FOREWORD

There are no disciplines so all-encompassing in human endeavours as food science and nutrition. Whether it be biological, chemical, clinical, environmental, agricultural, physical – every science has a role and an impact. However, the disciplines of food science and nutrition do not begin or end with science. Politics and ethics, business and trade, humanitarian efforts, law and order, and basic human rights and morality all have something to do with it too.

As disciplines, food science and nutrition answer questions and solve problems. The questions and problems are diverse, and cover the full spectrum of every issue. Life span is one such issue, covered from the nutritional basis for fetal and infant development, to optimal nutrition for the elderly. Another such issue is the time span of the ancient and wild agro-biodiversity that we are working to preserve, to the designer cultivars from biotechnology that we are trying to develop. Still another is the age-old food preparation methods now honoured by the 'eco-gastronomes' of the world, to the high tech food product development advances of recent years.

As with most endeavours, our scientific and technological solutions can and do create new, unforeseen problems. The technologies that gave us an affordable and abundant food supply led to obesity and chronic diseases. The "green revolution" led to loss of some important agro-biodiversity. The technological innovation that gave us stable fats through hydrogenation, flooded the food supply with trans fatty acids. All these problems were identified through a multidisciplinary scientific approach and solutions are known. When technology created the problem and technology has found the solution, implementation is usually more successful. Reducing trans fatty acids in the food supply is case in point. Beyond the technologies, the solutions are more difficult to implement. We know how obesity can be reduced, but the solution is not directly technological. Hence, we show no success in the endeavour.

Of all the problems still confounding us in food science and nutrition, none is so compelling as reducing the number of hungry people in the world. FAO estimates that there are 800 million people who do not have enough to eat. The World Food Summit Plan of Action, the Millennium Development Goals and other international efforts look to food science and nutrition to provide the solution. Yet we only have part of the solution—the science part. The wider world of effort in food science and nutrition needs to be more conscientiously addressed by scientists. This is the world of advocacy and action: advocacy for food and nutrition as basic human rights, coupled with action to get food where it is needed.

But all those efforts would be futile if they are not based on sound scientific information. That is why works such as this Encyclopedia are so important. They provide to a wide readership, scientists and non-scientists alike, the opportunity to quickly gain understanding on specific topics, to clarify questions, and to orient to further reading. It is a pleasure to be involved in such an endeavour, where experts are willing to impart their knowledge and insights on scientific consensus and on exploration of current controversies. All the while, this gives us optimism for a brighter food and nutrition future.

Barbara Burlingame
25 February 2003

INTRODUCTION

There is no factor more vital to human survival than food. The only source of metabolic energy that humans can process is from nutrients and bioactive compounds with putative health benefits, and these come from the food that we eat. While infectious diseases and natural toxins may or may not affect people, everyone is inevitably affected by the type of food they consume.

In evolutionary terms, humans have increased the complexity of their food chain to an astounding level in a relatively short time. From the few staples of some thousand years ago, we have moved to an extraordinarily rich food chain, with many food items that would have been unrecognizable just some hundred years ago.

In this evolution, scientific discovery and technical developments have always gone hand in hand. The identification of vitamins and other essential nutrients last century, and the development of appropriate technologies, led to food fortification, and thus for the first time humans were able to modify foods to better fulfill their specific needs. As a result, nutritional deficiencies have been reduced dramatically or even eradicated in many parts of the world. This evolution is also yielding some undesirable consequences. The abundance of high-density, cheap calorie sources, and the market competition has facilitated overconsumption and promoted obesity, a problem of global proportions.

As the food chain grows in complexity, so does the scientific information related to it. Thus, providing accurate and integral scientific information on all aspects of the food chain, from agriculture and plant physiology to dietetics, clinical nutrition, epidemiology, and policy is obviously a major challenge.

The editors of the first edition of this encyclopedia took that challenge with, we believe, a great deal of success. This second edition builds on that success while updating and expanding in several areas. A large number of entries have been revised, and new entries added, amounting to two additional volumes. These new entries include new developments and technologies in food science, emerging issues in nutrition, and additional coverage of key areas. As always, we have made efforts to present the information in a concise and easy to read format, while maintaining rigorous scientific quality.

We trust that a wide range of scientists and health professionals will find this work useful. From food scientists in search of a methodological detail, to policymakers seeking update on a nutrition issue, we hope that you will find useful material for your work in this book. We also hope that, in however small way, the Encyclopedia will be a valuable resource for our shared efforts to improve food quality, availability, access, and ultimately, the health of populations around the world.

Acceptability of Food *See* **Food Acceptability**: Affective Methods; Market Research Methods

ACESULFAME/ACESULPHAME

J F Lawrence, Health and Welfare Canada, Ontario, Canada

Background

Acesulfame K (potassium salt of 6-methyl-1,2,3-oxathiazine-4(3H)-one-2,2-dioxide; Figure 1) is a high-intensity artificial sweetener which is about 200 times as sweet as sucrose (compared to a 3% aqueous sucrose solution). It was accidentally discovered in 1967 by Dr. Karl Clauss, a researcher with Hoechst AG in Frankfurt, FRG, during his experiments on new materials research. The sweetener is not metabolized by the human body and thus contributes no energy to the diet. It is now approved for use in more than 20 countries.

Sweetness

The sweetness properties of acesulfame K are similar to saccharin. It has a clean, sharp, sweet taste with a rapid onset of sweetness and no lingering aftertaste at normal use levels. However, at high concentrations, equivalent to 5% or 6% sucrose solutions, acesulfame K does possess a bitter, chemical aftertaste. The intensity of sweetness of acesulfame K, in common with other artificial sweeteners, varies depending upon its concentration and the type of food application. For example, it is 90 times sweeter than a 6% sucrose solution, 160 times sweeter than a 4% sucrose solution and 250 times sweeter than a 2% sucrose solution. Mixtures of acesulfame K with other intense sweeteners, such as aspartame or cyclamate, result in some synergistic increases in sweetness. Mixtures with saccharin are somewhat less synergistic.

Production and Physical and Chemical Properties

Acesulfame K (Figure 1) is structurally related to saccharin. It also has many of the same physical and chemical properties.

Acesulfame was one of a series of sweet-tasting substances synthesized by Hoechst AG in the late 1960s. All of these had in common the oxathiazinone dioxide ring structure. The synthesis involved reaction of fluorosulfonyl isocyanate with either acetylene derivatives or with active methylene compounds such as α-diketones, α-keto acids, or esters. The latter reaction is used for the commercial production of acesulfame K. A generalized reaction scheme for synthesis of the oxathiazinone dioxide ring structure is shown in Figure 2. Many analoges have been prepared and evaluated for taste properties. The potassium salt of the 6-methyl derivative, acesulfame K, displayed the best sensory and physical properties and thus it has received extensive testing aimed at obtaining approval for its use in diet foods.

Acesulfame K is a white crystalline material which is stable up to 250 °C, at which temperature it decomposes. The free acid form of the sweetener has a distinct melting point of 123.5 °C.

Acesulfame K has a specific density of 1.83. When dissolved in water it produces a nearly neutral solution while the free acid is strongly acidic (pH of a 0.1 mol l^{-1} aqueous solution being 1.15). The sweetener is very soluble in water; a 27% solution can be prepared at 20 °C. The solubility of acesulfame K increases significantly with temperature. At 80 °C, 50% solutions can be prepared; because of this, greater than 99% purity can be obtained by crystallization. It is substantially less soluble in common solvents such as ethanol, methanol, or acetone.

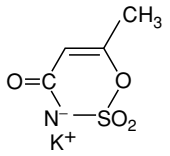

Figure 1 Structure of acesulfame K. Reproduced from Acesulphame/Acesulfame, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

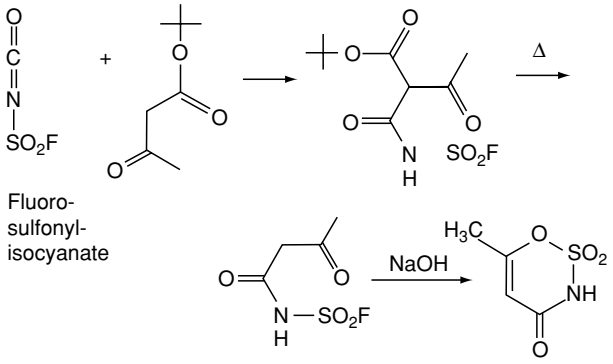

Figure 2 Synthesis of the acesulfame ring structure using fluorosulfonyl isocyanate and *tert*-butylacetoacetate as starting materials. Reproduced from Acesulphame/Acesulfame, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

The stability of acesulfame K in the solid state is very good. It can be stored at ambient temperature for 10 years without decomposition. Aqueous solutions at pH 3 or greater may also be stored for extended periods without detectable decomposition or loss of sweetness. However, below pH 3, significant hydrolysis may occur at elevated temperatures. For example, at pH 2.5 an aqueous buffered solution of acesulfame K would decompose by about 30% after 4 months of storage at 40 °C, whereas no decomposition occurs under the same conditions within the pH range of 3–8. At 20 °C, less than 10% decomposition of acesulfame K occurs after 4 months' storage at pH 2.5, indicating that under normal storage conditions aqueous solutions of the sweetener are very stable.

Acesulfame K is stable under most food-processing conditions, including the elevated temperature treatments encountered in pasteurization and baking.

Food Uses

Because of its stability, acesulfame K has been evaluated in a wide variety of diet food products, including table-top sweeteners, soft drinks, fruit preparations, desserts, breakfast cereals, and chewing gum. Table 1 lists approximate concentration levels of acesulfame K typically used in several types of foods.

Table 1 Typical use levels of acesulfame K in diet foods

Food products	*Concentration (mg kg^{-1})*
Soft drinks	1000
Coffee and tea	267
Jams and marmalades	3000
Ready-to-eat desserts	1000
Chewing gum	2000

Safety and Regulatory Status

Acesulfame K has been subjected to extensive feeding studies in mice, rats, and dogs. The substance is not considered to be carcinogenic, mutagenic, or teratogenic. It is excreted unmetabolized in test animals or humans. The current maximum acceptable daily intake (ADI: the maximum amount that can be consumed daily for a lifetime without appreciable risk) established by the Food and Agriculture Organization/World Health Organization (FAO/WHO) Joint Expert Committee on Food Additives in 1990 is 5 mg per kg body weight. This value is based on the highest amount fed to animals for which there was no effect.

The first regulatory approval for acesulfame K was by the UK in 1983. Since then it has received approval for specific uses in more than 20 countries.

Analysis

Thin-layer chromatography, isotachorphoresis, and high-performance liquid chromatography (HPLC) have been evaluated for the determination of acesulfame K in a variety of matrices, including liquid and solid food products, animal feed, and biological fluids. Of the three, HPLC is perhaps the most useful since the efficiency of the chromatography coupled with selective detection (ultraviolet absorbance) enable quantitative measurements to be made in rather complex food samples. In addition, the sample preparation is minimal, usually involving a water extraction for solid samples or a filtration and dilution of liquid samples before direct HPLC analysis. Acesulfame K has been incorporated into a multisweetener analytical method employing HPLC.

ACIDOPHILUS MILK

W Kneifel and C Bonaparte, University of Agricultural Sciences, Vienna, Austria

Background and History

Since the first documentation of the beneficial role of *Lactobacillus acidophilus* in correcting disorders of the human digestive tract in 1922, products containing *L. acidophilus*, especially various types of Acidophilus milk, have become increasingly popular. Today, a multitude of such products are commercially available, many of them being assigned to the category of probiotic foods. Most of these probiotics possess a bacterial microflora of well-documented and scientifically proven bacterial strains with several benefical properties. Besides other categories of foods containing special ingredients, these products have also recently been subclassified under the umbrella of functional foods.

In general, the human body is inhabitated by more than 500 different bacterial species; among them, the lactobacilli play an important ecological role. Besides their important gut-associated function, lactobacilli are also part of various other human-specific microbial ecosystems, e.g., skin, vagina, mouth, nasal, and conjunctival secretions. *L. acidophilus* is the best known of the health-promoting lactobacilli of mammals and a naturally resident species of the human gastrointestinal tract. It colonizes segments of the lower small intestine and parts of the large intestine, together with other lactobacilli species, such as *L. salivarius, L. leichmanii*, and *L. fermentum*. It is interesting to note that these resident *Lactobacillus* species should be distinguished from the spectrum of so-called transient *Lactobacillus* species, which are represented by *L. casei*.

Historically, in 1900, Australian researchers isolated *L. acidophilus* from fecal samples of bottle-fed infants for the first time and named it '*Bacillus acidophilus*.' The actual nomenclature *L. acidophilus* is derived from *acido* (acid) and *philus* (loving) and this designation reflects the acidotolerant potential of this species. In 1959, Rogosa and Sharpe presented a detailed description of this bacterium.

Fundamental Characteristics of *Lactobacillus acidophilus*

Together with 43 other species, *L. acidophilus* is listed as a member of the genus *Lactobacillus* which belongs to the heterogeneous category of lactic acid bacteria. Lactobacilli are Gram-positive, nonmotile, catalase-negative, nonspore-forming rods with varying shapes, ranging from slender, long rods to coccobacillary forms. They are considered as (facultative) anaerobes with microaerophilic properties. *L. acidophilus* usually appears as rods with rounded ends, with a size of 0.6–0.9 × 1.5–6 μm, mainly organized singly or in pairs or short chains (**Figure 1**). The cell wall peptidoglycan is of the Lys-D-Asp type; the mean proportion of guanine and cytosine in the DNA ranges between 34 and 37%. With rare exceptions, this bacterium shows good growth at 45 °C but not below 15 °C, having an optimum growth temperature in the range of 35–38 °C. Substrates with pH values of 5.5–6.0 are preferred. Metabolically, it is a typical obligately homofermentative bacterium and produces racemic lactic acid (both the L+ and the D− enantiomeric forms) from lactose, glucose, maltose, sucrose, and other carbohydrates. Usually, it follows the Embden–Meyerhof–Parnas pathway for glucose metabolism. Important growth factor requirements are acetic or mevalonic acid, riboflavin, pantothenic acid, niacin, folic acid and calcium, but not cobalamin, pyridoxine, and thymidine. Starch and cellobiose are fermented by most strains. Another differential key criterion for the distinction from other lactobacilli (e.g., *L. delbrueckii* subsp. *bulgaricus*) is its capability of cleaving esculin. Further differential criteria are the utilization of trehalose, melibiose, raffinose, ribose, and lactose. While

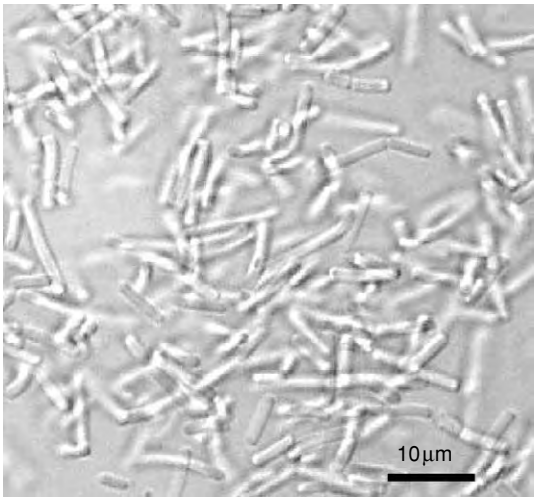

Figure 1 Microphotograph of a *Lactobacillus acidophilus* culture (deep-frozen culture concentrate cultured in MRS broth; for details see **Table 1**).

physiological parameters allow some distinction from other food-relevant lactobacilli, it is not possible to use a phenotypical basis to discriminate sufficiently among *L. acidophilus*, *L. johnsonii*, *L. gasseri*, *L. crispatus*, and *L. amylovorus*. All five species are usually assigned to the *L. acidophilus* cluster. A distinction of these species can be facilitated by applying genotypical techniques and methods based on DNA homology, the molar amounts of guanine plus cytosine in the DNA, or by the analysis of certain cell wall components.

Physiological Actions of *Lactobacillus acidophilus*

Because of the properties described above and its pronounced bile salt resistance, *L. acidophilus* is well adapted to the environmental conditions of the gastrointestinal tract. Proteins in the cell wall may be important in attaching the bacterium to the mucosal cells of the intestine. With strain-dependent variations, *L. acidophilus* contributes to the inhibition of the multiplication of pathogenic and putrefactive bacteria in the intestine due to the production of organic acid and trace amounts of H_2O_2. Furthermore, strain-specific inhibitory substances can be excreted by certain strains. In this context, numerous antagonistic peptides (bacteriocins) have been isolated from certain strains of *L. acidophilus*. For example, some of them were described as lactocidin, acidophilin, acidolin, lactosin B, and lactacin B and possess some 'antibiotic' potential against salmonellae, staphylococci, *Escherichia coli*, and clostridia, and partly also against other species of lactic acid bacteria. Because of their beneficial *L. acidophilus*-related properties, products containing this bacterium have been used in the treatment of gastrointestinal disorders and to reestablish the function of the intestine after treatment with antibiotics. Other features of these products are the provision of β-galactosidase to humans having an enzymatic deficiency for lactose digestion or, particularly when used in conjunction with fructooligosaccharides (oligofructose), the reduction of fecal enzymes (glucuronidase, nitroreductase, azoreductase) which obviously play some role in some stages of precancerogenesis. Since *L. acidophilus* produces equimolar amounts of L(+) and D(−) lactic acid, products fermented with this bacterium offer the advantage of a reduced D(−) lactate content, compared to classical yogurt. However, the acidification potential of this bacterium is often low and varies considerably among strains.

Products with *Lactobacillus acidophilus*

At present, a broad variety of products containing *L. acidophilus* is on the market. This bacterium has been incorporated into fermented as well as nonfermented milks of different levels of dry matter and fat (**Figure 2**). Cows' milk is the main substrate which is processed using the same basal technology as applied for the manufacture of yogurt or other cultured dairy products. Hence, continuous production lines with conventional or aseptic filling systems are used. Some of the products also contain added fruits and flavoring agents.

Fermented dairy products containing *L. acidophilus* as a single bacterial culture are primarily of local importance in Russia, Eastern European countries, and Scandinavia. In contrast, in other European regions, *L. acidophilus* is usually used in combination with other microorganisms (e.g., *Bifidobacterium* spp., *Streptococcus thermophilus, L. delbrueckii* subsp. *bulgaricus*, *L. casei*). Milk cultured with such multicomponent starter cultures (including *L. acidophilus*) is produced in increasing numbers and varieties and consumed frequently by many people. Among these dairy products, a distinction can be made between the so-called 'mild' yogurt products (yogurt-related fermented milks, with or without fruits) which are based on a fermentation with various thermophilic bacteria (many of them are assigned to the area of probiotics), and so-called 'Acidophilus milk' products which are usually fermented by means of mesophilic lactic acid bacteria (e.g., strains of *Lactococcus lactis* or *Leuconostoc cremoris* or combinations of both), in addition to *L. acidophilus*. A general flow diagram for the production of such an Acidophilus milk fermented under mesophilic

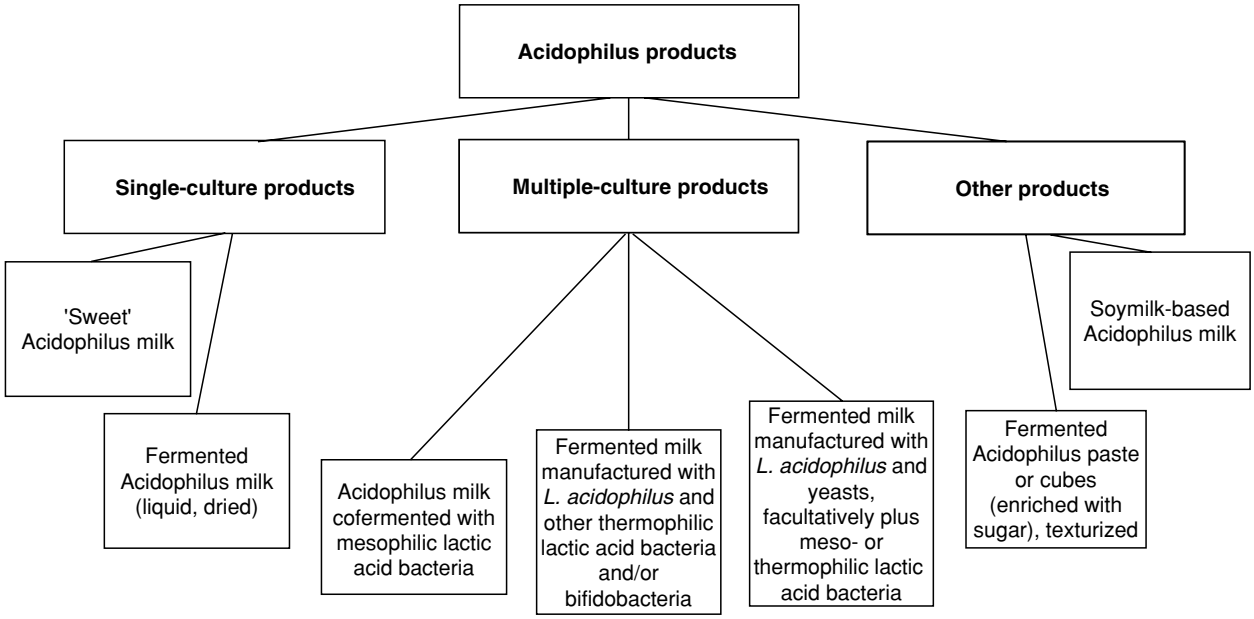

Figure 2 Survey of the diversity of food products containing *Lactobacillus acidophilus*.

conditions is presented in Figure 3. Deep-frozen culture concentrates or freeze-dried bacteria or, very rarely, liquid cultures are inoculated into the milk base. The fermentation is usually performed overnight for 15–20 h. Stirred products, with a liquid character, are usually made, but set-style fermented Acidophilus milk products with increased levels of solid-nonfat are also available.

Other categories of products include specially fermented drinks (e.g., *L. acidophilus* plus yeasts, with or without other lactic acid bacteria, resembling kefir and named acidophilin), texturized products with a reduced water content, which are offered in a pasty form or cut in cubes, or powdered milk which has been fermented with *L. acidophilus* before drying. Many of these product types have a local significance as dietary adjuncts. In Russia, these products even play some role as therapeutic agents and have been well recognized with regard to their medical relevance.

Nonfermented milk containing *L. acidophilus* is also offered by some dairies. Such products are usually produced from standardized milk which is supplemented with a culture concentrate (deep-frozen pellets or lyophylisate) of *L. acidophilus* under cooled conditions, followed by stirring before filling into cartons or beakers. Some of these products are also fortified with fat-soluble vitamins (A, D, E), water-soluble vitamins (thiamin), and trace elements (iron). While a pronounced metabolic activity of the *L. acidophilus* strains is desired for all those products which are produced by fermentation, storage-resistant but not fast-growing cultures (strains) are needed for the manufacture of 'sweet' (nonfermented) Acidophilus milk in order not to alter the sensory properties during storage.

The sensory characteristics of nonfermented 'sweet' Acidophilus milk are comparable with regular milk; those of fermented Acidophilus milk (mesophilic varieties) are similar to those of regular cultured or sour milks which are manufactured using a butter flavor-producing mesophilic culture, since almost no acetaldehyde, which is typical for yogurt, but some diacetyl-based butter aroma is generated during fermentation caused by citrate-fermenting mesophilic lactic acid bacteria. Since *L. acidophilus* possesses alcohol dehydrogenase activity, which is capable of reducing acetaldehyde, only low levels of this compound are found in the corresponding products. Thus, yogurt-related dairy products (thermophilic varieties) containing *L. acidophilus* often exhibit a milder and less acidic taste than classical yogurt, i.e., that manufactured by a cofermention of *S. thermophilus* and *L. delbrueckii* subsp. *bulgaricus*. Sensorically, this classical yogurt is dominated by acetaldehyde which introduces some kind of astringent characteristic and typical sharpness. Moreover, many classical yogurt cultures, in particular owing to the *Lactobacillus* component of the culture, exhibit a continued acidification activity even under cooled conditions on the shelves of retail shops. Besides the sensory changes, this 'overacidification' can also lead to textural problems (syneresis, whey separation).

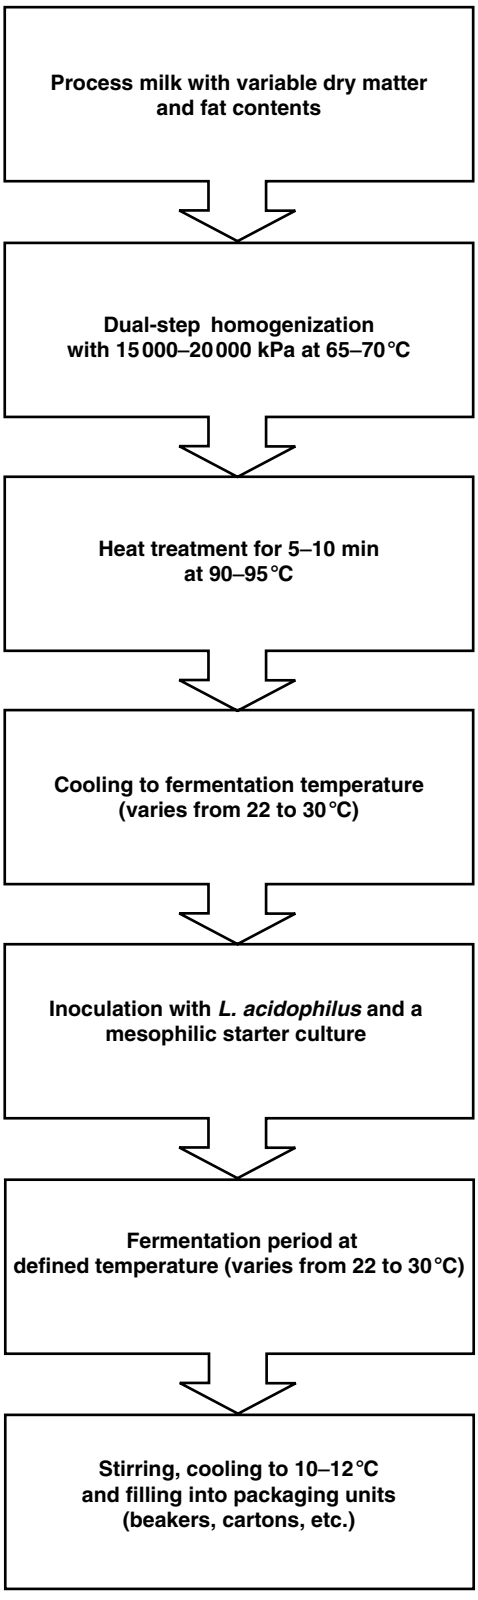

Figure 3 General production steps of the manufacture of fermented Acidophilus milk using a combined fermentation with *Lactobacillus acidophilus* and mesophilic lactic acid starter culture. Data compiled after various manufacturers' recommendations.

Obviously because of these effects, preferences of consumers for the milder yogurts with *L. acidophilus* have been observed in many countries.

A completely different group of Acidophilus products are the pharmaceutical preparations containing *L. acidophilus*. Capsules, suppositories, and soluble powders packaged in sachets are enriched with bacterial lyophylisates and used for therapeutic purposes. They are marketed in pharmacies and health stores.

Bacterial Viable Count and Bacterial Stability of Acidophilus milk

Although milk is a substrate containing almost a universal array of nutrients, it does not fully meet the growth requirements of *L. acidophilus*. For this purpose, additives and growth promoters consisting of a mixture of natural compounds which support and enhance bacterial growth are recommended for supplementation of the fermentation milk by most culture suppliers. Usually, they are added to the milk base in small amounts, before inoculation. In addition, the use of multicomponent cultures offers the advantage of inducing synergistic effects among the bacterial microflora which may also positively influence the propagation rate and the stability of the bacteria.

According to legal aspects and to consumer expectations, products labeled as Acidophilus milk or as containing *L. acidophilus* necessarily have to contain a significant number of these microorganisms. In this context, a group of experts of the International Dairy Federation has recommended that *L. acidophilus* shall be detected in such products at a level of at least 1 million CFU ml^{-1} or g, at their sell-by dates.

Recently, studies performed in several countries have shown that many commercially available products can meet this limit, but with a considerable number of products a decrease in the *L. acidophilus* counts has been observed during a storage period of approximately 3–5 weeks. Due to the fact that the expression of beneficial effects is based on a high number of active bacteria, a high viable count and pronounced bacterial stability have become important goals in product development and optimization.

Viable counts of *L. acidophilus*-containing dairy products are usually enumerated by culture methods based on plate count techniques with media designed for culturing lactic acid bacteria (e.g., MRS, Rogosa agar, TGV agar; for details see Table 1). To enhance the discriminatory power of these media (this is of particular relevance in the examination of products which contain a mixed microflora), media are modified by slight acidification and/or by supplementation

Table 1 Media used for culturing Lactobacillus acidophilus

Media	*References*

with antibiotics (e.g., vancomycin at different levels) or with other selective agents (cellobiose, conjugates with chromogenic indicator dyes, esculin, etc.). In many cases, the parallel use of different media selective for each of the bacterial components is necessary to allow the reliable microbiological monitoring of these Acidophilus products. Moreover, microscopical verification of isolates harvested from the different media usually completes their routine assessment. Although a number of media and methodologies have been described in the literature, no official standard method is available yet.

Properties and Determination

J D Dziezak, Dziezak & Associates, Ltd., Hoffman Estates, IL, USA

Background

In very general terms, an acid is a compound that contains or produces hydrogen ions in aqueous solutions, has a sour taste, and turns blue litmus paper red. A more comprehensive definition, given by the US chemist G.N. Lewis, states that acids are substances that can accept an electron pair or pairs, and bases are substances that can donate an electron pair or pairs. This definition, applicable to both nonaqueous and aqueous systems, requires that an acid be either a positive ion or a molecule with one or more electron-deficient sites with respect to a corresponding base.

The definition most widely used to describe acid–base reactions in dilute solution is one that was proposed independently by two scientists in 1923 – the Danish chemist J.N. Brønsted and the US chemist T.M. Lowry. The Brønsted–Lowry theory defines an acid as a proton donor, that is, any substance (charged or uncharged) that can release a hydrogen ion or proton. A base is defined as a proton acceptor or any substance that can accept a hydrogen ion or proton.

Table 1 Structure, ionization constant, pK_a, and key physical and chemical properties of acidulants[a]

Acid	*Structure*	*Ionization constant(s)*	*pK_a*	*Physical form*	*Melting point (°C)*	*Solubility (g per 100 ml of water)*	*Hygroscopicity*	*Taste characteristics*
Acetic acid	CH_3COOH	1.76×10^{-5} at 25 °C	4.76	Clear, colorless liquid	−8.5	Soluble	na	Tart and sour
Adipic acid		$K_1 = 3.71 \times 10^{-5}$ $K_2 = 3.87 \times 10^{-6}$ at 25 °C	4.43 5.41	Crystalline powder	152	1.9 g at 20 °C 83 g at 90 °C	Low level of hygroscopicity	Smooth lingering tartness; complements grape flavors
Citric acid		$K_1 = 7.10 \times 10^{-4}$ $K_2 = 1.68 \times 10^{-5}$ $K_3 = 6.4 \times 10^{-7}$ at 25 °C	3.14 4.77 6.39	Crystalline powder			Moderately hygroscopic	Tart; delivers a 'burst' of flavor
Anhydrous Hydrous					153 135–153	181 g at 25 °C 208 g at 25 °C		
Fumaric acid		$K_1 = 9.30 \times 10^{-4}$ $K_2 = 3.62 \times 10^{-5}$ at 18 °C	3.03 4.44	White granules or crystalline powder	286	0.5 g at 20 °C 9.8 g at 100 °C	Nonhygroscopic	Tart; has an affinity for grape flavors

Glucono-δ-lactone		1.99×10^{-4} (for gluconic acid)	3.7	White crystalline powder	153	59 g at 25 °C	Nonhygroscopic	Neutral taste with acidic aftertaste, when hydrolyzed
Lactic acid		1.37×10^{-4} at 25 °C	3.86	Liquid; also available in dry form	16.8	Very soluble	na	Acrid
Malic acid		$K_1 = 3.9 \times 10^{-4}$ $K_2 = 7.8 \times 10^{-6}$ at 25 °C	3.40 5.11	Crystalline powder	132	62 g at 25 °C	Nonhygroscopic	Smooth tartness
Phosphoric acid		$K_1 = 7.52 \times 10^{-3}$ $K_2 = 6.23 \times 10^{-8}$ $K_3 = 2.2 \times 10^{-13}$ K_1 and K_2 at 25 °C; K_3 at 18 °C	2.12 7.21 12.67	Liquid		Very soluble in hot water	na	Acrid
Tartaric acid		$K_1 = 1.04 \times 10^{-3}$ $K_2 = 4.55 \times 10^{-5}$ at 25 °C	2.98 4.34	Crystalline powder	168–170	147 g at 25 °C	Nonhygroscopic	Extremely tart; augments fruit flavors, especially grape and lime

This article discusses the physicochemical properties of acids and describes several methods for their analysis.

Strong Versus Weak Acids

The strength of a Brønsted–Lowry acid depends on how easily it releases a proton or protons. In strong acids, owing to their weaker internal hydrogen bonds, the protons are loosely held. As a result, in aqueous solutions, almost all of the acid reacts with water, leaving only a few unionized acid molecules in the equilibrium mixture. The reaction takes place according to eqn (1):

$$HA + H_2O \rightleftharpoons H_3O^+ + A^- \qquad (1)$$

In this equation, HA represents the undissociated acid, H_3O^+ the hydronium ion formed when a proton combines with one molecule of water, and A^- the conjugate base of HA.

Unlike strong acids, weak acids exist largely in the undissociated state when mixed with water, since only a small percentage of their molecules interact with water and dissociate. Most acids found in foods, including acetic, adipic, citric, fumaric, malic, phosphoric and tartaric acids, and glucono-δ-lactone, are classified as weak or medium strong acids.

Physicochemical Properties

Physicochemical properties, including the ionization constant, pH, the apparent dissociation constant (pK_a) and buffering capacity, are discussed below and are listed in Table 1.

Ionization Constant

The tendency for an acid or acid group to dissociate is defined by its ionization constant, also denoted as pK_a. The ionization constant, given at a specified temperature, is expressed as:

$$K_a = \frac{[H_3O^+][A^-]}{[HA]}, \qquad (2)$$

where the brackets designate the concentration in moles per liter. The ionization constant is a measure of acid strength: the higher the K_a value, the greater the number of hydrogen ions liberated per mole of acid in solution and the stronger the acid.

Acids with more than one transferable hydrogen ion per molecule are termed 'polyprotic' acids. Monoprotic or monobasic acids are those that can liberate one hydrogen ion, such as acetic acid and lactic acid. Those containing two transferable hydrogen ions are called diprotic or dibasic acids and include, for example, adipic acid and fumaric acid. Acids such as citric acid and phosphoric acid, which have three transferable hydrogens, are called triprotic or tribasic acids. Ionization of polyprotic acids occurs in a stepwise manner with the transfer of one hydrogen ion at a time. Each step is characterized by a different ionization constant.

pH

Measurement of acidity is an important aspect of ascertaining the safety and quality of foods. Such measurements are given in terms of pH, which is defined as the negative logarithm of the hydronium ion concentration (strictly, activity):

$$pH = \log_{10}\frac{1}{[H_3O^+]} = -\log_{10}[H_3O^+]. \qquad (3)$$

The lower the pH value, the higher the hydrogen ion concentration associated with it. A pH value of less than 7 indicates a hydrogen ion concentration greater than 10^{-7} M and an acidic solution; a pH value of more than 7 indicates a hydrogen ion concentration of less than 10^{-7} M and a basic solution. When the hydronium and hydroxide ions are equal in concentration, the solution is described as neutral. (*See* **pH – Principles and Measurement**.)

It is also important to note that, because the pH scale is logarithmic, a difference of one pH unit represents a 10-fold difference in hydrogen ion concentration.

pK_a

The term pK_a is defined as the negative logarithm of the dissociation constant:

$$pK_a = \log_{10}\frac{1}{K_a} = -\log_{10} K_a. \qquad (4)$$

The pK_a corresponds to the pH value at the midpoint of a titration curve developed when one equivalent of weak acid is titrated with base, and the pH resulting from each incremental addition of base is plotted against the equivalents of hydroxide ions added.

