity, and even weight loss; combined with regulated conservation of nutrient, it allows the ratio of body zinc content to body mass to remain relatively constant. Animals will not readily eat a zinc-deficient ration that is producing a deficiency state. Only with force-feeding will a diet of low zinc density produce tissue desaturation. In humans, however, social and cultural factors intercede to overcome whatever

anorexia might result from consumption of a zinc-poor diet or one that has a poor zinc bioavailability; thus, people – as opposed to animals – will consume generous amounts of energy and protein while on zinc-deficient diets. An opposing combination of conservation and desaturation of tissue zinc can therefore occur in humans. The fact that a certain degree of conservation of tissue zinc is maintained under conditions of zinc-poor diets does not eliminate the possibility of the intracellular and molecular roles of the nutrient being disrupted and altered by the responses to zinc deprivation.

How the deficiency manifestations, described below, are related to zinc deficiency at the tissue and cellular level is still poorly understood. Between 60 (conservative estimate) and 300 (generous estimate) enzymes, are believed to be zinc metalloenzymes or enzymes dependent on zinc as a cofactor in their catalytic activity. Specifically, the disruption of cell proliferation that leads to growth failure and to impairment of function of cells in the gut and bone marrow that are rapidly turning over can be attributed to the defects in enzymes responsible for DNA regeneration and RNA production. Furthermore, over 2000 nuclear transcription factors that employ zinc to regulate their protein configuration during gene activation (zinc finger proteins) have been identified in the past decade. Recently, *in vitro* experiments have confirmed that decreasing cellular zinc restricts the expression of a zinc-finger transcription factor for regulation of interleukin-2 in lymphocytes. Zinc deficiency promotes protein degradation and enhances protein turnover; this would explain both the rapid response to zinc deficiency by growing animals and the limitation of total growth. (*See* **Coenzymes**.)

The loss of stabilization of intracellular structures by zinc in a freely exchangeable intracellular form also accounts for some of the molecular defects in zinc deficiency. Zinc is thought to stabilize membranes, to stabilize ribosomes, and to contribute to associations between membranes and functional proteins. Soluble zinc plays a role in signaling among cells and between compartments within cells.

Manifestations of Zinc Deficiency

Clinical Signs and Symptoms

Deficiency in laboratory animals and livestock We have understood human zinc deficiency better using the basis in its observation and study in laboratory rodents, as well as poultry, swine, ruminants, felines, canines, and subhuman primates. The dietary regimens have various formats, including *ad libitum* feeding of a zinc-poor diet with pair-feeding of control animals as well as force-feeding of an energy-adequate, zinc-depleted ration. Clinical manifestations documented in zinc restricted animals have included dermatitis and hair loss, depressed immune functions, altered reproductive performance, teratogenesis, and skeletal abnormalities.

Deficiency in human adults Although the anorectic response does not dominate in humans with either primary, experimental or secondary zinc deficiency, substantial homology exists between the clinical manifestations in animals and those in humans. The manifestations of zinc deficiency in humans have been catalogued from observations of iatrogenic deficiency, genetic predisposition (acrodermatitis enteropathica), patients with secondary deficiency, endemic deficiency situations, and experimental depletion in volunteers. Recently, there has been a trend to use the response of populations suspected of endemic zinc deficiency to define functional manifestations of deficiency. As a rule, as the severity of zinc deprivation increases, there are a wider array and a greater intensity of clinical manifestations. In chronic deficiency, the zinc deficiency manifestations have a gradual onset, whereas in acute deficiency, signs and symptoms appear rapidly.

The manifestations of human zinc deficiency include the following: behavioral alterations and central nervous system change (anorexia, depression, psychosis, hypogeusia, hyposmia, night blindness, seizure disorder, impaired cognitive performance); integumentary changes (bullous, pustular lesions; keratotic lesions; rough skin; loss of scalp, facial and body hair; impaired wound healing); gastrointestinal manifestations (diarrhea, impaired nutrient digestion and absorption); impaired growth and development (linear growth retardation; weight loss); altered reproductive biology (oligospermia; hypogonadism and reduced potency; fetal teratogenesis); and impaired immunity (recurrent infections; reduced delayed cutaneous hypersensitivity). Situations such as acute deficiency induced during total parenteral nutrition, or the congenital zinc malabsorption syndrome, *acrodermatitis enteropathica*, can bring out the most severe extremes, with manifestations from all systems. In a mild deficiency, anorexia, dry rough skin and oligospermia may be the only manifestations.

Deficiency in children and adolescents All of the signs and symptoms discussed above for adults, with the exception of those related to reproductive function, can be manifested in children and adolescents. However, the imperative of growth and development add additional dimensions to clinical manifestations.

Slow growth leading to growth retardation or even periods of growth arrest are seen in pediatric zinc deficiency. The juvenile deficiency also delays development of puberty and secondary sexual characteristics in both boys and girls. A neonatal seizure disorder has been ascribed to zinc deficiency in preterm infants, a manifestation apparently unique to this specific age-group. (*See* **Adolescents; Children:** Nutritional Problems; Nutritional Requirements; **Infants:** Nutritional Requirements.)

Physiological and Metabolic Consequences

Certain physiological and metabolic consequences of human zinc deficiency do not manifest with clinical signs and symptoms, but are detectable in the laboratory. The physiological alterations of zinc deficiency (information gathered from animal experiments or experimental restrictions in humans), including structural changes in microstructures, hematological abnormalities, metabolic and endocrinological alterations, immune defense defects, nervous system problems, changes in the homeostatic regulation of zinc supply, and assorted miscellaneous changes, are summarized below:

- impaired cell replication;
- impaired collagen synthesis and cross-linking;
- disorganized tubulin synthesis;
- dysplasia of buccal and esophageal mucosa;
- dense inclusion bodies in Paneth cells of the intestine;
- changes in pancreatic exocrine secretion;
- impaired tocopherol absorption;
- impaired platelet aggregation and prolonged bleeding time;
- increased amino acid oxidation;
- reduced leptin gene expression and leptin secretion;
- elevated plasma ammonium levels;
- impaired rhodopsin regeneration in retina;
- synthesis of retinol-binding protein and transport of retinol;
- impaired insulin secretion;
- impaired glucose tolerance;
- elevated cholesterol;
- deranged essential fatty acid and prostaglandin metabolism;
- decreased gonadal hormone production;
- increased lipid peroxidation;
- impaired cellular immunity;
- decreased CD4+: CD8+ T-cell ratio;
- decreased CD73+/CD11b T-cell ratio in the CD8+ subset;
- thymic hypoplasia and atrophy;
- decreased production of thymulin;
- structural changes in the brain;
- decreased seizure thresholds;
- changes in neurotransmitter storage and metabolism;
- decreased peripheral nerve conduction time;
- alteration of taste bud morphology;
- decreased metallothionein synthesis in liver and intestine;
- enhanced absorption of dietary zinc;
- increased retention of zinc; decreased urinary and fecal loss;
- decreased growth of tumors;
- impaired thermal regulation.

Assessment of Human Zinc Nutriture

The assessment of human zinc nutriture is complicated and confounded by issues related both to zinc biology and to analytical chemistry. In theory, the approach to define the status of an individual for any nutrient is to measure the total body pool and/or its availability to the sites of activity. In Golden's concept of a type II nutritional deficiency, the overall amount of zinc in the body or its concentrations in the tissues will not be severely altered; rather, adaptations such as growth arrest and retarded development will occur at an early stage of sensing zinc restriction, and tissue concentrations will be relatively conserved.

Tests that Assess the Total Body Pool and Various Component Pools

The only conceivable direct approach to estimating total-body zinc content is in a postmortem chemical examination or by *in vivo* neutron activation analysis. Neither is practical in the context of patients or populations. One can estimate total-body zinc by isotopic techniques. Radiozinc (^{65}Zn) and several stable isotopes serve in this connection. However, such is the nature of zinc biology that it makes it inappropriate to speak of standing zinc 'stores' or 'reserves.' For this reason, biopsies of various tissues such as bone and muscle would provide a less than useful index of zinc that is available for metabolic purposes.

Rather than ask how much total zinc is in the body, we must search for indicators of the metabolically active or nutritionally relevant zinc. Using multiple isotopes and complex mathematics, the size of various component pools, including the 'exchangeable zinc pool' can be estimated to provide a reliable estimation of individual 'nutriture.' More commonly, less expensive indirect measures are used, with the circulating concentration of zinc (in plasma or serum) being the most common, followed by whole-blood

zinc. In zinc deficiency, the concentration in the circulation declines. Unfortunately, it also declines for a myriad of reasons from normal meal patterns to stress and infection to prolonged fasting to use of contraceptive hormones, etc. The zinc in the circulation at any given moment, however, represents less than 0.01% of the total body supply. For the individual, a normal zinc level is a reasonable indication of adequate status, but an isolated low value is difficult to interpret. For populations, however, the prevalence of low zinc concentrations provides the best epidemiological diagnostic assessment.

The recent development of assays for circulating metallothionein I suggests the possibility of a substance that is low when the body demand is high and high when the demand is low. Newer tests (functional, see below) that are based on the state of regulation and expression of the metallothionein gene may be more sensitive with fewer confounding factors than any assay for the metallothionein protein itself, and more reflective of an active zinc pool. (*See* **Nutritional Assessment**: Importance of Measuring Nutritional Status; Biochemical Tests for Vitamins and Minerals.)

Tests that Assess Tissue Concentrations

A series of accessible tissues can be biopsied and assessed as indicators of zinc availability at peripheral sites, including: platelet zinc, lymphocyte zinc, granulocyte zinc, red cell zinc, buccal mucosa zinc, hair zinc, and nail zinc. The former three circulating cellular elements, in theory, represent tissue that is more rapidly turning over, and hence would represent more current peripheral availability. More than 50% of all circulating red cells are over 60 days old. Studies in experimental mild zinc deprivation in volunteers have shown that levels of zinc decline much earlier in platelets, lymphocytes, and granulocytes than in red cells or plasma. Buccal mucosa is easy to obtain, but it can be contaminated by other sources of zinc. The final three options represent integumentary tissue in which the zinc may be deposited in proportion to the zinc that was mobilized to the underlying, active dermal, or mucosal tissue. For hair and nails, however, the rate of outward growth operates independently of the deposition of the nutrient into the roots, confounding the interpretation of zinc content and concentration.