The pH of a system is at the pK_a when the concentrations of acid (HA) and conjugate base (A^-) are equal. At the pK_a and, to a lesser extent, in the area extending to within one pH unit on either side of the pK_a, the system resists changes in pH resulting from addition of small increments of acid or base. In other words, at the pK_a, acids and their salts function as buffers.

The number of pK_as that an acid has depends on the number of hydrogen ions it can liberate. Monoprotic acids have a single pK_a, whereas di- and triprotic acid have two and three pK_as, respectively.

Strong acids have low pK_a values, and strong bases have high pK_a values.

Buffering Capacity

A solution of a weak acid (or a weak base) and its corresponding salt is called a buffer solution. In these systems, the hydronium ion content is not significantly changed when a small amount of acid or base is added to that solution. The reason that buffer solutions resist appreciable changes in pH can be best illustrated by an example. If a small amount of hydrochloric acid is added to a buffer solution composed of acetic acid and sodium acetate, the protons from the hydrochloric acid would associate with the acetate ions to form unionized molecules of acetic acid. As the newly formed acid molecules ionize, the equilibrium would shift towards forming more hydronium ions (eqn (1)). This would result in only a very slight increase in pH.

Similarly, the addition of a small amount of sodium hydroxide to the same buffer solution would have little effect on pH. Hydroxide ions from the sodium hydroxide would combine with hydronium ions in the equilibrium mixture, forming undissociated molecules of sodium hydroxide. More of the acid molecules would then dissociate to replace the hydronium ions lost; though a new equilibrium system would be created, it would produce only a minimal effect on pH.

The quantity of acid or base that a buffer solution is capable of consuming before a change in pH is realized is termed the 'buffering capacity.' The buffering capacity is defined as the number of moles of strong acid or base required to increase the pH by one unit in 1 l of buffer solution. The buffering capacity of a solution is greatest at its pK_a value where the concentrations of acid and conjugate base are equal.

Analytical Methods

Quantitative determinations of acidity play an important role in ensuring food product quality and stability. Information obtained on acid levels can help in detecting cases of food adulteration, monitoring fermentation processes, and evaluating the organoleptic properties of fermented foods. pH determination, titratable acidity, chromatographic methods, and capillary electrophoresis are procedures commonly employed by the food industry to determine food acids. (*See* **Adulteration of Foods**: Detection.)

pH Determination

pH can be measured by two techniques: colorimetric and potentiometric. The colorimetric method involves adding a suitable indicator to a solution and matching the color of the solution to a standard solution containing the same indicator. This method can estimate pH to the nearest 0.1 pH unit.

A more accurate technique and the one most frequently employed, the potentiometric method, uses a pH meter to determine hydrogen ion concentration. The two electrodes of the meter – a calomel reference electrode and a glass indicator electrode – are immersed in the solution, of known temperature, whose pH is to be measured. The electrode potential of the indicator electrode is linearly related to changes in hydrogen ion concentration and therefore pH.

Titratable Acidity

The total concentration of acid in a solution can be determined by titration. The titration process is performed by placing in a flask a known volume of acid solution whose concentration is unknown. To the flask, a few drops of indicator, e.g., phenolphthalein, which is colorless in acid solutions and pink in basic solutions, is introduced. A base solution of known concentration is then gradually added until the acid is completely neutralized. This point is indicated when the solution permanently changes color. The concentration of acid can then be calculated from the volume of base solution used.

The value obtained, called titratable acidity, is an estimate of the total acid in the solution. It accounts for both the free hydronium ions present in the equilibrium mixture and the hydrogen ions released from undissociated acid molecules. For weak acids, the titratable acidity is different from the actual acidity (hydrogen ion concentration), since these compounds exist largely in the undissociated state in solution. For strong acids, however, titratable acidity and actual acidity are virtually the same, since strong acids and their salts are completely ionized in solution.

Chromatographic Methods

Gas chromatography (GC) and high-performance liquid chromatography (HPLC) have almost entirely replaced paper and thin-layer chromatography as methods for identifying and quantifying food acids.

Gas Chromatography GC has been used to analyze organic acids in fruit and fruit juice. Analysis involves preparing volatile derivatives such as methyl esters of the organic acids, prior to their injection into the gas chromatograph. Derivatives are chromatographed on a nonpolar stationary phase column and detected by a flame ionization detector.

By use of GC, malic acid has been shown to be a major constituent of many fruits, including apples, pears, grapes, peaches, and nectarines, and significant

levels of citric acid have been found in citrus fruits such as orange, lemon, and grapefruit, and in non-citrus fruits, including pears, nectarines, cherries, and strawberries. (*See* **Chromatography**: Gas Chromatography.)

High-performance Liquid Chromatography HPLC is used more extensively than GC to determine organic acids because the technique requires little or no chemical modification to separate these nonvolatile compounds. Separation is usually done on either a reversed-phase C8 or C18 column or a cation-exchange resin column operated in the hydrogen mode. Acids are detected by either refractive index (RI) or ultraviolet (UV) detectors. RI detection requires prior removal of any sugars present that potentially can interfere with quantification; sugar removal is not required for UV detection at 220–230 nm.

Adulteration of a commercial cranberry juice drink was detected using HPLC when the test yielded different results for organic acids, sugars, and anthocyanin pigments than those obtained for a standard juice drink. Atypical citric and/or malic acid contents and presence of a natural colorant, probably grape skin extract, confirmed that the drink was adulterated.

In wine-making, HPLC is used to monitor concentrations of tartaric, malic, succinic, citric, lactic, and acetic acids, which contribute tartness and stability to the finished product. A common approach involves using a column containing a strong cation exchange resin and eluting the sample with dilute sulfuric acid; the eluant is then analyzed for acids by RI detection. This column has the additional advantage of permitting the simultaneous detection and quantification of ethanol and the monitoring of wine for adulteration with methanol. Organic acids in wine can also be separated using ion chromatography with a conductivity detector. (*See* **Chromatography**: High-performance Liquid Chromatography.)

Capillary Electrophoresis

A relatively new technique, capillary electrophoresis, is also useful for separating and quantifying organic acids in food systems. This technique utilizes an electrical field to separate molecules on the basis of their charge and size. Small volumes of sample, usually a few nanoliters, are injected on to a fused silica capillary tube, which is usually less than 1 m in length and 50 μm in internal diameter. The ends of the tube are placed in electrolyte reservoirs containing electrodes. A voltage in the range of 20–30 kV is delivered to the electrodes by a power supply and causes the charged molecules to move. Because organic acids are negatively charged, they migrate away from more neutral or positively charged molecules, such as sugars and phenols, respectively. Acids are detected by a UV detector, and the signal is sent to a data collector. The resulting separation is graphically represented as an electrophoregram.

Enzymatic Analysis

Enzyme assays provide another means of analyzing acids. For example, an enzymatic assay of L-malic acid uses an NAD(P)-linked malic enzyme and involves spectrophotometrically measuring the absorbance of NADPH, a reaction product, at 340 nm.

Natural Acids and Acidulants

J D Dziezak, Dziezak & Associates, Ltd., Hoffman Estates, IL, USA

Background

Acids, or acidulants as they are also called, are commonly used in food processing as flavor intensifiers, preservatives, buffers, meat-curing agents, viscosity modifiers, and leavening agents. This article discusses the functions that acidulants have in food systems and reviews the more commonly used food acidulants.

Functions of Acidulants

The reasons for using acidulants in foods are numerous and depend on what the food processor hopes to accomplish. As outlined above, the principal reasons

for incorporating an acidulant into a food system are flavor modification, microbial inhibition, and chelation.

Flavor Modification

Sourness or tartness is one of the five major taste sensations: sour, salty, sweet, bitter, and umami (the most recently determined). Unlike the sensations of sweetness and bitterness, which can be developed by a variety of molecular structures, sourness is evoked only by the hydronium ion of acidic compounds.

Each acid has a particular set of taste characteristics, which include the time of perceived onset of sourness, the intensity of sourness, and any lingering of aftertaste. Some acids impart a stronger sour note than others at the same pH. As a general rule, weak acids have a stronger sour taste than strong acids at the same pH because they exist primarily in the undissociated state. As the small amount of hydronium ions is neutralized in the mouth, more undissociated acid (HA) molecules ionize to replace the hydronium ions lost from equilibrium (eqn (1)). The newly released hydronium ions are then neutralized until no acid remains. Taste characteristics of the acid are an important factor in the development of flavor systems.

$$HA + H_2O \rightarrow H_3O^+ + A^- \qquad (1)$$

As pH decreases, the acid becomes more undissociated and imparts more of a sour taste. For example, the intense sour notes of lactic acid at pH 3.5 may be explained by the fact that 70% of the acid is undissociated at this pH, compared with 30% for citric acid. In addition to sourness, acids have nonsour characteristics such as bitterness and astringency, though these are less perceptible. At pH values between 3.5 and 4.5, lactic acid is the most astringent. Acids also have the ability to modify or intensify the taste sensations of other flavor compounds, to blend unrelated taste characteristics, and to mask undesirable aftertastes by prolonging a tartness sensation. For example, in fruit drinks formulated with low-caloric sweeteners, acids mask the aftertaste of the sweetener and impart the tartness that is characteristic of the natural juice. In another example, in substitutes for table salt, acids remove the bitterness from potassium chloride and provide the salty taste of sodium chloride. Other acids, such as glutamic and succinic acids, possess flavor-enhancement properties. (*See* **Flavor (Flavour) Compounds**: Structures and Characteristics; **Sensory Evaluation**: Taste.)

Because acids are rarely found in nature as a single acid, the combined use of acids simulates a more natural flavor. Two acids that are frequently blended together are lactic and acetic.

Microbial Inhibition

Acidulants act as preservatives by retarding the growth of microorganisms and the germination of microbial spores which lead to food spoilage. The effect is attributed to both the pH and the concentration of the acid in its undissociated state. It is primarily the undissociated form of the acid which carries the antimicrobial activity: as the pH is lowered, this helps shift the equilibrium in favor of the undissociated form of the acid, thereby leading to more effective antimicrobial activity. The nature of the acid is also an important factor in microbial inhibition: weak acids are more effective at the same pH in controlling microbial growth. Acids affect primarily bacteria because many of these organisms do not grow well below about pH 5; yeasts and molds, in comparison, are usually acid-tolerant. (*See* **Spoilage**: Bacterial Spoilage; Molds in Spoilage; Yeasts in Spoilage.)

In fruit- and vegetable-canning operations, the combined use of heat and acidity permits sterilization and spore inactivation to be achieved at lower temperatures; this minimizes the degradation of flavor and structure that generally results from processing. (*See* **Canning**: Principles.)

Acidification also improves the effectiveness of antimicrobial agents such as benzoates, sorbates, and propionates. For example, sodium benzoate – an effective inhibitor of bacteria and yeasts – does not exert its antimicrobial activity until the pH is reduced to about 4.5. (*See* **Preservation of Food**.) Blends of acids act synergistically to inhibit microbial growth. For example, lactic and acetic acids have been found to inhibit the outgrowth of heterofermentative lactobacilli.

Chelation

Oxidative reactions occur naturally in foods. They are responsible for many undesirable effects in the product, including discoloration, rancidity, turbidity, and degradation of flavor and nutrients. As catalysts to these reactions, metal ions such as copper, iron, manganese, nickel, tin, and zinc need to be present in only trace quantities in the product or on the processing machinery. (*See* **Oxidation of Food Components**.)

Many acids chelate the metal ions so as to render them unavailable; the unshared pair of electrons in the molecular structure of acids promotes the complexing action. When used in combination with antioxidants such as butylated hydroxyanisole, butylated hydroxytoluene, or tertiary butylhydroquinone, acids have a synergistic effect on product stability. Citric acid and its salts are the most widely used chelating agents. (*See* **Antioxidants**: Natural Antioxidants; Synthetic Antioxidants.)

Other Functions

One of the most common reasons for adding acids is to control pH. This is usually done as a means to retard enzymatic reactions, to control the gelation of certain hydrocolloids and proteins, and to standardize pH in fermentation processes. In the first example, the lowering of pH inactivates many natural enzymes which promote product discoloration and development of off-flavors. Polyphenol oxidase, for example, oxidizes phenols to quinones, which subsequently polymerize, forming brown melanin pigments that discolor the cut surfaces of fruits and vegetables. The enzyme is active between pH 5 and 7 and is irreversibly inactivated at a pH of 3 or lower. In the second example, acidification to 2.5–3 is required for high-methoxyl pectins to form gels. Because pH influences the gel-setting properties and the gel strength obtained, proper pH control is critical in the production of pectin- and gelatin-based desserts, jams, jellies, preserves, and other products. In the final example, standardization of pH is done routinely in fermentation processes, such as wine-making, to ensure optimum microbial activity and to discourage growth of undesirable microbes. Acids are also added postfermentation to stabilize the finished wine. (*See* **Beers**: Biochemistry of Fermentation; **Colloids and Emulsions**; **Enzymes**: Functions and Characteristics; **Phenolic Compounds**.)

Acid salts function as buffers in various systems. (*See* **Acids**: Properties and Determination.) For example, in confectionery products, acid salts are used to control the inversion of sucrose into its constituents, glucose and fructose, the latter being hygroscopic. The resulting lower concentration of fructose yields a less hygroscopic food system and a longer shelf-life.

Acids are a major component of chemical leavening systems, where they remain nonreactive until the proper temperature and moisture conditions are attained. The gas evolved by reaction of the acid with bicarbonate produces the aerated texture that is characteristic of baked products such as cakes, biscuits, doughnuts, pancakes, and waffles. The onset and the rate of reaction of these compounds are controlled by such factors as the solubility of the acid, the mixing conditions for preparing the batter, and the temperature and moisture of the batter. Many chemical leavening systems are based on salts of phosphoric and tartaric acids. (*See* **Leavening Agents**.)

Acids have also been used for other purposes. For example, they are added to chewing gum to stabilize aspartame and to cheese to impart favorable textural properties and sensory attributes.

Commonly Used Acidulants

Among the most widely used acids are acetic, adipic, citric, fumaric, lactic, malic, phosphoric, and tartaric acids. Glucono-δ-lactone, though not itself an acid, is regarded as an acidulant because it converts to gluconic acid under high temperatures.

Acetic Acid

Acetic acid is the major characterizing component of vinegar. Its concentration determines the strength of the vinegar, a value termed 'grain strength,' which is equal to 10 times the acetic acid concentration. Vinegar containing, for example, 6% acetic acid has a grain strength of 60 and is called 60-grain. Distillation can be used to concentrate vinegar to the desired strength. (*See* **Vinegar**.)

Fermentation conducted under controlled conditions is the commercial method for vinegar production. Bacterial strains of the genera *Acetobacter* and *Acetomonas* produce acetic acid from alcohol which has been obtained from a previous fermentation involving a variety of substrates such as grain and apples. Vinegar functions in pH reduction, control of microbial growth, and enhancement of flavor. It has found use in a variety of products, including condiments such as ketchup, mustard, mayonnaise, and relish, salad dressings, marinades for meat, poultry, and fish, bakery products, soups, and cheeses. Pure (100%) acetic acid is called glacial acetic acid because it freezes to an ice-like solid at 16.6 °C. Though not widely used in food, glacial acetic acid provides acidification and flavoring in sliced, canned fruits and vegetables, sausage, and salad dressings.

Adipic Acid

Adipic acid, a white, crystalline powder, is characterized by low hygroscopicity and a lingering, high tartness that complements grape-flavored products and those with delicate flavors. The acid is slightly more tart than citric acid at any pH. Aqueous solutions of the acid are the least acidic of all food acidulants, and have a strong buffering capacity in the pH range 2.5–3.0.

Adipic acid functions primarily as an acidifier, buffer, gelling aid, and sequestrant. It is used in confectionery, cheese analogs, fats, and flavoring extracts. Because of its low rate of moisture absorption, it is especially useful in dry products such as powdered fruit-flavored beverage mixes, leavening systems of cake mixes, gelatin desserts, evaporated milk, and instant puddings.

Citric Acid

The most widely used organic acid in the food industry, citric acid, accounts for more than 60% of all acidulants consumed. It is the standard for evaluating the effects of other acidulants. Its major advantages include its high solubility in water; appealing effects on flavor, particularly its ability to deliver a 'burst' of tartness; strong metal chelation properties; and the widest buffer range of the food acids (2.5–6.5).

Citric acid is naturally present in animal and plant tissues and is most abundantly found in citrus fruits including the lemon (4–8%), grapefruit (1.2–2.1%), tangerine (0.9–1.2%) and orange (0.6–1.0%). (*See* **Citrus Fruits**: Composition and Characterization.)

The principal method for commercial production of the acid is fermentation of corn. Formerly, the acid had been obtained by extraction from citrus and pineapple juices. Citric acid is available in a liquid form, which solves processing problems related to incorporating the acid into a food system, such as predissolving citric acid crystals and caking or crystallate deposits on processing equipment. Also available are granulated forms which allow the particle size to be customized to meet the particular need.

Citric acid has numerous applications. It is commonly added to nonalcoholic beverages where it complements fruit flavors, contributes tartness, chelates metal ions, acts as a preservative, and controls pH so that the desired sweetness characteristics can be achieved. Sodium citrate subdues the sharp acid notes in highly acidified carbonated beverages; in club soda, it imparts a cool, saline taste and helps retain carbonation. The acid is also used in wine production both prior to and after fermentation for adjustment of pH; in addition, because of its metal-chelating action, the acid prevents haze or turbidity caused by the binding of metals with tannin or phosphate. The calcium salt of citric acid is used as an anticaking agent in fructose-sweetened, powdered soft drinks, where it neutralizes the alkalinity of other ingredients that support browning, such as magnesium oxide and tricalcium phosphate.

Citric acid has also found use in confectionery and desserts. In hard confectionery, buffered citric acid imparts a pleasant tart taste; it is added to the molten mass after cooking, as this prevents sucrose inversion and browning. Citric acid is used in gelatin desserts because it imparts tartness, acts as a buffering agent, and increases the pH for optimum gel strength.

Low levels of the acid, ranging from 0.001 to 0.01%, work with antioxidants to retard oxidative rancidity in dry sausage, fresh pork sausage, and dried meats. Citric acid is also used in the production of frankfurters: 3–5% solutions are sprayed on the casings after stuffing and prior to smoking to aid in their removal from the finished product. Used at 0.2% in livestock blood, sodium citrate and citric acid act as anticoagulants, sequestering the calcium required for clot formation so that the blood may be used as a binder in pet foods.

In seafood processing, citric acid inactivates endogenous enzymes and promotes the action of antioxidants, resulting in an increased shelf-life. Citric acid also chelates copper and iron ions that catalyze the oxidative formation of off-flavors and fishy odors associated with dimethylamine. In processed cheese and cheese foods, citric acid and sodium citrate function in emulsification, buffering, flavor enhancement, and texture development. Sodium citrate is also combined with sodium phosphate as a customized emulsification salt for processed cheese. Cogranulation of citric acid with malic and fumaric acids yields new tart flavor profiles.

Fumaric Acid

The extremely low rate of moisture absorption of this acid makes it an important ingredient for extending the shelf-life of powdered food products such as gelatin desserts and pie fillings. Fumaric acid can be used in smaller quantities than citric, malic, and lactic acids to achieve similar taste effects.

Fermentation of glucose or molasses by certain *Rhizopus* spp. is the method used to produce fumaric acid commercially. The acid is also made by isomerization of maleic acid with heat or a catalyst, and is a byproduct of the production of phthalic and maleic anhydrides. Fumaric acid is also made in particulate form, where the acid makes up about 5–95% of the particulate, with the remainder being other acids such as malic, tartaric, citric, lactic, ascorbic, and related mixtures.

Applications of fumaric acid include rye bread, jellies, jams, juice drinks, candy, water-in-oil emulsifying agents, reconstituted fats, and dough conditioners. In refrigerated biscuit doughs, the acid eliminates crystal formations that may occur in all-purpose leavening systems. In wine, it functions as both an acidulant and a clarifying aid, although it does not chelate copper or iron.

Glucono-δ-lactone (GDL)

A natural constituent of fruits and honey, GDL is an inner ester of D-gluconic acid. Unlike other acidulants, it is neutral and gives a slow rate of acidification. When added to water, it hydrolyzes to form an equilibrium mixture of gluconic acid and its δ- and γ-lactones. The acid formation takes place slowly when cold and accelerates when heated. As

GDL converts to gluconic acid, its taste characteristics change from sweet to neutral with a slight acidic afteraste.

GDL is produced commercially from glucose by a fermentation process that uses enzymes or pure cultures of microorganisms such as *Aspergillus niger* or *Acetobacter suboxydans* to oxidize glucose to gluconic acid. GDL is extracted by crystallization from the fermentation product, an aqueous solution of gluconic acid and GDL.

Because of its gradual acidification, bland taste, and metal-chelating action, GDL has found application in mild-flavored products such as chocolate products, tofu, milk puddings, and creamy salad dressings. In cottage cheese prepared by the direct-set method, GDL ensures development of a finer-textured finished product, void of localized denaturation. It also shortens production time and increases yields. In cured-meat products, GDL reduces cure time, inhibits growth of undesirable microorganisms, promotes color development, and reduces nitrate and nitrite requirements. (*See* **Curing**.)

Lactic Acid

Lactic acid is one of the earliest acids to be used in foods. It was first commercially produced about 60 years ago, and only within the past two decades has it become an important ingredient. The mild taste characteristics of the acid do not mask weaker aromatic flavors. Lactic acid functions in pH reduction, flavor enhancement, and microbial inhibition. Two methods are used commercially to produce the acid: fermentation and chemical synthesis. Most manufacturers using fermentation are in Europe.

Confectionery, bakery products, beer, wine, beverages, dairy products, dried egg whites, and meat products are examples of the types of products in which lactic acid is used. The acid is used in packaged Spanish olives where it inhibits spoilage and further fermentation. In cheese production, it is added to adjust pH and as a flavoring agent.

Malic Acid

This general-purpose acidulant imparts a smooth, tart taste which lingers in the mouth, helping to mask the aftertastes of low- or noncaloric sweeteners. It has taste-blending and flavor-fixative characteristics and a relatively low melting point with respect to other solid acidulants. The low melting point allows it be homogeneously distributed into food systems. Compared with citric acid, malic acid has a much stronger apparent acidic taste. As DL-malic acid is the most hygroscopic of the acids, resulting in lumping and browning in dry mixes, the encapsulated form of this acid is preferred for dry mixes.

Malic acid occurs naturally in many fruits and vegetables, and is the second most predominant acid in citrus fruits, many berries, and figs. Unlike the natural acid, which is levorotatory, the commercial product is a racemic mixture of D- and L-isomers. It is manufactured during catalytic hydration of maleic and fumaric acids, and is recovered from the equilibrium product mixture.

The acid has been used in carbonated beverages, powdered juice drinks, jams, jellies, canned fruits and vegetables, and confectionery. Its lingering profile enhances fruit flavors such as strawberry and cherry. In aspartame-sweetened beverages, malic acid acts synergistically with aspartame so that the combined use of malic and citric acids permits a 10% reduction in the level of aspartame. In frozen pizza, malic acid is used to lower the pH of the tomato paste without chelating the calcium in the cheese, as would citric and fumaric acids. This application improves the texture of the frozen pizza.

Phosphoric Acid

The second most widely used acidulant in food, phosphoric acid, is the only inorganic acid to be used extensively for food purposes. It produces the lowest pH of all food acidulants. Phosphoric acid is produced from elemental phosphorus recovered from phosphate rock.

The primary use of the acid is in cola, root beer, and other similar-flavored carbonated beverages. The acid and its salts are also used during production of natural cheese for adjustment of pH; phosphates chelate the calcium required by bacteriophages, which can destroy bacteria responsible for ripening. As chemical leavening agents, phosphates release gas upon neutralizing alkaline sodium bicarbonate; this creates a porous, cellular structure in baked products. The main reason for incorporating phosphates into cured meats such as hams and corned beef is to increase retention of natural juices; the salts are dissolved in the brine and incorporated into the meat by injection of brine, massaging, or tumbling. When used in jams and jellies, phosphoric acid acts as a buffering agent to ensure a strong gel strength; it also prevents dulling of the gel color by sequestering prooxidative metal ions.

Tartaric Acid

Tartaric acid is the most water-soluble of the solid acidulants. It contributes a strong tart taste which enhances fruit flavors, particularly grape and lime. This dibasic acid is produced from potassium acid tartrate which has been recovered from various byproducts of the wine industry, including press cakes from fermented and partially fermented grape

juice, less (the dried, slimy sediments in wine fermentation vats), and argols (the crystalline crusts formed in vats during the second fermentation step of wine-making). The major European wine-producing countries, Spain, Germany, Italy, and France, use more of the acid than the USA.

Tartaric acid is often used as an acidulant in grape- and lime-flavored beverages, gelatin desserts, jams, jellies, and hard sour confectionery. The acidic monopotassium salt, more commonly known as 'cream of tartar,' is used in baking powders and leavening systems. Because it has limited solubility at lower temperatures, cream of tartar does not react with bicarbonate until the baking temperatures are reached; this ensures maximum development of volume in the finished product.

ADAPTATION – NUTRITIONAL ASPECTS

P S Shetty, Food and Agriculture Organization, Rome, Italy
J C Waterlow, London School of Hygiene & Tropical Medicine, London, UK

Introduction

The word 'adaptation' is used in many different contexts: biological or Darwinian; physiological or metabolic; behavioral or social. In nutrition, we are concerned with the last two. The difference between 'adaptation' and 'homeostasis' is that the latter represents the maintenance of a set point for some physiological characteristic such as body temperature or pH – this is Claude Bernard's '*fixité du milieu intérieur*.' Adaptation involves a change in the set point, for example, the increase in hemoglobin concentration found in people living at high altitude or the decrease in sodium concentration in the sweat in people exposed to high environmental temperatures. Such adaptations take time; one speaks of people 'becoming adapted,' whereas homeostasis is a rapid and continuous process. For adaptation to be more than just a response, it must represent a new steady state, capable of being maintained, and we think of it as beneficial to the organism, preserving, within limits, normal function. It is here that the real difficulty arises. For most bodily characteristics or functions, there are no clear definitions of a 'normal' range, within which physiological adaptations can operate. Basal metabolic rate (BMR) is an exception, but for most functions that are important for the quality of life, such as work capacity or resistance to infection, there are no such defined limits, so it is difficult to decide whether an adaptation is 'successful.' We shall return to this point later.

In nutrition, it is convenient to look separately at adaptation to inadequate intakes of energy and protein before going on to the more realistic situation of overall deficiency of food and deficiency or excess of micronutrients.

Adaptation to Low Energy Intakes

The human body responds to an inadequate intake of food energy by a whole series of physiological and behavioral responses. Experimental studies of semistarvation in normal adults have helped in understanding the physiological changes that characterize this adaptive response to a lowered energy intake in humans. The metabolic responses that occur during acute energy restriction and the physiological mechanisms that are involved may, however, be different from the changes observed in individuals who are chronically undernourished as a result of long-standing marginal energy intakes.

In previously well nourished adults, a reduction in BMR is a constant finding during experimentally or therapeutically induced energy restriction. This finding has been explained on the basis of a loss of active tissue mass, as a result of the loss of body weight, together with a decrease in the metabolic activity of the active tissues. The latter would indicate a greater efficiency or metabolic adaptation, on the assumption that the same amount of work is being done at lower cost. Recalculating the data from the two separate semistarvation studies, one short term and the other longer term, it has been shown that the early fall in BMR seen during energy restriction is mainly accounted for by enhanced metabolic efficiency (Table 1). This reduction in BMR per kilogram of active body tissues seen in the first 2 weeks of energy restriction remained essentially unchanged over the subsequent period of semi-starvation. The greater contribution to the fall in BMR during prolonged energy restriction, however, was the result of a slow decrease in the total mass of active tissues. It seems reasonable, therefore, to suggest that the reduction in BMR during energy restriction occurs in two different phases. In the initial phase, there is a marked decrease in the BMR, which is not attributable to the changes in body weight or body composition. This decrease in BMR per unit active tissue is a measure of increase in

Table 1 Changes in body weight, active tissue mass (ATM), and basal metabolic rate (BMR) following short- and long-term semistarvation in humans

	Semistarvation			
	Short-term[a]		*Long-term*[b]	
	Baseline	*Day 14*	*Baseline*	*Day 168*
Body weight (kg)	71.6	65.4	67.5	51.7
ATM (kg)	44.9	42.2	38.8	28.7
BMR: MJ day^{-1}	7.3	5.7	6.6	4.2
kcal day^{-1}	1742	1370	1575	1004
BMR decrease:				
kJ day^{-1}		21.4%		36.3%
kJ kg^{-1} ATM		16.3%		13.8%

[a]Data from experiments conducted on 12 human subjects by Grande *et al*. (1958).
[b]Data from experiments conducted on 12 human subjects by Keys *et al*. (1950).

'metabolic efficiency' in well-nourished individuals who are energy-restricted and is often cited as evidence of 'metabolic adaptation.' With continued energy restriction, the lowered level of cellular metabolic rate remains nearly constant, and any further decrease in BMR is accounted for by the loss of body weight. Thus, the longer the duration of energy restriction, the more important the contribution of decreased body tissues becomes to the reduction in BMR. This reduction in lean body tissue with prolonged energy restriction is considered to be a passive process and a consequence of body tissues being used as substrates and metabolic fuel to compensate for the lack of food energy.

The biochemical and physiological mechanisms involved in reducing the cellular metabolic rate are poorly understood. It has recently been estimated that ~90% of BMR is contributed by mitochondrial oxygen consumption, of which only ~20% is uncoupled by mitochondrial proton leak and the rest coupled to ATP synthesis. It is not known how much changes in mitochondrial function contribute to the increasing efficiency of tissue metabolism. Several physiological changes in hormonal and substrate function may operate to influence the changes in metabolic efficiency seen during the early part of energy restriction. Several hormones are now known to be sensitive to changes in the levels of energy intake, dietary composition, and energy balance status of the individual. Changes in sympathetic nervous system (SNS) activity and catecholamines, alterations in thyroid hormone metabolism, and changes in insulin and glucagon play an important role in this response. The reduction in SNS activity and catecholaminergic drive that we observed was counter to traditional views on the control of substrate mobilization during starvation. Traditionally, the increase in lipolysis, maintenance of glucose homeostasis, and increase in glucagon output on fasting have been considered as being the result of an enhanced sympathetic drive during energy restriction. It now appears that the lipolytic activity associated with energy restriction appears to be under the dominant control of declining plasma insulin levels. Insulin is the primary hormonal signal that allows for an orderly transition from the fed to the fasted state without the development of hypoglycemia. While the SNS activity is toned down, signaled by the decrease in energy flux, the energy deficit lowers insulin secretion and initiates changes in peripheral thyroid metabolism. The reduction in the activities of these three thermogenic hormones acts in a concerted manner to lower cellular metabolic rate. Changes in other hormones such as glucagon, growth hormone, and glucocorticoids may also participate and, in association with insulin deficiency, help promote endogenous substrate mobilization leading to an increase in circulating free fatty acids (FFA) and ketone bodies. Contribution may also be made by the reduction in Na^+–K^+ pumping across the cell membrane and futile substrate cycling, although how much they contribute to the reduced energy output is not known. The elevated FFA levels, alterations in substrate recyling, and protein catabolism will also influence the resting energy expenditure. These changes are thus not only aimed at lowering the metabolic activity of the active cell mass but also essential for the orderly mobilization of endogenous substrates and fuels during a period of restricted availability of exogenous calories. These hormonal and metabolic changes aid the survival of the organism and may be considered as being 'adaptive' in nature.

Adaptation to lowered energy intake in chronically undernourished adults on subsistence food intakes in the developing world appears, however, to be different. Ferro-Luzzi summarized the adaptive responses in individuals who were maintaining energy balance in spite of life-long exposure to low energy intakes – the state of so-called 'chronic energy deficiency.' Adaptation was represented as a series of complex integrations of several different processes that occurred during energy deficiency and resulted in a new level of equilibrium being achieved at a lower level of energy intake. People who have gone through the adaptive process may be expected to exhibit more or less permanent sequelae (or costs of adaptation), which include smaller stature and body size, altered body composition and a lower BMR, with the likelihood of enhanced metabolic efficiency of energy handling. However, this has been difficult to prove, largely because marked changes in the body composition (in particular in the fat and lean compartments) make interpretation of changes in the metabolic rate per unit of active tissue mass highly unreliable as indicators of metabolic efficiency. Changes in body composition as well as in body size and dimensions may play a dominant role in adaptation to long-term inadequacy of energy intake from childhood, however undesirable they may be. These physiological adaptations are not beneficial changes, as they influence employability and economic productivity, although they may help in furthering survival of the individual.

Adaptations to a reduction in food energy intake may also be manifest as physiological and behavioral changes in physical activity, aimed at reducing the energy expended by the individual every day to make up for the energy deficit. Reductions in either intensity or duration of physical activity can save much energy and hence may be a crucial response to

energy restriction and an important feature of the adaptive response. Studies on semistarvation of previously well nourished adults showed a marked impairment in both intensity and duration of activity. About 40% of the reduction was attributable to a decrease in actual costs of performing tasks, whereas 60% of the reduction was due to a decrease in tasks undertaken. In previously well-nourished semistarved adults, behavioral reduction in voluntary activity seems to be quantitatively more important. Analysis of the pattern of an individual's physical activity during a voluntary reduction in food intake shows that the behavioral responses were associated with a distinct change in activity pattern.

Physiological changes in the physical work capacity of undernourished young men are also difficult to demonstrate, and the overwhelming evidence seems to support the view that differences, if any, are largely due to changes in body composition and not to adaptive differences in cell function. Spurr summarized the results of several of his studies in Colombia, which demonstrated that maximal oxygen uptake ($Vo_{2\ max}$) was lower in malnourished young adults; the degree of reduction being related to the progressive severity of undernutrition. He was also able to demonstrate that 80% of the reduction in $Vo_{2\ max}$ in moderate and severe categories of undernutrition was accounted for by differences in muscle cell mass. Assessment of endurance at 70–80% of the $Vo_{2\ max}$ in the undernourished also failed to demonstrate any differences in the maximum endurance time. However, assessment of productivity in agricultural environments shows that work productivity is affected indirectly by nutritional status, through its influence on stature, body weight, body composition, and $Vo_{2\ max}$.

Chronically undernourished adults are likely to demonstrate increased ergonomic or 'real life' efficiency. By this is meant a reduction in the effort needed to do any piece of physical work. It is reasonable to suppose that tradition and experience have enabled people living on marginal intakes and hence likely to be chronically undernourished to find the most economical methods of doing the tasks they have to do. This manifestation of increased efficiency might be regarded as a training effect, quite distinct from the behavioral adaptation that accompanies undernutrition, which is mainly related to how individuals allocate time and energy to different productive and leisure activities, with inevitable biological and economic consequences. In undernutrition, more time is given to work activities, while leisure and home production activities are reduced; this is an important form of behavioral adaptation. Marginally undernourished individuals tend to become more sedentary at the expense of decreased social interactions and discretional noneconomic activities. Latham showed that when energy-deficient individuals are forced over a period of time to limit their activities, they forego activities to conserve energy, some of which they do consciously and wilfully, some they do unconsciously. Thus, restricting physical activity or performing it more efficiently is an important coping strategy for undernourished individuals and may form part of the behavioral adaptive response to a lowered intake of food energy.

Adaptation to Low Protein Intakes

Most of our knowledge on this subject has been derived from experimental studies on man. Adaptation to low protein intakes has two proximate functions: to secure nitrogen balance and to maintain lean body mass (LBM). As regarding balance, there is an obligatory loss of nitrogen from the body which has been estimated in male Caucasian adults to amount to about 55–65 mg of nitrogen per kilogram per day and which has to be balanced by the intake. There is little evidence that this loss is lower in people long accustomed to low protein intakes, or to an intake mainly from vegetable sources, so there does not seem to be much opportunity for adaptation at this point. There is, however, evidence, that on lower protein intakes or in children recovering from malnutrition, the efficiency of utilization of food protein may be increased above the usual level of about 70%. This effect may be regarded as a response to depletion, i.e., loss of body nitrogen, but is none the less an adaptive response aimed at conserving body nitrogen.