Tests that Assess the Intactness of Zinc-dependent Functions

The functional assessment of nutritional status involves evaluating the intactness of zinc-dependent physiological functions. For zinc, performance-related tests include growth attainment, gustatory acuity, immune functions, dark adaptation, serum thymulin activity and reconstitution, and zinc metalloenzyme activities, to mention some of the more readily available options. The ratios of specific CD markers on T-lymphocytes represent a newer version of an immune-function measure. When evaluated at a single point in time, the values for these or other functional test must be classified in terms of normative curves of standard populations. As healthy individuals vary widely along these parameters, this weakens their reliability for clinical assessment. A substantial overlap in the distributions of performance results exists for truly deficient and truly sufficient individuals. Moreover, deficits in most of these functions are not specific to zinc deficiency and may be caused by other nutritional or pathological factors. (*See* **Nutritional Assessment**: Functional Tests.)

Tests that Assess the Homeostatic Regulation of Zinc

More specific functional tests for zinc are found in those that examine its regulation. When the metabolism of a nutrient is homeostatically regulated to achieve fairly constant total body content, as in the case with zinc, functional assessment of nutritional status can also involve evaluation of the operation or regulation. Isotopic turnover, again with ^{65}Zn, is an index. Urinary zinc output after a zinc load has been used to determine the threshold when body needs have been met, and the body is no longer in a strict conservation mode. Zinc absorption tests have also been used to gauge regulation, as high rates of uptake will occur in the zinc-deficient state. The regulation of zinc by assessment of the function of metal regulatory elements in gene expression or of rapidly turning over products of the homeostatic mechanism, such as the messenger RNA for metallothionein I, is the most modern and sophisticated candidate in this line.

Responses to Zinc Supplementation

It has been stated correctly that, given the limitations and caveats in the interpretations of all of the classes of zinc status tests, the surest approach to diagnosis of zinc status is retrospective, after a therapeutic trial with zinc. Static indices such as plasma zinc levels or the concentrations in accessible tissues are of limited interpretation in a zinc supplementation trial, as they would be expected to rise passively with increased availability. However, a positive response in *functional* tests either of tests of zinc-dependent functions or of tests of homeostatic regulation would be a significant indication that a zinc-responsive deficit in function or an upregulation state had existed at the time of the original inquiry. Zinc doses should be in the dietary range, as high-dose supplements raise the

specter of a pharmacological effect of zinc, unrelated to underlying nutritional status.

Practical Recommendations for Zinc Status Evaluation

Despite the theoretical considerations that the major response to zinc deficiency involves conservative and adaptive mechanism of a nonspecific nature, total-body zinc and zinc in various tissues and compartments are influenced in most forms and etiologies of human zinc deficiency. Given the pitfalls in the interpretation of any given tests, a battery of tests, combining circulating zinc level assay with several of the other tissue assays and functional tests, is recommended. When a short-term clinical supplementation trial is possible, it can give the most definitive diagnosis short of isotopic studies.

Clinical Conditions Associated with Zinc Deficiency

It follows from the discussion of pathogenesis of zinc deficiency that any disease or disorder that produces decreased intake, decreased absorption, excess losses, impaired utilization, or increased demand could predispose to zinc deficiency. The clinical conditions that have been associated with human zinc deficiency are as follows:

- protein–energy malnutrition;
- vegetarianism;
- zinc-poor diet;
- experimental depletion;
- psychogenic eating disorders (anorexia nervosa; bulimia);
- high-fiber, high phytate diets;
- high-dose iron supplements;
- cancer cachexia;
- synthetic diets;
- zinc-poor total parenteral nutrition;
- acarodermatitis enteropathica;
- Crohn's disease;
- jejuno-ileal bypass;
- chronic renal failure;
- ulcerative colitis;
- celiac disease;
- intestinal helminthiasis (ascariasis, trichuriasis);
- intestinal giardiasis;
- alcoholism;
- alcoholic hepatitis;
- viral hepatitis;
- alcoholic cirrhosis;
- acute alcoholic pancreatitis;
- primary biliary cirrhosis;
- infantile biliary atresia;
- cystic fibrosis;
- Schwachman's syndrome;
- phenylketonuria;
- sickle cell disease;
- thalassemia;
- porphyria;
- muscular dystrophy;
- acquired immunodeficiency syndrome;
- hyperparathyroidism;
- thermal burns;
- short-gut syndrome;
- exocrine pancreatic insufficiency;
- thiazide diuretic use;
- parenteral ethylene diamine tetraacetate chelation therapy;
- oral ethylene diamine pentaacetate chelation therapy;
- oral D(−) penicillamine therapy;
- diabetes mellitus;
- persistent diarrhea;
- ileostomy fluid loss;
- exfoliative dermatitis;
- psoriasis;
- prolonged lactation;
- twin pregnancies;
- very low birth weight;
- rapidly proliferating malignancies;
- synthetic growth hormone therapy.

Prevalence of Zinc Deficiency

When the parameter is zinc deficiency in a medical and clinical context, the prevalence and incidence of the diseases and conditions discussed in the preceding section – and their management – would determine the global prevalence of zinc deficiency. Viewed as a public health problem on a population and epidemiological basis, however, marginal and deficient zinc status is emerging as a subject of great interest. In the classical regions of endemic zinc deficiency, the rural oases of Iran and Egypt, its occurrence has been attributed to interference with zinc bioavailability by the high-extraction, unrefined cereal diets. Characteristics of the diet and the occurrence of adverse health conditions would determine endemic zinc deficiency. Brown and Wuehler have made a crude estimate of risk of endemic zinc deficiency through an assessment of zinc in the global food supply. This is based on national food balance sheets and estimates of the content of zinc and of major inhibitors of its biological availability, primarily phytic acid. They conclude that the daily rations provide 7–9 mg of absorbable zinc per capita in South and South-east Asia, the Middle East, and throughout Africa, with 9–11 mg available in Latin America and China, and 11–12 ng in the affluent countries of North America, Western Europe, and Oceania, placing the former

two geographic categories at risk of endemic zinc deficiency. This has potentially important implications, as a recent population intervention trial with oral zinc has suggested that the incidence of malarial attacks, diarrheal episodes, and acute respiratory infections may be reduced by daily zinc supplements.

Within societies, social and economic deprivation is a common denominator for the expression of zinc deficiency or marginal zinc status in both industrialized and nonindustrialized countries.

As with other nutrients, it is believed that young children, pregnant women, and the elderly would be the most at risk for zinc deficiency. Infants who are exclusively breast-fed are generally protected against zinc deficiency, but formula-fed infants, especially those with iron-fortified diets, could also share some risk for zinc deficiency. Adolescence is associated with a rapid growth spurt, and this could attenuate the adequacy of zinc from a diet that was sufficient when less of the nutrient was being deposited or utilized for cell growth and replication. Zinc loss resulting from recurrent infections, parasites, and climatic conditions (heat, humidity) would also be factors in the etiology of marginal zinc deficiency. (*See* **Elderly**: Nutritional Status.)

Despite these theoretical considerations, bolstered by some experience in attempting to document the zinc status of the various populations and subgroups discussed above, the pitfalls and limitations of diagnostic indices for zinc status have limited both the number of population-based surveys of human zinc status that have been performed and the reliability of the estimates of prevalence of deficiency. The most reliable approach to assessing the prevalence of zinc deficiency would alter that prevalence at the same time, namely a therapeutic trial of zinc supplementation. The individuals who respond with a *functional* improvement, i.e., accelerated growth, better appetite, and improved physiological or cognitive performance, could be classified retrospectively as having been zinc-deficient.

Treatment of Zinc Deficiency

The treatment of clinical or subclinical zinc deficiency requires the restoration of adequate body pools and tissue concentrations of zinc. It invariably involves the administration of amounts of zinc in excess of the daily requirements as zinc-rich foods or in the form of zinc salts or chelates. Salts such as zinc sulfate and chelates such as zinc gluconate are available commercially as oral tablets; no convincing evidence of improved bioavailability of chelates has been forthcoming. The most efficient uptake of zinc from supplements is achieved on an empty stomach, but gastric irritation symptoms often move patients to combining their zinc with meals, to the detriment of its absorption rate.

When subjects cannot tolerate food or oral medications, the intravenous (parenteral) route can be used. For parenteral administration, pharmacological preparations of zinc chloride or zinc sulfate are available in single formulation or in combination with trace elements. The daily dosage original guidelines they put forth by expert panels of various North American physicians groups have remained valid for decades: they put forth the following guidelines for daily parenteral administration of zinc: stable adults, 2–5-4.0 mg; adults with disease-related, enteral losses, 12–17 mg; term infants, $\geq 150\,\mu g\,kg^{-1}$; premature, low-birthweight infants, $> 300\,\mu g\,kg^{-1}$. To avoid the toxicity reported with excessively rapid dosing, parenteral zinc should never be given as a bolus. Zinc chloride and zinc sulfate are compatible in solution with most other intravenous forms of essential micronutrients.

Prevention of Zinc Deficiency

Prevention of zinc deficiency can be considered at the level of the healthy individual adult or child, at the level of the zinc deficiency or a predisposing medical condition, or at the level of public health of nutritionally vulnerable populations or subgroups.

Prevention in Healthy, Normal Individuals

Spontaneous clinical zinc deficiency is unlikely to occur in healthy individuals on a dietary basis, but they are at risk of marginal deficits. The US Institute of Medicine's Food and Nutrition Board in its *Dietary Reference Intakes* has revised the recommendations for dietary intakes that would keep most healthy individuals replete, as has an expert panel for the UN agencies of the World Health Organization and International Atomic Energy Agencies. In a departure from the approach of the past, in which the safe and adequate level for the individual (recommended dietary allowance, safe dietary intake) was the focus of recommendations, the new approach is focused more on the normative distribution of zinc intakes within a population that would be considered to be at low risk for endemic zinc deficiency. For the US population, this is based on the estimated average requirement derived from actual normative zinc intake data. For the world at large, the UN still used a factorial approach to determine the requirement for uptake of zinc, and then added assumptions for different levels of bioavailability in different regional cuisines (high (45–55%), medium (30–35%), and low (10–15%)), and finally adjusted for a standard population variance. For instance, for an infant, 6–12 months of age,

the WHO/IAEA recommended population daily zinc intake for a diet of medium bioavailability is 5.6 mg. For children aged 6–10 years, this figure is 7.5 mg, rising to 13.1 mg in late adolescence; for men above 18 years, 9.4 mg; for women above 18 years, 6.5 mg; for pregnant women, 10 mg; and for lactating women, 12.2 in the first 6 months of breast-feeding. To calculate the intake that would cover 97.5% of the population, a 50% overage is added to these values for the respective individual protective intakes. (*See* **Dietary Requirements of Adults**.)