When a person moves from a normal intake, providing say 1.5 g of protein (250 mg of nitrogen) per kilogram per day to an intake close to the obligatory loss, the nitrogen output falls to a new low level in 7–10 days in the human adult, 1–2 days in the infant and about 30 h in the rat. This is the first stage of adaptation. During this stage, there is a small loss, amounting to 1–2% of body N, which probably has no physiological significance.

The main variable in this adaptation is the urinary excretion of urea. Urea production, which is a measure of amino acid oxidation, is related to nitrogen intake, although at the present time, there is some controversy about the strength of the relationship. Only part of the urea produced is excreted in the urine; the remainder passes into the colon, where it is hydrolyzed by gut bacteria to ammonia. A relatively small part of this ammonia is recycled to urea. The rest of it enters the amino acid pool, and there is increasing evidence that microbes in the gut are

capable of using it to synthesize indispensable as well as dispensable amino acids. In the normal individual, on an adequate nitrogen intake and in a steady state, these reactions are essentially exchanges, and there is no net gain of nitrogen. However, with a deficient intake or an increased demand for growth, amino acids derived from the colonic hydrolysis of urea can make a significant contribution to the body's nitrogen economy. Hence, the term 'urea salvage,' introduced by Jackson is appropriate, salvage representing an important component of adaptation. Since the proportion of urea hydrolyzed to that excreted increases on a low protein intake, it follows that the maintenance of nitrogen balance involves control of the rate of hydrolysis. It is thought that this control may be exerted by a urea transporter, which is sensitive to the protein level of the diet.

A second phase of adaptation comes into play if the protein intake is inadequate to cover the obligatory losses, so that there is a prolonged negative nitrogen balance. This inevitably leads to a loss of body protein. Since the magnitude of the obligatory loss is determined by the body protein mass, as this mass decreases, the loss will decrease until eventually the nitrogen balance is restored. This would represent an adaptation at the expense of a certain loss of lean body mass. Whether that loss is important will be discussed below. An example of such an adaptation is provided by the poor Indian laborers, studied by Shetty's group in Bangalore, whose lean body mass was substantially less (13%) than that of taller controls with the same body mass index (BMI). An important finding was that in these men, the main deficit was of muscle rather than of visceral mass. Presumably, this adaptation has its cost in terms of reduced muscular capacity, but it seems justifiable to regard it as a successful adaptation, since these men could live reasonable lives.

The metabolism of plasma albumin provides an interesting example of adaptation to low protein intake. In children with protein-energy malnutrition, one of the most constant findings is a reduction in plasma albumin concentration. This is accompanied by a fall in the rate of albumin catabolism, as if in an effort to maintain the concentration in plasma. The same effect has been shown in adults on experimental low protein intakes; the relative change in the rate of albumin breakdown was much greater than the change in albumin concentration. Thus, the breakdown rate would provide a much more sensitive measure of the state of protein nutrition than the albumin concentration; unfortunately, it is not a measurement that is practical on a large scale.

In real life, it is in famines, refugee camps, or concentration camps that we are faced with the question: what are the limits of adaptation to a food supply that is inadequate in both energy and protein – in other words, to semistarvation? Nowadays, the response is generally measured by the level of the body mass index (BMI = weight (kg)/height^2 (m)). Factors that affect the response of the BMI are the degree of deficiency, its duration, and the relative deficiencies of energy and protein. In total starvation, of which, as already mentioned, there have been a number of experimental studies, no steady state can be achieved, and no adaptation is possible. In the famous Minnesota semistarvation experiment, subjects were fed half their normal intakes of energy and protein; after 24 weeks, their BMI had fallen to about 16 from an initial level of about 22, and they showed severe functional and psychological impairment. This was in marked contrast to the Indian laborers referred to above who had a similarly low BMI. It seems that by life-long exposure to presumably inadequate food intakes they had adapted to a steady state of what would be currently described as 'chronic energy deficiency,' yet, their vital functions of energy and protein turnover were well maintained.

Some cases of semistarvation present with edema, which is quite commonly seen in famines and in refugee camps. Although the cause of the edema is controversial, it is a reasonable hypothesis that it results from a particular deficiency of protein in relation to energy, although there may be other deficiencies as well. In one study in a refugee camp, subjects with edema had a higher BMI, as might be expected from the accumulation of fluid, than those without edema, but they also had a substantially higher mortality rate. Women adapted better than men; this is apparent in several accounts. It appears, therefore, that when protein is particularly deficient, the capacity for adaptation is reduced.

From a physiological point of view, if the requirement for successful adaptation is the maintenance of LBM within 'normal' limits, it becomes crucial to define those limits. There are many difficulties. The BMI is a crude estimate of LBM, since it does not separate fat from lean tissue. However, the fat content of the body has a bearing on the capacity for adaptation, since it has been shown, not surprisingly, that in starvation, the loss of LBM is inversely related to the size of the initial fat stores. A low BMI with loss of muscle mass would explain the association mentioned above with decreased maximal oxygen consumption and reduced work capacity. However, it does not explain other associations that have been found, such as reduced resistance to infections and low birth weight of infants. Interestingly, there is no effect on breast-milk output, suggesting that this function, basic for the survival of the race, is well

protected. What, then, are the normal limits? Is there a threshold or cutoff point of LBM, as assessed by BMI, above which function is normal and below which it falls off? Some evidence from epidemiological studies suggest that there is no threshold, but a steady fall-off with falling BMI. However, because BMI is influenced by many factors beyond physiological homeostasis, it is difficult to establish with certainty the limits within which adaptation may be regarded as successful.

Adaptation to Variations in Micronutrient (Mineral and Vitamin) Intakes

One of the major processes by which adaptation to changes in nutrient intakes occurs, particularly that of micronutrients, is by changes in gastrointestinal function. The gastrointestinal tract has extensive potential for adaptation. For instance, following intestinal resection, the residual intestine is capable of a considerable increase in size and absorptive capacity. This is achieved by dilatation and an increase in rugosity and by hypertrophy of the villi and microvilli. This increases the available surface area of contact with the nutrients and thus increases the absorptive capacity. The enzyme activities and the turnover of cells are also increased. The ileal part of the intestines adapts better than the jejunum. Changes in the function of the intestines, such as slowing down the transit, also helps the process of adaptation by increasing absorptive capacity. These adaptive changes are maximized by the mucosal exposure to nutrients and by the role played by several key hormones. Intestinal adaptation is, however, limited by inadequate blood supply or poor nutritional status.

Calcium represents the best example of a micronutrient whose absorption by the gastrointestinal tract is modulated to demonstrate adaptation. The physiological need for calcium changes throughout the lifecycle, i.e., growth, puberty, pregnancy, lactation, and menopause. Calcium intakes are also highly variable world-wide, with a more than fourfold difference between the lowest intake and the highest. Hence, the absorption of calcium from the diet must be adaptable and responsive to both dietary and physiological circumstances. This process of adaptation and physiological plasticity is largely orchestrated by vitamin D, which stimulates intestinal calcium absorption by both genomic and nongenomic mechanisms. The renal output of dihydroxy vitamin D_3, which is regulated, reflects the perceived needs of the organism for calcium, which in turn influences the tightly regulated process of intestinal calcium absorption. The latter regulation occurs both by genomic receptor mediated action (i.e., through calbindin) and by nongenomic mechanisms (through transcaltachia). There are other social and behavioral adaptations, too, which influence the individuals' choice of diet and determine what is available for intestinal absorption. It is hence believed that vitamin D-mediated calcium absorption by the intestines satisfies the requirement for it to be considered as an adaptive function.

One would expect that the requirements of most micronutrients are amenable to adaptation when intakes are lowered, although the evidence for such changes is not readily available.

ADIPOSE TISSUE

Contents

Structure and Function of White Adipose Tissue

R G Vernon and D J Flint, Hannah Research Institute, Ayr, UK

Distribution and Structure of Adipose Tissue

White adipose tissue is quantitatively the most variable component of the body, ranging from a few percent of body weight to over 50% in obese animals and people. In mammals, adipose tissue is found within the abdominal cavity, under the skin, within the musculature where it is found between muscles (intermuscular) and within muscles (intramuscular) (e.g., marbling of meat) and in a few highly specialized locations such as the eye socket. Within these locations, the tissue occurs in discrete depots (e.g., perirenal, epididymal, omental, popliteal); there are about 16 in most species. Comparative studies have revealed that the distribution of adipose tissue depots evolved early in mammalian evolution and has been retained in most species. In some species (e.g., pigs, whales) subcutaneous depots have become enlarged and have fused to form a continuous layer; this also occurs in obese individuals. Adipose tissue depots are also found in birds, reptiles, and amphibians.

White adipose tissue is a soft tissue, devoid of rigidity, and is well supplied with capillaries and nerve endings from the sympathetic nervous system. In mature animals, adipocytes (fat cells) comprise about 90% of the mass of the tissue but only 25% or less of the total cell population. The 75% or so nonadipocytes are often termed the stromal–vascular fraction and comprise mainly endothelial cells of blood vessels and adipocyte precursor cells. Adipocytes vary enormously in size from several picolitres to about 3 nl in volume, depending on the amount of lipid present. The mature fat cell is essentially a lipid droplet surrounded by a film of cytoplasm (containing mitochondria, endoplasmic reticulum, etc.) and bounded by a plasma membrane; the nucleus is pushed to the periphery and appears as a blip on the surface of the cell. Within a depot, there will be fat cells of various sizes so that it is usual to refer to the 'mean fat cell volume' of a tissue; this varies amongst adipose tissue depots in an individual. The adipocyte mean cell volume also varies with size of the animal, larger animals having larger fat cells; this occurs both within and between species.

Functions of Adipose Tissue

The major function of white adipose tissue is the storage of energy as triacylglycerol (fat, lipid). Fat is a highly efficient form of energy storage, not only because of its high energy content per unit weight, but also because it is hydrophobic. Hence, 1 g of adipose tissue may contain about 800 mg of triacylglycerol and about 100 mg of water. In contrast, glycogen not only has a lower energy content per unit weight than fat, but also is much more hydrated. The development of copious stores of fat was probably very important for the evolution of homeothermy in mammals and birds. Homeotherms have a much higher basal metabolic rate and so need a more substantial energy reserve than poikilotherms (reptiles, fish, and amphibians). The ability to accrue copious amounts of adipose tissue was also essential for exploitation of habitats where food supply is

scarce (e.g., deserts) or seasonal (e.g., arctic). Northern species such as polar bears and reindeer build up substantial depots of fat during the summer to provide reserves of nutrients during the winter. Such species thus have substantial seasonal fluctuations in the amount of adipose tissue in their bodies. Additional reserves of adipose tissue are also accumulated during pregnancy in most species to help support the development of the fetus during the later stages of pregnancy and to facilitate milk production. The use of adipose tissue lipid is very important during early lactation in dairy cows, for example, in which appetite increases more slowly than milk production at the beginning of lactation. It is also important for milk production in some species of bears and seals that fast during lactation.

It is now apparent that adipose tissues are not solely a store of fat. Subcutaneous adipose tissue will act as insulation; adipose depots in the eye socket may have a protective function. More importantly perhaps, adipose tissue produces a number of biologically active substances, e.g., prostaglandins, insulin-like growth factor 1 and binding proteins, adipsin, cytokines (e.g., tumor necrosis factor α), estrogens (primarily estrone), and leptin. Some of these substances are probably important for adipose tissue function and development, but some have other roles. Adipose tissue is the major source of estrogens in postmenopausal women. The mammary gland grows in a bed of adipose tissue and is thought to require factors secreted by adipose tissue for its development. Lymph nodes are located in adipose tissue depots and in some species (e.g., guinea-pigs), at least, there is an interaction between adipocytes and lymphoid cells. Adipose tissue may have another role in defense systems of the body as it secretes adipsin and several other proteins involved in an alternative pathway of complement production. Another important protein produced by adipocytes is the cytokine tumor necrosis factor-α; production of this factor is normally low, but it is markedly increased during obesity, when it appears to play a major role in the development of insulin resistance in the tissue, and hence noninsulin-dependent diabetes.

Perhaps the most important and interesting protein secreted by adipocytes is leptin, which has a key role in appetite control and energy balance (**Figure 1**). Leptin was discovered only recently through studies on the basis of a genetically obese strain of mice (ob/ob mice); these mice produce a nonfunctional form of leptin. Leptin is released into the blood and travels to the brain, where there are leptin receptors in discrete areas involved in appetite control. Low levels of leptin in the blood increase appetite, whereas administration of high doses inhibit appetite. Leptin not only modulates appetite, but also increases energy expenditure, stimulating thermogenesis in brown adipose tissue, suggesting a key role in the control of energy balance in the body. Leptin synthesis is regulated by insulin, glucocorticoids, and catecholamines, but most interestingly, the concentration of leptin in the blood in the fed state is proportional to the amount of fat in the body; this led to the idea that leptin acts as a 'lipostat,' matching appetite to adiposity. However, the leptin concentration in the blood is decreased by fasting, and leptin is involved in the changes in secretion of several pituitary hormones during fasting. Thus, it has been suggested that the major

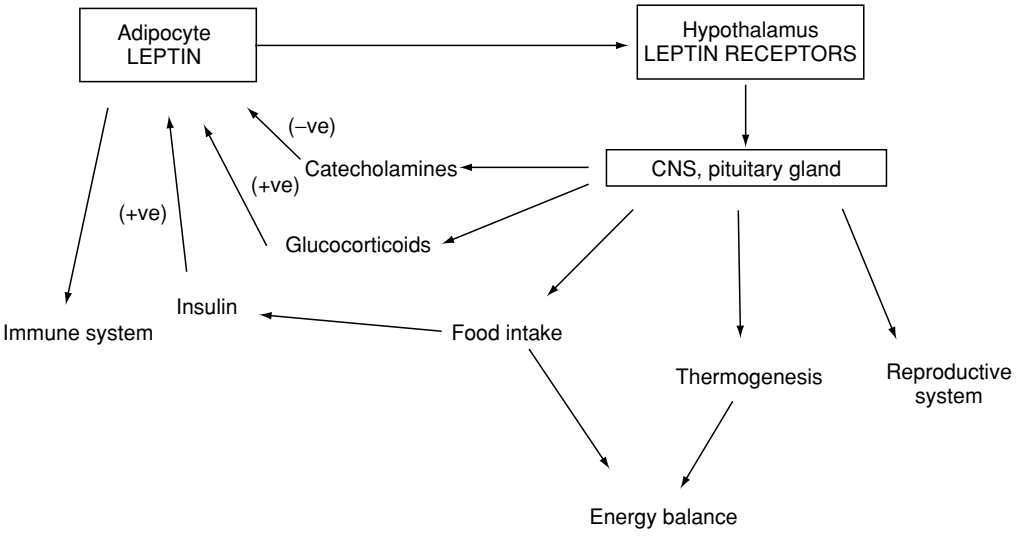

Figure 1 Leptin production and function. CNS, central nervous system.

role of leptin may be in adaptation to fasting and acting as a signal of too little rather than too much adipose tissue. Leptin appears to be required for normal functioning of the immune system and also for reproductive function. Indeed, a lack of leptin may well be the main reason for the failure of the menstrual cycle in anorexics and very lean athletes. This makes good physiological sense as it insures that females do not become pregnant, unless they have adequate reserves of adipose tissue lipid.

Adipose tissue thus has a variety of functions, in addition to being an energy store. While the accumulation of adipose tissue lipid reserves provides a buffer against starvation, and some degree of adiposity is important for the various other functions of the adipose tissue described above, there is a cost in that additional body mass decreases speed and agility and so increases the chance of succumbing to predation. Thus, in most wild animals for which food is generally plentiful, there are usually only small amounts of adipose tissue (predation rather than starvation being the greatest threat to mortality). In such species, it seems likely that the leptin system, and probably other systems, will be acutely tuned to maintain the minimal amounts of adipose tissue needed. In general, it is only species living in environments where the availability of food is erratic or seasonal that accumulate large amounts of adipose tissue since, for these species, starvation is a greater threat than predation. In such species, the leptin system must be modulated to allow the accumulation of adipose tissue lipid. It would also appear that the leptin system can be readily subverted in humans and also domestic pets for excess adiposity is becoming a major problem.

In addition to white adipose tissue, there is also another form, brown adipose tissue, which differs morphologically and biochemically, and has an important role in thermogenesis.

Development of Adipose Tissue

Adipose tissue develops both by accretion of lipid in adipocytes and by increases in the number of adipocytes. Mature adipocytes are thought to be unable to divide; rather, they are produced from a pool of precursor cells within the tissue. The sequence of events in the formation of mature adipocytes (Figure 2) is still partly speculative, and much has been gleaned from studies of certain cell lines (e.g., ob17 and 3T3 L1 cells), which will differentiate and develop into adipocytes in cell culture. Current thinking envisages a pluripotent stem cell that can give rise to muscle and bone cells as well as adipocytes. Once committed to adipocyte formation, this cell is termed an adipoblast.

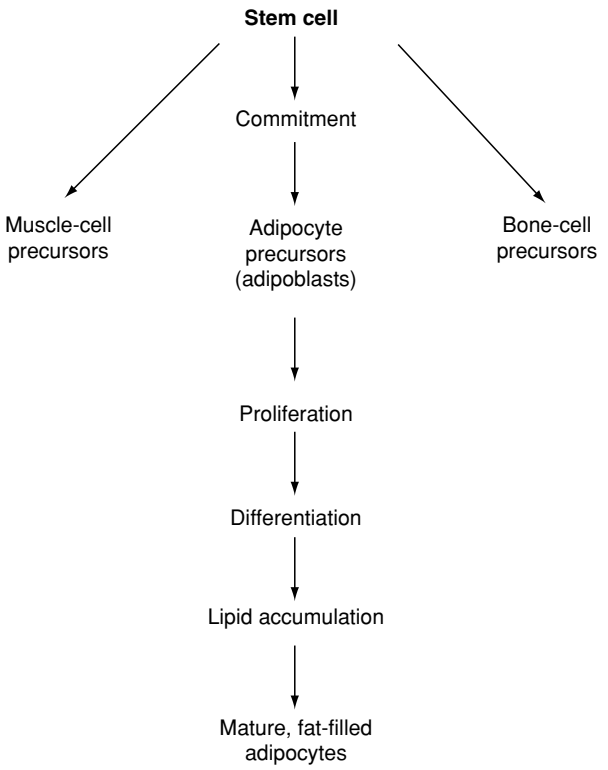

Figure 2 Adipocyte development.

This is envisaged (it has not been isolated) as an undifferentiated cell, devoid of lipid droplets but able to proliferate. At some point, these cells begin to differentiate, acquiring, in stages, the enzymes and other proteins characteristic of adipocytes. Once differentiated, these cells can begin to accumulate lipid, which appears at first as a series of small droplets within the cell. As these become larger, they fuse to form the single lipid droplet characteristic of mature adipocytes. Both differentiating cells and cells with several small lipid droplets (multilocular phase) are often referred to as preadipocytes, the term adipocyte usually being used to describe cells with a single lipid droplet. Multilocular adipocytes are very similar in appearance to mature brown adipocytes, and it was once thought that the brown adipocyte was a stage in the development of the white adipocytes. It is now recognized that this view is incorrect, except possibly for a few special cases (e.g., the perirenal adipose tissue depot of newborn lambs).

Adipocytes begin to appear in the fetus about half way through gestation, developing in small clumps around blood vessels. Within a depot, both the number and size of adipocytes increase in phases (Figure 3). In addition, it is now clear that development is not synchronized in all depots; abdominal depots in general develop earlier than those

associated with the musculature. In most species, the fetal stage is a period of active proliferation but little hypertrophy, so that cells are small at birth (about 10 pl in volume). The suckling period usually results in rapid hypertrophy and hyperplasia; this is followed by a more quiescent period when muscle growth predominates. When the rate of muscle growth begins to slacken, nutrients are diverted into adipose tissue, and the fattening phase begins. This phase is associated with marked hypertrophy, due to lipid deposition, in most depots and further hyperplasia, especially in the carcass depots. During the fattening phase, depot-specific differences in adipocyte size appear. Adipocytes do not increase in size indefinitely; once a maximum is reached (about 1–3 nl, depending on species), this seems to trigger the formation of new adipocytes from the precursor pool. The view prevalent in the 1970s that all hyperplasia occurred in young animals, including humans, is now thought to be invalid.

A great deal of research has gone into identifying the hormones and other factors that promote the proliferation and differentiation of adipocyte precursor cells. At present, the picture is far from clear, in part because of probable species differences and also because much of the work has involved the use of cell lines that do not all appear to have identical hormonal requirements for development. A variety of peptide growth factors (e.g., insulin-like growth factor 1, fibroblast growth factor, platelet-derived growth factor, epidermal growth factor) can stimulate preadipocyte proliferation, whereas insulin, thyroid hormones, and glucocorticoids appear to be important for differentiation of preadipocytes into adipocytes in a variety of species. Glucocorticoid hormones and also testosterone are thought to have important roles in site-specific development of adipose tissue. Derivatives of arachidonic acid (an essential fatty acid) such as 15-deoxy-$\Delta^{12,14}$-prostaglandin J_2 are also thought to have a major role in adipogenesis, acting via the recently discovered (and inappropriately named!) peroxisome proliferator-activated receptor-γ. Growth hormone has a complex role, stimulating insulin-like growth factor 1 production in adipose tissue and hence proliferation of preadipocytes and in addition may be required for the cells to become 'committed' to differentiation. In addition to positive effectors, tumor necrosis factor α and transforming growth factor β can inhibit differentiation. In contrast to hyperplasia, much more is known about the control of hypertrophy, for this is dependent on the metabolic rates of the pathways of lipid synthesis and degradation.

Deposition and Mobilization of Fat

The synthesis of triacylglycerol (esterification) requires a supply of fatty acids and glycerol 3-phosphate (Figure 4). The latter is mostly synthesized from glucose. Fatty acids, however, may be synthesized *de novo* within the cell or obtained from blood triacylglycerols. Fatty acids can be synthesized in adipocytes from a variety of precursors, including glucose, acetate, lactate, and some amino acids. Glucose is quantitatively the most important in man and some laboratory species (e.g., rats, mice), whereas acetate is most important in ruminants. Liver is also an important site of fatty acid synthesis in many mammals and is the major site of fatty acid synthesis in birds (avian adipocytes have essentially no capacity for fatty acid synthesis) and also in humans on a typical Western diet. Some of the fatty acids synthesized in the liver are incorporated into very-low-density lipoprotein

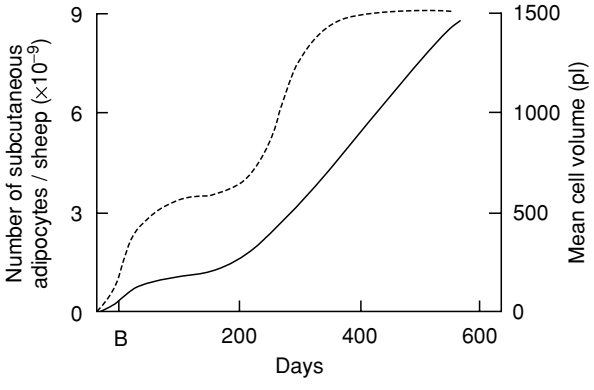

Figure 3 Developmental changes in adipocyte number (broken line) and mean cell volume (solid line) of sheep subcutaneous adipose tissue from 25 days before birth (B) until 600 days after birth.

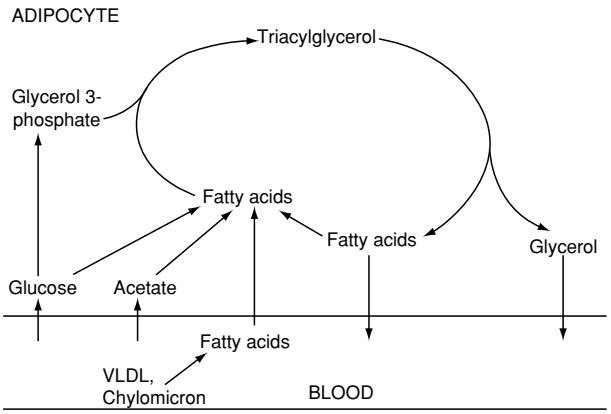

Figure 4 Pathways for synthesis and hydrolysis of triacylglycerol in adipocytes. VLDL, very-low-density lipoprotein.

(VLDL) triaclyglycerols for transport to adipocytes and other tissues. Dietary fatty acids are also incorporated into triacylglycerols in the intestinal cells and secreted as another form of lipoprotein, called chylomicrons. Triacylglycerols are essentially insoluble in water and so cannot be taken up directly by adipocytes from blood lipoproteins; thus, the fatty acids are released by the action of the enzyme lipoprotein lipase. This enzyme is synthesized in adipocytes and then secreted, after which it migrates to the inner surface of the cells lining the blood capillaries. Whereas most of the fatty acids released by the action of lipoprotein lipase are taken up by the adipocytes, some are released into the blood and used by other tissues. The relative importance of *de novo* synthesis and lipoprotein lipase activity as a source of fatty acids for fat synthesis depends on the diet and the species. When animals are fed high-fat diets, chylomicron lipids are the major source. When animals are fed diets rich in carbohydrates, the major source becomes VLDL lipids or *de novo* fatty acid synthesis in adipocytes, depending on whether adipocytes or the liver are the major site of fatty acid synthesis in the species.

Once synthesized within the adipocyte, triacylglycerols are stored in the lipid droplet. Fatty acids are released from them when required by the action of the enzyme hormone-sensitive lipase (distinct from lipoprotein lipase). This enzyme cleaves two molecules of fatty acids to yield a monoacylglycerol that is then hydrolyzed to glycerol and fatty acid by a separate enzyme. Essentially all the glycerol is released from the cell as it cannot be metabolised by adipocytes. Some fatty acids, however, are usually reesterified, and so the ratio of fatty acid to glycerol leaving the cell is normally less than the theoretical 3:1. Released fatty acid is bound to albumin in the blood and transported to the liver and other tissues. Fatty acid esterification and triacylglycerol hydrolysis (lipolysis) occur continuously, i.e., there is a continual turnover of adipocyte triacylglycerol. Net accretion or loss of lipid thus depends on the relative rates of these two processes.

Regulation of Adipose Tissue Metabolism

Both lipid synthesis and hydrolysis are under complex hormonal control. Hormones regulate the amounts of key enzymes and other proteins involved, as well as their activities. In addition, the 'signal transduction' systems (a series of reactions transmitting hormone-induced signals to targets in the cell), through which hormones achieve their effects, are also subject to endocrine control themselves, and changes in the ability of adipocytes to transmit such signals are an important part of the adaptations to some physiological states (e.g., lactation).

Regulation of fatty acid synthesis depends on the precursor. For glucose, control begins at the point of entry into the cell where its transport is dependent on a specific carrier protein (transporter); the major glucose transporter of adipocytes is called 'glut 4.' Insulin stimulates glucose transport both by promoting recruitment of glut 4 into the plasma membrane and by increasing its activity. Within the cell, glucose is initially phosphorylated and then metabolized by a long series of reactions, some in the cytosol, some in the mitochondria, to produce acetyl coenzyme A (CoA) in the cytosol. Several enzymes, in particular phosphofructokinase and pyruvate dehydrogenase, have key roles in controling this flux. Insulin, for example, activates pyruvate dehydrogenase. For acetate, the control is much simpler as its initial reaction results in the production of acetyl CoA. The conversion of acetyl CoA to fatty acid is catalyzed by two enzymes, acetyl CoA carboxylase and fatty acid synthetase. The former is thought to be the most important enzyme controling flux. Both the amount of acetyl CoA carboxylase and its activation status (it is an enzyme that exists in active and inactive forms in the cell) change markedly with physiological, nutritional, and pathological condition. The amount and activity, for example, are decreased by fasting, high-fat diets, diabetes, and lactation. Insulin increases both the amount and activity of the enzyme. These effects of insulin are antagonized by growth hormone. Catecholamines and glucagon also cause inactivation of the enzyme and hence a fall in the rate of fatty acid synthesis.

Insulin increases the synthesis and secretion of lipoprotein lipase; this effect is accentuated by glucocorticoids. Gastric inhibitory polypeptide also increases lipoprotein lipase activity; this effect is likely to be important for promoting fat deposition in animals eating high-fat diets as such diets stimulate secretion of this hormone. Thus, insulin and certain gut hormones increase fat synthesis by increasing the supply of fatty acids for esterification. Insulin also promotes glycerol 3-phosphate formation, in part at least, by increasing glucose uptake by adipocytes. The rate of fatty acid esterification itself may not be stimulated directly by hormones but varies directly with fatty acid availability. Curiously, adipocytes secrete adipsin and two related proteins, which interact in the presence of chylomicrons, to produce acylation-stimulating protein, which then acts on adipocytes to stimulate esterification and glucose uptake.

The enzyme controling lipolysis, hormone-sensitive lipase, exists in active and inactive states in the fat cell. Glucagon and adrenaline (epinephrine), and also

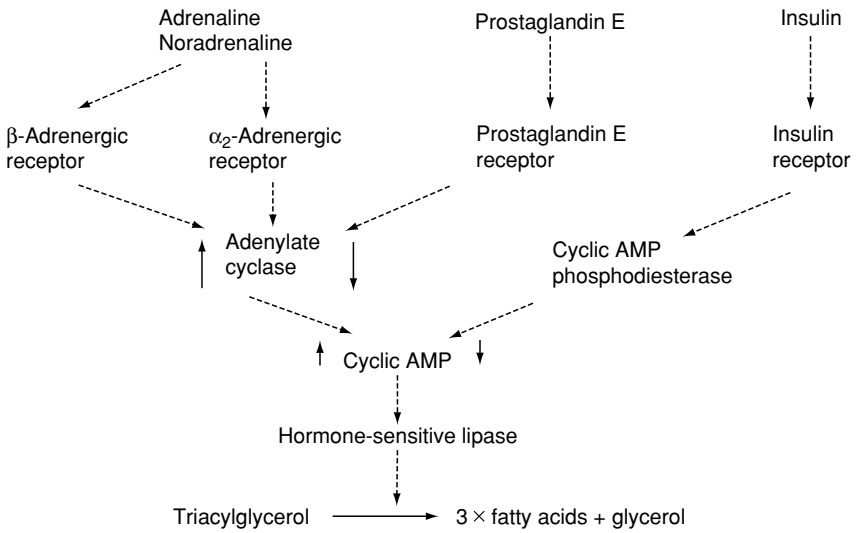

Figure 5 Control of triacylglycerol hydrolysis (lipolysis) by the catecholamines (adrenaline and noradrenaline) and insulin. AMP, adenosine monophosphate; ↑, ↓, activity/concentration increased or decreased by stimulus, respectively.

noradrenaline (norepinephrine) (which is released from nerve endings of the sympathetic nervous system within the tissue itself), interact with specific receptor proteins in the plasma membrane (Figure 5). This causes activation of a key enzyme, adenylate cyclase, which synthesizes cyclic adenosine monophosphate (cAMP). Increased concentrations of cAMP both activate hormone-sensitive lipase and promote its movement from the cytosol to the surface of the lipid droplet, resulting in increased lipolysis. This stimulatory mechanism is attenuated by several inhibitory systems. Adenosine and prostaglandin E_2, which are both produced within adipose tissue, interact with their own receptors, leading to inhibition of adenylate cyclase. Curiously, adrenaline and noradrenaline can both activate and inhibit adenylate cyclase. They activate adenylate cyclase by interacting with β-adrenergic receptors and inhibit by interacting with α_2-adrenergic receptors. The effect of adrenaline and noradrenaline on lipolysis will thus depend in part on the relative number of β- and α_2-adrenergic receptors in the adipocytes. There is considerable site- and gender-specific variation in the ratio of α_2- to β-adrenergic receptor number of adipocytes in some species. For example, in women, intraabdominal adipocytes have a ratio of about 1:1, whereas subcutaneous femoral and gluteal adipocytes have a ratio of about 10:1 α_2-:β-adrenergic receptors. This ratio is thought to be responsible for the very poor lipolytic response to catecholamines of these subcutaneous adipocytes in women and hence the relatively large size of these cells compared with adipocytes elsewhere in the body. In addition to the above, insulin activates the enzyme, cAMP-phosphodiesterase, which catalyzes the degradation of cAMP and so reduces its concentration. The rate of lipolysis then will depend on the concentration of a whole range of hormones, locally produced factors, and neurohumoral transmitters (substances, such as noradrenaline, which are released by nerve endings in tissues). In addition, the ability of the 'signal transduction' system to transmit signals varies with age and with physiological state. For example, during lactation, when fat is often mobilized to support milk production, the system can become more responsive to agents that promote lipolysis. Thyroid hormones, glucocorticoids, sex steroids, and growth hormone all act on one or more components of the signal transduction system, altering its ability to respond to stimulatory and/or inhibitory agents.

Adipose tissue metabolism is thus under complex control. In general, insulin promotes fat synthesis and inhibits lipolysis, whereas catecholamines and glucagon inhibit synthesis and promote lipolysis. In addition, steroid hormones, thyroid hormones, and growth hormone act to modulate the effects of insulin and catecholamines, in part at least, by modifying the ability of the signal transduction systems to transmit signals.

Composition of Stored Fat

Triacylglycerols comprise about 95% of adipose tissue lipid; the remainder includes diacylglycerols, phospholipids, unesterified fatty acids, and cholesterol. The fatty acid composition of the triacylglycerols shows species variation (Table 1), but oleic and

Table 1 Fatty acid composition of adipose tissue triacylglycerols (representative values)

Fatty acids (g per 100 g of total fatty acids)				
Fatty acid	*Humans*	*Pig*	*Sheep*	*Chicken*
Myristic	4	1	3	1
Palmitic	23	26	22	26
Palmitoleic	5	3	4	6
Stearic	6	13	20	7
Oleic	49	42	39	40
Linoleic	9	13	3	19
Linolenic	1	2	2	1
Other	3		7	

palmitic acids are major components in all species. The proportions of polyunsaturated fatty acids (linoleic and linolenic) are usually low in adipose tissue from ruminant animals and higher in chicken and pig adipose tissue. This reflects the dietary supply; as described above, fatty acids are derived both from dietary lipid (via chylomicrons) and from *de novo* synthesis (which produces palmitic acid). There is some capacity for chain elongation of palmitic acid to produce stearic acid, and for desaturation, which converts palmitic to palmitoleic and stearic to oleic acids, but the tissue cannot synthesize linoleic or linolenic acids. In simple-stomached species, such as humans and pigs, varying the fatty acid composition of the diet will alter the fatty acid composition of adipose tissue lipids. For ruminant animals, however, dietary polyunsaturated fatty acids are mostly hydrogenated in the rumen to produce oleic and stearic acids. The small amount of linoleic and linolenic acids escaping this fate is conserved for essential functions (membrane synthesis, prostaglandin production), so that adipose tissue lipids (and milk fat) normally contain little linoleic or linolenic acids. This is ironic, for linolenic acid is the major fatty acid of the ruminant diet. If hydrogenation in the rumen is avoided (e.g., by coating dietary lipid with formaldehyde-treated casein), large quantities of these polyunsaturated fatty acids are absorbed, producing adipose tissue rich in linoleic and linolenic acids.

Minor changes in the fatty acid composition occur during development, and there are minor differences between adipose tissue depots, but these are small compared with the changes that can be elicited by dietary manipulation.

Structure and Function of Brown Adipose Tissue

M J Stock*, St George's Hospital Medical School, Tooting, London, UK

S Cinti, Universita degli Studi di Ancona, Ancona, Italy

Brown Adipose Tissue

Brown adipose tissue (BAT), or brown fat, is a small but highly specialized tissue, the main function of which is to produce heat (thermogenesis). This function requires a good blood supply and a dense population of mitochondria – two features that account for its reddish brown color and distinguish it from white adipose tissue (WAT) (see **Figure 1**). It is found in most mammals, particularly in the neonate, and plays an important role in the control of body temperature during exposure to the cold. There is

*Author deceased.

evidence indicating that it is also involved in the regulation of energy balance. The tissue was first described some 300 years ago, but its thermogenic function was not recognized until the early 1960s, and only during the 1980s did its capacity for thermogenesis and its unique metabolism come to be fully appreciated. (*See* **Thermogenesis**.)