Sources of highly available zinc include oysters, herring, lean beef, and lean pork. Increasingly, ready-to-eat breakfast cereals and breakfast snack bars are zinc-fortified. Almost all multivitamin-mineral supplements currently contain zinc. Although breast milk has relatively low zinc concentrations, its zinc is highly absorbable. Exclusive breast-feeding should be protective for the infant, although an occasional case of zinc deficiency from an idiopathic abnormal milk supply has led to infantile zinc deficiency.

Prevention in Persons Predisposed to Deficiency

If an individual has a history of zinc deficiency, or has one of the conditions listed above (see Section Physiological and Metabolic Consequences), more attention to primary prevention, or to avoiding recurrence, is required. Eliminating or ameliorating the primary medical or psychological condition should reduce the tendency to underconsumption and/or malutilization of the nutrient. If the underlying disorder cannot be addressed, chronic use of some multiple – two or three times – of the usual recommended level may be necessary.

Prevention in Vulnerable Populations

If epidemiology suggests that a population is prone to zinc deficiency or marginal zinc status, some public health measures are warranted. The classical populations in which zinc deficiency on a dietary basis was described were juveniles in rural areas of Iran and Egypt with a common factor of total zinc intakes in the acceptable range but a consumption of inhibitors of bioavailability (dietary fiber, phytic acid) that reduced its absorption. For such a population, changes in dietary practices to introduce sources of highly absorbable zinc or to adopt alternative processing of traditional cereal grains (germination, fermentation, phytase treatment) might be a solution. Possibilities in plant genetics and plant breeding to reduce inhibitors such as phytic acid or to increase the affinity of the leaves and other tissue to hold divalent cations are under exploration. The final approach is fortification of a staple food with zinc. Hence, the strategies for ensuring a generous intake of zinc in underprivileged populations include popular nutrition education for better food choices, and fortification of some common food-stuffs with additional zinc. As growing children are the usual victims of endemic marginal zinc status, a food vehicle targeted to this age group can provide more effective coverage. Confectionary, breakfast cereals and soft drinks are among the options for reaching the vulnerable population with fortification of zinc. (*See* **Food Fortification**.)

In underprivileged groups in both developed and developing countries, subsections of the population of children who respond to zinc supplementation with improved growth have been identified. Whether or not the additional burden of zinc loss owing to recurrent infections combines with poor appetite and restricted variety of foods to generate a subclass of zinc marginal individuals is worth considering. Once again, increased loss of zinc can be overcome by compensatory increased intakes of the mineral. Chronic supplementation with zinc is likely to be unsustainable and poses a potential risk to copper nutriture and immune function in at least a subsegment of a long-term supplemented population.

ZOONOSES

R Cichon, A Platt-Samoraj and J Uradziński,
Warmia and Masuria University in Olsztyn, Poland

Introduction

Zoonoses are defined as 'those diseases and infections which are naturally transmitted between vertebrate animals and man.' In an obligate zoonotic disease, such as anthrax, transmission occurs only from animal to human, whereas in facultative zoonoses, infections are mostly transmitted among humans. Animal-based food may harbor the etiological agent which has infected its living host.

None of these zoonotic diseases is transmitted to humans exclusively by means of food. Food is only occasionally the vehicle of transmission. Since the oral route represents only one of several possible ways of infection, zoonoses are not then foodborne diseases in the general meaning.

It is impossible to give here a complete survey of all zoonoses potentially transmitted to humans via food. This article highlights three of the most important: brucellosis, Q fever, and leptospirosis.

Brucellosis

Brucellosis is an acute febrile disease, or a chronic disease with a wide variety of symptoms. It is a true (an obligate) zoonosis transmitted to humans generally by domestic animals, especially cattle, pigs, and goats. Brucellosis is variously known as undulant fever, Malta fever, Mediterranean fever, or mimic fever.

Occurrence and Prevalence of Disease

This disease is caused by pleomorphic organisms of the genus *Brucella*, which also includes the organisms that are responsible for infectious abortion (Bang's disease) in cattle and swine. Brucellae are highly infectious, even in very small numbers. The organisms can appear as a coccus, a bacillus, or with characteristics of both (a coccobacillus). They may appear singly and, less frequently, in pairs, short chains, or small groups. The brucellae are nonmotile and nonsporing, and they possess neither capsules nor flagellae. Resting stages are not known.

The genus *Brucella* contains six species of bacteria. Important causes of human disease are the three main species: *Brucella melitensis* of goats and sheep, biotypes 1–3; *B. abortus* of cattle, biotypes 1–9; and *B. suis* of pigs, European hares, and reindeer, biotypes 1–4, with the possible exception of biovar 2. Of the others, *B. ovis* causes disease only in sheep, mainly rams; *B. canis* affects dogs, but is occasionally transmitted to humans, causing a mild type of brucellosis; and *B. neatomae* has been isolated from the desert wood rat. Brucellae have also been isolated from many other animal species, both wild and domestic, e.g., poultry, rabbits, rodents, foxes, hares, elk, deer, moose, polecats, hedgehogs, and insects (flies, mosquitoes, ticks, and bedbugs). It seems, therefore, that there are many types of animal reservoir of brucellae. The extent of the role of insects and wild animals in the transmission of brucellosis to humans is not known. The fact that *B. ovis* and *B. canis* were not discovered until 1953 and 1967, respectively, has led to speculation that the genus *Brucella* may be in a phase of rapid evolution and that new species may be emerging.

Brucellosis is distributed everywhere throughout the world. The following groups of people whose occupation brings them into contact with animals are especially endangered: farmers, veterinarians, workers in slaughterhouses and meat-packing and -processing plants, as well as laboratory personnel. It is particularly common in areas where goats, sheep, cattle, and swine are raised. *B. melitensis* infection is prevalent in the Mediterranean area, central Asia, and some parts of Latin America, especially Mexico and Peru; it does not occur in northern Europe, the USA, Canada, South-east Asia, or Australia. Bovine brucellosis (*B. abortus* infection) is moderately prevalent in most parts of the world, with the exception of many developed countries, although it persists in some southern areas of the USA. Porcine brucellosis (*B. suis* infection) is still fairly widespread in Latin America, South-east Asia, and the Pacific region. Canine brucellosis due to *B. canis* occurs in many countries, but poses only a minimal threat to human health.

Mechanism of Entry into Food and Transfer to Human

In the more susceptible species of domestic animal (cattle, goats, sheep, and pigs), enormous multiplication of brucellae occurs in the uterus in the latter part of pregnancy and, to a lesser extent, in the mammary glands during lactation. Abortion, and sometimes parturition at the normal time, leads to

massive contamination of the environment. On the other hand, excretion of brucellae in the milk, usually in much smaller numbers, may continue for years. Thus, milk and dairy products are frequently the source of foodborne brucellosis. Moreover, brucellae are intracellular parasites of the reticuloendothelial system and penetrate the whole body of the infected host.

B. melitensis and *B. suis* transmit more easily to humans then *B. abortus*. The usual portal of entry in humans is by the mouth, either directly by consuming infected dairy and meat products, or indirectly through contact with hands contaminated during work. Less commonly infection may occur via conjunctiva or by inhalation. An outbreak of brucellosis from consumption of wild greens contaminated by sheep and goat urine and feces has also been reported.

Detection in Foods

The detection of *Brucella* species involves cultivation, various serological methods, animal tests and, occasionally, microscopic examination.

There is a simple and sensitive method of detecting *Brucella* contamination in milk, known as the milk ring test. In this test, a *Brucella* antigen stained with hematoxylin is added to milk. Any agglutinins in the milk, which are carried by the cream as it rises to the surface, react with the antigen. Clumping follows, and a blue ring, indicative of the presence of brucellae, is formed. This test can be used to detect contaminated cows' milk but a similar ring test is available for goats' milk. Milk ring tests are unreadable with sheep milk. Recently, a rapid polymerase chain reaction (PCR) method has been developed for detection of *Brucella* species in milk and in milk products. There is also an immunoenzymatic assay (milk enzyme-linked immunosorbent assay (ELISA)), which is more sensitive then the milk ring test and it is a better screening test then PCR.

Fate of Bacteria During Processing of Storage

Brucellae in milk and meat are readily destroyed by conventional pasteurization methods properly used in dairy or meat processing. They are very sensitive to sunlight, being killed in a few hours, and also quite sensitive to acid conditions (pH 4 or below). However, highly relevant to the transmission of brucellae by food products is the extent of survival of these organisms in food. The organisms survive for only a few hours in raw milk at 37 °C, and for 48 h at 8 °C. At ordinary room temperature the organism will survive, according to another report, for several days until souring of the milk kills them. It is possible that other organisms may influence the survival of brucellae since, in sterile milk, they may survive for 17 days. Moreover, they can survive in tapwater for 10 days at 25 °C or 57 days at 8 °C, but in the presence of organic matter, such as cattle urine and feces, soil, and even lake water at 25 °C, they can survive for more than 2 years.

It appears that the brucellae are a group of sturdy organisms, which can survive prolonged periods in milk and dairy products as well as in meat products.

Methods of processing milk products, e.g., cheesemaking from raw milk, generally do not destroy them. Survival of *Brucella* in unpasteurized soft cheese is discussed. If present in cheese, the organism will survive from 38 days to more than 180 days, but aging of cheese tends to destroy the bacteria. In Cheddar cheese, no brucellae survived after 1 year. However, the European Union veterinary advisory committee in 1995 concluded that a ripening time or cheese age of 60 days is sufficient to eliminate a potential brucellosis risk to the consumer. Brucellae in naturally contaminated milk have been shown to survive during the processing of the milk to butter, buttermilk, and icecream. The organism has also been shown to survive in icecream stored below freezing for more than 1 month. Brucellae may survive in ham during pickling in brine for 21 days, and in salted and otherwise cured meats for 150 days, but not after the smoking process. *B. suis* has also been shown to survive for 21 days in pork under refrigeration and *B. abortus* in sausages for 175 days.

Symptoms of Illness and Treatment

Brucellosis in humans provides serious diagnostic problems, partly because the clinical symptoms are variable and often ill-defined and the complications can affect many systems. The incubation period ranges from 10 to 14 days. The onset is influenza-like with recurrent or undulating fever reaching temperatures up to 40–41 °C in the evening, falling to normal each morning. Limb and back pains are unusually severe. Sweating, headache, muscle ache, malaise, and fatigue, as well as anorexia and weight loss are the other symptoms. If untreated, symptoms may persist for months and complications may enter an ill-defined chronic syndrome, involving several body systems and organs.

For reasons which are not known, children, who are the main milk drinkers, seem to be less susceptible to brucellosis than adults. Evidence suggests that in humans, natural infection and complete recovery produce some resistance to reinfection.

Tetracycline alone or in several drug combinations may determine the effective treatment of acute brucellosis in humans if the treatment is prolonged for

6 weeks. Patients with chronic brucellosis frequently need symptomatic treatment in addition to antibiotics, and their response to antibiotic treatment is often disappointing.

Prevention of Brucellosis

Vaccination of animals, particularly when young, and testing animals and slaughtering reactors are probably the best means of controlling brucellosis. Occupationally exposed workers can be protected by wearing impermeable clothing, rubber boots, gloves and face masks, and by practicing good personal hygiene.

Since food and water are not the only modes of transmission, control in these aspects only will not minimize the occurrence of the disease. Nevertheless, removal of these sources of infection will do much to minimize human brucellosis. Thus, meat of all kinds, especially from unknown sources or from contaminated areas, must be cooked thoroughly. Raw milk should never be drunk without pasteurization, no matter what the source. Milk products, such as cheese, butter, and icecream, should be prepared from pasteurized milk. It must be emphasized that, in countries in which brucellosis has been eradicated, individuals can acquire the disease by consuming imported dairy products or by visiting countries in which the disease is endemic.

Q Fever

The Q (for 'query') fever infection was observed for the first time in Queensland, Australia, in 1935, during an outbreak of the febrile illness among abattoir workers. The disease also occurs in the USA, Canada, and Europe. Although a number of animals are susceptible, it is not certain that infection results in overt disease, except in the guinea-pig and in humans.

Occurrence and Prevalence of the Disease

The disease is transmitted generally by tick bites from wild animals (the natural reservoir) to domestic animals, especially ruminants. The infection is frequently symptomless in animals; the mammary gland, parenchymatous organs, muscles, lymph nodes, and uterus of infected slaughter cattle may harbor the organism. The microorganisms grow particularly well in the placenta of these animals, where they may reach a titer value of 10^9 viable organisms per gram of tissue. Transmission of disease from ticks to humans is uncommon. Sporadic cases or outbreaks of the human disease, Q fever, occur primarily among individuals involved in the transport of infected domestic animals and in the meat and dairy industries.

Mechanism of Entry into Food and Transfer to Humans

The main source of infection is highly infectious dust from tick feces deposited on the hides of animals or from dried placenta following parturition. The disease is usually transmitted to humans in three ways: by airborne dissemination in aerosols or dust contaminated with organisms; by processing of animal products, usually wool and hides; or by ingestion of infected food, especially raw milk. It seems to be well established that the infection may be transmitted by drinking infected milk. Milk may contain up to 10^3 infective doses per gram, even when serologically negative.

Detection in Food

Coxiella burnetii, the infectious agent of Q fever, differs sufficiently from other organisms of the genus *Rickettsia* to be classified in a separate genus, *Coxiella*, in the family Rickettsiaceae. Attempts to isolate *C. burnetii* in the laboratory are hazardous and should be avoided. The diagnosis of Q fever can be confirmed serologically by significant increases in complement fixation, agglutination, or direct fluorescent antibody levels to phase I or II antigens. The complement fixation test (CFT) is widely used and regarded as reliable. However, some cows excrete coxiellae without positive CFT titers. The agglutination test is the method of choice for epidemiological survey work. Additionally, the capillary agglutination test (CAT) requires very small amounts of reagents; it is performed similarly to the *Brucella* ring test by overlaying serum, milk, or whey with a partially purified phase I *C. burnetii* antigen. Positive results are indicated by a colored ring (cream layer) and/or agglutination throughout the serum or milk column. Also, ELISA, PCR, and PCR-ELISA techniques are available. PCR technique is more sensitive than standard culture techniques for retrospective diagnosis with frozen samples.

Fate of Bacteria During Processing or Storage

C. burnetii has a high degree of resistance to physical and chemical agents, comparable to that of sporogenic bacteria. This resistance might be attributable to the endospore-like forms. At 4 °C, viability is retained for over 1 year in dried form such as tick feces or wool, as well as in sterile skim milk or unchlorinated water. Meats remain infected for at least 1 month. Whether common dairy pasteurization will kill the organism depends on the procedure applied. Complete inactivation is not always accomplished by exposure to 63 °C for 30 min or 85–90 °C for a few seconds. However, with the

high-temperature, short-time method, no viable coxiellae have been demonstrated as yet in naturally infected milk.

Symptoms of Illness and Treatment

Q fever usually becomes apparent 2–4 weeks after exposure to the causative agent. In most cases Q fever may resemble a mild type of influenza. However, the severity of illness ranges from a subclinical infection to a febrile flu-like illness accompanied by respiratory symptoms, severe headache, arthralgia, and myalgia. Interstitial pneumonia, resembling a viral or primary atypical pneumonia, occurs in about 50% of patients. The characteristic rash of other rickettsial diseases does not occur. Usually, Q fever is a self-limited disease which lasts for 2–3 weeks, but fulminating pneumonia and chronic infections in the form of lipogranulomatous liver disease and endocarditis may complicate its course. To prevent complications, all patients with acute Q fever should be treated with tetracycline and chloramphenicol. Prolonged therapy with tetracycline, usually in combination with a rickettsiacidal drug, is required. *C. burnetii* is also inhibited by rifampicin, and only to a very limited extent by penicillin, streptomycin, or erythromycin.

Prevention of Disease

Persons at risk, such as abattoir workers, dairy and farm workers, veterinary personnel, woolsorters, tanners, and some laboratory research workers, should be monitored serologically at regular intervals and during respiratory or influenza-like illnesses. Also an effective vaccination as a preventive measure should be considered for such groups of population. If Q fever is diagnosed, treatment should be instituted promptly to prevent the serious complications that can develop after the illness.

Leptospirosis

Leptospirosis is a zoonosis that is worldwide in distribution and encompasses a broad spectrum of animal hosts. The primary reservoir hosts are wild animals. Domestic animals, especially dogs, cattle, and swine, may also be an important source of human infection.

Occurrence and Prevalence of the Disease

Leptospires, the causative agents of leptospirosis, have been isolated from approximately 160 mammalian species in the temperate zone. The disease is more widespread in tropical countries where the infectious agent may be one of some 150 pathogenic serotypes of *Leptospira interrogans*, carried by a large variety of hosts. The most important reservoirs or carriers are various rodents, particularly the common Norway rat (*Rattus norvegicus*), which is the principal carrier of the often very virulent serotype *L. interrogans* serovar *icterohaemorrhagiae*. In animals, particularly rodents and dogs, pathogens may colonize the kidneys following infection, which may or may not be symptomatic. Pathogenic leptospires, multiplying in the convoluted tubules, are shed in the urine of infected animals, and susceptible hosts become infected through contact with urine or urine-contaminated environs such as moist soil and surface water. Humans are accidental hosts. In general, infections in humans occur through broken skin and mucous membranes. Thus, persons who work in foul, watery places such as sewers, rice fields, and poorly built mines are exposed to the causative agent.

Mechanisms of Entry into Food and Transfer to Humans

There are two sources of leptospires which may be involved in contamination of food: (1) urine of infected animals, especially rats; and (2) infected soil, dust, and water. However, the possibility of leptospirosis transmitted by contaminated food or water is rare. This is understandable in view of the extreme sensitivity of the organism to acidity. Thus, the stomach serves as a protective barrier. Nevertheless, one case of foodborne leptospirosis has been reported: 8 days previously, the patient had consumed ham which appeared to have been gnawed by rats, and presumably have been urinated on by the rodents. While leptospires may be shed into the milk from infected animals, there are no proven cases of milk-borne leptospirosis in humans. However, milk has a leptospiricidal property which is not destroyed by pasteurization.

Fate of Bacteria During Processing or Storage

Leptospires are very sensitive to heat. They are killed within 10 s at 60 °C and 2 h at 32 °C. Therefore, any pasteurization method used should be effective in killing the organism during food processing.

Leptospires are quite sensitive to many chemical and environmental factors. They are killed by long-chain fatty acids as well as by detergents. These substances, however, have no effect in the presence of albumin or other serum proteins which combine with these chemicals. The organisms are also killed by sea water, chlorine in the water supply, and ultraviolet light. They are killed at varying rates (a few minutes or hours) in liquids at pH values below 5 and above 8.5.

Moisture may play an important role in their survival. Thus, leptospires have been shown to survive for 279 days during the winter in soils with 70% moisture and only 3 days with 10% moisture. Leptospires have also shown a remarkable ability to survive at extremely low temperatures. Thus, when quick-frozen to −70 °C, they survive for many years with no loss in virulence.

In milk, stored at 40 °C for 2 months, pasteurized or heated at 80 °C for 5 min, leptospires are killed within 3 h. This leptospiricidal property of raw or pasteurized milk is destroyed by boiling. Dilution of the milk also decreases the leptospiricidal property. Thus, it has been shown that 1:20 to 1:80 dilutions allow the organisms to survive in milk for 60 days. Leptospires have been shown to survive for 33 h at 5 °C in refrigerated bovine meats. Survival of the organism from 3 to 12 days in muscle, liver, kidney, and spleen at 3–5 °C has also been reported.