Location

BAT is most obvious in small mammals, hibernators, and neonates, and is usually found around the kidneys, heart and aorta, along the intercostal muscles and sternum, in the axilla, in the subcutaneous inter- and subscapular regions, and deep within the neck, around the main arteries and veins. This distribution suggests that the tissues act as a jacket to heat the major organs and warm the blood passing from the periphery into the trunk. The distribution varies considerably between species, and some (e.g., dog, human) have little or no interscapular BAT, whereas in others (e.g., rodents), the interscapular depot may account for 20–30% of the total. BAT rarely exceeds 2–3% of body mass, and is present in such small quantities in large adult mammals that it is often impossible to detect visually. In spite of this, BAT has been identified histologically in human adults up to the age of 80 years or more, and biochemical tests suggest that it might retain its thermogenic activity. BAT depots often contain white adipocytes, and some WAT depots may contain brown adipocytes, but these can be difficult to see.

Histology and Development

Brown adipocytes appear polygonal under the microscope, with a diameter of 10–25 μm, compared with 20–150 μm for white adipocytes. The adipocytes are organized in discrete lobules, surrounded by connective tissue, extensive blood vessels and numerous sympathetic nerves terminating on the adipocytes and blood vessels. Unlike white adipocytes, the nuclei are spherical and located centrally, and the lipid is stored in small, multilocular droplets. Between the droplets and packing the cytoplasm are numerous, well-developed mitochondria that possess distinctive and regular cristae, often traversing the width of the mitochondrion. The endoplasmic reticulum (particularly the rough reticulum) and Golgi apparatus are relatively small, and lysosomes, peroxisomes, and clusters of glycogen granules are often present; adjacent cells are usually connected by gap junctions.

Cytogenic studies indicate that brown adipocytes are derived from stem cells closely associated with vascular structures, and it is now generally agreed that these are distinct from stem cells that give rise to white adipocytes. Mature brown adipocytes cannot undergo mitosis, and the recruitment (hyperplasia) seen during cold adaptation occurs by cytogenesis and mitosis of newly differentiated brown adipocytes. The first appearance of differentiated BAT cells varies between species, and in some neonates (e.g., guinea-pig, rabbit, puppy, lamb), the tissue is well developed and functional at birth. In other species (e.g., rats, mice), the tissue is not fully functional at birth, but becomes thermogenically active within a few days. By contrast, the Syrian hamster is born without BAT, and it takes about 2 weeks for the tissue to develop, during which time, the animal is essentially poikilothermic. Morphology is highly dependent on age, strain, environment, and various physiological and pathological conditions. Brown adipocytes will transform gradually into what look like white adipocytes during prolonged inactivity.

Innervation

The innervation of BAT is another feature that distinguishes it from WAT, since the metabolic activity of the tissue is almost entirely determined by the release of noradrenaline at sympathetic nerve terminals on the brown adipocytes. In some depots (e.g., rodent interscapular BAT), the sympathetic nerves enter as obvious bundles. This makes experimental techniques such as surgical sympathectomy and nerve stimulation and recordings relatively easy to undertake, although there can be problems in distinguishing between effects on adipocytes and those on the vascular supply. The parenchymal sympathetic fibers innervating adipocytes and arterioles release mainly noradrenaline, and this explains why the tissue content and turnover of noradrenaline are high; noradrenaline turnover is a good index of sympathetic activation in response to various environmental and dietary stimuli. Apart from noradrenaline, histamine, adenosine, and various peptides may modulate the sympathetic activation of BAT. Neuropeptide-Y (NPY) is found colocalized with noradrenaline in perivascular sympathetic nerve endings, and the depletion of sensory peptides – CGRP (calcitonin gene-related peptide) and Substance P – by capsaicin suggests that the tissue contains afferent fibers.

Blood Supply

The high oxygen supply required to support thermogenesis is provided by an extensive network of vessels, estimated to be four to six times denser than that in white adipose tissue. The vascular supply can support a blood flow in excess of 20 ml per gram of tissue per minute; during maximal stimulation in cold-adapted rodents, this relatively small mass of tissue can receive over 30% of cardiac output. Blood flow increases result partly from the vasomotor activity of the sympathetic nerves, but also from autoregulatory increases caused by sympathetic activation of metabolism and the release of metabolites. Aerobic heat production can be so intense that the oxygen supplied in arterial blood is almost completely extracted, and the venous blood appears desaturated. The small amounts of oxygen remaining probably represent blood that bypassed the capillary network via arteriovenous anastomoses (i.e., vascular shunts). These vascular shunts, of which there are many, probably act to convect the heat generated away from the tissue, thereby avoiding thermal damage (BAT temperatures can rise to over 44 °C). The thermogenic capacity of BAT can be determined from measurements of blood flow and oxygen extraction, and estimates of up to $500\,W\,kg^{-1}$ can be compared with values of only $60\,W\,kg^{-1}$ for the maximal aerobic power of skeletal muscle. (*See* **Exercise**: Muscle.)

Metabolism

The exceptional heat-producing capacity of BAT is due to its mitochondria, which possess a 32-kDa polypeptide called uncoupling protein (UCP). This is now known as UCP1, since two other, similar mitochondrial proteins (UCP2 and UCP3) have been discovered, but UCP1 is unique to BAT mitochondria and is responsible for the only significant, physiological example of uncoupled oxidative phosphorylation in mammalian metabolism. UCP forms a proton conductance channel in the mitochondrial inner membrane, and dissipates the proton electrochemical gradient generated by oxidation of substrates via the electron transport system. This has the effect of uncoupling oxidation from the phosphorylation of ADP (adenosine diphosphate) to ATP (adenosine triphosphate), thereby dissipating the energy released as heat, as well as increasing the rate of oxidation due to the loss of respiratory control.

The proton conductance pathway is under inhibitory control by purine nucleotides (e.g., ADP, ATP, GDP), which bind to UCP, and is activated following sympathetic activation of the adipocyte β-adrenergic receptors, which also stimulate lipolysis and the release of free fatty acids from the triglyceride droplets. These fatty acids provide the principal fuel for thermogenesis. The rapid activation of the proton conductance pathway following sympathetic

stimulation can be detected by measuring the mitochondrial binding of purine nucleotides – usually GDP (guanosine diphosphate) – *in vitro*, whereas chronic, adaptive changes in thermogenic capacity depend on immunoassay of mitochondrial UCP concentrations.

High rates of oxidation in any tissue require adequate levels of all the enzyme systems of intermediary metabolism, and BAT is particularly well endowed with those required for glycolysis, the tricarboxylic acid cycle, and the mitochondrial electron conductance chain. Since fatty acids are the main fuel for thermogenesis, adenyl cyclase activity and the subsequent cascade that leads to the intracellular release of fatty acids from stored triglyceride are prominent features of BAT metabolism. However, the lipid stored in the multilocular droplets is not sufficient to sustain thermogenesis for long periods, and brown adipocytes then rely on their remarkable capacity for lipogenesis. In cold-adapted rats and mice, the lipogenic capacity of BAT is high enough to account for a major fraction of the amount of dietary carbohydrate that the animal converts to lipid. As well as the fatty acids supplied *de novo* by lipogenesis, the high level of lipoprotein lipase allows BAT to take up fatty acids released by the hydrolysis of circulating triglycerides.

In addition to the normal complement of respiratory enzyme systems, brown fat cells also contain peroxisomes, and these proliferate during chronic stimulation of the tissue. Peroxisomal oxidation of substrates is not linked to phosphorylation, and could therefore make a contribution to cellular thermogenesis. However, the contribution is probably very small, and their function may be more to do with controling levels of free radicals as well as the cytosolic metabolism of fatty acids that are not preferentially metabolized by mitochondria. Another interesting feature of BAT metabolism is the presence of an enzyme, 5′-deiodinase, that converts thyroxine (T_4) to the physiologically active hormone, triiodothyronine (T_3). The enzyme is under sympathetic control, and its activity can increase several hundred-fold in cold-adapted animals. The T_3 produced is more than sufficient to saturate the nuclear receptors, and it is possible that much of the T_3 is exported and exerts effects on other tissues. (*See* **Hormones**: Thyroid Hormones.)

Functions of BAT

Thermoregulation

Shivering is an acute response to cold exposure and not a particularly effective mechanism for protecting the body against hypothermia. As a consequence, many animals resort to a form of heat production called nonshivering thermogenesis (NST), which, unlike shivering, can be sustained without fatigue and disruption of locomotor activity or sleeping behavior. NST appears as an adaptive response to chronic cold exposure in many mammals, but particularly in small animals where heat losses are greater due to the large surface area relative to body mass. The high degree of surface heat loss and immature neuromuscular development also explain why the neonates of most mammalian species (including humans) depend on NST to maintain body temperature until shivering, locomotor activity and other behavioral thermoregulatory responses develop. A third group is the hibernators, who rely on NST for the rapid rewarming that occurs during arousal.

Depending upon the species, NST can raise heat production by 100–300% above that in a warm, thermoneutral environment, and is associated with large increases in the activity of the sympathetic nervous system. Pharmacological blockade (particularly with β-adrenergic antagonists) can inhibit completely the cold-induced rise in heat production, and demonstrates the dominant role of the sympathetic nervous system in mediating NST. The effector tissue is BAT, and a considerable body of evidence now exists to link BAT function to NST. For example, the capacity for NST is inversely proportional to age, bodyweight, and acclimation temperature, and this coincides with histological, physiological, and biochemical indices of BAT activity. Conversely, deacclimation and decreased NST is associated with a parallel decline in BAT activity. Perhaps the most convincing evidence comes from *in vivo* measurements of BAT oxygen consumption, which, in spite of enormous technical difficulties, have shown that the tissue can account for well over 60% of NST. Even this may be an underestimate, since it is not possible to measure the contribution of all the numerous, small and diffuse BAT depots.

Energy-balance Regulation

Evidence linking BAT to energy-balance regulation comes mainly from studies on laboratory rodents that represent examples of two extremes of metabolic efficiency. At one extreme, there are normal, young rats and mice that fail to become obese in spite of an excessive energy intake, and at the other extreme, there are examples of obesity developing in rats and mice (e.g., genetic and hypothalamic obesities), even when energy intake is normal. The explanation for these differences appears to depend on an adaptive form of heat production called diet-induced thermogenesis (DIT), which is absent or defective in obese

animals, but provides a mechanism whereby normal animals can adjust energy expenditure to compensate for energy consumed in excess of requirements. DIT can produce increases in total heat production of 60–70%, and account for up to 90% of the excess energy consumed by hyperphagic rats. In rats feeding normally, the level of DIT is low, but sufficient to control energy balance by compensating for errors in the control of energy intake.

The control and metabolic origins of DIT are identical in almost every respect to NST, although cold is a more potent stimulus and produces more dramatic changes than dietary stimuli. As a consequence, the changes in sympathetic activity, BAT hypertrophy and hyperplasia, mitochondrial proliferation, guanosine diphosphate binding and UCP concentration in rats exhibiting DIT are smaller than those seen in cold-adapted rats. However, these changes in BAT function are sufficient to account for up to 80% of the diet-induced changes in thermogenic capacity seen in hyperphagic rats. By contrast, BAT is usually atrophied and relatively inactive in obese rodents, although it will respond to exogenous noradrenaline, and the animals retain the capacity to adapt to the cold and exhibit NST. This suggests that the defective DIT in these obese rodents is due to a failure of the sympathetic activation of BAT, rather than a defect in BAT itself. This contrasts with what is seen in a transgenic mouse bearing a 'toxigene' that causes a genetic ablation of BAT. These mice fail to exhibit NST and DIT, and become obese – sometimes without eating any more than normal. (*See* **Obesity**: Etiology and Diagnosis.)

Other Functions

In addition to cold- and diet-induced thermogenesis, there are several pathological conditions in which BAT has been implicated as a source of increased heat production. Fever, sepsis, and cancer cachexia are three examples where increased sympathetic activation of BAT is thought to be at least partly responsible for the hypermetabolic response seen in animal models of these conditions, and often involve cytokines such as the interleukins. Patients with pheochromocytoma (adrenomedullary tumor) have very high circulating levels of adrenaline and noradrenaline, and it is thought that the elevated heat production in this condition is due to the stimulatory effect of these catecholamines on BAT; the best examples of active BAT in human adults have been seen in patients with pheochromocytoma.

In spite of increased energy intakes, pregnant rats and mice show little or no change in BAT activity, but during lactation, the tissue atrophies, and its sympathetic activation and thermogenic capacity decline to levels seen after sympathectomy or fasting. Similar reductions can be seen in warm-adapted nonlactating animals, which suggests that BAT thermogenesis declines to compensate for the elevated heat production associated with milk synthesis in the lactating mammary glands. Increased heat production during exercise could also account for the lower BAT activity seen in exercise-trained animals. This is particularly noticeable in cold environments, where exercise can prevent many of the changes in BAT function associated with NST.

Control of BAT

Neural

The control over the sympathetic supply to the various BAT depots originates from the hypothalamus, which receives afferent information on thermal and nutrient status from the periphery, as well as having its own receptor mechanisms and pathways. One of the main thermosensitive and thermoregulatory areas is the preoptic/anterior hypothalamus (POAH), but this is thought to modulate BAT thermogenesis via inhibitory pathways that descend to the lower brainstem. The area that appears to exert a major influence over BAT is one that has been classically associated with the control of energy intake – the ventromedial hypothalamus (VMH), often loosely referred to as the 'satiety center'. Electrical stimulation of the VMH increases BAT thermogenesis, whereas lesions cause the tissue to atrophy, and the latter observation helps explain why VMH-lesioned animals can become obese without overeating. There are connections between the VMH and other hypothalamic areas concerned with feeding behavior (e.g., lateral hypothalamus, paraventricular nucleus), and with the POAH, which provide a neural basis for integrating information on energy intake and body temperature, and modulate the level of NST and DIT accordingly.

Hormonal

Adrenaline stimulates BAT thermogenesis, but it is not as potent as noradrenaline, and in most physiological situations, the circulating levels of adrenaline are probably not sufficient to activate the tissue's β-adrenoceptors. However, views may change on this in the light of recent, more sensitive measurements that show that circulating levels of adrenaline may have been previously underestimated. Although thyroid hormones (T_3 and T_4) are necessary to maintain BAT function, and T_3 is itself produced by the tissue, hyperthyroidism suppresses BAT activity. This is probably due to reduced sympathetic activation

compensating for high levels of heat production in other, thyroid-sensitive tissues.

Glucocorticoids exert little or no direct effects on BAT, even though the tissue has glucocorticoid receptors. However, these adrenocorticoids have central inhibitory actions on the sympathetic outflow to BAT, which are particularly noticeable in genetically obese rodents. Adrenalectomy in these rodents completely restores sympathetic activity, BAT thermogenesis, and DIT to levels seen in lean animals. Only very low replacement doses of glucocorticoids are required to reverse the effects of adrenalectomy, suggesting that these obese animals are hypersensitive to the inhibitory actions of glucocorticoids. The glucocorticoids are thought to inhibit thermogenesis via feedback inhibition of hypothalamic corticotrophin-releasing factor (CRF). In addition to its effects on the pituitary, CRF is a potent stimulus for the sympathetic activation of BAT. Insulin exerts direct, metabolic effects on BAT that are essentially similar to those that it exerts on white adipose tissue, but it also influences the tissue indirectly via its actions on the glucoreceptors of the VMH.

A recent and exciting discovery has been the identification of the lipostatic hormone, leptin. In addition to influencing energy balance (i.e., fat stores) via the hypothalamic control of food intake, leptin also causes sympathetic activation of BAT thermogenesis. This is likely to prove a complex relationship because increased sympathetic activity decreases the expression and release of leptin from both WAT and BAT.

Pharmacological

For many years, the β-adrenergic receptor subtype responsible for activation of BAT lipolysis and thermogenesis was thought to be the β_1-adrenoceptor. However, there is much recent evidence to suggest that the receptor is atypical (neither β_1 nor β_2), and it is now classified as the β_3-adrenoceptor. Much of this evidence came from experiments using novel thermogenic drugs developed for the treatment of obesity, and which were designed to be highly selective agonists of BAT thermogenesis, with little or no effect on β_1-or β_2-mediated functions. Subsequent to the pharmacological identification, the gene sequence for the β_3-adrenoceptor was identified in the human genome. Treatment with novel β_3-adrenoceptor agonists results in significant weight loss (mainly as fat) without affecting food intake in both genetic and dietary obese rodents. However, because the rodent β-adrenoceptor is different, these agonists are not effective in humans, and trials with human β_3-adrenoceptor agonists have yet to be undertaken. BAT also contains α-adrenergic receptors, which are known to be important for activating the conversion of T_4 to T_3 by the 5′-deiodinase, and may also play a minor, facilitatory role in thermogenesis. ADOLESCENTS

J J B Anderson, University of North Carolina, Chapel Hill, NC, USA

Introduction

Adequate amounts of energy from carbohydrates, fats, and high-quality protein are considered the critical nutrients for the hormone-driven processes of growth and development of the skeleton and the other organ systems of the body. Developmental sequences vary by gender; Tanner staging is frequently used to assess skeletal development. The needs for nutrients other than those that provide energy and essential amino acids (and N) continue to undergo evaluation as new data are published, and several micronutrients have new recommendations (see below). It has become clear in recent years that adolescents in the USA are not consuming the recommended numbers of servings of foods each day from the basic food groups, which suggests that a very

high percentage are not meeting daily nutrient requirements.

Because of the wide availability of healthful foods but limited physical activities, overweight and obesity have reached epidemic proportions in the US and many technologically advanced nations. The energy imbalance in children as well as in adolescents results from changing societies that value time, speed, and technological advances in their daily lives over physical activities and sports, e.g., physical work, walking, climbing stairs, and other physically demanding chores. It has been estimated in the 1990s that between 30 and 50% of North American adults are overweight (body mass index or BMI >25). Lower percentages of adolescents are overweight, but they represent a much greater prevalence than is desirable because of the tracking of body weight into adulthood and the potential risks for diabetes mellitus type 2, hypertension, and cardiovascular diseases. Obesity in children favors the development of elevated blood pressure and total cholesterol. This trend toward more overweight and obesity in adolescents is facing many nations, especially those in Asia, which have plentiful food available for their youth and declining levels of physical activity.

This review covers the nutritional needs for adolescents, and it also highlights the problem nutrients that are either too little consumed or ingested in excess. Other issues of adolescent nutrition are also addressed.

Nutrient Requirements

Nutrient requirements are divided into macronutrients and micronutrients. Phytomolecules, which are technically not classified as nutrients and which are consumed only in plant foods, may have significant, but under-appreciated, health benefits.

Energy-providing Nutrients

Fats and carbohydrates, when metabolized, generate approximately 85% of the energy used by cells; the other 15% is obtained from the metabolic degradation of the organic backbone of amino acids. Fats also provide the essential fatty acids that exist in plant foods and in fish, but only very minimally in other animal products.

The current adolescent Recommended Dietary Allowances (RDAs) for energy, as kilocalories or kilojoules, are listed in Table 1. As these RDAs are currently under review, it is likely that they will be altered, especially because of the problem of overconsumption of food energy relative to daily energy-expending activities (see above).

Proteins

Proteins supply the essential amino acids, as well as nonessential amino acids; all the amino acids also generate N that is used in the cellular synthesis of many organic molecules, such as nucleic acids.

Table 1 lists the recommended intakes of protein, assuming high-quality protein food sources (protein digestibility and absorption of approximately 75%).

Micronutrients

More than 20 essential micronutrients have been established for humankind, and RDAs exist for most of them. A few micronutrients have become classified as having less scientific basis for establishing RDAs; these micronutrients have therefore been given Adequate Intakes (AIs), even though they may previously have had RDAs. Calcium is a good example. In the 10th edition of the RDAs, calcium RDAs for adolescent girls and boys were 1200 mg per day from 13 to 19 years of age. In the 1997 edition, the calcium AIs have been increased to 1300 mg per day for the same age range.

Other micronutrients with AIs include vitamin D, fluoride, and choline.

Table 2 lists the recommended intakes of the micronutrients.

Water

Often a forgotten nutrient, water carries no specific recommendation. Aside from thirst, a general guide to water consumption is the drinking of 1–1.5 l of water and/or juices, but not counting caffeinated or alcoholic beverages because they have mild diuretic effects. Athletes and those with physically demanding work will need more than the amounts given. The goal is to maintain water balance and, therefore, to avoid dehydration.

Dietary Fiber

No specific recommendation has been made for dietary fiber, but food-labeling guidelines in the US suggest that 25 g of fiber (total of both soluble and insoluble fibers) per day should be consumed with a 2000-kcal diet and 30 g of fiber with a 2500-kcal diet. It is generally assumed that the vast majority of adolescents in the USA consume only 10–15 g of fiber per day.

Phytochemicals

The broad group of phytochemicals, which are not nutrients *per se*, have become increasingly recognized as being important components of our diets because of their numerous roles, such as antioxidants, in

Table 1 Food and Nutrition Board, National Academy of Sciences – National Research Council Recommended Dietary Allowances[a], revised 1989 (abridged), designed for the maintenance of good nutrition of practically all healthy people in the USA

[a]The allowances, expressed as average daily intakes over time, are intended to provide for individual variations among most normal persons as they live in the USA under usual environmental stresses. Diets should be based on a variety of common foods in order to provide other nutrients for which human requirements have been less well defined. See text for a detailed discussion of allowances and of nutrients not tabulated.

[b]Weights and heights of Reference Adults are actual medians for the USA population of the designated age, as reported by NHANES II. The median weights and heights of those under 19 years of age were taken from Hamill *et al*. (1979) (see pp. 16–17). The use of these figures does not imply that the height-to-weight ratios are ideal.

[c]Retinol equivalents. 1 retinol equivalent = 1 μg of retinol or 6 μg of β-carotene. See text for calculation of vitamin A activity of diets as retinol equivalents.

[d]α-Tocopherol equivalents. 1 mg of d-α tocopherol = 1 α-TE. See text for variation in allowances and calculation of vitamin E activity of the diet as α-tocopherol equivalents.

This table does not include nutrients for which Dietary Reference Intakes have recently been established [see *Dietary Reference Intakes for Calcium, Phosphorus, Magnesium, Vitamin D, and Fluoride*, 1997 and *Dietary Reference Intakes for Thiamin, Riboflavin, Niacin, Vitamin B_6, Folate, Vitamin B_{12}, Pantothenic Acid, Biotin, and Choline*, 1998].

promoting health. Because these nonnutrient molecules come exclusively from plant foods, adolescents who avoid fruits and vegetables will consume little of these molecules and not receive their beneficial effects. Genistein, a soy-derived isoflavone, has been shown to have several possible benefits on health.

Nutrition and Skeletal Growth

Growth of the skeleton (height) is typically completed during adolescence by both girls and boys, and bone mass is practically maximized at this same time. For a large majority of girls in the USA, the bone mass achieved during this adolescent period is considered to be less than optimal because of limited selections of nutrient-dense foods and preferences for low nutrient-dense foods. Figure 1 illustrates the declining consumption of milk and the increasing intake of soft-drink beverages over the last two decades in the USA. Concern has arisen that girls, and possibly boys, are not getting sufficient calcium and other essential nutrients from milk and related dairy products, because so many of these nutrients are essential for the growth of skeletal tissue, and also that adolescent females may be consuming excessive amounts of phosphorus, which alters the calcium:phosphorus ratio in a deleterious way (see Calcium and Phosphorus sections).

Although not the only nutrient required for the extracellular mineral phase of bone, calcium may be the limiting nutrient for mineralization. This divalent cation is provided in the diet by only a few foods that are commonly used and available in most countries. In the USA, dairy foods (exclusive of butter) and calcium-fortified foods provide the bulk of the cation, i.e., approximately 60–70%, in the diets of adolescents. Dark green leafy vegetables, such as broccoli, provide modest, but important, amounts of calcium.

The problem of a shortfall in calcium in the presence of adequate, or possibly, excessive phosphorus consumption is that the low calcium:phosphorus ratio potentially produces a persistent elevation in parathyroid hormone (PTH) that in turn prevents adequate mineralization of the skeleton during the

[a]As cholecalciferol. 1 μg of cholecalciferol = 40 IU vitamin D.
[b]In the absence of adequate exposure to sunlight.
[c]As niacin equivalents. 1 mg of niacin = 60 mg of tryptophan.
[d]As dietary folate equivalents (DFE). 1 DFE = 1 μg of food folate = 0.6 μg of folic acid (from fortified food or supplement) consumed with food = 0.5 μg of synthetic (supplemental) folic acid taken on an empty stomach.
[e]Although AIs have been set for choline, there are few data to assess whether a dietary supply of choline is needed at all stages of the life cycle, and it may be that the choline requirement can be met by endogenous synthesis at some of these stages.
[f]Since 10–30% of older people may malabsorb food-bound B_{12}, it is advisable for those older than 50 years to meet their RDA mainly by consuming foods fortified with B_{12} or a B_{12}-containing supplement.
[g]In view of evidence linking folate intake with neural tube defects in the fetus, it is recommended that all women capable of becoming pregnant consume 400 μg of synthetic folic acid from fortified foods and/or supplements in addition to intake of food folate from a varied diet.
[h]It is assumed that women will continue consuming 400 μg of folic acid until their pregnancy is confirmed and they enter prenatal care, which ordinarily occurs after the end of the periconceptional period – the critical time for formation of the neural tube.

This table presents Recommended Dietary Allowances (RDAs) in bold type and Adequate Intakes (AIs) in ordinary type followed by an asterisk (*). RDAs and AIs may both be used as goals for individual intake. RDAs are set to meet the needs of almost all (97–98%) individuals in a group. For healthy breastfed infants, the AI is the mean intake. The AI for other life stage groups is believed to cover their needs, but lack of data or uncertainty in the data prevent clear specification of this coverage.

adolescent growth phase, and also earlier during prepuberty. The net result is suboptimal skeletal development and peak bone mass accrual by the end of adolescence that is less than maximal. So, low dietary calcium intakes, especially in relation to elevated phosphorus intakes, may be disadvantageous for young girls and also for young boys. The problem may be more widespread than previously thought because of the possibility that the fracture rate in adolescent girls may be underestimated.

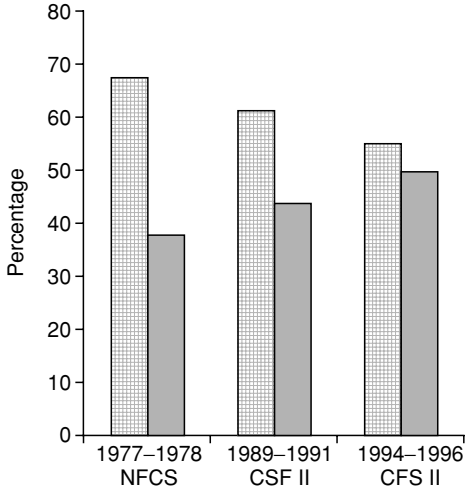

Figure 1 Percentages of US individuals in USDA National Food Consumption Surveys (NFCS and CSF) consuming milk ▦ and soft drinks ■ between 1977–1978 and 1994–1996. Note the decline in milk consumption while soft-drink consumption increased, according to percentage of consumers.

Specific Problem Micronutrients: Deficits and Excesses

Most of the mineral micronutrients reviewed below exist in the body in solutions as cations (positively charged) or anions (negatively charged). The vitamins, however, exist as organic molecules that may carry a slight electrical charge that permits their binding, usually for only brief times, to other molecules.

Calcium

Inadequate consumption of calcium in the diets of adolescents, especially females, in the USA has gained them the label, 'the lost generation.' Calcium intakes have reached an all-time low, and it has been predicted that the present generation of girls, and perhaps boys, are placing themselves at increased risk for skeletal fractures late in life, as longevity is increasing in the USA and most other nations. The concern about increased age-adjusted rates of osteoporosis assumes that tracking, or following the same relative path as age increases, of bone mass and density occur, similar to the tracking of high blood pressure with increasing age. Therefore, an individual who has less bone at peak bone development is, during aging, assumed to follow a path, i.e., track, at the relatively lower level of bone mass to reach critically low bone values sooner, e.g., after the menopause, than an individual who develops a greater peak bone at the end of the skeletal growth phase (Figure 2).

Iron

Low iron consumption by females is one of the most common nutrient problems throughout the world.

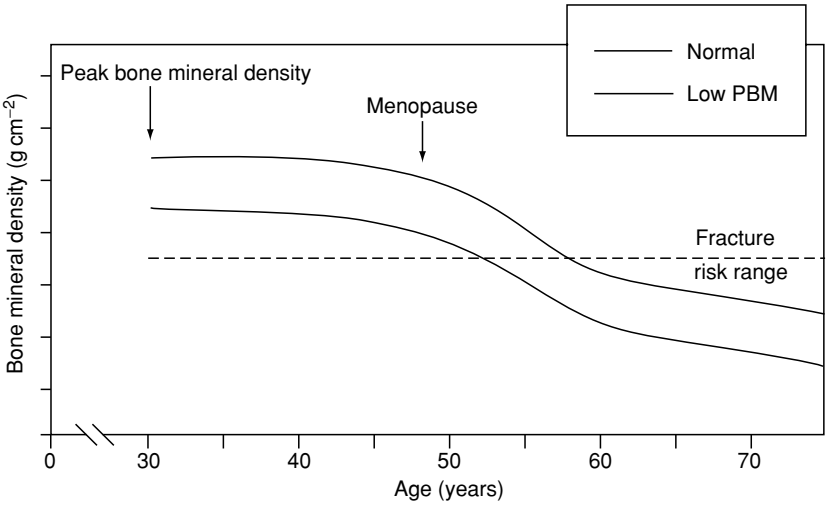

Figure 2 Tracking of bone mass of females from early adulthood to postmenopausal life. Adapted from Anderson JJB (2000) Nutrition in osteoporosis, in Mahan K and Escott-Stump S (eds) *Krause's Food, Nutrition, and Diet Therapy*, 10th edn. Philadelphia, PA: Saunders with permission. PBM = peak bone mass.

Adolescent females are particularly likely to develop iron deficiency, and even the more severe iron-deficiency anemia, if they have little red meat in their diets. In the USA, iron-fortified foods, especially ready-to-eat breakfast cereals, have reduced the severity of the two forms of iron deficits.

Zinc

Too little zinc consumption by adolescents results from poor intakes of plant foods. Red meats have good amounts of zinc, as well as iron, but these would not be consumed by many adolescents who avoid red meats.

Magnesium

Insufficient magnesium typically signifies poor selection of plant foods, especially dark green leafy vegetables. Although magnesium intakes by adolescents are lower than recommended, it has been difficult to pinpoint real physiologic problems, except possibly that optimal heart function may be compromised.

Potassium

Too little potassium consumption reflects a limited selection of fruits and vegetables, the highest potassium-containing sources of this monovalent cation. Both potassium and magnesium have intracellular roles, and in part, adequate intakes of potassium are needed to counter the high intakes of sodium. Therefore, a dietary balance between potassium and sodium is needed to maintain efficient cellular functions that require potassium ions. Renal mechanisms tend to conserve sodium at the expense of potassium and magnesium, which are excreted in increased amounts when sodium intakes are higher than recommended.

Sodium

Excessive amounts of sodium in the diet may contribute to higher blood pressure levels, but still within the normal range, even in adolescents. Sodium consumption by adolescents is a concern, because the taste for this mineral, or perhaps sodium sensitivity, becomes established early in life and continues into adolescence. Higher blood pressure is typically associated with excessive intakes of sodium throughout adolescence tracks with age.

Phosphorus

Excessive consumption of phosphorus from foods and soft drinks that contain phosphoric acid reduces the calcium:phosphorus ratio in the total diet and, thereby, may increase the circulating level of PTH, though the elevated PTH concentration usually remains within the upper range of normality. The net effect is increased calcium losses, i.e., a negative calcium balance. In the USA, food-labeling regulations do not require that information on the phosphorus content of foods be included. This omission means that consumers cannot estimate their daily phosphorus consumption or calculate a calcium:phosphorus ratio of a food or their entire daily intake. In addition, a food may include hidden amounts of phosphorus because of the wide use of phosphate additives in food processing. The magnitude of this potential problem of excessive phosphorus has not been investigated by governmental agencies.

Folic Acid

Recent advances in understanding this nutrient have focused on obtaining sufficient intakes of folic acid to prevent neural tube defects in offspring, but other important roles of this B vitamin exist in cell divisions, e.g., in red blood cell formation, and gut epithelial turnover of cells. In addition, adequate intakes of folate also maintain lower circulating levels of homocysteine, which is now considered a risk factor for coronary heart disease.

Vitamin D

The hormonal form of vitamin enhances intestinal calcium absorption, when calcium intakes are low, and also it increases osteoblastic bone-forming activities. This hormonal metabolite of vitamin D also stimulates osteoblast cells in bone to make new organic matrix (osteoid) and therefore new bone tissue. This metabolite, along with PTH, also contributes to calcium homeostasis, i.e., regulation of blood calcium concentration. Too little intake of vitamin D from the few foods that contain it, and too little sun exposure for skin biosynthesis of this vitamin, puts individuals at risk for reduced functions in the gut and bone tissues. Adolescent intakes of vitamin D are low in the USA because the consumption of milk that is fortified with this vitamin has declined (see above).

Vitamin K

An established requirement for vitamin K exists for both blood clotting and bone health. The daily amount needed for the production of mature osteocalcin may be higher than that needed for the blood-clotting factors, but insufficient information has been generated to be certain. Vitamin K intakes may be insufficient in adolescents because of limited consumption of dark green leafy vegetables and legumes.

Problem Areas

A few problem areas involving meeting nutrient requirements by adolescents need special attention

because of their potentially adverse effects on nutritional status.

Adolescent Athletes

The female athlete triad of disordered eating, amenorrhea or oligomenorrhea, and osteopenia or low bone mass, but generally not osteoporosis, has a marked adverse effect on skeletal mass that has been shown to increase the risk of stress fractures of athletes, especially those participating in cross-country running and other endurance events involving running or repetitive jumping as in volleyball. The risk of fracture, however, is reduced if estrogen is replaced in these athletes.

However, Dutch investigators have suggested that physical activity during adolescence may be even more important for bone development than calcium intake, so long as dietary calcium is in the adequate range, i.e., approximately 1000 mg per day. This conclusion has also been reached for female gymnasts, even amenorrheic gymnasts, because of the positive effects of weight-loading on the skeleton.

Consumption of Alcoholic Beverages

Over-consumption of alcoholic beverages by adolescents in the USA has become a big problem. The adverse effects of excessive alcohol consumption on the nutritional status of adolescents may result from insufficient food consumption, too many empty calories from low-nutrient dense alcoholic beverages, and unwise food choices.

Strict Vegetarians

Vegans or strict vegetarians place themselves at risk for deficits of several micronutrients if supplements are not taken. Fortunately, most vegans know about the pitfalls of this practice of eating, and they do not develop serious deficiencies. However, a few problems, such as iron, zinc, and cobalamin deficiencies, may arise because of the avoidance of all animal foods. Vegans may also not be able to consume sufficient amounts of calcium or of omega-3 polyunsaturated fatty acids. One of the potential disadvantages of a vegetarian diet is a low estrogen status across the life cycle in females. The lower estrogen status may have an adverse effect on the skeleton, although it may be protective against estrogen-dependent cancers and other chronic diseases.

Nutrition Education

Despite the fairly high level of knowledge about nutrition by youth in the US, health practices, including food selection, are too often detrimental to the support of continued skeletal growth. Part of the reason for insufficient calcium consumption by adolescent girls is their limited knowledge about daily calcium allowances and the amounts of calcium in foods. Adolescents, especially females, clearly do not eat the way they should and even, perhaps, know how to eat. These unhealthy eating practices result primarily from bad attitudes toward specific foods, negative reactions to parental influences, and peer pressure.

The serious problem in skeletal development in the more technologically advanced nations relates to the unwise food and drink choices being made by our children, especially after about 10 years of age. In the USA, adolescent females are not only not getting sufficient amounts of calcium, but consuming too little of the nutrient-dense foods in general. The practices of meal-skipping, grazing, snack/convenience food selection, and soft-drink consumption insure suboptimal intakes of several micronutrients in addition to calcium. Surveys of food-consumption patterns of girls demonstrate that inadequate mean consumption exists for the following micronutrients: calcium, magnesium, iron, zinc, and both fat-soluble and water-soluble vitamins, especially E, folate, cobalamin, and other B vitamins. Vitamins D and K typically have not been assessed in these surveys. Mean sodium and phosphorus intakes were higher than recommended.