Symptoms of Illness and Treatment

Leptospirosis may appear in either a mild or severe form, and both types have similar incubation periods – 7–14 days. Most leptospiral infections are mild and virtually all pathogenic serotypes cause febrile illness in humans. The most prominent symptom is continuous fluctuating fever with temperatures of 38.9–41.9 °C for 2–12 days or more, severe headache, muscle pain, and nausea that persists for approximately 7 days. Jaundice occurs during this phase in more severe infections. The different forms of leptospirosis are known by other names which are suggestive of the causative serotype, duration of symptoms, or the mode or place of transmission or original discovery. Thus, the disease is also known as Fort Bragg fever, canicola fever, 7 days' fever, mud or swamp fever, canecutter's disease, pea picker's disease, and swineherd disease. In the severe form of leptospirosis, also known as Weil's disease, these symptoms are more intense, particularly gastrointestinal bleeding, renal failure, and central nervous system symptoms such as anorexia, nausea, and vomiting.

Clinical manifestations of leptospirosis, however, are not sufficiently characteristic for a specific diagnosis of leptospirosis. As a result, the disease is often initially misdiagnosed as meningitis or hepatitis. Thus, microscopic demonstration of the organisms, serological tests, or both, is necessary for diagnosis. The microscopic agglutination test is more frequently used for serodiagnosis of this disease. Highly sensitive immunoenzymatic assays (ELISA) have recently been used for the detection of leptospiral antibodies in serum. Although leptospires are sensitive to penicillin and tetracycline *in vitro*, use of these drugs in the treatment of leptospirosis is controversial. If treatment is initiated within the first week of disease onset, the general belief is that it can be effective. Later in the disease, immunological damage may already have begun, rendering antimicrobial therapy ineffective.

Prevention of the Disease

Human leptospirosis may be controlled by reducing its prevalence in wild and domestic animals. Although little can be done about controlling the disease in wild animals, leptospirosis in domestic animals can be reduced through vaccination. Doxycycline is a valued preventive drug. Administration of 200 mg weekly may be effective prevention against leptospirosis in endangered people. This group of persons should wear impermeable clothes and boots. An awareness of the possible contamination of, for example, soil, mud, stagnant water, ponds, and streams, and avoiding polluted food or water, along with control of rat populations, is essential to the prevention of the infection. Even though transmission of the disease by ingestion is very rare, there remains the hazard of foodborne transmission. Heating and cooking food and avoiding unchlorinated water would still be a safe rule to follow, particularly if the source of drinking water may be contaminated by animal discharges.

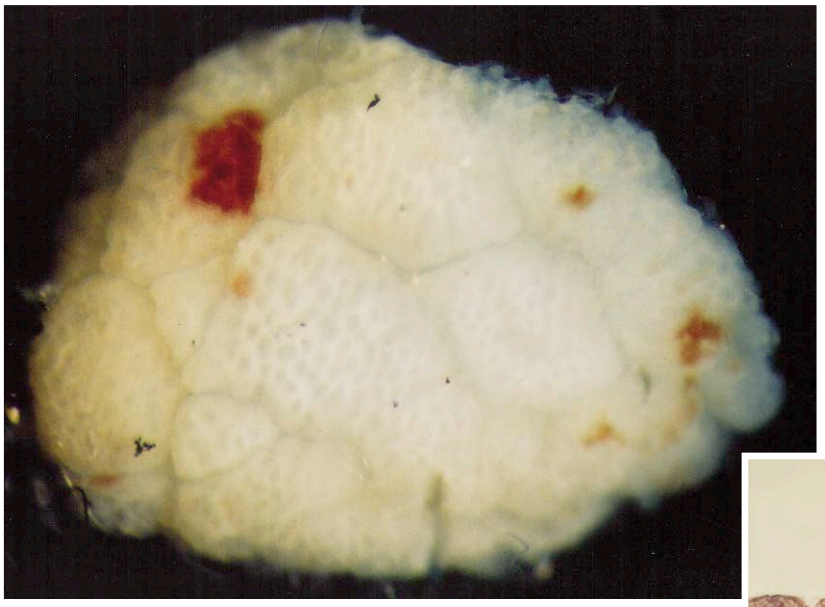
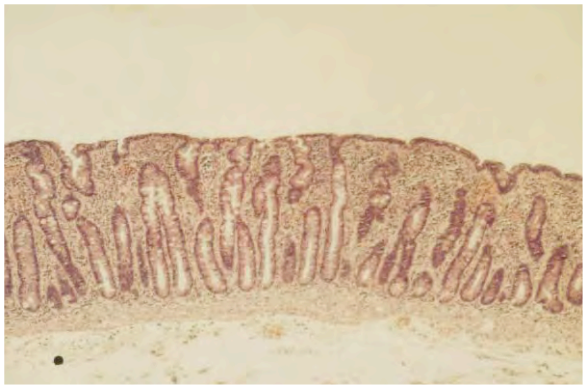
Plate 22 Celiac (Coeliac) Disease
(a) Dissecting-microscopic appearance of normal mucosal biopsy showing finger-like villi; (b) light-microscopic appearance of normal mucosal biopsy.



(a)



(b)

Plate 23 Celiac (Coeliac) Disease (a) Dissecting-microscopic appearance of biopsy from untreated celiac patient with total absence of villi and a 'flat'-looking mucosal surface; (b) light-microscopic appearance of untreated celiac mucosa with absence of villi, deep crypts, and an increase in inflammatory cells.

Plate 24 Cereals Harbor elevator in Rouen, France, with a total storage capacity of 300 000 tonnes. This is able to load grains into vessels at a rate of 5000 tonnes h^{-1}. Photo courtesy of J. Pfeiffer.

Plate 25 Citrus Fruits Navels are the most important sweet, juicy, and seedless orange marketed for fresh fruit consumption.

Plate 26 Citrus Fruits Limes are normally harvested for fresh marketing when mature but wth green or light green to silver-colored rinds.

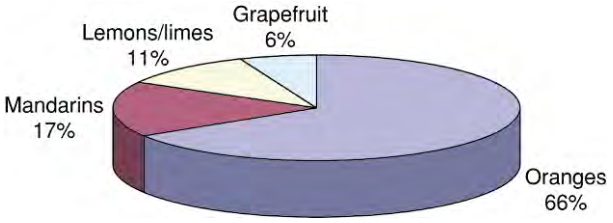


Plate 27 Citrus Fruits Average production percentages for the main citrus types grown in the world between 1995 and 1996 and between 1998 and 1999.

Plate 28 Citrus Fruits A range of internal pigments are now available in grapefruit, with consumer interest in the newer red fleshed cultivars (left to right: Marsh, Thompson, Rio Red, Flame, and Star Ruby).

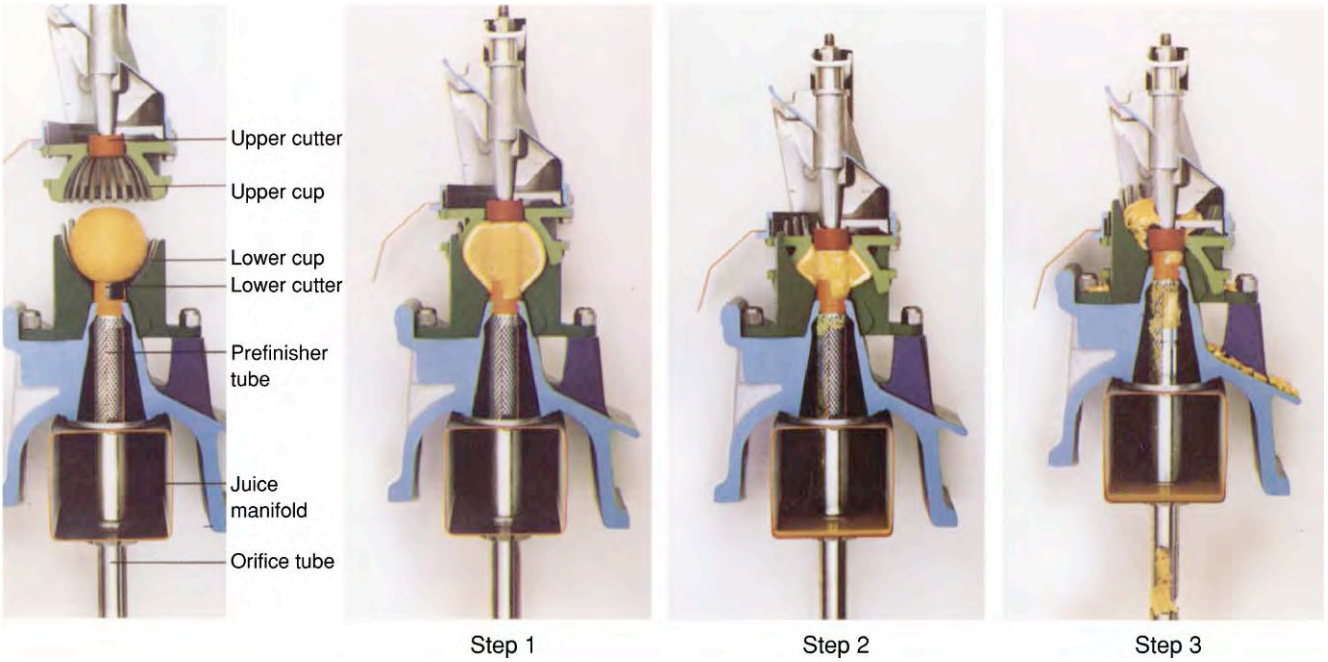

Plate 29 Citrus Fruits FMC juice extractor principle. Courtesy of FMC Food Tech Citrus System, Catania (Sicily) Italy.

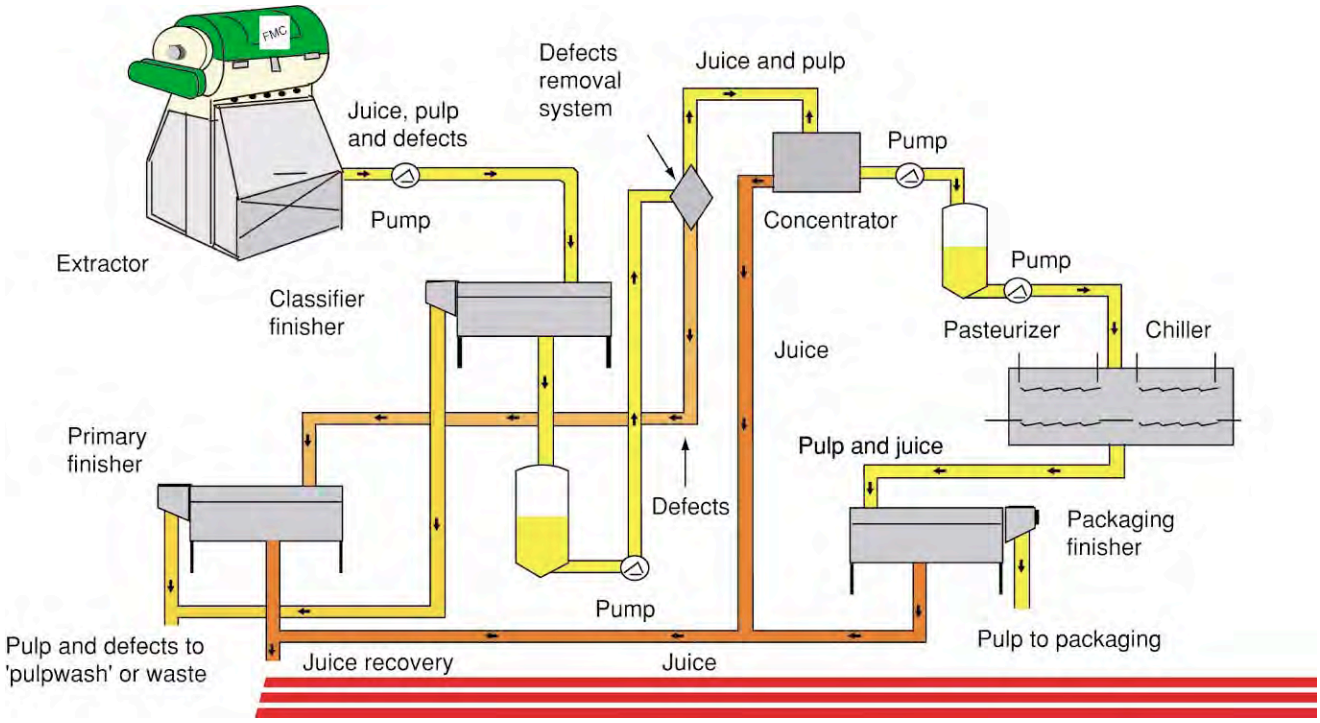

Plate 30 Citrus Fruits Premium pulp recovery process. Courtesy of FMC Food Tech Citrus System, Catania (Sicily) Italy.

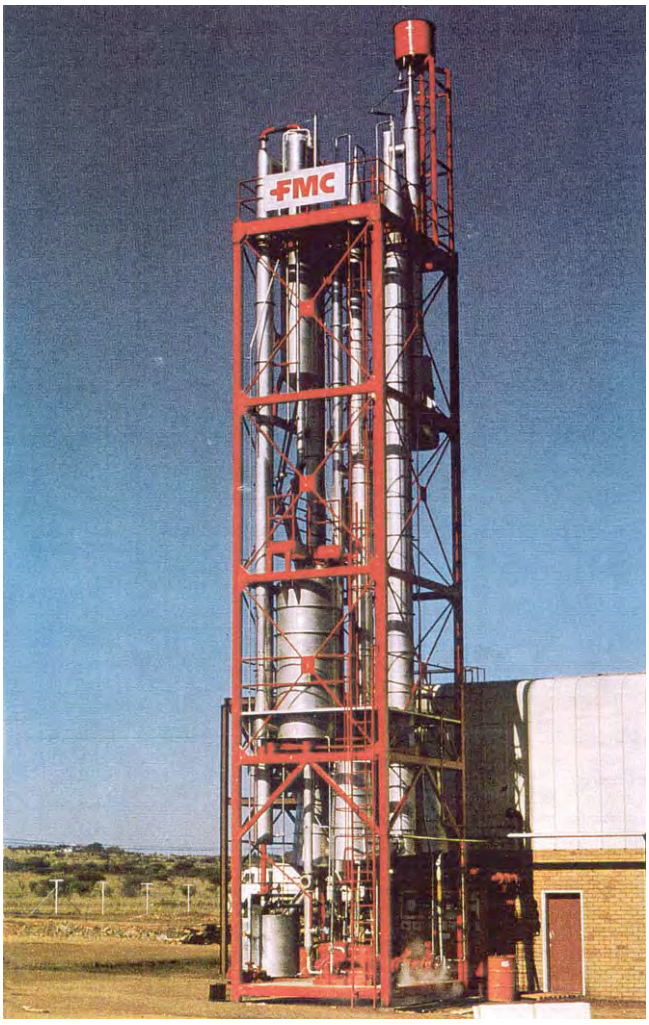

Plate 31 Citrus Fruits Model thermally accelerated short-time evaporator. Courtesy of FMC Food Tech Citrus System, Catania (Sicily) Italy.

Plate 32 Citrus Fruits Harvesting Fortune mandarins for export in Spain.

Plate 33 Citrus Fruits
Moroccan clementine exports
in open 10-kg packages.

Plate 34 Citrus Fruits
Grapefruit are often borne in clusters, like a small bunch of grapes and this has been suggested as the origin of the fruits name.

Plate 35 Citrus Fruits Oroblanco is a new low acid white-fleshed hybrid grapefruit.

Plate 36 Citrus Fruits Star Ruby is a newer grapefruit cultivar with a deep red pigmented flesh.

Plate 37 Coconut Palm Coconut palm.

Plate 38 Coconut Palm Inflorescence.

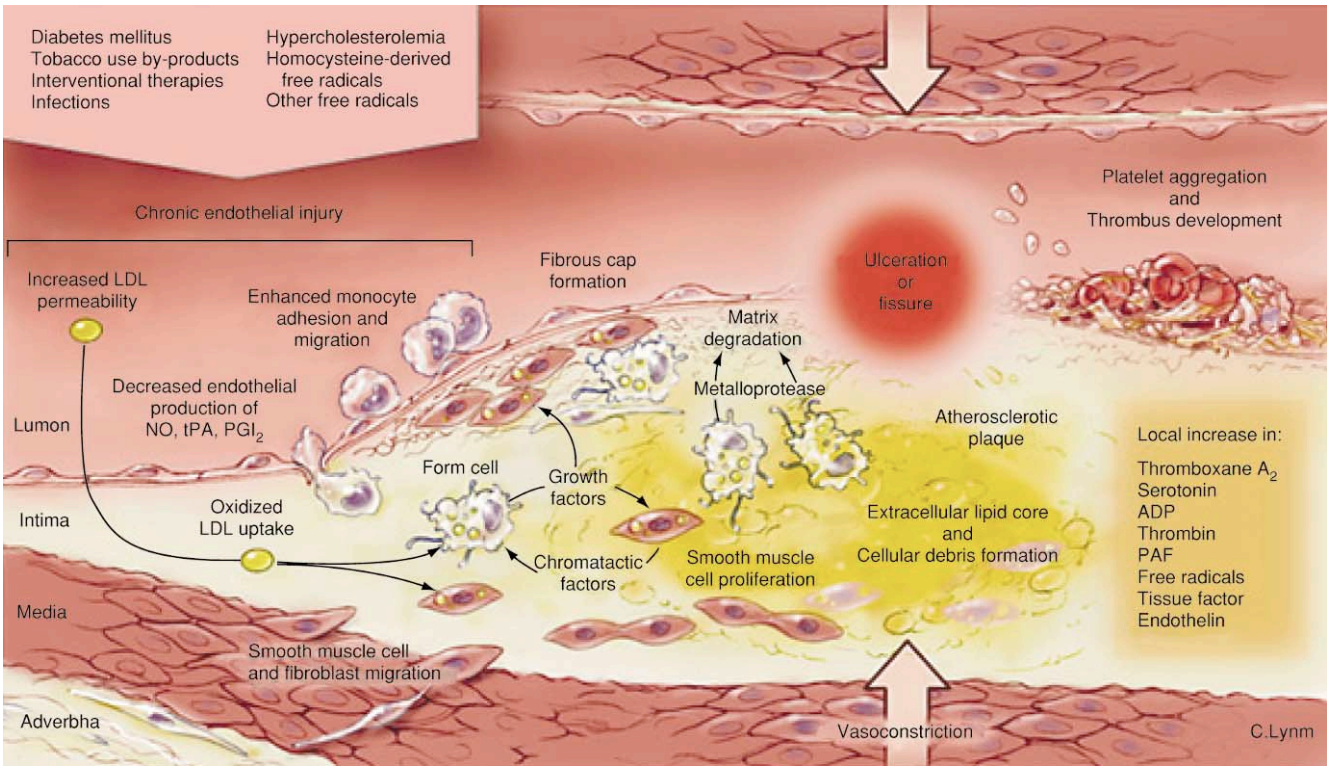

Plate 39 Coronary Heart Disease Mechanisms in the initiation and progression of atherosclerosis. Endothelial injury results from a variety of factors such as smoking, high blood cholesterol and homocysteine, and ulceration of atherosclerotic plaques, etc. (see text). At the site of endothelial injury, there is a downregulation of endothelial-derived nitric oxide (NO), tissue plasminogen activator (tPA), and prostacyclin (PGI_2) with increased adhesion of platelets and leukocytes, increased permeability to lipoproteins, and vasoconstriction. ADP, adenosine diphosphate; LDL, low-density lipoprotein; PAF, platelet activating factor. From Lefkowitz RJ and Willerson JT (2001) Prospects for cardiovascular research. *Journal of the American Medical Association* 285: 581-587 with permission.