Avoidance of dairy products by young girls has become widespread, at least in the USA, for fear of weight gain, despite the fact that low-fat milks and no-fat yogurts are widely available. Thus, dairy foods can be consumed with little or no fat. Education of the appropriate fats and amounts of daily fat intake for these females is either lacking or not appropriately highlighted. Some fat is clearly needed for skeletal growth, so that extremely low intakes may be deleterious. Of course, some mono- and polyunsaturated fats found in salad dressings and cooking oils are now being recommended for overall balance within the types of fatty acids and also for optimal health outcomes, but young females are barely aware of these important needs.

Finally, nutrition education messages about the consumption of soft drinks should target both parents and children to limit the number of servings because they displace nutritious beverages, such as milk and fruit juices (see **Figure 1**), especially when two or more 400-ml (12-ounce) soft drinks are consumed in a day (more than 22% of one adolescent population in the USA). Since many of the soft drinks contain phosphoric acid as the acidulant, the calcium:phosphorus ratio becomes even further skewed away from a recommended ratio of 0.70–0.75. The widespread use of soft drinks, in place of milk, has contributed to

the increase in phosphorus consumption and the low calcium:phosphorus dietary ratio of USA adolescents. How serious this trend of increased phosphorus consumption is cannot be resolved without a better understanding of the overall phosphorus intake from processed foods, lowly processed foods, and soft drinks that contain phosphoric acid.

ADULTERATION OF FOODS

Contents
History and Occurrence
Detection

History and Occurrence

M Tsimidou and D Boskou, Aristotle University of Thessaloniki, Thessaloniki, Greece

Introduction

Food is a basic prerequisite for human survival and also for social and economic welfare and progress. Problems related to food have varied from one period of history to another, from continent to continent, and from country to country. The problem of food adulteration has been a major one and the protection of the consumer has occupied the attention of civil authorities from ancient times.

Food is considered adulterated if it contains poisons or other substances which may render it injurious to the health of the consumer, or if it contains filth or it is decomposed; if it contains a coloring agent or other food additive, that is not approved or contains materials that disguise inferior quality; if any important constituent has been wholly or in part abstracted or any specified ingredient has been substituted by a nonspecified ingredient; if it contains any substance that increases its weight and bulk or changes its strength to improve appearance. A food is misbranded if it is illicitly labeled or it is a food for which standards of identity have been written and it fails to comply with these standards.

History

Food has been liable to adulteration to a greater or lesser extent since very early times. Mosaic and Egyptian laws made provision for preventing contamination of meat, while several centuries before the time of Christ India had regulations prohibiting the adulteration of grain and edible fats. Athens had its public inspector of wines. Adulteration was also common during the Roman period. Evidence for this is given in Apicius' famous cookbook (*De Re Coquinaria*). During the Middle Ages in England, pepper and other costly spices imported from the east were adulterated by mixing with ground nutshells, local seeds, and olive pits.

Between the 13th and 16th centuries, bread, wine, beer, spices, and valuable natural coloring materials were often adulterated. In England in 1319, a meat-market overseer succeeded in putting a butcher in the pillory for selling unsound beef. Wines were 'sophisticated' (adulterated) with burnt sugar, juices, starch and gums, and other substances. Such practices may have reduced the quality of the wine but they were not injurious to health. After the 18th century, however, food adulteration became dangerous. Vinegar was often adulterated with sulfuric acid, wine with preservatives containing lead salts, green vegetables in vinegar with copper (to improve color), essential oils with oil of turpentine, confectionery products with colorings containing lead and arsenic, chocolate with Venetian red (ferric oxide), and red pepper with vermilion (mercury sulfide). 'Black extract', obtained by boiling poisonous berries of *Cocculus indicus* in water and concentrating the fluid, was used in beer. This extract imparted flavor, but also narcotic properties and intoxicating qualities to the beverage.

Bread was not only the basic item of diet for many centuries but also the one most subjected to adulteration. The incorporation of sieved boiled potatoes, chalk, or bone ashes in the flour was a common fraudulent practice, but the most serious example was the addition of alum, which whitened flour of inferior quality.

Recipe books of the 18th century contain instructions, which today would cause alarm. The recipe for preserving green color in pickles is characteristic: 'To render pickles green, boil them with a halfpenny or allow them to stand for 24 hours in copper brass pans.' It is not surprising that records of that period list a number of deaths from copper poisoning.

Frederic Accum, writing from London in 1820, gives a vivid description of the adulteration of bread, alcoholic drinks, tea, coffee, and many other foods. Accum claimed that: 'Indeed, it would be difficult to mention a single article of food which is not to be met

with in an adulterated state; and there are some substances which are scarcely ever to be genuine.' Even if these accusations are somewhat overstated, the seriousness of intentional adulteration of food, which prevailed between 1800 and the early 1900s, is undisputed.

The second decade of the 19th century marks the beginning of the second period in the history of food adulteration. In the first period (ancient times to about 1820) food was procured from small enterprises and individuals who were, to a certain extent, responsible for their own transactions. In the second period (early 1800s to 1900s), the methods of food production changed significantly. Large-scale food production became necessary because of the industrial revolution, which led to a move of population from country to city. This created conditions that were conducive to large-scale adulteration of food. In the second half of the 19th century the first publicly supported analytical laboratories for food inspection were established in Germany and the USA. Intentional adulteration of food remained a serious problem until the beginning of the 20th century. Regulatory pressures and the effectiveness of analytical methods reduced the frequency and magnitude of food adulteration. Further improvements have been achieved up to the present time and, owing to strict legal standards and also to the growth of an increasingly critical public, deliberate adulteration in industrialized countries has become less serious. Of course, fraudulent practices still continue in most countries, especially those which lack adequate means to insure that laws and regulations are enforced.

Food Additives

The excessive use of additives and the use of nonpermitted ones present a serious threat to food safety. It could be argued that a fourth phase of food adulteration began some 40 years ago, when foods containing chemicals became prevalent in the diet. Since then, we have moved gradually from an outrage over fraud, sometimes practiced with dangerous substances, to a growing concern over the more subtle toxic effects of common chemicals added to food to assist manufacture and storage. As a result, there has been a shift in focus from food adulteration to safety of food, and to a different approach which emphasizes not only evaluation of the food in its entirety, but also evaluation of individual components. Current legislation relating to food additives provides statutory lists of all permitted additives which may be used and, where appropriate, the maximum levels for their use. Nevertheless, as the food industry becomes increasingly sophisticated and relies more and more on the use of additives, many consumers believe that governments are unable to control the situation and that preservatives, antioxidants, colorings, flavor or texture modifiers, and other chemicals are and always will remain a potential hazard. (*See* **Food Additives: Safety.**)

Food Legislation

The use of government regulatory powers to control the purity and safety of foods is very old but the first serious efforts to regulate malpractice took place only in the 19th century. The first general food laws were passed in the UK in 1860. Accum's book, *A Treatise on Adulteration of Food and Culinary Poisons* (1820), aroused the indignation of the British public. In 1850, Thomas Wakley, editor of the *Lancet*, established an Analytical Sanitary Commission under the direction of Arthur Hill Hassal, the first man to investigate food adulteration from a scientific point of view. He turned the microscope into a weapon in the detection of adulterants. The Commission's reports, published in the *Lancet* from 1851 to 1854, led to the formation of a parliamentary committee to investigate food adulteration and, in 1860, to the passage of the world's first Food and Drink Act. This law made it a criminal offence to sell adulterated food and drink. It also established the appointment of public analysts to examine foodstuffs produced throughout the country. In 1866, a second country, New Zealand, passed pure food legislation and, in 1874, Canada passed the Food and Drug Law.

In the 20th century, new regulations were developed in industrialized countries, and old regulations were repeatedly updated, taking into account the advice of governmental and international committees. Modern food law establishes and maintains standards for the composition of food, controls the use of additives and extent of contamination, controls packaging materials and unsanitary practices in the production of food, and restrains unwarranted and misleading claims and advertisements. Effective food surveillance systems have also been developed which insure that there is a constant supply of the right kind of food to keep people properly fed and that the food we eat is wholesome as a result of strict adherence to national and international law. The current worldwide access to data and information through the internet may soon reveal that administrative traceability can be successfully used to monitor the sale of fraudulent food products in the global market of the 21st century.

International Standards

The Food and Agriculture Organization (FAO), the World Health Organization (WHO) and the Joint Codex Alimentarius Commission are concerned with the safety of food and food ingredients. The aims of the Codex Alimentarius include protecting the health of the consumer and insuring fair practices in the food trade, coordination of all food standards work, determining priorities and initiating, guiding, and finalizing the preparation of food standards. There are published recommended international standards for individual foods (sugars, edible oils, canned fruits and vegetables, processed meat, fish products, cocoa products, etc.), as well as provisions with respect to food hygiene, food additives, contaminants, and labeling. The key role of the Codex Alimentarius in developing international food standards was recognized when the World Trade Organization (WTO) was set up in 1995. The WTO agreements accept the Codex Alimentarius standards and this enhanced status has raised the profile of the activities of the Codex. However, the impact of WTO on the Codex is not yet clear and fears have been expressed that the body may lose its ability to take decisions based strictly on science.

All of the standards are detailed specifications, most of which require analytical methods for their realization. This task is backed by other standardizing organizations such as the International Union of Pure and Applied Chemistry (IUPAC), the International Standards Organization (ISO), and the Association of Official Analytical Chemists (AOAC), which are involved in the development of methods of sampling and analysis. These organizations consult with the various international bodies representing individual commodity interests, such as the International Dairy Federation (IDF), the International Association for Cereal Chemistry (ICC), the International Olive Oil Council (IOOC), the International Office of Cocoa and Chocolate (IOCC), and others.

European Union Laws

In the European Union (EU), a huge market with a population of 320 million, a programme of food law measures has been designed to create a single European market in foodstuffs. The laws of the community are expressed in the form of regulations and directives. Regulations, made under Article 43 of the Treaty of Rome, are binding on all member states and are directly applicable. The directive has no force of law in a member state until it is incorporated into the legislation of that country. Dates are prescribed in directives to insure compliance within the time stated. Some of the rules and specifications of the EU directives rely on Codex Alimentarius or other international guidelines. The Community is also laying down tougher rules for food analysis which laboratories must adopt. Bringing a multitude of national laws into line with a common objective is a difficult task but food legislation at EU level is expected to deal successfully with questions such as protection of public health, consumer information, and fair-trading. The member states of the EU have speeded up harmonization, since their governments are aware that outdated legislation can no longer act as a basis for competition in this large market. Council directives 89/397/EEC and 93/99/EEC laid down uniform general rules for the official control of foodstuffs and also for laboratories entrusted by the member states to carry out food inspection and analysis. Since 1993 coordinated food inspection programs among the responsible authorities in member states were also set up to establish compliance with food legislation and insure that food is fit for consumption. In July 1996, the so-called Black List Anti-Fraud Regulation came into effect in the EU. This regulation aims to reduce fraud within export refund and intervention measures by intensifying inspection. Those found to have committed a fraud are excluded from EU funds for at least 6 months.

Regulating the Safety of Food in the USA

In the USA there were no food regulation laws prior to the 1900s. At that time food companies could add anything to their products. In 1902, the Director of the Bureau of Chemistry in the US Department of Agriculture (USDA), Harvey Wiley, who was the leader of a campaign against food adulteration, set up a group of male volunteers to evaluate the safety of common food preservatives and ingredients. This group became known as the Poison Squad. At about the same time the Poison Squad was formed, Upton Sinclair wrote a book, *The Jungle*, dealing with the unsanitary conditions of the Chicago meat-packing industry. This crusade resulted in the passage of the Pure Food and Drug Act in 1906: this Act defined food adulteration and made the distribution and sale of adulterated foods and drugs illegal. These early efforts of the Poison Squad marked the beginning of food toxicology and provided impetus for the regulation of substances added to foods.

In 1931, the Food and Drug Administration (FDA) was formed as a separate unit of the USDA to administer the law. This agency regulates food under two general criteria – adulteration and misbranding. The FDA was ineffective until 1938, at which time the

passage of the Federal Food, Drug and Cosmetic Act of 1938 updated and tightened the definition of adulteration. This gave the agency the power to fine violators of the laws.

After 20 years of application, interpretation, and enforcement of this Act, a significant revision took place in 1958. The Food Additives Amendment of 1958 led to a major change in the FDA's approach to its activities. Congress applied the term 'safe' as the criterion for action, supplementing the term 'adulteration.'

Over the years, with advances in science and analytical methods, the FDA has become more confident in its evaluation of food safety and US courts have given general endorsement to the agency's decisions. In the fake food fight, the Agency has sought and won convictions against companies and individuals engaged in selling bogus fruit juices, honey, maple sugar, cream, olive oil, seafood, and many others.

The FDA has major responsibilities for food supply in the USA, but other agencies also exert significant regulatory control over foods and beverages. The major agencies so far involved are the Department of Health and Human Services, the US Department of Agriculture Inspection Services, the US Department of Commerce, the Environmental Protection Agency and Centers for Disease Control and Prevention (CDC). The FDA relies heavily on industry and consumers to help identify instances of economic fraud. The detective work of FDA inspectors in the premises of suspect companies is also valuable. Cooperation with other foreign government bodies prevents adulterated foods banned in one country being shipped to another. Some adulterants recently reported in FDA files are: beet sugar or corn syrup in orange juice; canola oil in olive oil; sugar, water, hydrolyzed inulin syrup in apple juice; corn oil in dairy cream; corn syrup in maple and sorghum syrups or honey; water and sodium tripolyphosphate in scallops; potato starch in horseradish; salt and water in milk and sawdust in ginseng dietary supplement. The Safe Food Act of 1997, by which the food safety and inspection functions of 12 agencies have been consolidated into a single independent agency, is expected to combat even more effectively dishonest or fraudulent practices not only in a federal but also in an international context. (*See* **Food and Drug Administration**.)

Toxicological Implications of Economic Adulteration of Food

In the past, the deliberate adulteration of food with untested chemicals or poisonous substances was widespread. In the 20th century, developments in the analytical field and improvement of legislation have brought many of these illegal and unethical practices under control, but cases of food adulteration with toxicological consequences have not completely disappeared.

One serious case of malpractice in the food industry is the use of denatured rapeseed oil for edible purposes. This caused the outbreak referred to as Spanish toxic oil syndrome. In 1981, a disease broke out in Spain which rapidly took on epidemic proportions. The reported symptoms were respiratory distress, nausea, fever, vomiting, headaches, myalgias, abdominal pain, and skin eruptions. Approximately 20 000 people were affected and more than 400 deaths were recorded. For many years, scientists all over the world tried hard to find an explanation and identify the toxic compounds causing the illness. Today, toxicologists and chemists are convinced that the toxic oil syndrome should be attributed to aniline used for denaturation, but there are different opinions concerning the nature of the toxic compounds. Phenylalamine, originating from the glucosinolates present in rapeseed oil, was for many years believed to be the etiological agent in toxic oil syndrome. The course of events, however, in the two factories processing the aniline containing rapeseed oil and simulating studies conducted in the UK do not confirm this hypothesis.

Another explanation may be the formation of *N*-phenyl-amino propane diol esters of fatty esters under conditions favoring dehydration. This suggests that deodorization sludges containing free fatty acids (and aniline) were catalytically treated with glycerol to obtain reconstruction of triacylglycerols. The problem will remain unresolved unless experts visit Seville again, study in more depth the conditions of the episode, and implement simulation processes that include esterification of fatty acids with glycerol in the presence of aniline.

Cases of Economic Adulteration of Food

Cases of adulteration frequently reported in the literature concern not only the basic foods (oils and fats, milk and dairy products, meat, fish, and cereals) but also fruit juices, alcoholic beverages and wine, honey, chocolate, coffee and spices, essential oils, and flavorings.

Some cases of the last decades with serious economic and other implications are briefly discussed below.

Wines

Some Austrian, German, and Italian wines were found in 1985 to have been illegally supplemented with diethylene glycol (DEG), not a permitted food additive, to improve body and sweetness. Soon after the scandal, a 30% drop in demand for wines was observed in Austria. In 1987 some Japanese wines were also reported to contain the same adulterant. (*See* **Wines**: Types of Table Wine.)

Fruit Juices

One case which involved economic fraud and cover-up efforts is the adulterated apple juice for babies scandal. For many years, Beech-nut Nutrition Corporation purchased and used concentrated apple juice which contained cheap ingredients such as corn syrup, invert sugar, malic acid, caramel, and imitation flavor. Although it was the director of research and development who discovered the use of these adulterants, he was forced to resign. The FDA took action and in 1988 the company was heavily fined.

Citrus juices are frequently adulterated in many ways. The price of grapefruit juice is always lower than that of orange juice, so their admixture can be expected. Misbranding of fruit juices made from imported concentrates is a common problem in Florida.

Vanilla Extracts

The adulteration of vanilla extracts with inexpensive synthetic vanillin represents a loss of millions of dollars to the vanilla extract industry. To obtain equal strength of flavor, either 28 g of synthetic vanillin or 4.5 l of single-fold vanilla extract is required. The ratio of cost is approximately 1:120, and this significant difference is a strong stimulus for adulteration.

Nonvanilla vanillin can be prepared from lignin, eugenol, or guaiacol. Synthetic products have a characteristic vanilla-like note but they are inferior in organoleptic properties because the quality of natural vanilla derives not only from the concentration of vanillin but also from the presence of other valuable volatile flavor compounds.

Olive Oil

Olive oil, a food staple in the warmer regions around the Mediterranean, is now becoming more popular throughout Europe, the USA, Japan, and Australia. Olive oil is often adulterated with seed oils and olive residue oil (olive pomace, olive kernel, or olive husk oil). Esterified oil, which is prepared by re-esterifying low-grade olive oil or olive oil soapstock recovered from alkali refining, has also been used to adulterate olive oil products. A survey in 1982 in the USA demonstrated that many olive oil products (imported or locally produced) contained undeclared olive husk oil, esterified oils, and seed oils. The European legislation for olive oil characteristics issued in 1991 (and amended many times since then) is an important tool against sophisticated frauds. The most recently reported cases of virgin olive oil frauds are those where lower-grade olive oil (desterolized or mildly deodorized), or other oils having a similar composition (hazelnut oil, high oleic-sunflower oil) have been used. (*See* **Olive Oil**.)

Fish, Meat and their Products

Meat and fish commercial products, being the main food protein sources for human consumption, are most frequently adulterated with other proteins of inferior-quality fish species or of nonmeat origin (e.g., undeclared soya protein in pork sausages). Authentication of species is important because all meats are not safe for consumers (e.g., meat from cows which had bovine spongiform encephalopathy (BSE)) or meats which should not be used (endangered or overexploited resources). Identification is more complex, especially when the analysis has to be carried out on cooked products. Fish traded in fillets or as fish fingers is the most frequent case of economic adulteration. Surimi, which was used in the past as a substitute for crab sticks, is no longer a cheap raw material because of overexploitation. Characteristic incidences of substitution of cheaper materials for more expensive ones include the fraudulent replacement of salmon, trout, plaice or lemon sole, and caviar. DNA analysis seems to be the answer to speciation problems related to fish trade. (*See* **Fish**: Fish as Food; **Meat**: Eating Quality.)

Milk and Dairy Products

The addition of water is still the most frequent case of milk adulteration. False labeling of the animal origin of milk, the use of reconstituted powdered milk, and the addition of partially hydrogenated vegetable oils are currently a matter of investigation for milk and dairy products. Roquefort in France, manchego in Spain, pecorino in Italy and feta in Greece are cheeses of large economic importance which are frequently adulterated or misbranded. The manufacture of these products is strictly regulated in these countries and within the EU. Consumption of products containing undeclared milk has been associated with certain food allergies. (*See* **Milk**: Liquid Milk for the Consumer; **Cheeses**: Chemistry and Microbiology of Maturation.)

Wheat and Other Cereals

The main cases of adulteration reported and addressed analytically are the admixture of wheat and barley cultivars, the fraud of durum wheat flour with common wheat (mainly in pasta products), and the misbranding of various commercial types (cargo, milled, broken grains, parboiled) or the origin of Basmati rice. (*See* **Cereals**: Bulk Storage of Grain.)

Genetically Modified Food

The rapid pace of development of genetically modified organisms (GMOs), especially food plants, and the commercialization of novel foods derived from GMOs have caused intense debate and consumer concern. Although there is no evidence of actual or potential harm of GM food, nothing can be certain in a field of rapid scientific and technological progress. The present EU legislation (regulations 258/97/EC and 1139/98) recognizes that a genuine choice of non-GM foods should be available to the public and that food containing identifiable GM material should be properly labeled. Against this background numerous questions have emerged concerning analytical aspects, ranging from sampling procedures to robustness of methods. (*See* **Genetically Modified Foods**.)

Detection

M Tsimidou and D Boskou, Aristotle University of Thessaloniki, Thessaloniki, Greece

Introduction

Methods of detecting food adulteration are based on physical, chemical, biochemical, and other techniques. All these methods, which have replaced the early organoleptic and other empirical tests, are continuously updated because food adulteration is unceasing, and new problems are always arising. A number of analytical procedures are usually available for most cases of adulteration so that the analyst has the flexibility to choose the appropriate one (number of samples to be analyzed, sensitivity required, etc).

Proximate analysis of a foodstuff indicates the extent of abstraction for the main compositional components – moisture, fat, protein, carbohydrates, fibre, and ash. However, it cannot answer problems of authenticity or speciation. Very often, adulteration can be detected from the presence of minor components that occur in the adulterant and not in the food itself. In such cases, trace chemical analysis is necessary to assess the purity. Data banks of authentic values that account for seasonal, regional or other variation may support authenticity testing in some cases (fruit juices).

This article outlines the main applications of analytical techniques that are routinely used in laboratories authorized to check the purity of foods and drinks, and also presents in brief the state of the art in authenticity testing.

Sensory Methods

Sensory methods have not been incorporated yet into legislation for the detection of food adulteration, although routine analysis of a sample always includes the examination of its organoleptic characteristics. International organizations such as the International Standards Organization (ISO), American Society for Testing Materials (ASTM), and others have developed and recommended sensory methods for foods in general and for particular commodities. Such methods are useful in trade (e.g., grading of goods) and the management of resources. Moreover, the US Food and Drug Administration (FDA) has accepted results of sensory panel tests as *prima facie* evidence of product efficacy, and in some cases, legal

decisions in the USA have relied exclusively upon sensory evaluation data.

The limitations concerning the application of sensory methods for the detection of adulteration are fewer now that multivariate statistical techniques are employed. With these methods, sensory data are better evaluated, and more reliable conclusions can be drawn. For example, the results of Free-choice Profiling tests can be analyzed by the Generalized Procrustes method. The latter adjusts for several types of variation in the way each panelist describes samples and then manipulates the data to combine terms that appear to measure the same characteristics. Such an approach has been meaningfully applied to classify coffee, tea, and alcoholic beverages.

Separation Techniques

Gas Chromatography (GC)

GC has proved to be essential for the analysis of lipids and, therefore, is widely used in the detection of adulteration of edible fats. Adulteration of fats is usually detected by GC analysis of fatty acid methyl esters (FAMEs), triacylglycerols, sterols, and their dehydration products.

Fatty acid composition Separation of FAMEs, based on different molecular weights and degrees of unsaturation, is usually achieved on capillary columns. Positional and geometrical isomers of the FAMEs are also analyzed under the same conditions. Standard methods are available for the analysis of FAMEs. Edible fats have characteristic fatty acid compositions and can be grouped into various categories. The percentage values for each fatty acid are compared with those recommended by national and international organizations. An increase in the levels of certain fatty acids indicates the presence of certain adulterants (e.g., lauric acid, (12:0), content >0.1 indicates the presence of lauric oils to sunflower oil margarine). An increase in the *Trans* isomers, naturally found in low levels in animal fats, is an indication of treatments such as hydrogenation.

Triacylglycerol composition Triacylglycerols are separated according to carbon number. This is important for the detection of cocoa butter equivalents (CBEs) in cocoa products. The addition of 5% noncocoa butter apart from milk fat is permitted in many countries, and it is a common practice in the industry. Fincke, and also Padley and Timms, proposed a methodology based on the well-documented linear relationship between C_{50} and C_{54} species for all cocoa butters. All CBEs contain fewer C_{52} triacylglycerols compared with cocoa butter, and this difference causes a significant deviation from the above relationship. Levels of POP, POS, and SOS (P=palmitic, O=oleic, S=stearic acid) for natural cocoa butters of different origins were used to construct a ternary diagram to discriminate them from synthetic ones.

Analysis of sterols and other minor components Identification and determination of sterols by GC are mainly used to reveal the presence of vegetable fats in animal fats or admixtures of vegetable fats. The principle of recommended procedures involves saponification of the sample, isolation of the sterols from the nonsaponifiable matter on thin-layer plates, and GC analysis of sterols or their derivatives. The separation is usually with SE-30, OV-17 or JXR at elevated temperatures (230–240 °C). Qualitative and quantitative differences among sterol fractions are well established for a great variety of vegetable fats. Sterol dehydration products formed during refining have been successfully used to identify cheaper edible oils in virgin olive oil or vegetable oils in chocolate. Various groups of researchers developed excellent procedures for the determination of steroidal hydrocarbons, which are useful to verify the thermal treatment of oils and to demonstrate the presence of desterolized oils in an admixture. A minor component of olive residue oil, erythrodiol, a triterpenic diol, is used as an indication of adulteration of genuine olive oil with olive residue oil. The detection is based on GC of the combined sterol and triterpenic diol fraction after silanization. The presence of wax esters with 40–60 carbon atoms indicates the presence of solvent extracted or refined oils in virgin olive oils.

Recent applications GC–mass spectroscopy (GC–MS, GC–MS–MS) techniques have been proved unequivocal in identifying the presence of undesirable components and in revealing adulteration. For example, a GC–MS method was used to identify the illegal addition of diethylene glycol in wines or ethylene oxide in spices. Improvements in column technology required new sample application techniques. A variety of injection modes compatible with capillary columns have emerged. Headspace sampling techniques are ideal for trapping very volatile components prior to GC analysis. They can also be employed to explore the volatiles of samples that contain large amounts of nonvolatile components. This is the case in fermented beverages such as wine, beer, and distilled liquors. The profile of the aromatic compounds of fermented beverages chromatographed by headspace techniques is used to check misbranding of

these heavily taxed commodities. The test involves a comparative GC analysis of the suspected sample and a standard for the particular brand.

High-performance Liquid Chromatography (HPLC)

HPLC techniques are increasingly being used in routine analysis and incorporated into the legislation of many countries. Today, well-established procedures for many classes of organic compounds or individual food components are available; many of these procedures can be used to check food adulteration.

Carbohydrate composition Carbohydrate analysis by HPLC is usually performed on amino-bonded reversed-phase columns. A 70–80% aqueous acetonitrile solution is suitable to elute low-molecular-weight sugars, isocratically, within 20 min; for the detection of the eluate, refractive index detectors are necessary. The sample injected (10–100 μl) must be free from particulate material; careful extraction and clean-up are, thus, essential. Simultaneous determination of glucose, fructose, and sucrose is careful to detect the illegal addition of inverted sugar in manufactured products. Nutritional claims may also be checked by HPLC profiling of carbohydrates. For example, lactose content extrapolates the fat level of skim milk powder; raffinose and stachyose determination is an indicator of the additon of texturized soya in meat products, etc. Oligosaccharide analysis is carried out by similar elution systems to those used for low-molecular-weight sugars (40–60% aqueous acetonitrile, ~30 min) or by anion exchange chromatography and pulsed amperometric detection (potassium hydroxide-based mobile phase). Molecular-weight carbohydrate analysis is necessary for the control of the addition of undeclared starch syrups in honey, fruit juices, and other valuable natural products. The authenticity of instant coffee, using measurements of total glucose (to detect maltodextrins or caramel), total xylose, and free mannitol (to detect husks and skins) and free fructose (to detect chicory), is assisted by the use of pulsed amperometric detection, which provides an increased sensitivity over the refractive index detection.

Triacylglycerol composition The HPLC analysis of triacylglycerols is achieved on reversed-phase columns, isocratically or by gradient nonaqueous elution. The separation is based on the concept of equivalent carbon number (ECN): ECN=CN−2DB, where CN is the carbon number of the triacylglycerol molecule, and DB is the double bond number. Triacylglycerols with the same equivalent carbon number are referred to in the literature as 'critical pairs'. The complete resolution of critical pairs is not necessary for detection of adulterated oils and fats or fat speciation, as long as the separation is characteristic and reproducible. The International Union of Pure and Applied Chemistry recommends a simple isocratic procedure using acetone–acetonitrile mixtures and refractive index detection to determine the nature and the relative percentages of triacylglycerols in fat. Based on such simple procedures, the EU has proposed a maximum level of 0.5% trilinolein for olive oil. The distribution of saturated (S) and unsaturated (U) fatty acids in the *1, 2, 3* positions of triacylglycerol molecules is used as a basis for differentiating pork from other fats. The addition of pork to beef would increase the SSU:SUS ratio, thus permitting its detection even at low levels (2%).

Amino acid composition The search for an equally powerful technique for amino acid analysis may explain the fact that the first reported application of HPLC to food and beverage analysis was the determination of free amino acids in cocoa beans in 1980. Precolumn derivatization of amino acids with various reagents (phenyl isothiocyanate, dansyl chloride, 2,4-dinitrofluorobenzene or *o*-phthaldialdehyde), reversed-phase columns, gradient elution with mixtures of acetonitrile (or methanol) and a buffer and a suitable detector (UV-Vis or fluorescence) are the usual chromatographic parameters. Ion-exchange chromatography is followed by postcolumn derivatization with the ninhydrin reaction and detection in the visible region. Among the most important applications are the determination of authenticity and type of juices, and the detection of the origin of honeys. The concentration and relative proportions of amino acids are two of the best criteria for identification of the type of juices and for estimation of the content of juice in a beverage or syrup. This evaluation of results is based on the small variability of relative quantities of L-amino acids in juices, which cannot be easily manipulated. Besides, commercial amino acid mixtures are expensive adulterants. A stepwise regression analysis performed on amino acid data produced by HPLC is very useful in solving complex problems of adulteration such as the presence of more than one adulterant, or the addition of acidulants and coloring agents.

Other applications HPLC is a very promising technique for the determination of minor components and metabolites. For example, illegal addition of coloring matter in juices and wine can be detected by HPLC analysis of pigments; diacetyl determination in butter, flavonoids in apple and pear juice, and naringin and prunin in grapefruit are also used to detect aroma

supplementation or the type of fruit. HPLC analysis of minor components usually involves careful extraction and clean-up of the determinant. The widespread application of solid-phase extraction with commercial cartridges facilitates these steps.

Electrophoresis and Related Techniques

In recent years, electrophoretic techniques have been used to reveal adulteration of many food products rich in protein. Among the most important applications reported are the detection of: the addition of soya protein to meat products (polyacrylamide gel electrophoresis (PAGE)); the substitution of cow's milk for goats milk in goat dairy products (PAGE, isoelectric focusing (IEF)); the origin (season, area, and strain) of wheat flour (PAGE) and the partial replacement of wheat flour by other cereal flours (PAGE). Electrophoretic techniques are used almost exclusively for the species identification of fishery products. The large amount of fish species consumed, the close relations among some of them, and the removal of the external features due to processing are the major difficulties in the identification of fish species. The latter is achieved using, as determinants, sarcoplasmic and myofibrillar proteins under well-established standard procedures. Reference samples are considered necessary for identification. Today, preparations of species-specific proteins are commercially available. Information is also available for the characteristic electrophoretic protein patterns of a great number of fish species. PAGE with an anionic detergent (sodium dodecyl sulfate, SDS) and a reducing agent (mercaptoethanol) used to separate subunits by size is of great value for the identification of salmon, rainbow trout or brown trout eggs. Electrofocusing is suitable because as an equilibrium technique, it is easily standardized. It is the preferred procedure for the identification of raw species. Enzymic staining instead of amido black is used with IEF to differentiate some species having similar protein profiles (e.g., mutton from goat meat using phosphogluconate dehydrogenase). Two-dimensional electrophoresis (IEF and SDS–PAGE) is a powerful technique able to resolve 1000 proteins in a mixture. Conjunction of electrophoretic systems with image analysis equipment is a means of quantitative estimation of the various species present in a mixture. Simplified speeded up PAGE procedures (e.g., the Micrograd system) are applied for discrimination of the most relevant wheat varieties. HPLC is sometimes used to complement the PAGE data and *vice versa*.

Capillary zone electrophoresis The potential of capillary zone electrophoresis will be tested in a routine analysis of various analytes in the near future. At the moment, it is not considered as an alternative method for protein speciation.

Spectrometry–Spectroscopy

Ultraviolet-visible techniques are frequently used for the assessment of adulteration of citrus juices, coffee and tea, virgin olive oils, and colored food products. Minerals in foods are almost exclusively determined using atomic absorption and emission spectroscopy. Infrared radiation is the basis of automated equipment for the quality control of milk, grains, or fats. More sophisticated techniques are employed, where necessary (nuclear magnetic resonance, mass spectrometry).

UV-Vis Spectrophotometry

Citrus products The approximation of orange juice and pulpwash content in citrus products is based on equations derived from absorption data of the alcoholic extract in the visible region (465, 443, and 425 nm; carotenes) and the ultraviolet (325, 280, and 254 nm; polyphenols, flavonoids, and ascorbic acid) regions. The ratio $A_{273\,nm}/A_{326\,nm}$ is found to be constant for lemon juice (A = absorbance). Any deviation from this constant value indicates the addition of grapefruit, orange, or apple juices. Luminescence spectrophotometry is also useful for the characterization of mixtures of citrus fruit juices.

Tea and coffee The caffeine content of these highly priced commodities and their products is a significant quality criterion. The method, which is based on measurement of the absorbance at 276 nm, is sensitive enough to test decaffeinated green or roasted coffee samples.

Oils and fats The state of autoxidation is indicated by the specific extinction values at 232 nm (conjugated dienes) and 268 nm (conjugated trienes). The specific extinction at 268 nm is also suitable to check admixing of virgin olive oil with residue or refined olive oil because conjugated trienes are present in the processed oils.

Colored foods Ultraviolet-visible spectra of permitted and nonpermitted pigments are important for the identification of added coloring matter in food. Careful extraction and isolation of the dyes are necessary prior to analysis. Lists for permitted colors (FDA, EU) and spectra for food colors are available for comparison (German Research Society).

Atomic Absorption and Emission Spectroscopy

Atomic absorption has a high sensitivity but does not permit multicomponent analysis. The latter is feasible when inductively coupled plasma–atomic emission spectrometry (ICP) is coupled with MS. ICP–atomic emission spectrometry coupled with a pattern recognition program can provide information for the presence of pulp wash in juices on the basis of the increased levels of calcium, silicon, and sodium. Barium, rubidium, and copper were the most important elements for the geographical differentiation of orange juices using a similar approach. Sample digestion is a crucial step in this sensitive analytical technique. Wines can be classified according to origin and grape cultivar on the basis of simultaneous determination of a considerable number of minerals and multivariate analysis of data. It is worth noting that for different regions, different elements were found useful for the discrimination. It seems that grape varieties selectively take up certain elements from the soil.

Near-infrared Reflectance or Transmission Spectroscopy (NIR/NIT) (0.7–2.5 μm) and mid-infrared Spectroscopy (2.5–15 μm)

NIR, or NIT, spectroscopy has been used in the analysis of a wide array of raw materials and food products. Many of its industrial applications are designed for specific products and production lines. Quality control of products includes determination of moisture, protein, fat, carbohydrates/starch, and ash content. Milk and dairy products (whole, skim, powdered milk, cheese, caseinates, whey concentrates, etc.), meat and products, grains, vegetables, baked goods, and snacks are the most frequently analyzed materials. The combination of NIR technology with multivariate analysis software enables processing of all recorded absorption data.

Mid-IR spectroscopy was extensively used in the dairy industry in the proximate analysis of milk and soon became a standard method (AOAC, 1980). Infrared Milk Analyzers evolved as the tools for producer payment and efficient, rapid, cheap routine quality control (one milk sample per 20 s). Fourier transform IR spectroscopy and attenuated total reflectance technology are powerful potential methods in the field of proximate analysis of food components.