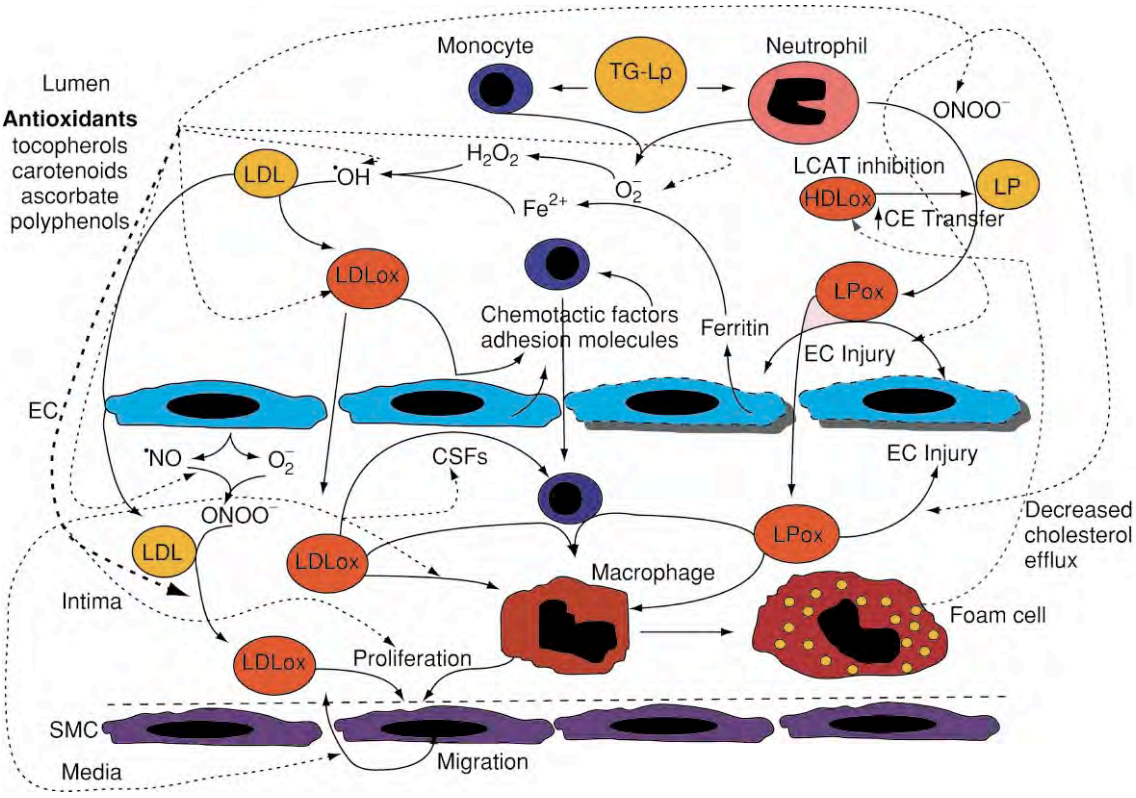

Plate 40 Coronary Heart Diseases Possible effects of antioxidants in the atherogenic process. CE, cholesteryl ester; CSFs, colony-stimulating factors; HDLox, oxidized HDL; LCAT, lecithin: cholesterol acyl transferase; LDLox, oxidized LDL; Lpox, oxidized lipoproteins; TG-Lp, triacylglicerol-rich lipoproteins; EC, endothelial cells; SMC, smooth muscle cells.

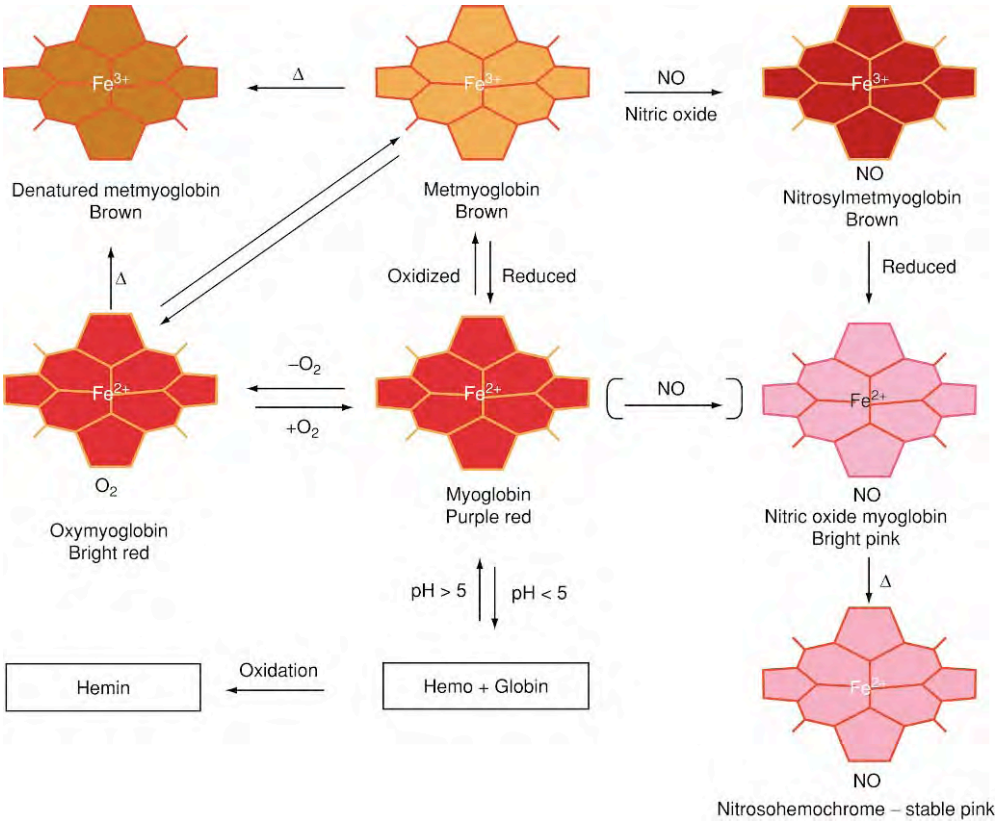

Plate 41 Curing
Changes in the pigment heme during curing and respective color and iron state.

Plate 42 Date Palms (a) Young actively bearing date palm with offshoots or suckers. (b) Bunches of fruit from the same tree photographed at the end of the 'khalaal' stage.

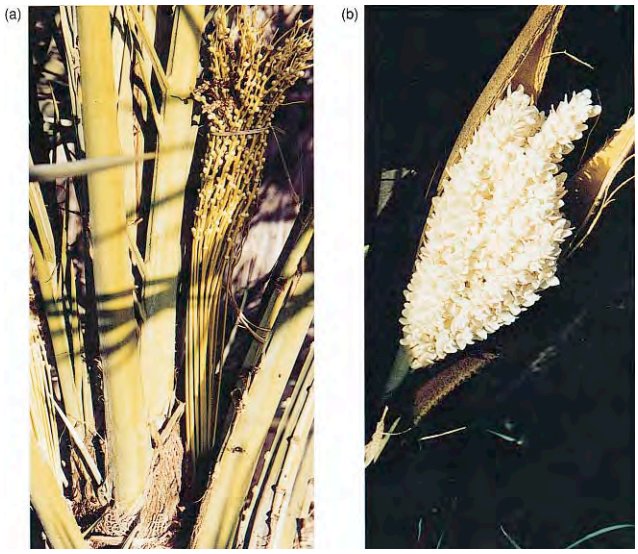

Plate 43 Date Palms (a) Female flower with branches of male inflorescence inserted and tied to the female. (b) Opened male inflorescence with abundant pollen.

Plate 44 Date Palms Eighteen of the most popular date cultivars sold in Riyadh, Saudi Arabia. Their names are as follows: 1=Assela, 2=Labana, 3=Sabbaka, 4=Rothana, 5=Manifi, 6=Naboot-Ali, 7=Sefri, 8=Mabroom, 9=Roshidia, 10=Sokary, 11=Khodri, 12=Safawi, 13=Halaw/Helwa, 14=Hanini, 15=Barhi, 16=Juffair, 17=Qattar, 18=Seeleg.

Plate 45 Date Palms Basket, woven from date fiber and filled with 110 different confectionery products made from dates and date syrup (and dates from 14 dry date cultivars). The background shows semisoft brown date, date leaves, and bunches of mature dates.

Plate 46 Dental Disease
Categories of dental fluorosis according to Dean's index.

Plate 47 Effluents from Food Processing Round-ended rods. False trichome branching. Note the appearance of the trichome branches being 'stuck' together. False trichome branching does not have contiguous cytoplasm between the branches. Filamentous bacteria, *Sphaerotilus natans.*

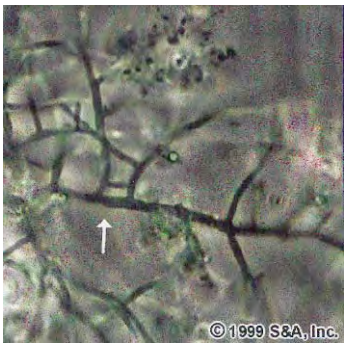

Plate 48 Effluents from Food Processing True trichome branching. True branching refers to contiguous cytoplasm between the branches. Filamentous bacteria, nocardia form. Subject to copyright and patent protection of Stover & Associates, Inc., as part of the FIL-IDENTPro™ Filamentous Bacteria Typing Program.

Plate 49 Effluents from Food Processing
Filamentous bacteria type 021N. This slide was photographed at 1000 x magnification under phase contrast. Subject to copyright and patent protection of Stover & Associates, Inc., as part of the FIL-IDENTPro™ Filamentous Bacteria Typing Program.

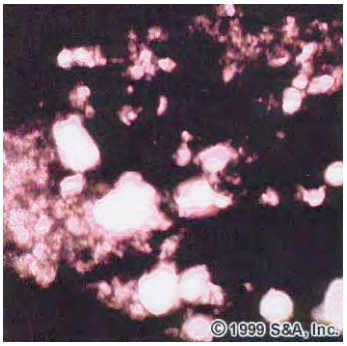

Plate 50 Effluents from Food Processing India ink staining for extracellular polysaccharide. India ink particles penetrate the flocs almost completely, at most leaving a small clear center. In activated sludge containing large amounts of extracellular material (as shown in picture), large clear areas indicate areas of low cell density. This slide was photographed at 10 x magnification. Subject to copyright and patent protection of Stover & Associates, Inc., as part of the FIL-IDENTPro™ Filamentous Bacteria Typing Program.

Plate 51 Effluents from Food Processing
Unidentified species of the phylum Rotatoria, commonly called rotifers. This slide was photographed at 100 x magnification. Subject to copyright and patent protection of Stover & Associates, Inc., as part of the FIL-IDENTPro™ Filamentous Bacteria Typing Program.

Plate 52 Fermented Foods Tempe. Growth of a fungus, *Rhizopus oligosporus*, binds cooked, dehulled soybeans into a solid cake. Tempe is a traditional Indonesian meat substitue that also has a small part of the vegetarian market in Japan, the USA and Europe.

Plate 53 Fermented Foods Oncom (ontjom) in Bandung market, Indonesia. Oncom is similar to tempe but uses peanut press cake and the orange-spored fungus, *Neurospora sitophila.* The material in the background is fried tempe.

Plate 54 Fermented Foods Natto. A Japanese *Bacillus* proteolytic fermentation of whole soybeans producing a characteristically slimy, strongly flavoured product.

Plate 55 Fermented Foods Thu-nuo, dried disks. A traditional Thai *Bacillus* proteolytic fermentation of soybeans.

Plate 56 Fermented Foods Tapé in Bandung market, Indonesia. Cooked cassava roots fermented with fungi to produce a slightly soured, slightly alcoholic, and sweetened cassava.

Plate 57 Flavor (Flavour) Compounds Flavor compounds: highly efficient distillation columns. Reproduced from Flavour Compounds Production Methods, *Encyclopaedia of Food Science, Food Technology and Nutrition,* Macrae R, Robinson RK and Sadler M (eds), 1993, Academic Press.

Plate 58 Flavor (Flavour) Compounds Yellowfin tuna. Reproduced from Flavour Compounds, Production Methods, *Encyclopaedia of Food Science, Food Technology and Nutrition,* Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Plate 59 Flavor (Flavour) Compounds Effluents from food processing. Reproduced from Flavour Compounds, Production Methods, *Encyclopaedia of Food Science, Food Technology an Nutrition,* Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

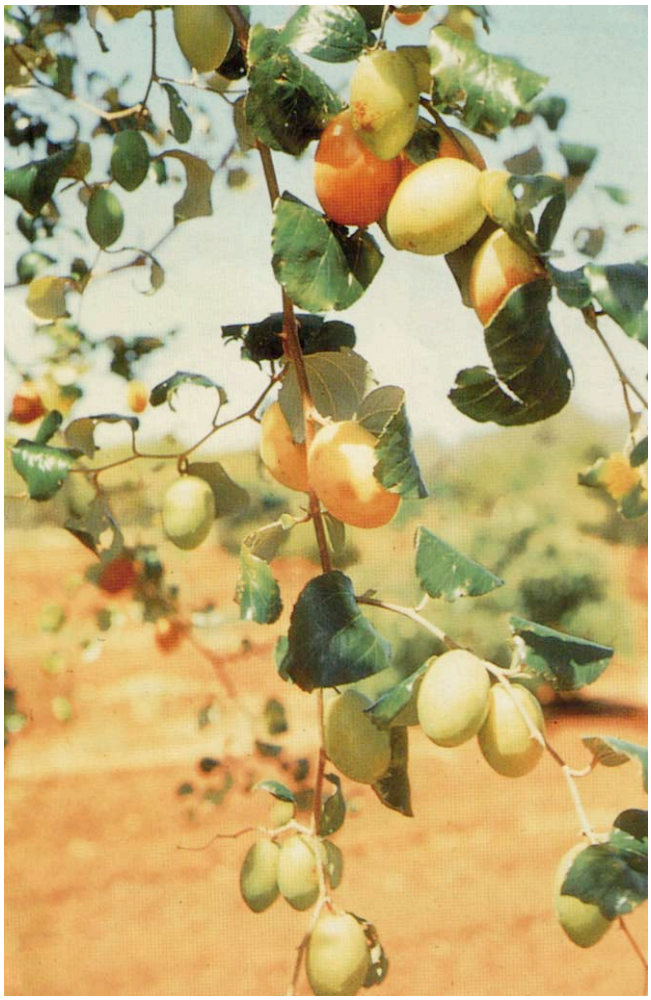

Plate 60 Flavor (Flavour) Compounds Fruits of tropical climates: *Zizyphus mauritiana* Lam. (Indian jujube). Reproduced from Flavour Compounds, Production Methods, *Encyclopaedia of Food Science, Food Technology and Nutrition,* Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Plate 61 Flavor (Flavour) Compounds Road-side markets in Bangkok displaying citrus, banana, rambutan, mango, and lychee. Reproduced from Flavour Compounds, Production Methods, *Encyclopaedia of Food Science, Food Technology and Nutrition,* Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Plate 62 Flavor (Flavour) Compounds A collection of the more exotic tropical fruit of South-east Asia. Courtesy of TA Cooke, Plant Pathology, QDPI, Australia. Reproduced from Flavour Compounds, Production Methods, *Encyclopaedia of Food Science, Food Technology and Nutrition,* Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Plate 63 Flavor (Flavour) Compounds Fruits of tropical climates: *Prunus serotina* var. *salicifolia* (capulin cherry). Reproduced from Flavour Compounds, Production Methods, *Encyclopaedia of Food Science, Food Technology and Nutrition,* Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Plate 64 Flavor (Flavour) Compounds Filtration line for 450hl output per hour; consisting of FILTROstar candle-type precoat filte and PVPP (polyvinyl pyrrolidone, a filter aid dispersed into a cellulose-based matrix) stabilizing plant Filter-o-mat S. Reproduce from Flavour Compounds, Production Methods, *Encyclopaedia of ood Science, Food Technology and Nutrition,* Macrae R, Robinso RK and Sadler MJ (eds), 1993, Academic Press.

Plate 65 Flavor (Flavour) Compounds Kieselgur filtration plant with 35m^2 filtering area and slurry feeder DOSIMAT 500. Special execution with automatic filtration monitoring. Reproduced from Flavour Compounds, Production Methods, *Encyclopaedia of Food Science, Food Technology and Nutrition,* Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

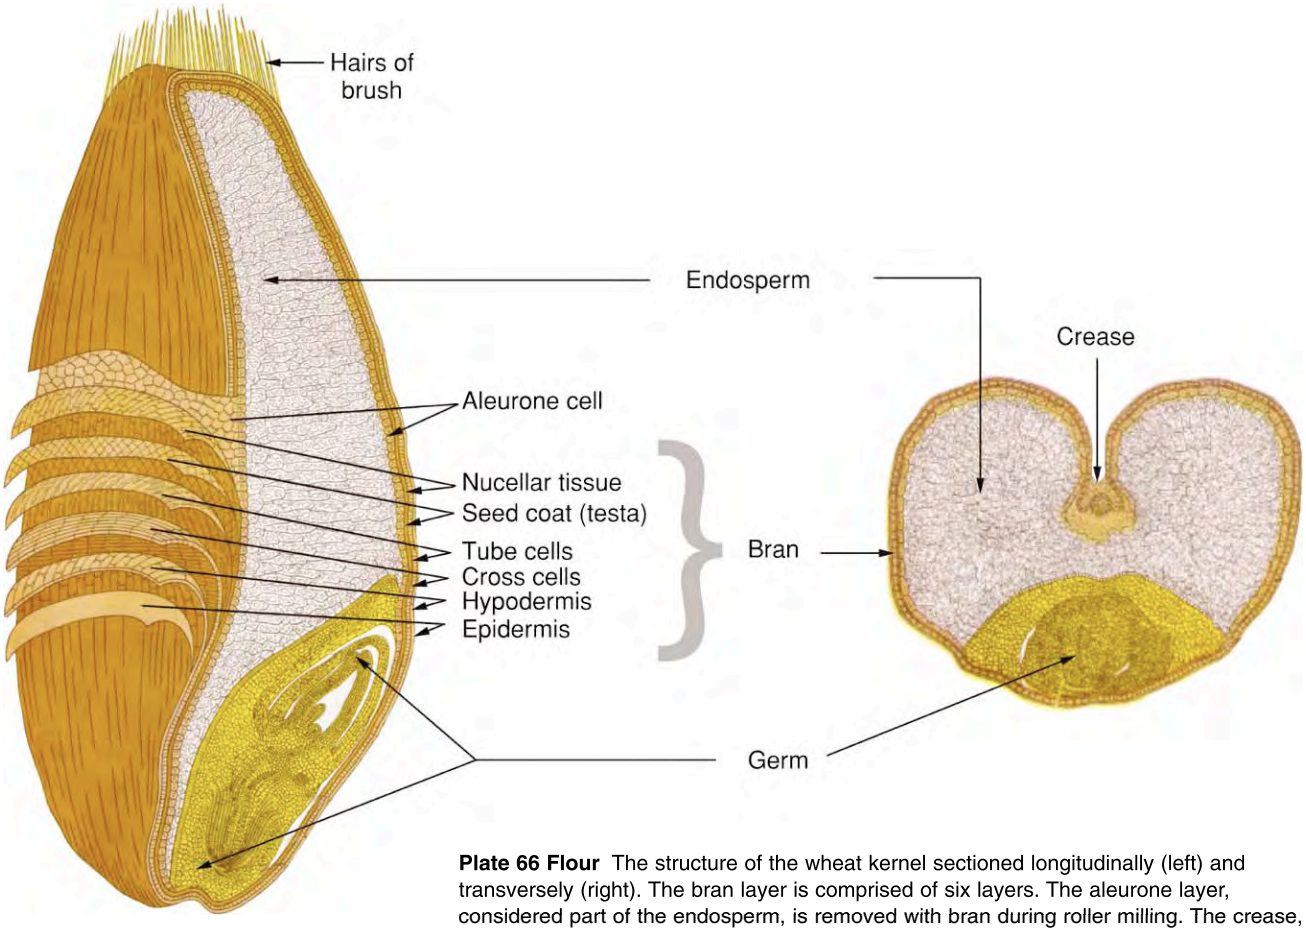

Plate 66 Flour The structure of the wheat kernel sectioned longitudinally (left) and transversely (right). The bran layer is comprised of six layers. The aleurone layer, considered part of the endosperm, is removed with bran during roller milling. The crease, which runs the full length of the kernel, prevents fully efficient separation of bran from endosperm.

Plate 67 Fruits of Temperate Climates Interspecific hybridisation in *Rubus* breeding (R. *phoenicolasius* is used as the donor of resistance to raspberry beetle (*Butyrus tomentosus)),* showing the wild accession (left), a commercial red raspberry (right), and the resultant F_1 hybrid.

Plate 68 Fruits of Tropical Climates Flowers and fruit of *Carissa macrocarpa* (num-num).

Plate 69 Fruits of Tropical Climates Fruit of *Dovyalis caffra* (kei-apple).

Plate 70 Fruits of Tropical Climates Fruit of *Mimusops zeyheri* (moepel).

Plate 71 Fruits of Tropical Climates
Fruit of *Garcinia livingstonei* (African mangosteen).

Plate 72 Fruits of Tropical Climates
Leaves and mature fruit of *Parinari curatellifolia* (mobola plum).

Plate 73 Fruits of Tropical Climates
Fruit of *Vangueria infausta* (wild maedlar).