Isotopic Analysis

The isotopic composition of various constituents has been used since the late 1970s as a means of determining the authenticity of foods of plant origin. ^{14}C activity analysis and stable isotope ratio analysis (SIRA), utilizing an isotope ratio mass spectrometer (IRMS) or a gas chromatography combined with IRMS, are the most frequently used techniques. The ratios are usually expressed as 'δ' units, where

$$\delta_{\text{isotope ratio}} = \left(\frac{R \text{ sample} - R \text{ reference standard}}{R \text{ reference standard}} \right) \times 10^3.$$

^{14}C activity measurement The use of ^{14}C analysis in the food industry for determining the origin of ethanol in wines and other fermented beverages dates back to 1952. Since then, ^{14}C-activity measurement has been extended to other natural products, e.g., spices and flavors. Atmospheric carbon dioxide through photosynthesis provides plants with the unstable isotope ^{14}C. The age of a certain plant or plant material is approximated from the measurement of its ^{14}C content. Hence, inexpensive artificial flavorings from petrochemicals, materials free of ^{14}C activity, can be easily detected. The technique is used in the USA to check the purity of champagne from the addition of artificially carbonated drinks. In a similar way, the vintage of a wine can be effectively determined because the ^{14}C activity of agricultural products has been well documented for the last four decades. However, this approach fails in detecting semisynthetic molecules derived from natural precursors or manipulated levels of ^{14}C to resemble expected levels.

Stable isotope ratio analysis Photosynthesis initiates isotopic fractionation of ^{13}C and ^{12}C. Most plants cultivated for food fix carbon dioxide by Calvin synthesis (or the C_3 photosynthetic mode). Exceptions to this rule are sugar cane and corn syrup, which follow the Hatch–Slack (C_4) pathway. C_4 plant material is more abundant in ^{13}C, and thus ^{13}C:^{12}C ratios are higher than in C_3 plants. Therefore, the ^{13}C:^{12}C ratios are used to detect the low-cost sugar cane and high-fructose corn syrups (HFCS) in valuable natural products such as honey and most juices (except for pineapple, which follows the Crassulacian acid metabolism). No other analysis could identify the above adulterants in these products. The Association of Official Analytical Chemists has adopted a method for honey, which involves complete burning of a sample to carbon dioxide and water, purification of carbon dioxide, and measurement of the ^{13}C:^{12}C ratio in an isotope ratio mass spectrometer.

A very important application of the ^{13}C:^{12}C ratio is the detection of synthetic vanillin in vanilla extract. Vanilla plants follow an intermediate biosynthetic path compared with C_3 and C_4 modes, and the extracts have very characteristic ^{13}C:^{12}C ratio limits. In this way, natural vanillin can be differentiated from its synthetic counterpart. Sophisticate fraud involves enrichment of the plant material with ^{13}C to escape

MS detection. The ^{13}C:^{12}C ratio is also useful for ensuring the authenticity of corn oil and can provide a good indication of the presence of corn oil in other oils. An atypical carbon δ value is also indicative of the addition of cane sugar spirit to brandy. The combination of IRMS and site-specific isotopic fractionation (SNIF) (site-specific natural isotopic fractionation)–NMR appears to be useful to overcome technical limitations in certain cases.

Another very important application is the discrimination between natural citrus juices and reconstituted juices (water addition). Plant water, compared with ground- or rain-water, is richer in ^{18}O due to losses in the lighter ^{16}O isotope during leaf evapotranspiration. ^{18}O:^{16}O values are also used to check wine appellation claims as well as the addition of beet sugar syrups prepared with tap-water.

To establish isotopic methods for the identification of origin, it is necessary to construct the natural variability of the different bioelement's stable isotope ratios within the area of interest. Such data banks have been installed for wine-producing areas within the European Union since the beginning of the 1990s.

The distribution of ^{2}H in water is influenced by similar factors as in the case of oxygen isotopes. Deuterium concentrations are used to detect the addition of groundwater to orange juice (fresh or reconstituted) or the addition of beet invert sugar to orange juice. Analytical difficulties due to the exchangeable oxygen-bound hydrogen atoms are overcome through the formation of nitrate esters (the level of carbon-bound ^{2}H is determined).

Site-specific isotopic fractionation–nuclear magnetic resonance spectroscopy (SNIF–NMR) SNIF–NMR is a sophisticated technique for detecting the presence of added sugars in fruit juices and characterizing the origin of wines. It takes into account the nonrandom distribution of deuterium within organic molecules, in particular ethanol molecules. The methodology involves fermentation of the fruit juice to ethanol and deduction of the botanical origin of the sugars from the $^{1}H/^{2}H$ ratio at the methyl and methylene site of the molecule. The methyl site isotope ratio is much lower in ethanol from beet sugar than that from grape or citrus fruit fermentation. Addition of 1% beet ethanol induces a ^{2}H:^{1}H shift of 0.88 p.p.m. The analytical requirements are great (equipment, sample size, data banks), and the sensitivity of the method is extremely low in the case of commercial orange juice blends.

Microscopic Methods

Standard microscopic methods have been developed for the authentication of herbs, spices, flours, and honey. These examinations are simple in principle, but the evaluation of results requires considerable experience of the microscopist. *Herbs and spices* are ground, and a slide is prepared and examined under different power objectives. For comparison, ISO standards describing histological characteristics of a great number of spices and condiments can be used. The potential of microscopic examination of pollen for the recognition of geographical origin of *honey* has been extensively studied. The principle of the method is the identification of pollen from characteristic and preferably indigenous plant species of a region. The visualization of *proteins* in cereal products, cheese, or chocolate is carried out using fluorescence microscopy with specific stains. Microscopy is used as a screening method in the detection of adulteration or misdescription of meat and meat products. Staining or polarization microscopy enhances the potential of this examination.

Biospecific Methods

Enzymatic Methods

Enzymatic methods are applied to check the purity of fruit juices and starch and to characterize various sugars in foodstuffs and formulae.

Fruit juices Among the various parameters required in the evaluation of fruit juice quality, the determination of sugars and organic acids is extremely important. Enzymatic determination of sucrose and invert sugars is more accurate and specific compared with chemical methods. By applying enzymatic techniques, more reliable sugar/invert sugar ratios can be calculated.

Determination of organic acids is also useful in detecting adulteration or checking the type of processing and the raw materials used. The addition of synthetic D,L-malic acid is revealed by a combination of enzymatic determination of L-malic acid (the natural existing isomer) and HPLC. Enzyme kits are also available to catalyse the oxidation of D-malic acid to pyruvate. The concentration of the formed NADH monitored spectrophotometrically depends on the original concentration of D-malic acid. Deviation from the narrow range of the citric/isocitric acid ratio in orange juice indicates adulteration with sugar solutions and citric acid. Other organic acids such as ascorbic, dehydroascorbic, lactic, and formic acids are also easily determined enzymatically.

Starches There is a need for a reliable and reproducible technique to determine starch purity. The latter, for example, is extremely important for the EU

refunds for food-grade starches. A multienzyme regime consisting of α-amylase, amyloglucosidase, and a debranching enzyme, pullalanase, is utilized to overcome the problem of incomplete starch hydrolysis (EC Regulation 4154/87).

Other applications Enzymatic determination of glucose, sucrose, and starch or glucose, maltose, sucrose, and partially hydrolyzed starch is recommended by various bodies for the characterization of sugars added to meat products, sausages, baby foods, etc. These determinations of complex mixtures are readily carried out with commercial multienzyme test kits.

Very sensitive enzymatic methods are also available for the determination of ethanol. Such methods are particularly useful in the quality control of wine, beer, other alcoholic beverages, alcohol-free products, and alcohol-containing chocolate products.

Immunochemical Methods

Immunochemical procedures were initially developed for clinical analysis, but today, they find many applications in food quality control. Immunodiffusion and newer techniques such as the various forms of enzyme-linked immunosorbent assay (ELISA) and radioimmunoassay (RIA) are the techniques most widely used in food analysis.

Speciation of meat and meat products Identification of meat species is important not only for economic but also for religious reasons (e.g., kosher food). The speciation of fresh, unheated frozen or mildly cooked meat is carried out by immunodiffusion and ELISA tests. Immunodiffusion procedures are used as screening techniques because they are influenced by the antigen content, which varies from sample to sample. ELISA tests are more suitable for quantification.

Identification of thoroughly cooked meat species involves tedious steps for both sample (extraction and protein recovery) and sera preparation. Double-diffusion techniques are capable of detecting 5–10% meat species in cooked beef sausages by employing antigens resistant to thermal denaturation (e.g., adrenal antigens). Recently, multiple species-specific thermostable antigens have been used to detect various species with ELISA systems. In these cases, cross-reactivity has been reported for very closely related systems (beef/lamb and turkey/chicken). Combinations of immunoassays and electrofocusing in order to increase sensitivity have also been used to solve similar problems.

Detection of 'foreign' protein in food products Soya protein in various forms–milk, meal and texturized – is added illegally to dairy and meat products to increase the total protein to a predetermined or a standard level. An array of different immunochemical precipitation techniques have been applied to the detection of soya protein in food products. The main limitation for all the techniques is that the immunoreactivity of soya antigens is influenced by the soya variety and the types of thermal process, which, in practice, are unknown. Such techniques are suitable for screening. ELISA techniques are preferred for quantification, whereas RIA techniques, which offer equally accurate results to the former, are expensive for routine use. Indirect hemagglutination and immunoelectrophoresis, though more sensitive and specific, are laborious and expensive procedures and require trained personnel.

Other applications Gliadin, the ethanol-soluble fraction of gluten, can be routinely determined by ELISA tests, but some precautions have to be taken to eliminate the problem of nonspecific binding. These tests are valuable for monitoring the legal limit of cereal proteins, added to foods for economic or technological reasons, or to ensure the absence of gluten in gluten-free products.

Substitution of barley wort for maize or rice as a cheaper source of starch in beer manufacturing is determined by double diffusion and immunoenzyme assays. This replacement is illegal in some countries.

Recent Challenges

Sophisticated types of adulteration, the development of a new generation of ingredients and foods through biotechnology or using alternative means of cultivation as well as the application of new technologies for processing foods raised new questions and challenges. Moreover, the public is aware about hazards related to diet and demands suitable labeling of the nonconventional products so that free choice is exercised at the time of purchasing, and also potential abuse of the technology is controlled. Therefore, in the last decade, a vast array of new applications and new techniques were developed to reveal any possible illegal practices against food purity and nutritional value.

DNA Techniques

The development of methods using species-specific DNA fragments amplified by polymerase chain reaction (PCR) may be successfully applied to detect some cases of sophisticated types of adulteration, even on heavily processed foods. Nucleic acids are thermostable molecules in comparison with the thermosensitive protein molecules so that tests based on them

are much more sensitive than the conventional ELISA tests. Still, due to specialized training requirements, expensive equipment, and access demands to DNA sequence databases, the techniques are not used routinely unless there is no other method adequate to solve the problem.

Following the DNA changes, treatments that induce DNA fragmentation can be identified.

To determine the cultivar, the restriction-fragment length polymorphism (RFLP) concept is applied. Restriction enzymes are used to cut the strands of DNA at specific points where a specific sequence of nucleotides is recognized. The fragments separated by microelectrophoresis are stained or characterized using specific radioactive gene probes. The presence of common wheat in durum wheat is based on a specific DNA sequence on the D-genome, a set of chromosomes found only in common wheat.

DNA-fingerprinting analysis can be used to identify fish species, but extensive databases on the sequence of DNA of many commercially important species are a prerequisite.

Detection of inserted DNA is based on a comparison with the genetically modified and nongenetically modified material. Several controls are necessary to ensure that the PCR reaction is successful. Products such as coarsely ground cereals, flour, soya lecithin, unrefined fats, chocolate, soy sauce, tofu, cakes and other baked products, cornflakes and popcorn, meat and sausages, tomato, and ketchup are among the products that can be tested for illegal labelling or admixture with genetically modified organisms.

Detection of Irradiated Foods

Methods to identify whether or not a food product has been treated with ionizing radiation without requiring comparison with the respective non-treated counterpart are based on different principles, e.g., thermoluminescence, electron spin resonance (ESR) and gas chromatography of irradiation-induced compounds in fats. In 1996, the European Committee for Standardization (CEN) adopted five standards for methods to detect irradiated foods. The standards are applicable to herbs and spices, shrimps and prawns, frog legs, poultry and other meats, liquid egg, fruits, and vegetables.

Thermoluminescence methods (EN 1788) are based on the emission of light when energy trapped in crystalline lattices during irradiation is released by heat. In food products, such lattices are silicate minerals originated from exposure to wind or soil (herbs and spices) or other sources such as the minerals from the sea sand found in the intestine of shrimps. ESR detects stable radiation-specific radicals produced upon irradiation of food, which are trapped in solid and dry components such as bones or cellulose. ESR does not apply equally effectively to all foods. CEN standard 1786 'for food containing bone' was validated for beef, chicken, and trout bones. The favorable detection limit of the method permits the identification of radiation, even in complex cases (e.g., chicken burgers). Radicals from cellulose are also used as a means for identification in some plant products, but only when the signal is positive (CEN 1787). The sensitivity of the method is dose-dependent. Further validation of the procedure is expected for foods containing crystalline sugars and crustaceae. Gas-chromatographic determination of radiolytic hydrocarbons (EN 1784) or 2-alkylcyclobutanones (EN1785) seems very useful in detecting irradiation of products containing even low levels of lipids.

Detection of 'Organic' Foods

No chemical or other method seems potent enough to distinguish foods produced organically from conventional foods. Therefore, an extensive and formalized system of documentation, inspection, and certification, like that which has been applied to EU countries, seems more realistic for the authenticity control.

AERATED FOODS

G M Campbell, Satake Centre for Grain Process Engineering, Manchester, UK

Background

Many foods, such as bread, ice cream, and whipped cream, gain their distinctive texture and appearance from the presence of bubbles. This article describes the processes used to create aerated foods, considers methods for characterizing aerated foods, and identifies the factors contributing to the stability of aerated foods during and after manufacture. The creation of aerated foods uses a wide range of aeration processes, including low-viscosity whipping, beating, and shaking, high-viscosity dough and paste mixing, gas injection, and slow and rapid gas generation or expansion through fermentation, leavening agents, extrusion, and puffing. A variety of whisks and mixers are used, both in the kitchen and on the commercial scale, to aerate foods. The air content and bubble size distribution depend on mixer design and operation. Air contents of aerated foods can be determined from density measurements, and cover the range from a few percent for some confectionery products to greater than 95% of the total volume of, for example, popcorn or rice cakes. Aerated food systems are inherently unstable, and the bubbles must be stabilized against drainage of the liquid films, coalescence of bubbles, and disproportionation. Surface-active materials such as emulsifiers, lipids, proteins, fat crystals, and ice crystals stabilize bubbles in foods.

Aerated Foods

Most food processing, either domestic or commercial, is concerned with creating desirable, distinctive, or novel textures, along with an attractive appearance. Many of the most appealing foods deliver their characteristic texture and appearance by exploiting the presence of bubbles. Examples include bread, cakes, ice cream, breakfast cereals, meringues, whipped cream, waffles, soufflés, aerated chocolate bars, beer, champagne, popcorn, and many others (*See* **Beers**: History and Types; **Biscuits, Cookies, and Crackers**: Nature of the Products; **Bread**: Breadmaking Processes; **Butter**: The Product and its Manufacture; **Cakes**: Nature of Cakes; **Cereals**: Breakfast Cereals; **Cheeses**: Types of Cheese; **Cream**: Types of Cream; **Eggs**: Use in the Food Industry; **Ice Cream**: Properties and Analysis; **Snack Foods**: Range on the Market; **Soft Drinks**: Chemical Composition). Bubbles in foods offer no nutritional benefit; they represent pure luxury and proclaim the skill of the chef or industrial counterparts. Aeration transforms food from merely flavorsome fuel into textural novelty. The textures achieved vary from the soft but strong crumb of bread to the crispness of breakfast cereals, the crunch of honeycomb, the smoothness of whipped cream, the 'melting bubbles' of aerated chocolate bars, and the tingle of carbonated beverages.

The results of food aeration are:

1. an increase in volume of the product;
2. a change in the texture and rheology of the product, aiding mastication and giving a different mouth feel and appearance;
3. enhanced ability to hydrate rapidly or to take up sauces, due to increased surface area;
4. possibly a modification of digestibility;
5. the possibility of a reduced shelf-life, as the finely divided air bubbles or increased porosity may enhance oxidation reactions and affect fat and flavor ingredients;
6. a decrease in the intensity of flavors.

Aerated foods offer product differentiation and marketing advantage in the highly competitive, innovative, and dynamic food market. They also inspire delight and praise in the dining room. Their creation requires detailed understanding, empirical and fundamental, of the complex interactions between food chemistry and physics in the kitchen or in the manufacturing environment.

Aeration Processes and Equipment

Aerated foods are produced in one of three ways: (1) liquid is forced around air to form bubbles; (2) gas is sparged into liquid to form bubbles; (3) gas is generated within the food to create bubbles. The first of these can be divided into low- and high-viscosity systems, while the third method can be divided into slow and rapid generation of gas, giving a total of five categories of aeration method. Within these five broad categories a very wide range of specific processes and operations are used, including whipping cream, beating eggs, dough and paste mixing, widgets in beer, fermentation, gas injection, frying, vacuum puffing, and extrusion. Table 1 describes the range of aeration methods used within these five categories, and lists examples of foods created using these processes. Several aeration operations may contribute together or consecutively during the process; for example, in breadmaking, bubbles are incorporated into the high-viscosity dough during mixing (a type 1b process); these bubbles are inflated slowly by carbon dioxide gas generated by yeast fermentation (type 3a), and are further inflated by steam generation and thermal expansion during baking (also type 3a), while also undergoing coalescence and rupture along with setting of the matrix structure.

The major food aeration methods are as described below.

Type 1(a)

- Whipping, beating, or shaking of low-medium viscosity liquids to entrap air.
- Pressure beating (dissolution of air or gas under pressure), for example, in a syrup, fat mixture, or chocolate, for confectionery manufacture.

Type 1(b)

- Mixing of doughs or high-viscosity pastes, in which air bubbles are entrapped as surfaces come together. The high viscosity of the dough or paste prevents rising and disengagement of bubbles. In raised bread, the bubbles incorporated by mixing act as nucleation sites for the CO_2 produced during fermentation. During creaming of butter and sugar, sugar crystals aid aeration; fat crystals in cake batters and ice cream act similarly, with the particle

Table 1 The five categories of processing method used to produce aerated food products

Category	*Processing methods*	*Food products*
1 (a) Low-intermediate-viscosity whipping	Beating, whipping, shaking, pressure beating	Whipped cream, milkshakes, batters (for cakes, pikelets, crumpets, Yorkshire puddings), soufflé, beaten egg whites, meringues, marshmallow, chocolate bars, mousses, dairy desserts, frozen desserts, milkshakes, sherbet, frappé, fruit fool
1 (b) High-viscosity mixing or layering	Dough mixing, paste mixing, entrapment, pulling, layering	Bread doughs, biscuit doughs, meat doughs, soft butter, creamed butter and sugar, ice cream, chocolate bars, puff pastry, choux pastry, croissants, vol au vents, fondant, cream fillings, icing, pulled taffy, peanut butter
2 Gas injection	Sparging, gas injection during pressure beating, widgets, pressurized containers, steam injection	Carbonated soft drinks, widgets in beer, cappuccino, instant whipped cream, ice cream, bubble gum, boiled sweets
3 (a) Slow *in situ* generation or expansion of gas	Fermentation, chemical raising agents (baking powder, sodium bicarbonate), steam generation and thermal expansion during slow cooking processes, vacuum expansion	Proving bread dough, baked goods, unleavened bread, doughnuts, waffles, puff pastry, choux pastry, vol au vents, pizza bases, soda bread, cakes, crumpets, crackers, beer, wine, carbonated soft drinks, ginger beer, Swiss cheese, honeycomb, chocolate bars, boiled sweets
3 (b) Rapid *in situ* generation or expansion of gas	Steam generation and thermal expansion during frying, extrusion, rapid dry heating, puffing, vacuum expansion, microwaving, pressure release	Popcorn, popped sorghum, puffed rice, puffed wheat, cornflakes, extruded breakfast cereals, poppadoms, crispbreads, snacks, potato crisps, micronized wheat, coatings, chocolate bars, beer, wine, soft drinks, bubble and squeak

size of the crystals affecting the size and number of bubbles entrained.
- Entrapment of air between sheeted layers, as in pastries and croissants, or between pulled strands, as in pulled taffy and candies.

Type 2

- Gas injection, e.g., air or nitrogen injection in ice cream and sugar confectionery, carbon dioxide injection in soft drinks, nitrous oxide injection in instant whipped cream, steam frothing of cappuccino.

Type 3(a)

- Fermentation, in which aeration is achieved through carbon dioxide production by yeast in bread, beer, and wine, or by *Propionibacterium* in Swiss cheeses.
- Steam generation during slow to moderate cooking, baking, or frying. Steam generation is often accompanied by thermal expansion of the gases already in the bubbles, and by evaporation of other dissolved components (e.g., CO_2, ethanol).
- The use of chemical raising agents such as baking powders in cakes, or sodium bicarbonate in soda bread, honeycomb, or dulce de leche.
- Vacuum expansion, followed by rapid cooling to set the expanded product, e.g., chocolate bars.

Type 3(b)

- Rapid dry heating or toasting of small or thin products to induce blistering or slight puffing.
- Frying in very hot oil, such that internal steam is formed rapidly, causing the product to puff.
- Expansion extrusion, in which superheated product under pressure emerges suddenly from an extruder, such that internal moisture immediately vaporizes into steam bubbles, to produce crisp snacks, cereals, and sugar confectionery.
- Puffing, in which products such as breakfast cereals containing superheated moisture are subjected to a sudden release of pressure.

In addition, special cases exist, such as popcorn, freeze-dried coffee, and candy floss (cotton candy). Despite the wide variety of processes, aeration equipment comprises primarily mixers of various designs, extruders (*See* **Extrusion Cooking:** Principles and Practice), or specialized puffing or expansion equipment. Most other aeration processes are achieved by heating or by chemical raising agents. (*See* **Leavening Agents**.)

Mixers for food aeration include high-speed whisks and beaters with stainless-steel wire assemblies for egg foams, whipped cream, and cake batters, and high- and low-speed heavy-duty mixers for doughs and pastes. Pressure beating delivers greatly accelerated aeration and produces fine foams, with air consumption of up to $1000\,l\,h^{-1}$. Blades can be mounted horizontally within the mixer bowl, or, more usually, vertically from the top or through the base of the bowl. Industrial-scale high-speed whisks operate at speeds of around 200 rpm with a specific power input of around $50\,W\,kg^{-1}$. Low-viscosity mixers must use high speeds to entrain air and break up the bubbles, while in dough mixing bubbles are entrained unavoidably simply through the action of surface renewal during mixing. In both high- and low-viscosity mixing operations the air content and bubble size distribution depend on the balance between entrainment and disentrainment of air, along with bubble break-up and coalescence.

In modern breadmaking processes the bubble structure created in the dough directly affects the baked loaf structure. Some dough mixers use pressure-vacuum mixing, in which the dough is mixed initially under high pressure to provide additional oxygen (which contributes to development of the gluten network), followed by mixing under a partial vacuum to reduce the air content in the dough. Some batch dough mixers, e.g., the Biplex, operate initially at slow speed to blend and hydrate the ingredients, then at high speed to develop the dough.

Continuous dough mixers lack the versatility of batch mixers to modify the bubble structure in the dough and in the resulting bread. Continuous, tubular, pressurized scraped-surface aerator-freezers with a residence time of about 30 s are used in icecream manufacture to give air contents of up to 50% by volume.

Characterization of Aerated Foods

Aerated foods can be characterized in terms of their rate of aeration, air content, bubble size distribution, the resulting texture, and the stability of the aerated structure. Foamability (the ease with which a foam is formed, in terms of rate and air content) and foam stability are usually applied to transient food foams such as beer and wine foams and beaten egg whites. Foamability may be measured by sparging gas or by rapid whipping to determine the time required to form a prescribed volume of foam, while foam stability is characterized by the half-life of the foam, the rate of foam drainage, or the change of conductivity of the foam. Foamability and foam stability are often inversely related – a greater foam volume is achieved

at the expense of a less stable foam. Stability is conferred through a range of stabilization mechanisms, discussed below.

For more solid aerated foods, texture is of greater importance, and rheometers and textural measurements, including sensory evaluation, are applied. Rheometers may be empirical, imitative, or fundamental. Crisp aerated foods can be characterized by calculating the apparent fractal dimension of the jagged stress–strain curve resulting from crushing. Mechanical properties of solid aerated foods depend on the mechanical properties of the matrix, the amount and distribution of the air, and whether the foam is of open or closed gas cells. Closed gas cells occur in aerated chocolate bars, for example, in which each bubble is discrete, while bread has an open-cell or sponge structure, in which the gas cells are interconnected to form a porous network. Mechanical properties of foams, such as Young's modulus, collapse stresses, crushing strength, and fracture toughness can be related to the density of the foam by a power law model:

$$\frac{\sigma}{\sigma_m} \propto \left[\frac{\rho}{\rho_m}\right]^n \tag{1}$$

where σ is a general mechanical property, σ_m is the mechanical property of the matrix material in the foam, and ρ and ρ_m are the density of the foam and of the matrix material, respectively. The exponent n is usually in the range 2–3. For constant matrix properties, mechanical properties vary with foam density raised to the power of n, such that as air content increases, the foam becomes less strong.

Air contents of aerated foods range from 2% for some confectionery products to greater than 95% for popcorn, rice cakes, and beer foam, with every air content in between. The air content of highly aerated fluid fluids such as icecream and whipped cream is characterized in terms of the overrun, OR, calculated as:

$$OR = \frac{\text{Weight of unwhipped product} - \text{weight of whipped product}}{\text{weight of whipped product}} \times 100\% \tag{2}$$

where weights are measured in a container of constant volume. The overrun represents the additional air added. In aerated foods with lower air contents, the void fraction of air as a fraction of the total volume is more usually calculated as:

$$\alpha = \left(1 - \frac{\rho}{\rho_{gf}}\right) \times 100\% = \left(\frac{OR}{OR + 100}\right) \times 100\% \tag{3}$$

where ρ is the density of the product, and ρ_{gf} is the gas-free dough density. Table 2 gives typical values of the density and air content of a range of aerated foods, from which the other parameters describing aeration can be calculated. Figure 1 shows typical air contents and specific volumes of a selection of aerated food products.

Density measurements indicate the gross air content of a food, but not how that air is distributed. The size distribution of bubbles or gas cells determines the texture, appearance, and mass transfer behavior of an aerated food. The size distribution can be determined by image analysis of an aerated surface or of thin slices of the product. When thin slices of a food material are taken, the holes appearing on the slice are, on average, smaller than the bubbles from which they came. The hole size distribution measured is therefore different from the true bubble size distribution, which must be reconstructed using stereological techniques.

Stabilization of Aerated Foods

The lifetimes of aerated food products range from a few seconds for wine foams, to minutes for beer foams and soufflés, hours for whipped cream, days

Table 2 Typical values of density and air content of aerated foods (dependent in all cases on temperature, composition, and processing factors)

Food	*Density (g cm^{-3})*	*Void fraction of air (%)*
Popcorn	< 0.07	> 95
Rice cakes	0.11–0.13	90–92
Puffed rice	0.13–0.17	88–90
Extruded products	0.10–0.33	75–90
Meringue	0.17–0.18	88–90
Beaten egg whites	0.15–0.20	80–85
Baked loaf	0.20–0.35	72–85
Sponge cake	0.25–0.35	70–80
Risen dough	0.25–0.40	68–80
Marshmallow	0.35–0.45	68–75
Cake	0.35–0.40	68–72
Whipped cream	0.40–0.60	40–60
Ice cream – hard	0.54–0.55	50
Cake batter	0.55–0.80	30–50
Aerated chocolate bar	0.70–0.80	40–45
Nougat	0.80–0.90	30–40
Fruit fool	0.75–0.8	25–30
Ice cream – soft	0.78–0.8	28
Milkshake	0.90–0.95	9–13
Micronized wheat	1.15–1.25	7–11
Bread dough (unrisen)	1.15–1.20	4–8
Wheat grains	1.25–1.35	2–3

for bread, weeks for cakes, and several months for Swiss cheeses, cereals, chocolate bars, and ice cream. Aerated systems are inherently unstable, and the bubble structure must be stabilized against collapse. In solid aerated foods such as crackers, snacks, and chocolate bars, stability is achieved through the solid matrix. These products are however delicate due to their fine aerated structure, and their high surface area makes them prone to oxidative deterioration or picking up atmospheric moisture; these factors ultimately limit their shelf-life. During the formation of these products, however, and in other more liquid food foams, the bubbles must be stabilized against their thermodynamic tendency to coalesce. Stability is conferred to aerated foods through the action of indigenous or added emulsifiers, proteins (as in beer foams, egg foams, proving bread doughs, cakes), fat or ice crystals or other particles (whipped cream, ice cream, puff pastry), or through a high-viscosity or solid continuous matrix (chocolate bars, meringues, breakfast cereals, Swiss cheese, mousse).

In low-viscosity foams, three distinct mechanisms of destabilization occur: drainage, coalescence, and disproportionation. Drainage occurs when liquid flows from the thin lamellae between bubbles into the Plateau borders that form at the meeting point of three bubbles. Plateau borders form a continuous pathway through the foam, allowing liquid to drain until the bubble lamellae thin sufficiently to allow coalescence. If the foam is stable against coalescence, drainage will continue until a relatively dry polyhedral foam skeleton remains. Higher viscosity in the liquid slows both drainage and coalescence.

Coalescence between bubbles is thermodynamically favorable because of the resulting reduction in surface area. The presence of surface active materials (e.g., emulsifiers and proteins) stabilizes against coalescence; pure liquids, free of surfactants, are unable to produce stable foams. The presence of hydrophilic particles may stabilize a foam, while hydrophobic particles destabilize foams by thinning the film between bubbles, as illustrated in Figure 2.

Disproportionation in foams is the growth of large bubbles at the expense of smaller ones, equivalent to Ostwald ripening in emulsions. The gas pressure in smaller bubbles is greater than that in larger bubbles, due to the contribution of surface tension, γ, as described by the Laplace equation:

$$P_b = P_\infty + \frac{2\gamma}{r} \tag{4}$$

where r is the bubble radius, and P_b and P_∞ are the pressures inside and outside the bubble, respectively. The higher Laplace pressure in smaller bubbles causes a higher gas solubility in the neighboring region. This results in a mass transfer driving force between small and large bubbles that causes diffusion of gas to the latter. The process is self-accelerating, as the loss of gas makes small bubbles even smaller, the Laplace pressure higher, and the gas solubility greater. Ultimately small bubbles implode and the foam coarsens. However, the increasing concentration of surface-active components at the surface of the shrinking bubble slows down and can even arrest the process. Disproportionation is a major factor in foam stability of carbonated beverages such as beer, due to the high solubility of carbon dioxide in water. The presence of a small proportion of nitrogen in the gas phase stabilizes against disproportionation, as the loss of carbon

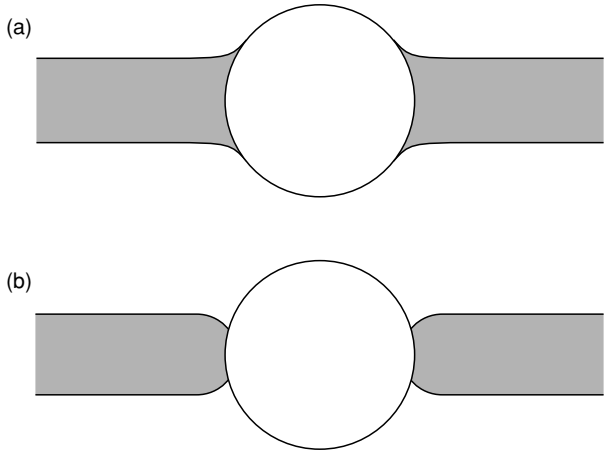

Figure 2 Effect of particles on foam stability: (a) stabilization of bubble lamellae by hydrophilic particles which draw liquid to the particle and oppose film thinning; (b) destabilization by hydrophobic particles.

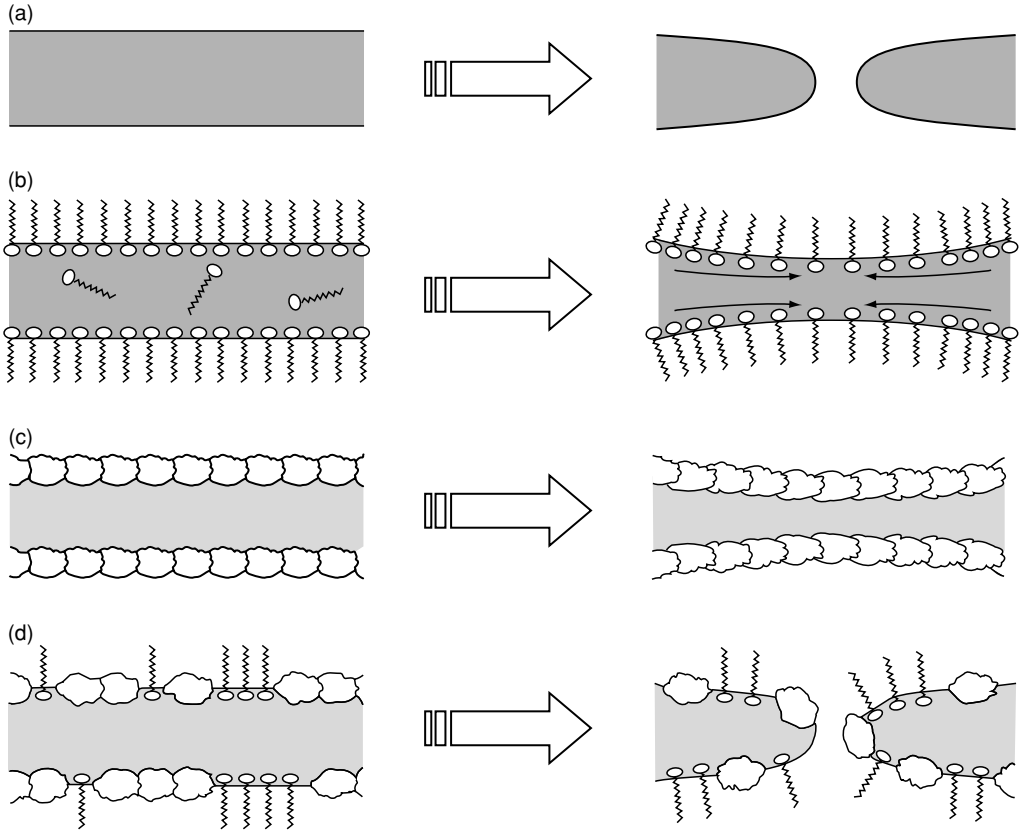

Figure 3 Illustration of film stability between bubbles with (a) no surfactant present; (b) low-molecular-weight surfactants such as lipids; (c) protein-stabilized bubbles; and (d) mixed protein–lipid systems.

dioxide by disproportionation from a small bubble lowers the partial pressure of carbon dioxide remaining in the bubble, lowering its concentration in the surrounding liquid, and thus ultimately removing the driving force for diffusive mass transfer.

Most aerated foods are not low-viscosity foams, and in most aerated foods, bubble coalescence is the most significant destabilization mechanism. Stability against bubble coalescence in both low- and high-viscosity systems is conferred by the presence of surface-active materials such as low-molecular-weight lipids and high-molecular-weight proteins (*See* **Emulsifiers:** Organic Emulsifiers). These two types of surfactant stabilize against coalescence via different mechanisms, as illustrated in Figure 3. Two adjacent bubbles will coalesce when the lamella between them thins and breaks as a result of drainage or mechanical disturbance (Figure 3a). When the lamella thins, it experiences greater stress which rapidly causes further thinning and breakage of the film. If a low-molecular-weight surfactant is present at the surface, its concentration decreases at the point of film thinning. This creates a surface tension gradient which causes surfactant molecules from the adjacent area to diffuse rapidly to the depleted region, sweeping liquid into it and restoring the thickness of the region (the Marangoni effect), and thus safeguarding against coalescence (Figure 3b). The effectiveness of low-molecular-weight surfactants thus depends on their rates of surface lateral diffusion. Large-molecular-weight surface-active molecules such as proteins have low lateral diffusivities; they stabilize against coalescence via a different mechanism, in which they interlink to form a rigid layer at the surface (Figure 3c). If both proteins and low-molecular-weight surfactants such as lipids are present, competing for space at the bubble interface, these two stabilization mechanisms can interfere; the presence of protein prevents rapid surface diffusion of lipid molecules, while the presence of lipids prevents the formation of a rigid interlinked protein network (Figure 3d). Such mixed systems are responsible for the reduction in egg foam volume when a small amount of egg yolk is allowed in with the whites, the reduction in loaf volume when small amounts of polar lipids are added to bread dough formulations, and the disastrous effects of lipids on beer foam stability. In other cases low-molecular-weight lipids may act cooperatively with proteins to improve foam stability.

AEROMONAS

S J Walker, Campden & Chorleywood Food Research Association, Gloucestershire, UK

Background

The genus *Aeromonas* belongs to the bacterial family Vibrionaceae and it has been suggested that this genus should be considered to contain some bacterial pathogens for humans, which may cause food poisoning. Other closely related genera within the family are *Vibrio* and *Plesiomonas* species. Both *P. shigelloides* and some *Vibrio* species are known to cause human gastroenteritis. With *Aeromonas* species, however, this pathogenic ability is not yet proven. These bacteria have traditionally been considered to be waterborne, although they may be isolated from a wide range of environments. (*See* **Vibrios**: *Vibrio cholerae*; *Vibrio parahaemolyticus*; *Vibrio vulnificus*.)

Aeromonas Species

Historically, the taxonomy of this genus has been confused, but the genus may be divided into two main groups. The first is the nonmotile species *A. salmonicida*. This microorganism is a pathogen for many species of fish and particularly the salmonids, but is not considered to be of significance in food safety or spoilage. Therefore, this species will not be considered further. The second group is the motile species. A phenotypic classification in 1981 divided this group into the species *A. hydrophila, A. caviae*, and *A. sobria*, which could be distinguished by simple biochemical tests. DNA studies have resulted in the genus being recognized as a separate family, Aeromonadaceae, as part of the Proteobacteria. At least 16 DNA-DNA hybridization groups (equivalent to a genomospecies) are recognized in the genus. The taxonomy of *Aeromonas* continues in this state of flux.

Much of the published literature on *Aeromonas* has not distinguished the motile species or has used out-of-date nomenclature. Consequently, the name *A. hydrophila* will be used as a general name for the motile species in this article. The name is derived from Greek, i.e., *Aeromonas* (a gas-producing unit), *hydrophila* (water-loving).

A. hydrophila as a Pathogen?

The potential for *A. hydrophila* to cause disease has been recognized since 1960. However, the significance of *A. hydrophila* as a direct cause of human gastroenteritis is a matter of debate. Although recognized as an opportunistic pathogen, it is only since the 1980s that there has been increased attention to its clinical significance in healthy individuals.

Some studies have found that the incidence of *A. hydrophila* in diarrheal stools is significantly greater than in those from control groups (e.g., 10.6% and 0.6% of samples positive respectively), and it may often be obtained in high numbers. These observations are most pronounced in infants and young children. The presence of a bacterium in a diarrheal stool, however, does not confirm its role as the causative agent of the syndrome. Other pathogens (including bacteria, viruses, or parasites) may initiate disease and alter the gut environment, and only then may *A. hydrophila* become prominent in the bacterial fecal flora. Much clinical data are of limited use as, in many cases, *A. hydrophila* was not looked for specifically, whilst, in other incidents, the presence of other pathogens could not be ruled out. The confusion in taxonomy and methodology for *A. hydrophila* may also have impaired the abilities of clinical microbiologists to isolate this bacterium from stool samples. A major survey on infectious intestinal disease in the UK found that *A. hydrophila* was as frequently isolated from control cases as from those presenting at general practitioners.

Many strains of *A. hydrophila* possess a wide range of potential virulence factors (i.e., strategies which may aid pathogenicity). These include the production of adhesins, cytotoxic enterotoxins (which lead to fluid secretion in the gut), protease enzymes, and hemolysins (aerolysins), although not all may be present in some isolates. Similar virulence factors are present in many recognized foodborne bacterial pathogens. The virulence factors of *A. hydrophila* produce typical responses in both *in vitro* and *in vivo* model systems for pathogenicity. Human feeding studies with *A. hydrophila*, however, have been inconclusive, with only two of 57 volunteers getting diarrhea after consuming high levels of enterotoxin-producing strains. The validity of this study has been challenged as the strains used may not have possessed all the other virulence factors necessary for gut colonization and so disease.

Consequently, in spite of the abundance of circumstantial evidence for pathogenicity, the case to include *A. hydrophila* as a foodborne pathogen resulting in gastroenteritis has not been conclusively proven.

Symptoms

Human infection with *A. hydrophila* may produce a wide range of localized and systemic illnesses. The symptoms are dependent on the bacterium, host, inoculum size, and infection site. Many of the motile *Aeromonas* species have been implicated in human illness and it is likely that many of them have been mistakenly reported as *A. hydrophila* in the past.

The most common type of infection involves the gastrointestinal tract and this is the illness of most concern to the food industry. Gastroenteritis may occur at all ages and in both sexes, although it is most commonly reported in young children. Symptoms are generally more pronounced in the very young, elderly, and immunocompromised. The most common symptom is an acute profusely watery diarrhea which may last for several days. Other associated symptoms include fever and vomiting. Generally, the disease is self-limiting and symptoms subside within 1 week. In a few cases, the disease may persist for more than 10 days and is classified as chronic. This results in weight loss and may require hospitalization. Chronic disease may last for several months. A second manifestation of gastroenteritis is a 'dysentery-like' illness characterized by diarrhea containing blood and/or mucus and cramping abdominal pain. Hospitalization and antimicrobial therapy are often required. More rarely, a 'cholera-like' illness may occur when the diarrheal stool is turbid and contains white grains ('rice-water stools'). This results in rapid and extensive dehydration, usually requiring hospitalization and aggressive antimicrobial therapy.

Other types of *A. hydrophila* illness include wound infection, septicemia, and localized infections. Wound infections are most common after traumatic injury and in many cases the injury has been associated with water or soil. Infection is most common in the hands, arms, and legs. In most cases with healthy adults, the infection remains localized but, in the immunocompromised, it may become more serious and result in amputation, septicemia, or even death. Septicemia and the infection of a variety of bodily sites occur most commonly, but not exclusively, with immunocompromised individuals. The symptoms of *A. hydrophila* septicemia are similar to those produced by other Gram-negative bacterial pathogens and the mortality level in the immunocompromised is approximately 50%. Both septicemia and localized infections generally require antibiotic therapy and often hospitalization.

Incidents of Foodborne Disease

Although there has not yet been a fully confirmed foodborne outbreak of *A. hydrophila* gastroenteritis, a number of suspected incidents have been reported. Three outbreaks affecting between three and 472 individuals have implicated oysters as the vector of transmission. Levels of the bacterium isolated ranged from 9 per 100 g to 2×10^4 per gram of food, although in the former case, the value obtained was after frozen storage for 1 year.

Cooked prawns have been implicated in three small incidents (1–20 cases) in the UK. Levels obtained in one outbreak were approximately 5×10^6 cells of *A. hydrophila* per gram of food. Several incidents implicating both treated and untreated water have also been reported.

A number of the incidents involving *A. hydrophila* cannot be fully confirmed as the feces of individuals were not specifically tested for this bacterium. Confirmed outbreaks are more likely to be reported with the increased awareness of this bacterium. (*See* **Food Poisoning**: Tracing Origins and Testing.)

Ecology

A. hydrophila may be isolated from a wide range of environmental sources, but has traditionally been considered to be an aquatic bacterium. It has been isolated from fresh waters, estuaries, coastal waters and, occasionally, open ocean waters. The incidence, numbers present, and survival of the bacterium are affected by the pH, temperature, salt content and dissolved oxygen in the water. Several studies have noted that the presence/level of *A. hydrophila* in sources of drinking water does not correlate well with the usual indicators of water quality (e.g., fecal indicator organisms). Furthermore, *A. hydrophila* may be isolated (at low levels) from chlorinated and unchlorinated potable water supplies. A statistical relationship between *A. hydrophila* in water supplies and health risks has been suggested, but there is no firm evidence of serious health effects of humans after exposure to such drinking water. The presence of *A. hydrophila* in potable water supplies may be of concern to food-processing operations, as it may lead to product and/or equipment contamination. Adequate chlorination of the water will insure destruction of the bacterium.

The presence of *A. hydrophila* in water undoubtedly contributes to its common occurrence in fish and seafood. The bacterium is a common component of the intestinal microflora of healthy fish. It is likely that poor processing techniques and poor hygienic practices may result in the contamination of fish flesh and seafood products. (*See* **Fish**: Spoilage of Seafood; **Shellfish**: Contamination and Spoilage of Molluscs and Crustaceans.)

In addition to fish, *A. hydrophila* may be obtained from the feces of a large range of both wild and domestic animals. In these studies, the animals were considered to be healthy. As with fish, poor processing techniques and poor hygienic practices during slaughter, butchery, dressing, and processing of meat and poultry products may contribute to the incidence of this bacterium in raw-flesh foods. (*See* **Poultry**: Chicken; Ducks and Geese; Turkey.)

A. hydrophila is not considered to be a normal inhabitant of the microbial flora of the human gut and its presence is usually transient. The fecal carriage rate for healthy individuals is usually 0–5%. Although asymptomatic carriers could serve as vectors for transmission of this bacterium (e.g., food handlers) no documented evidence of this is available.

As a consequence of this bacterium in human and animal feces, *A. hydrophila* can be commonly isolated from sewage samples and drainage from animal lairages. These may also contribute to the incidence in water samples.

Occurrence in Foods

A. hydrophila may be isolated from a very wide range of foodstuffs. It is not surprising that it is common (up to 100% of samples are positive) in a wide range of seafood, including fish (both wild and farmed), shrimps (raw and cooked), oysters, crabs, and scallops. The bacterium is also common in raw meats and may be isolated from a high proportion (50–100%) of red meat and poultry samples. Cooked meats may occasionally contain *A. hydrophila*, indicating that postprocess contamination has occurred. In fresh (and cooked) meats and poultry this bacterium is generally present in low numbers (less than 100 per gram) but may greatly increase during storage at chill temperatures, particularly when vacuum or modified-atmosphere packaging is used. In the past, *A. hydrophila* has been considered as a spoilage bacterium in these foods. Up to 50% of raw milk samples may contain. *A. hydrophila* and it has also been isolated from pasteurized milk, cream, and some dairy products. The incidence in pasteurized products is much lower than in raw milk and represents postprocess contamination. A wide variety of vegetable products (including parsley, spinach, celery, alfalfa, beansprouts, broccoli, lettuce, and root vegetables) may contain *A. hydrophila* and the incidence is usually between 5 and 40% of positive samples.

In addition to the above foods, *A. hydrophila* has been isolated from drinking-water samples and also from bottled mineral waters, although levels are generally low (less than 10 per ml). Studies have shown that when *A. hydrophila* was inoculated in mineral water, it was able to survive for 100 days.

The high levels of *A. hydrophila* found in some foods have also been associated with spoilage, where it may produce pungent off-odors. In addition the organisms can produce extracellular lipase or protease enzymes which are mildly heat-resistant and still active at temperatures of 0 to $-2\,^{\circ}C$.

Factors Affecting Growth

Of particular concern with the incidence of *A. hydrophila* in foods is the ability of the bacterium to grow at refrigeration temperatures. This bacterium may grow at temperatures as low as $0\,^{\circ}C$. Consequently, refrigerated storage alone cannot be relied upon to inhibit the growth of *A. hydrophila* completely. On occasions, high levels of the bacterium have been isolated from chilled foods which had been stored for prolonged periods. Reducing the storage temperature, however, will reduce the rate of growth of *A. hydrophila* and refrigeration may act in combination with other preservation factors to inhibit growth. The optimum and maximum temperatures for growth are 28–30 and $42\,^{\circ}C$, respectively.

A. hydrophila is not heat-resistant and has a decimal reduction time (*D* value) of between 2.2 and 6.6 min at $48\,^{\circ}C$. Consequently, this bacterium will be readily destroyed by processes such as milk pasteurization and frankfurter processing. It is important to insure that heat processes are carefully controlled to insure microbial destruction.

This bacterium is not a good competitor with many other bacteria present in raw foods, but may reach high levels if the competing bacterial flora has been removed by heating or its growth is retarded. For example, vacuum packaging may prevent the growth of the main spoilage bacteria of raw meats (i.e., *Pseudomonas* species), but *A. hydrophila* may continue to grow and even dominate the bacterial flora. The use of modified atmospheres containing 100% carbon dioxide will inhibit growth of *A. hydrophila*, but a small decrease in this level may permit growth. (*See* **Chilled Storage**: Use of Modified-atmosphere Packaging; Packaging Under Vacuum.)

A. hydrophila is not an acid-tolerant bacterium and at chill temperatures (less than $5\,^{\circ}C$) it will grow only poorly, if at all, at pH values less than 6.0. Therefore, growth would not be expected in even mildly acidic refrigerated products. At lower pH values, the bacterium will slowly die, although this may require in excess of 20 days. When stored at $30\,^{\circ}C$ the minimum pH value for growth has been variously reported to be between 4.0 and 5.0. As with other bacteria, organic acids (e.g., acetic, lactic, and citric acids) which occur

in foods are more effective at inhibiting growth than are mineral acids (e.g., hydrochloric acid).

The maximum level of salt permitting growth depends on the other conditions, but is 6% (w/v) when other conditions are optimal. With refrigerated samples (less than 5 °C), growth is poor when the salt concentration exceeds 2% (w/v).

Irradiation, at the doses proposed for foods (i.e., 10 kGy), would successfully eliminate *A. hydrophila* from foods. The decimal reduction value is reported as 0.14–0.22 kGy. (*See* **Irradiation of Foods**: Basic Principles.) The organism is sensitive to many of the novel technologies being developed, e.g., high-pressure processing.

Little is known about the effect of freezing on *A. hydrophila*, but this process cannot be relied upon to insure the destruction of the bacterium and it has been isolated from a wide variety of frozen foods.

The presence of *A. hydrophila* in chlorinated water suggests that the bacterium is resistant to this biocide. Chlorination can be a very effective means of controlling *A. hydrophila*, but the levels used must be carefully controlled. Other disinfectants, including those commonly used in the food industry, and ultraviolet treatment of water may also be effectively used to control *A. hydrophila*. Overall, *A. hydrophila* is not a hardy bacterium and is readily controlled by many of the processes used in the food industry. Care is needed to insure that postprocess contamination is minimized.

Detection Methods

A. hydrophila is not difficult to grow and produces good growth on many laboratory media. A wide variety of methods are used for this bacterium. Most of the media used have been developed from those used for the detection of Enterobacteriaceae or *Vibrio* species. It is likely that *A. hydrophila* has been misidentified as an enteric bacterium and so its incidence and clinical significance will have been underestimated.

The bacterium may be isolated using quantitative or qualitative procedures. With quantitative methods, the sample is usually inoculated directly on a solid selective agar medium. With qualitative methods, the sample is usually placed in a liquid-selective enrichment medium (to allow multiplication of *A. hydrophila*) prior to inoculation of the agar medium. Incubation temperatures used for both liquid and solid media range between 25 and 37 °C, although 30 °C is being increasingly accepted.

A variety of agar media have been used for food and water samples. Most of these contain selective agents (usually based on ampicillin, bile salts, or ethanol) and differential agents (e.g., starch, dextrin, xylose, amino acids). With liquid media, alkaline peptone water and ampicillin broths are most widely used. Both liquid and solid media containing ampicillin have been shown to be very useful, although a few strains are sensitive to this antibiotic.

At present, there is no general consensus on the best media for *A. hydrophila* and it is likely that the use of multiple solid and/or liquid media will be required for optimal recovery of this bacterium. The individual motile *Aeromonas* species can be separated using conventional biochemical tests. Additional tests to identify biotypes and serotypes are not widely used for food isolates.

Given the complexity of the taxonomy of the genus and that some isolates, even of *A. hydrophila*, are not pathogenic, a variety of molecular techniques have been proposed for the detection and/or identification of this organism in clinical, veterinary, and food situations. These include polymerase chain reaction (PCR) detection of the enterotoxin and hemolysin genes, restriction fragment length polymorphism (RFLP)-PCR to identify the species, and random-amplified polymorphic DNA (RAPD)-PCR probes for detection and identification.

AFLATOXINS

M O Moss, University of Surrey, Guildford, UK

Background

The aflatoxins are a group of carcinogenic, acutely toxic mold metabolites that may be produced in a range of foods, animal feeds, and the raw materials used in their manufacture. The discovery, physicochemical properties, occurrence, toxicology, control, analysis, and significance will be discussed.

Discovery

A bird food catalog for the year 2000 has a letter to customers advising that adverse climate conditions led to a very poor year for the groundnut crop, resulting in unacceptable levels of aflatoxin contamination, and that there would be limited supplies for bird foods this year. Indeed, this particular supplier withdrew all stocks of peanuts. In 1998, the European Union set a limit of 2 μg kg^{-1} for aflatoxin B_1 in foods for human consumption, a regulation that was included in British legislation in 1999. These two observations make it clear that aflatoxin is an important contaminant, and it is essential to understand its origin, occurrence, and significance.

In 1960, there were reports of large-scale deaths of turkey poults and other poultry in England, which were initially considered to be due to a viral infection and were called turkey X disease. The initial symptoms were a loss of appetite, feeble fluttering, and lethargy, death usually occurring within a week of the appearance of symptoms. Autopsy showed hemorrhages and necroses of the liver. It soon became clear that the birds were poisoned by a contaminant in the pelleted feeds that formed the major part of their food. The toxic component was shown to be associated with groundnut meal contaminated with the green spored mold *Aspergillus flavus*, and it was soon demonstrated that the mold was secreting a toxin that was called aflatoxin to reflect its source. As chromatographic analyses improved, it was shown that aflatoxin is a family of compounds that were labeled according to the color perceived when thin-layer chromatography (TLC) plates were examined under UV light; aflatoxins B_1, B_2 (blue), G_1, and G_2 (green), of which aflatoxin B_1 is the most toxic. Chronic toxicity studies in rats demonstrated that, for this species, aflatoxin was amongst the most carcinogenic compounds known at the time, and the study of aflatoxin became truly international, generating an enormous literature very rapidly.

The chemical structures were illucidated within a few years of the initial outbreak of turkey X disease (Figure 1), and, with an increased understanding of their occurrence and properties, it was appreciated that at least two animal diseases described earlier were due to the presence of aflatoxins. A serious liver disorder of dogs known as canine hepatitis and the presence of liver carcinomas in rainbow trout in fish farms, where protein rich feeds based on slaughter house offal were replaced with plant proteins based on cotton seed meal. Indeed, it is certain that aflatoxins, either alone or in the presence of other mycotoxins, have caused many acute and chronic illnesses in farm animals and several in humans. One of the best documented outbreaks of acute aflatoxicosis in humans occurred in India in 1975. Nearly 1000 people were ill, and almost 100 died following the consumption of contaminated corn.

Physicochemical Properties

The aflatoxins are white crystalline solids that are optically active and have a strong absorbance at about 365 nm with a fluorescence emission of 415–450 nm, depending on the solvent or physical status (Table 1). Fluorescence is especially strong when the aflatoxins are absorbed on silica gel, making this a

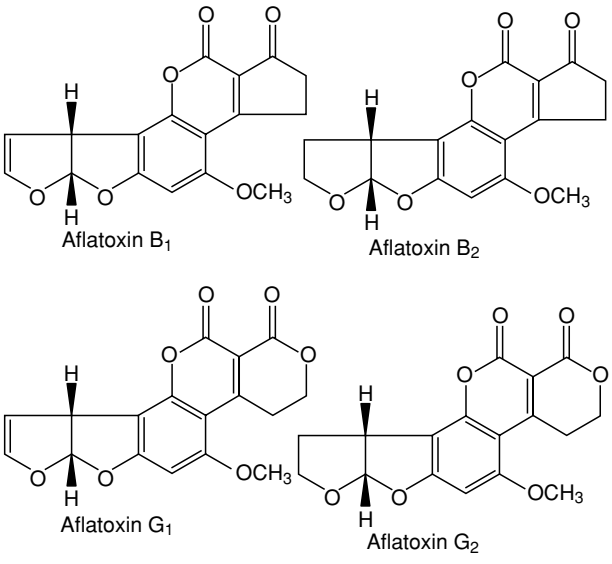

Figure 1 Structures of the four most common naturally occurring aflatoxins.

Table 1 Some physico-chemical properties of the aflatoxins

Aflatoxin	*Formula*	*Molecular weight*	*Melting point (°C)*	*Optical rotation $[\alpha]_D(CHCl_3)$*	*λ_{max} (nm) ε*
B_1	$C_{17}H_{12}O_6$	312.063	268–269	−558°	223 25 600 265 13 400 362 21 800

G_2	$C_{17}H_{14}O_7$	330.0739	230	−454°	217 28 000 245 12 900 265 11 200 365 19 300
M_1	$C_{17}H_{12}O_7$	328.0582	299	−280°	226 23 100 265 11 600 357 19 000

sensitive means of detection on thin-layer chromatograms. The aflatoxins are soluble in a range of organic solvents such as chloroform, ethanol, methanol, and acetone, and insoluble in lipophylic solvents such as hexane, petroleum ether, and diethyl ether.

Occurrence

Because so many compounds have similar chromatographic and fluorescent properties to aflatoxins, there were many early reports of their production by molds from several genera including *Penicillium* and *Rhizopus*. However, the only confirmed sources of aflatoxins are a small group of closely related aspergilli, namely *Aspergillus flavus, A. parasiticus, A. nomius*, and *A. ochraceoroseus*. There are also reports that an isolate of *A. tamarii* produces aflatoxin B_1, although no other isolates of this species have been shown to produce aflatoxins. This isolate has subsequently been referred to a new species, *A. pseudotamarii*. By far the most commonly isolated aflatoxigenic species are *A. flavus*, which produces aflatoxins B_1 and B_2, and *A. parasiticus*, which produces all four aflatoxins shown in Figure 1. On a world-wide basis, perhaps 35% of *A. flavus* isolates are aflatoxigenic, whereas almost all strains of *A. parasiticus* produce aflatoxins.

The most commonly implicated commodities are corn and peanuts, although aflatoxins have been detected in a much wider range of foods. Table 2 provides the results of surveys carried out during the last few years in a number of different countries.

The highest levels of aflatoxin contamination are always associated with postharvest spoilage, when commodities are stored with an inappropriate moisture content and temperature. However, aflatoxin contamination is not simply a problem of poor storage but can occur in the field before the crop is harvested. The spores of these species of *Aspergillus* can land on the stigma of the developing plant, germinate and penetrate to the immature seed tissue just as if they were pollen grains. The mold can establish an endophytic growth within the tissues of the plant without causing any perceptible harm to the plant. Indeed, if the crop continues to develop in a healthy manner and is harvested and correctly stored, there may be no detectable aflatoxins produced, despite the presence of viable mycelium in the plant tissue. However, if the plant is subject to some form of stress, and drought stress is the most common, then low, but significant, levels of aflatoxin

Table 2 Reports of the occurrence of aflatoxins during 1991–1998

Commodity	*Country*	*Year*	*Incidence (%)*	*Range ($\mu g\,kg^{-1}$)*

may be formed in the seed tissue, even though, on harvest, the crop looks sound and is subsequently correctly stored.

The molds producing aflatoxins are tropical and subtropical, and, although their spores occur in temperate parts of the world, these species do not compete in a cool climate. Thus, the production of aflatoxins is not normally a problem in Britain and Scandinavia. However, in both these parts of the world, a special problem emerged when high-moisture barley was prepared as a winter feed by protecting it with propionic acid, or mixtures of acetic and propionic acids. When properly applied, these antifungal agents protect the material from mold spoilage, but if the dosing is not high enough, *Aspergillus flavus* is able to grow and, under these conditions of partial inhibition, actually produces enhanced levels of aflatoxin.

Aflatoxin B_1 is readily metabolized in the animal body and may be secreted in a number of body fluids. Thus, when cows are fed on animal feed contaminated with aflatoxin B_1, a significant proportion is secreted in the milk as aflatoxin M_1 (Figure 2), which is only slightly less toxic than B_1. Aflatoxin M_1 has also been detected in human milk, and because milk is consumed in relatively large quantities by both the very young and elderly, there have been many surveys to provide some guidance about exposure of the human population in different parts of the world. Table 3 gives some results from such surveys.

Table 3 Selection of surveys for aflatoxin M_1 in milk

Type of milk	*Country*	*Date*	*Incidence (%)*	*Concentration range (ng l^{-1})*
All milks	Thailand	1997	93	50– > 500

Swiss mouse (male)	> 5300

Toxicology

The aflatoxins show both acute and chronic toxicity, and one of the outstanding features in the toxicology of the aflatoxins is the wide variation in response amongst different species of animals and even between the male and female of the same species. Table 4 shows the variation in LD_{50}, which is a measure of acute toxicity, and Table 5 shows the variation in TD_{50} as a measure of carcinogenicity. It can be seen that for some animals, such as the rat, aflatoxins are very carcinogenic, and yet in other species, it is difficult to demonstrate carcinogenicity. This considerable variation in biological response arises from the requirement that the mold metabolite itself has to be metabolized in order that a toxic response occurs, and the metabolites responsible for acute toxicity differ from those reponsible for carcinogenicity. There are several metabolic reactions (Figure 3), such as the demethylation to aflatoxin P_1 and hydration to aflatoxin B_{2a}, which may lead to a decrease in toxicity. A critical reaction associated with the toxic response is

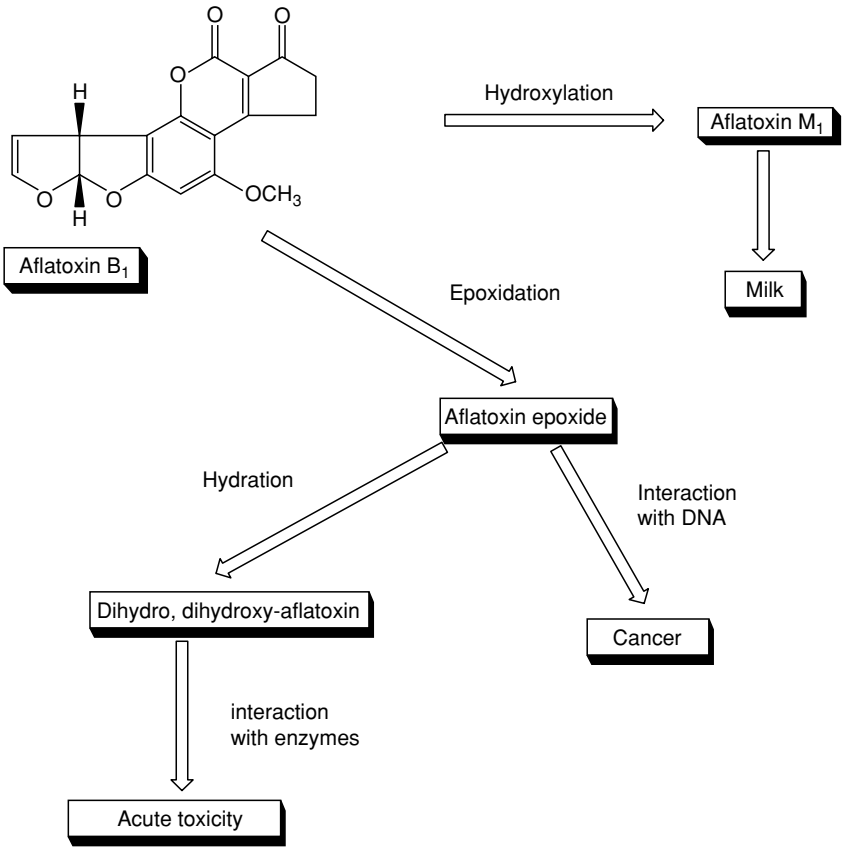

Figure 3 Some metabolic products from aflatoxin B_1.

the formation of the 8,9-epoxide, which may react with guanine residues in DNA, one of these being the third base in codon 249 of the p53 gene, the product of which is an important component in the tumor suppressor system. The epoxide itself can be further metabolized to the 8,9-dihydrodihydroxy derivative of aflatoxin, which can react with the lysine residues in protein molecules and is a good candidate for the acute toxin. An animal that readily forms the epoxide but does not efficiently metabolize this further may be especially sensitive to the carcinogenic activity of aflatoxin. However, an animal that forms the epoxide but effectively metabolizes this further to the dihydroxy derivative may be especially sensitive to the acute toxicity of aflatoxin. The structure of aflatoxin B_1 (which may not itself be toxic) may facilitate its ready transport into the liver cell, where it is metabolized to these far more hazardous molecules.

Where do humans fit into this picture? By extrapolation from both molecular biological studies, and the epidemiology of cases of acute aflatoxin poisoning reported, it would seem that humans are not as sensitive as birds, dogs, or cats but more sensitive than the rat to the acute toxicity of aflatoxin B_1. Similarly, an analysis of exposure versus liver cancer incidence again puts humans in the middle of the range of sensitivity to the carcinogenic activity of aflatoxin B_1. In the early days of the assessment of the role of aflatoxin in the epidemiology of liver cancer in humans, the issue was clouded by the undoubted role of other agents, such as infection with hepatitis B virus, in the initiation of liver cancer. It is probable that these two agents act synergistically, and it is possible to construct a risk assessment model to include both. Such a risk assessment has led to the suggestion that an estimated intake level of between 200 and 400 ng per day would correspond to a lifetime liver cancer excess risk of 1×10^{-5} in the USA. It is clear that it is prudent to assume that aflatoxins are carcinogenic to humans and that efforts should be made to control its occurrence in the food chain.

Control

The highest concentrations of aflatoxins are formed as a result of inappropriate storage conditions post-harvest, and if commodities can be rapidly dried and

stored so that the water activity does not exceed 0.78, growth of aflatoxigenic molds will be inhibited. Aflatoxin biosynthesis itself is inhibited at water activities below 0.83. There is a strong interaction between water activity and temperature in the production of aflatoxins, and if the temperature of storage can be maintained below 15 °C, the minimum water activity for toxin production may be as high as 0.9. Any kind of damage to the commodity can enhance aflatoxin formation.

Lower but significant levels of aflatoxin can be formed before harvest if the crop is subjected to drought stress, and the soil temperature (in the case of peanuts) is between 25 and 32 °C during the 6 or 7 weeks before harvest. Table 6 shows examples of preharvest contamination of corn in North Carolina during the period 1976–1980. It can be seen that during 1980, approximately 65% of the crop was contaminated by at least 20 μg per kilogram of aflatoxins and so could not be used for human consumption leading to an estimated loss of $31 million to the producers. The real cost was even higher if the problems for the animal farming industry were also taken into account.

Because it seemed almost inevitable that contamination will occur in some years, there is interest in the possibility of some form of biological control of preharvest contamination by inoculating the soil with nonaflatoxigenic strains of *Aspergillus flavus*. Greenhouse and field experiments do indicate that such nontoxigenic strains can outcompete or displace resident toxigenic strains leading to reduced preharvest aflatoxin contamination. Alternatively, strains of commodities such as corn and peanuts can be bred, in which aflatoxin biosynthesis is inhibited, even if these aflatoxin producing molds have established an endophytic relationship with the plant.

A number of physical and chemical methods have been tested for the removal of aflatoxins from contaminated materials. Although pure aflatoxins are relatively unstable in the presence of water, these compounds are remarkably stable at elevated temperatures when they are present in the complex matrix of a food. Cooking is thus not effective in removing aflatoxins. In particulate commodities such as peanuts, a significant reduction in contamination levels can be achieved by the identification and removal of damaged kernals. Because contaminated kernals are often (but not always) damaged or discolored, they may be removed by sieving, flotation, and density segregation, or by electronic sorting using a laser beam to identify the discolored kernals. Of several chemical methods tested, the only one that has shown any promise is the use of aqueous or gaseous ammonia at moderate temperatures and elevated pressures. This treatment leads to the production of several products, two of which have been characterized (Figure 4) and shown to be considerably less toxic than aflatoxin B_1.

Many countries have established legislation setting maximum permissible levels of aflatoxins in food and animal feeds, and a selection of these are shown in Table 7. In some countries, there is zero tolerance, which will be based on the sensitivity of analytical

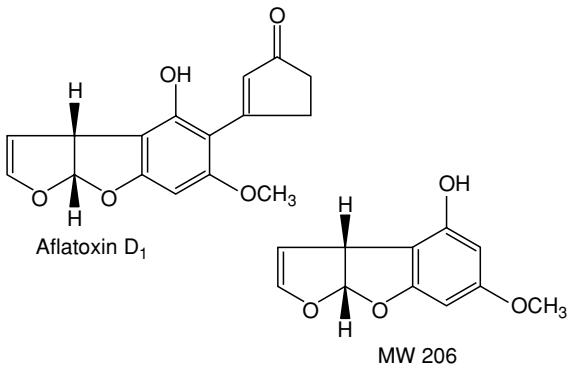

Figure 4 Breakdown products from ammonia treatment of aflatoxin B_1.

Table 6 Preharvest contamination in corn by aflatoxin in North Carolina

Crop year	*Aflatoxin concentration (μg kg^{-1})*		
	0–19	*20–100*	*> 100*
1976	64.2	27.7	8.0
1977	58.1	30.2	11.6
1978	87.0	12.0	1.0

USA	20	All foods

methods. When the FAO/WHO realized that a valuable plant protein such as groundnut meal, used in the formulation of foods for their food aid programme, could be contaminated with a potential carcinogen soon after the discovery of aflatoxin, they set a maximum concentration of 30 μg kg^{-1}. It was recognized that, in the absence of detailed knowledge of the risk, this was a compromise that recognized that a more stringent level could result in there being no material available for a food aid program. India still accepts this level. The European Union adopted a maximum acceptable level of 2 μg of aflatoxin B_1 per kilogram for groundnuts, nuts, dried fruit, cereals, and their products, and 0.05 μg of aflatoxin M_1 per liter in milk in 1998.

Analysis

The setting of stringent maximum tolerated levels implies the ability to obtain analytical results that are sensitive, specific, quantitative, and reproducible. In the early days of concern over the presence of aflatoxin in foods and animal feeds, there was not sufficient confidence in the chemical analysis of aflatoxins, and biological tests, such as the 1-day-old duckling test and the chicken embryo test, were used because they provided direct evidence of the toxicity of samples. With increasing confidence in the use of confirmatory tests in combination with TLC and high-pressure liquid chromatography (HPLC), these became increasingly acceptable. Most recently, highly specific monoclonal antibodies have become commercially available for the aflatoxins and several other groups of mycotoxins. These can be used in two ways, either directly as enzyme-linked immunosorbent assays (ELISA) or bound to a solid substrate as immunoaffinity columns. ELISA is not generally sufficiently quantitative at very low concentrations but can be very effectively used as a rapid screen for positive samples, which can then be analyzed by physicochemical methods. Immunoaffinity columns provide an excellent way of obtaining a very clean concentrated extract from a sample, which can then be quantified by HPLC.

In many parts of the world, TLC has to be the method of choice because of cost constraints. Using silica-gel plates, the four common aflatoxins can be separated and are sensitively detected because of their intense fluorescence under long-wave ultraviolet. Because so many compounds run with similar R_f values (position on the chromotogram relative to the solvent front both measured from the point of application of the sample) and fluoresce like aflatoxins, it is essential that positive samples are confirmed using a confirmatory test such as derivatization with an acid treatment. Aflatoxins B_1 and G_1 do not fluoresce so intensely in solution, thus reducing the sensitivity of the fluorescence detector in HPLC. However, postcolumn reaction with either bromine or iodine enhances fluorescence considerably and provides a confirmatory test as well.

There have been several collaborative studies in Europe under the Measurements and Testing Programme to validate methods to meet the stringent analytical requirements of European regulations. Such a collaborative study has, for example, evaluated the efficiency of using immunoaffinity columns for the clean-up of samples obtained from a wide range of food matrices for subsequent determination of aflatoxin B_1 and total aflatoxins by liquid chromatography. The European Union legislation for aflatoxin M_1 is especially stringent (0.05 μg l^{-1}), requiring both the validation of methods and the proficiency testing of a network of European Union National Reference laboratories set up to determine aflatoxin M_1 in milk.

Analysis contains three stages, sampling, extraction, and quantitation, and a competent analyst can now achieve the required degree of sensitivity, precision, and specificity required. The analyst needs only 50–100 g of material, and the real problems arise from a consideration of how that sample was obtained from, for example, a shipment of many tonnes of commodity. Except in liquid foods, such as milk, aflatoxins are not uniformly distributed in a commodity, and this was beautifully demonstrated when the UK Ministry of Agriculture, Fisheries and Food (MAFF) purchased a consignment of whole dried figs that had been rejected at the port of entry. The consignment, of just over 10 tonnes made up of 850 boxes each containing 12 kg, had been rejected because an analysis based on a 20-kg sample had indicated a contamination level of 33 μg kg^{-1}. Clearly, with a statutory limit of 4 μg kg^{-1} at that time, the UK had to reject the consignment.

Having purchased the consignment, MAFF analyzed 200 boxes as though each were a single sample. This gave a mean of 15.4 μg kg^{-1}, which still implies rejection but clearly shows that the answer depends on the method of sampling. A study of the distribution amongst these 200 boxes showed that more than 70 had less than 4 μg kg^{-1} and could have been accepted if only they could have been identified! A further 50 boxes had between 4 and 10 μg kg^{-1} and could have been accepted subject to further processing. Thus, about 67% of these 200 boxes were actually acceptable, but a few had contamination levels of > 200 μg kg^{-1}. Indeed, in a further study, individual boxes were divided into 12 × 1-kg samples and each

analyzed separately. In one of these boxes, 11 of the samples had $< 10\,\mu g\,kg^{-1}$, but a single sample had $2063\,\mu g\,kg^{-1}$! There is nothing unexpected in these results, and there are studies on other commodities such as peanuts and pistachio nuts that also demonstrate such a skewed distribution, but they provide quantitative information on which to design a sampling plan. Such a sampling plan has to be acceptable to both the producer and the consumer.

An example of a sampling plan agreed by the European Union for the analysis of figs and other dried fruit is outlined below:

1. Subdivide each lot into units of 25 tonnes (15–30 tonnes).
2. Each unit is sampled separately.
3. The number of incremental samples should be at least 100.
4. Each incremental sample should be about 300 g.
5. The aggregated sample is 30 kg.
6. The aggregated sample is divided into samples of 10 kg, each of which is homogenized and analyzed separately.

Significance

The presence of aflatoxins in foods and animal feeds is quite widespread, and it is possible that, with present agricultural practice, it may not be possible to prevent contamination in some parts of the world. The aflatoxins are acute toxins, and they have undoubtedly caused the death of farm animals and humans on several occasions. They also have chronic toxicity being immunosuppressive and carcinogenic. For these reasons, many countries have set legislative maximum levels in human foods. Some countries also set maximum acceptable levels in animal feeds in order to prevent the contamination of milk by aflatoxin M passing through the food chain. There is as yet no international agreement on these levels, and those countries that are importers of commodities that are susceptible to contamination tend to be more stringent than those that are producers and exporters. There is the potential for difficulties in international trade while this situation remains.

AGGLOMERATION

L Coucoulas, Leatherhead Food Research Association, Leatherhead, Surrey, UK

Definitions, History, and Scope

Agglomeration is a powder-size enlargement process, where small particles combine to form large, relatively permanent masses in which the original particles are still identifiable. These agglomerates have a coarse, open structure and a mean particle size ranging from 0.1 mm to a few millimeters. The process uses mechanical agitation in the presence of the required proportion of a liquid phase and perhaps other binding agents and is normally followed by evaporative drying. Agglomeration is sometimes confused with granulation. The latter is, in fact, a term describing all size enlargement processes: compaction, extrusion, prilling, nodulization, sintering, and agglomeration.

Agglomeration as a size enlargement process is not confined in its application to the food industry. The mineral-processing, chemical, surfactant, and pharmaceutical industries use several methods of granulation, including agglomeration, to solve their powder-handling problems. The advantages of agglomeration when compared with other granulation techniques such as compaction are lighter granules with large open pores and superior reconstitution properties.

Agglomeration started to be applied to food powders in the 1960s in the USA. Several processes were developed for dairy products, sugars, flour and cake mixes, chocolate drinks, instant coffee and tea, and other special drinks. Some of these processes are still used today although the majority have been superseded by continuous straight-through fluid bed processes, which are more economical and have less down time or product outside specification.

Agglomeration is employed to improve the handling properties of fine food powder materials when these are used either as intermediate raw materials or as final consumer goods. There are two distinct areas where agglomeration has a beneficial effect for both the consumer and the industrial user: dry handling and reconstitution of fine powders.

Dry Handling

Fine powders are used extensively in the food industry. They are produced from a variety of drying and crystallization processes such as oven drying, spray drying, vacuum or freeze drying, drum drying, etc., which may, when appropriate, be followed by a crushing and milling process. Fine powders invariably exhibit cohesive flow properties, which result in poor or no flowability in silos and hoppers, excessive dust formation, segregation, and loss of control of bulk density. Agglomeration eliminates these problems. (*See* **Drying**: Theory of Air-drying; Spray Drying.)

Agglomerated products exhibit:

1. improved flowability resulting from their having larger particles and a more uniform particle size distribution; for the consumer this means instantly and completely emptying packets with no material clinging to corners;
2. elimination of dust formation, owing to a substantial decrease in the proportion of fines;
3. uniform bulk density, which is usually a function of particle size and porosity, and less segregation in retail packages.

Reconstitution

The reconstitution of fine powders presents problems for the industrial user and the consumer. In industrial use long mixing times must be used with intensive mixing equipment interspersed with screening operations and settling tanks. For the consumer who is only equipped with a spoon and a cup, reconstitution of a soup mix or a chocolate drink needs to be convenient and quick, even in cold water and without the formation of partly hydrated lumps on the surface of the cup that may be mistaken for substandard product. Agglomerated powders are attractive because they have:

1. greatly improved dispersion and rehydration characteristics because of their open porous structure, which allows water to penetrate and disperse the granule with minimum stirring;
2. improved sensory properties, i.e., intense color and an attractive appearance.

Instant Powders

An agglomerated powder with greatly improved dry handling and reconstitution properties is termed an 'instant' powder. The properties and standards for testing the quality of an instant powder differ according to the type of powder. Apart from microbiological requirements that have always had to be fulfilled, the properties for testing the quality of an instant powder can be divided into three groups:

1. appearance, structure, size, and handling properties of the powder;
2. easiness and completeness of reconstitution;
3. appearance and lack of defaults of the reconstituted solution.

Fat-containing powders such as whole milk, spray-dried fats, some chocolate drinks and soup or gravy mixes are difficult to reconstitute in cold water even if they are agglomerated. Such powders are usually covered by a thin layer of surface fat that makes them water-repellent. Coating these powders with small amounts of wetting agents such as lecithin dispersed in fat makes them wettable and cold-water-soluble. This operation has in some instances been termed 'instantization.' In fact, instantization is the production of an instant powder that fulfills certain predetermined standards and may be achieved either by agglomeration or some other form of granulation, lecithination, or both.

The Agglomeration Process: Molecular Bonding and Growth

Knowledge of the types of bonds generated between agglomerating particles and the mechanisms of granule growth is of paramount importance in understanding the agglomeration process. Primarily, the bonds formed between solid particles are due to electrostatic and intermolecular attraction forces. In the presence of a liquid, though, the distance between centers of attraction is reduced and stronger bonds are formed. Their manifestation is termed 'liquid bridges.'

Liquid Bridges

As the name indicates, these are bonds formed between the liquid and the particles. They are strongly dependent on the wetting angle, the adsorption characteristics of the powder, and the amount and viscosity of the binding liquid. When the particles are held together by a low-viscosity liquid, owing to surface tension forces and depending on the liquid saturation, four different states are possible:

1. Pendular state – the liquid is held in discrete lens-like rings at the point of contact between the particles. The air forms a continuous phase throughout the agglomerate.
2. Funicular state – at higher liquid saturations the liquid rings coalesce to give a continuous liquid phase throughout the agglomerate, in which discrete pockets of air are entrapped.
3. Capillary state – the pore space is completely saturated with liquid but the liquid does not cover the external agglomerate surfaces. A negative capillary pressure is built up within the agglomerate, which gives it a degree of tensile strength.
4. In addition to the above, if the liquid covers the external surfaces of the agglomerate, the particles become completely encapsulated within the liquid.

Use of liquids with a high viscosity usually results in agglomerates of higher strength than is achieved using low-viscosity liquids, depending on the fluid cohesion strength and the fluid–solid adhesion force.

Solid Bridges

Liquid bridges hold the particles together during granule growth. Upon drying, these usually result in solid bridges through phase transformation, i.e., recrystallization of the dissolved material, hardening of binder liquid or chemical reaction. In this way the agglomerate comprises particles connected by solid bridges, in which capillary pores are present. The tensile strength of solid bridges is of the same order of magnitude as that of the constituent particles.

Mechanisms of Growth

The overall mechanisms of granule growth determine not only the rate of agglomeration but also the final properties of the agglomerate. Although these mechanisms are very strong functions of the process equipment used, the following steps are generally accepted:

1. nucleation of primary particles by random coalescence;
2. transition stage growth;
3. final 'ball' growth.

In the initial nucleation period, the feed particles grow by rapid random coalescence. During the transition period, particles grow by preferred coalescence between large and small granules (in the case of wide particle size distributions) or by crushing and layering (in the case of a narrow particle size distribution). The growth rate passes through a maximum, which can be perceived as the rate at which the diameter of the granule increases to a size such that any further increase is accompanied by a corresponding increase in attrition crushing.

The principal variable used to control agglomeration is the liquid saturation necessary to achieve the surface tackiness, which leads to a greater propensity of particle coalescence. Research has shown that in many cases this critical moisture content is around 70–90% of that needed to saturate the voidage in the powder being agglomerated.

The choice of equipment and process parameters, such as fluidization velocity and speed of rotation, determine to a large extent the growth

mechanism, which for the same moisture content can be based on coalescence or crushing and layering, or a combination of both. This explains the different densities of agglomerated products obtained from the same material and the same volume ratio of liquid to solids but made on different equipment or of products manufactured on the same equipment but at different agitation motions.

Characteristics of Agglomerated Powders in Contrast with the Starting Materials

It is the physical properties of fine powders that are the source of problems in powder handling. Agglomeration is essential in order to modify these and improve the usefulness of fine powders. There follows a brief description of these properties and how they are modified by agglomeration.

Shape

The shape and surface roughness of particles dictate the number of contact points between adjacent particles and the minimum proximity. The shape has a pronounced effect on the flowability; for example, particles that have a fibrous, highly asymmetric shape can interlock and inhibit free flow. Agglomeration changes the shapes of the particles dramatically and, in general, creates more symmetrical particles with fewer 'cooking points' and therefore improved flowability.

Particle Size

Particle size is a contentious property, because most particulate matter has an irregular shape and its size differs according to the method used to measure it. It is usually defined as the 'dimension of an imaginary spherical particle having the same value in the physical property measured as the irregularly shaped particle.' Not all of the particles of a powder are the same size, and a particle size distribution is usually employed to characterize a powder. The particle size distribution correlates well with many other material properties and bulk characteristics.

Figure 1(a) and (b) shows two particle size distributions. The first is typical of a powder resulting from a milling process. It contains a large proportion of very fine material, causing dust formation in dry handling and wet lump formation during reconstitution. Furthermore, the vast range of particle sizes will lead to acute flowability problems, time consolidation behavior, variable density due to nonuniformity of packing and, finally, segregation or compaction during transportation. Thus, the effects of a wide particle size distribution are spread across the whole range of uses of powdered material. Agglomeration changes the particle size distribution in two ways (Figure 1b). First, it shifts the mean to a larger particle size, thus eliminating all problems arising from the presence of a very fine material. Second, it gives a product with more uniform size, thus narrowing the width of the particle size distribution curve, which eliminates all the other problems outlined above.

Density, Porosity, Surface Area, Pore Size Distribution

In the case of particulate matter, there are four types of density used – true, particle, pouring, and tap density. True density is the density of the material when it does not include any interstitial pores; particle density is the density of the material when it is in

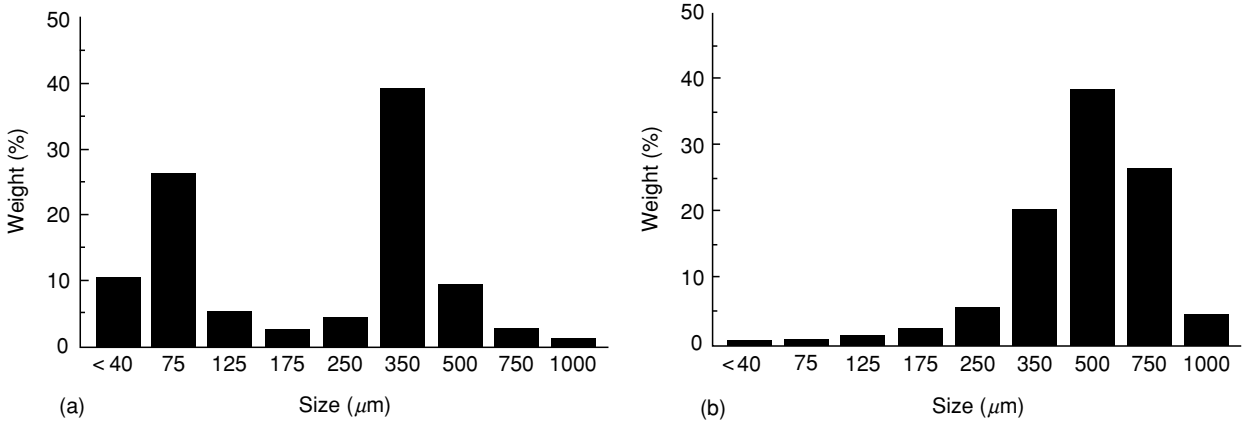

Figure 1 Particle size distributions of (a) a fine powder showing a bimodal particle size range and (b) an agglomerate with a narrow range of particle sizes. Reproduced from Agglomeration, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

particle form and includes interstitial pores; pouring density is the bulk density of the powder when it is poured into a container; and tapped density is the density measured after the container has been shaken and the powder has consolidated. Both of the latter include interparticle porosity. The difference between the poured and tapped densities determines the degree of consolidation and how much empty space will be left on top of a jar filled with product at the factory after it has been shaken through transportation. Density is also important during reconstitution. After wetting, the density of particles determines how fast they sink and whether they have time to dissolve or be stabilized in suspension.

The knowledge of surface area and pore size distribution provides insight into the structure and adsorption potential of particulate matter. This is often calculated from the particle size distribution and by use of the mercury porosimetry method.

In general, agglomerated granules are of larger size with a lower particle or bulk density. Such granules sink slowly into water and therefore can disperse and enter solution before reaching the bottom of the container. Agglomeration also increases the porosity and, particularly, the formation of large numbers of interconnecting micropores, which have potentially large capillary pressures during wetting, i.e., liquid is sucked into them by capillary action. It has been shown that the total wetting time is a decreasing function of porosity. Also, the presence of micropores is instrumental in the spontaneous deagglomeration process, which is essential for instant powders.

It is of interest to contrast the reconstitution of agglomerates with that of aggregates of fine powders. Agglomeration produces an increase in the amount of air between particles. During reconstitution air is replaced by water. In fine powders the surface area is large and the interstitial space small and usually not interconnected. As a result, water penetrates slowly and, after a short time, the space between particles is filled with high-concentration dissolution products, resulting in a sticky jelly with islands of unwetted powder and residual air. Furthermore, lumps form, which are wet and swollen outside, while dry inside. These hamper further reconstitution (even under strong agitation) because their structure is impervious to water. In an agglomerate the large amount of interstitial air results in the particles being dispersed in the liquid before the highly viscous solution is formed.

Cohesiveness

To insure easy and successful handling during processing, powders must be sufficiently 'flowable.' The factors that influence flowability include surface properties, shape and size distribution, and the geometry of the processing equipment. The forces that are involved are gravitational, cohesive (between particles), and adhesive (between particles and walls).

Agglomeration produces granules that show a marked improvement in the flowability properties, which is qualified by a significant decrease in their angle of repose. This occurs because, in general, there is an increase of the mean particle size coupled with a narrowing of the width of the particle size distribution curve.

Hygroscopicity

Hygroscopicity is the quantity that expresses the propensity of the material to pick up moisture, which occurs when the equilibrium relative humidity of the product is below atmospheric humidity. Therefore, when nonagglomerated hygroscopic powders are used in containers open to the atmosphere, the powders tend to pick up moisture and form lumps that are hard on the outside and enclose dry material. These problems of caking and lumping are often encountered in the discharge of powders both in hoppers and in vending machines, particularly since in the latter the atmospheric humidity is high. Anticaking agents are often included in hygroscopic powders and their function is to act as moisture scavengers and thus prevent moisture pick-up by the powder. The equilibrium relative humidity is a function of product moisture; thus, if water is used as an agglomerating medium it will at the same time increase product moisture content and product equilibrium relative humidity, decreasing the likelihood of moisture pick-up and caking.

Wettability

The wettability of a material is a property of the chemical composition of the surface of the material. Changes in the surface structure of a powder can be affected by the adsorption of a surfactant. The term 'instantizing' is often loosely used to describe a process whereby agglomeration is followed by coating with a surfactant, resulting in granules that are easily wettable. Fat-containing powders such as ordinary spray-dried whole-milk powder, chocolate drink powder, or dried soup mix have poor wettability and the object of the instantizing process is to improve it. In the case of powder products, however, the effective contact angle of the material in powder form controls the wetting process. The effective contact angle is a function of particle size, porosity, and moisture content as well as material wettability. The behavior of complex powders cannot therefore be predicted by simple static contact angle measurements. By measuring the height of wetted beds of

powders against time, however, it has been shown that agglomeration decreases the effective contact angle and the time required for bulk wetting provided that the agglomerate size lies within certain limits (0.4–1 mm for some powders).

Sensory Qualities

A final consequence of agglomeration is the change of the color and appearance of the product. These are important qualities from the consumer's point of view and their change might improve or diminish consumer appeal. For example, the color of an agglomerated product may be denser and richer than that of the original fine powder. Alternatively, a composite powder may be agglomerated to give a product of improved speckled appearance, which will also have minimum separation problems and enhanced reconstitution characteristics influenced by the most soluble of its individual components. (*See* **Sensory Evaluation**: Sensory Characteristics of Human Foods.)

Equipment and Processes used for Agglomeration

There are two main types of process used to agglomerate powders – the rewet process and the straight-through process.

The principle of the rewet process is the addition of water, or water containing a binding agent, to a dry powder, and then mixing of the particles in such a way as to cause interparticle collisions to occur and agglomerates to form. The particles of the powder can occur either by addition of the liquid as a spray (droplet agglomeration) or by condensation of water from steam or humid air on to the surface of the powder (surface agglomeration). The liquid may act on the powder material in several different ways:

1. It may dissolve part of it or transform it in such a way as to make the surface of the particles sticky or tacky and therefore make them adhere to each other in clusters.
2. If the fluid contains a binder in solution or in suspension, this binder may be responsible for the bonding function between the particles either on contact with the particles or as the agglomerate is redried and the binder crystallizes or precipitates. This process is commonly used to agglomerate inert materials.
3. It may be a material with a relatively high melting point, used as (1) or (2) above, but which on cooling solidifies to form the interparticle bond.

The straight-through process uses liquid feed as the raw material. In the first stage, this is dried into a powder, usually by spray drying, allowing a moisture content a few percent higher than that anticipated for the finished product. The particles thus formed show an increased tendency to adhere to each other. In the next stages of the straight-through process, the particles are agitated in ways similar to the rewet process.

In the next sections some of the types of plant used in the rewet or straight-through process will be described according to the mechanism used to promote interparticle collisions.

Agitation Tumbling Equipment (*See* Agitation)

This category includes plant that provides agitation by the rotation of a container around its central axis. It can comprise either batch or continuous units and these are mainly variations on the inclined dish agglomerator or the rolling drum.

The essential element of the inclined dish agglomerator is a dish, which is rotated on an inclined axis. The feed or recycled particles enter the dish and are sprayed with water whilst undergoing rolling motion. The relative positions of the input of feed material and sprays influence the size and structure of the agglomerates formed. Other features include a side or bottom scraper. An important aspect of the dish agglomerator is the pronounced size segregation that occurs as a result of the centrifugal forces (**Figure 2**). During continuous operation this allows the largest particles to be discharged first while the smaller particles have more time to grow. Therefore, a product of narrow particle size distribution is obtained and subsequent screening is unnecessary. Drying the product evaporates the moisture, leaving a granular product.

The rolling drum comprises a cylinder rotating around its longitudinal axis, which is slightly inclined to the horizontal so as to assist the continuous circulation of materials through the drum. It normally incorporates dam rings at either end in order to prevent spillback and increase the bed depth in the drum. The geometry of the drum makes it more suitable than the dish for handling dusty materials with minimum loss of fines, although most industrial dishes are covered to prevent fines from escaping in the atmosphere. The solids are wetted near the inlet end of the drum and the wet powder cascades on to the tumbling bed. Build-up of moist material is prevented by incorporating a stationary scraping bar, knockers that rap the walls, and reciprocating scrapers, and by roughening the inner surface of the drum.

An important design parameter affecting the performance of the drum is the critical rotational speed at which the material is carried completely around by centrifugal action. At low speeds the material forms a

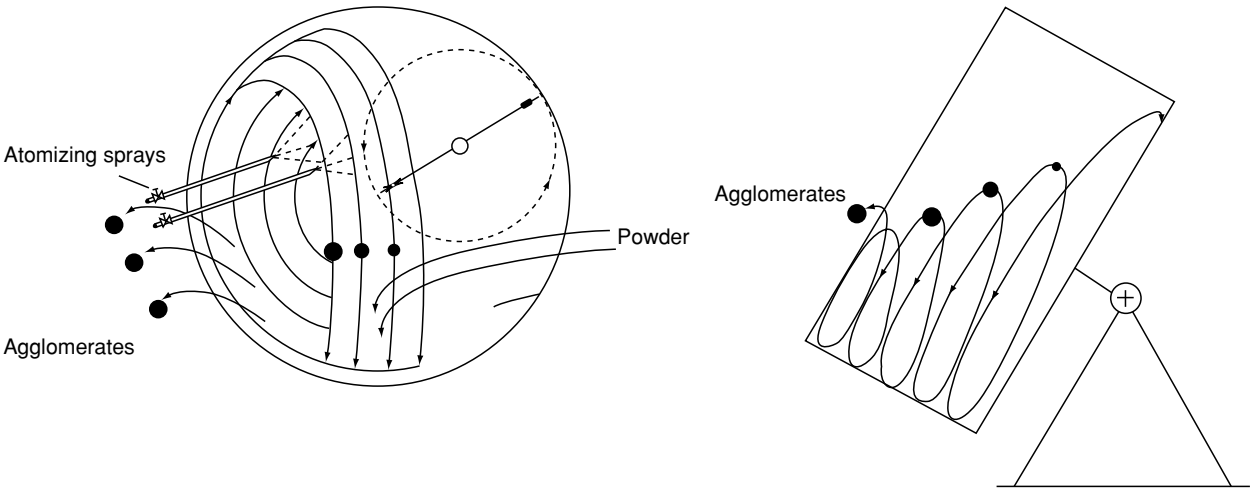

Figure 2 Particle size segregation in the dish agglomerator. Reproduced from Agglomeration, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

static bed and slides along the bottom with very little relative motion between the particles. Cascading takes place at around half the critical speed.

With all agitation and tumbling equipment the growth rate and final size depend on the residence time, binder saturation, and bulk loading. The speed of rotation, the angle of inclination, and the residence time can be varied to affect the density and strength of the granules produced. Sometimes mixers are incorporated inside the dishes to promote further particle collisions and break clusters in the case of very sticky materials. Agitation tumbling equipment has been used extensively in the chemical and mineral-processing industries but its use in the food sector is not so widespread. Maintaining a clean, contamination-free environment can be a problem as most available units are open to the atmosphere. Drying of the granules can be done using rotary drum driers or fluid beds. The large throughput and low cost of these units should make their application financially attractive in the future for food applications provided that the contamination problems are solved.

Mixers/Agglomerators

In this type of equipment water is sprayed on to a powder while the latter is in a turbulent state or in the form of a falling curtain. Shear processing leading to the formation of granules can be carried out in batch equipment including planetary mixers, ribbon blenders, Z-blade units, and high-speed intensive mixers. They rely on time and energy to effect the necessary contact between powder and liquid phases. All have their advantages for specific applications, although final granule properties may be adversely affected by excessive compression during prolonged mixing and the batch-mixed material requires sieving before drying in order to remove lumps.

In the NICA SYSTEM^{TM} turbine mixer/granulator, the powder phase, accurately metered, enters the inner section of a turbine, which deagglomerates the material and throws it outwards as primary particles. A gear pump feeds liquid binder to the underside of the inner turbine, at the periphery of which it is atomized into a mist. Mixing under high shear conditions takes place in the outer turbine; the degree of work and properties of the granule are controlled by varying the area of the exit port. Contact time is thus reduced to a fraction of a second. The resulting agglomerate is fed directly into a close-coupled fluidized bed and drying commences immediately. In this way, time-dependent problems such as solubility of the binder or lumping are eliminated.

The Schugi mixer/agglomerator (Figure 3) is a continuous device for blending small amounts of liquid with solids so that the product remains free-flowing. The mixing chamber consists of a 10-cm diameter hollow vertical cylindrical tube with a shaft running through its center. To the shaft are attached three sets of six knife-edged blades, the relative positions of which can be varied throughout the whole length of the mixing chamber. The shaft belt is driven at 3000 rpm. Liquids are introduced into the mixer through the jets, which are positioned above the top set of blades. The Schugi mixer is mounted vertically and solids are fed into the top. On entering, the solids are caught into contraflow turbulence created by the high peripheral velocity of the mixer blades. Liquids are pumped into the mixer under pressure and enter the mixing area as continuous threads of liquid. In the mixer the liquids are atomized by the combined

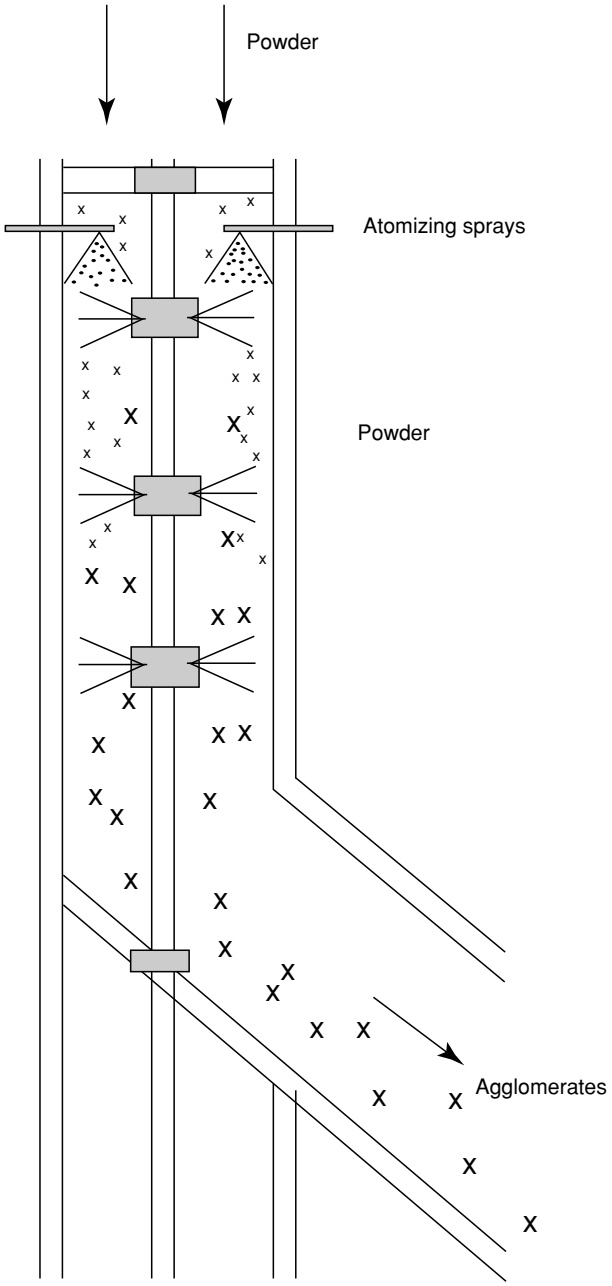

Figure 3 The Schugi mixer. Reproduced from Agglomeration, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

action of the top set of blades, which act in a similar fashion to a disk atomizer, and also by the solids themselves, which because of their high speed have a high energy potential. The atomized liquid is dispersed through the powder and the two adhere together to form agglomerates, which leave by spiralling around the walls of the mixer. The residence time is very short, of the order of 0.5 s, and that limits the temperature increase of the product to 2 °C.

The structure of the product formed depends both on the relative sizes of the liquid droplets and the powder particles and on the feed ratio of the two. Apart from the physical properties of the materials being mixed, the equipment control variables include the rotational speed, the position of the blades, the direction of rotation, and the size of the liquid injection jets. The agglomerated product is dried in a fluid bed.

A third type of mixer agglomerator is referred to as the 'agglomerating tube.' In this device agitation is insured by dropping the powder into a high-velocity stream of humidified air along the length of a tube. The resulting powder clusters are separated in a cyclone and then picked up by a hot air stream and blown through a second tube for drying. A considerable amount of impact between particles takes place inside the agglomerating tube, which makes it suitable for 'difficult' powders that tend to form sticky deposits easily.

In another process the powder is passed through a series of vibrating hoppers or conveyor belts and falls in the form of a thin continuous curtain inside the agglomerating vessel. Steam or atomized water is then injected on to the curtain, which has the force to redirect the traveling plane of the particles. The induced turbulence makes the particles collide and, because they are wet, adhere to each other. The powder clusters formed are carried on to a drying section.

It is evident that some of these units like the 'falling curtain agglomerator' are 'inhouse' types of equipment developed and modified to suit the particular needs of specific products. Recently, they have been superseded by the fluidized bed agglomerators, which together with the straight-through process are the 'state of the art' agglomerators in use today. It is, however, worth considering the use of mixing as the first stage in an agglomerating process, especially in cases where the nonwetting character of the powder requires high shear to effect the initial moistening of the material surface.

Fluid Bed Agglomerators – The Straight-through Process

Fluid bed operations are characterized by:

1. good random mixing;
2. stable, uniform temperature profile leading to effective interphase contact and controlled high rates of heat and mass transfer;
3. high thermal efficiency, which allows use of low exhaust air temperatures and therefore avoids degradation of thermally sensitive food powder components.

These exceptional properties of fluidized beds are the cause of their almost universal use in agglomeration processes – batch, continuous, spouted beds, vibrofluidizers – or in straight-through combinations.

The continuous rewet agglomerator usually consists of three sections that may or may not be separated by weirs. Powder is fed from the feed hopper into the first section of the fluid bed. Here it is rewetted by means of steam, atomized water, or binder solution delivered from jets positioned on top of the fluid-bed layer. The powder particles increase in size either by surface layering or random coalescence. Surface layering is more likely to happen with low-viscosity wetting agents which allow the moisture to distribute evenly around the particles. 'Blackberry'-type agglomerates form when particle surfaces are made just wet enough for collision of particles to lead to capture. Typical moisture contents of the rewetted powder in the first section are 6–10%. Too high wetting will result in deposits in the bed and a blocked distributor plate. Too low wetting will reduce the level of agglomeration and produce less stable agglomerates. Vibration is used to reduce channeling and break powder clusters. The agglomerated material passes into the second section, where it is dried in a hot air stream. After drying it moves to the third section for cooling. Feed particle sizes range between 30 and 300 μm. Agglomerates of 0.5–1.5 mm in size are typically produced.

Straight-through combination systems consist of a spray drier in which liquid feed material is dried to produce a powder at a moisture content slightly higher than would be expected for a final stable product (6–9%). The partially dried powder is then fed to a number of static and/or vibrating fluid beds, where final drying and cooling take place. Fine unagglomerated material is removed pneumatically and taken back to the atomization zone in the spray drier, where it is mixed with the atomized droplets. Agglomeration occurs through contact of fine powder and liquid feed in the atomization zone as well as through interparticle collisions of the damp particles in the fluid beds. The remainder of the operation consists of final drying to 2–5% moisture and cooling and is similar to that in rewet fluid-bed agglomeration. If a lecithination (instantization) stage is required to be included to improve the instant properties of the powder, this is usually carried out by spraying a lecithin-in-oil solution on the agglomerates after the drying stage. Lecithination may be carried out either by direct spraying on the fluidized powder or in a powder trap between two fluid beds. A conditioning fluid-bed stage is then usually added to the process in order to distribute the lecithin uniformly on the surface of the particles.

A number of such straight-through systems differing in geometry and number of stages have been produced by companies such as APV Anhydro (Invensys), NIRO, and others. Powders produced from the straight-through process are nondusty, free-flowing, and with a particle size ranging between 250 and 500 μm. The process has been successfully applied to a wide range of products where a liquid raw material needs to be dried and transformed into an instant powder. Its almost universal application is, however, offset by the high investment cost.

Microbiological Hazards of Agglomeration

Few outbreaks of foodborne diseases have been reported due to dried powders. Microbiological hazards are usually associated with the liquid raw materials and the emphasis of any manufacturer should be to insure that adequate heat treatment is given to any liquid product that is going to be spray-dried and agglomerated. Tests for *Salmonella*, Enterobacteriaceae (*Escherichia coli*, coliforms) and *Staphylococcus aureus* should be carried out routinely. There are, however, occasions where the product may be contaminated after drying through contact or handling. (*See* **Food Poisoning**: Tracing Origins and Testing.)

AGING – NUTRITIONAL ASPECTS

N P Hays and S B Roberts, The Jean Mayer USDA Human Nutrition Research Center on Aging at Tufts University, Boston, MA, USA

Aging

Life expectancy at birth in the USA is now 76.5 years, compared with about 47 years at the beginning of this century. Consequently, the proportion of the population that is elderly, as well as the mean age of the population, has increased. A continuation of these trends is anticipated through the beginning of the twenty-first century. One of the consequences of this profound demographic shift is an increased awareness that nutritional influences on health should be optimized for the older population. This manuscript is based on an earlier review by Roberts and Hays, describing the nutritional requirements of older people.

Old age is a time when maintaining a good nutritional status is a critical determinant of health – but at the same time is often more challenging than it is earlier in life. As described below, the body's need for some nutrients is actually increased relative to that in earlier adult life, while the body's subconscious ability to regulate food and nutrient intakes diminishes. For these reasons, the elderly are a group particularly vulnerable to inadequate dietary intakes. The consequences of excessive nutrient intakes, particularly of energy, are also more severe in older adults. Obese elderly persons are much more likely to suffer disabling comorbidities associated with obesity such as heart disease, osteoarthritis, and reduced mobility, which in turn can lead to a downward spiral of disability and frailty. Thus, it is important to know the nutritional requirements of elderly persons, and the food choices that can insure adequate nutrition.

Determining accurate recommended dietary allowances (RDAs) for any age group is challenging. Historically, RDAs have been focused towards preventing nutrient deficiencies, whereas there is now increasing recognition that increased or decreased intakes of some nutrients may also have protective functions against late-life chronic diseases such as coronary heart disease and some cancers. The newest update of the RDAs, now called dietary reference intakes (DRIs), does in fact consider these protective functions as a factor in setting nutrient recommendations. At the time of preparation of this manuscript, 1997 DRIs are available for calcium, magnesium, phosphorus, fluoride, and vitamin D, 1998 DRIs are available for thiamin, riboflavin, niacin, vitamin B_6, folate, vitamin B_{12}, pantothenic acid, biotin, and choline, and 2000 DRIs are available for vitamin C, vitamin E, and selenium. Recommendations for all other nutrients remain based on the 1989 RDAs (new DRIs for the remaining nutrients are expected to be released over the next several years). In some cases, the increased intakes that appear to decrease the risk of late-life chronic disease are unfeasible without resorting to nutrient interventions through fortification or supplementation. Despite increased recommendations for several nutrients in the new DRIs, the question of whether DRIs should recommend levels of nutrients compatible with what can be consumed through foods, or whether in some cases pharmacological supplementation may be appropriate, is an ongoing debate. Of particular relevance to this issue is the fact that, in epidemiological studies linking diet to disease, it is the consumption of foods, rather than nutrients, that is actually measured. Metabolically active 'phytochemicals' in such foods as fruits and vegetables may play important roles in disease prevention and are not at the present time understood well enough to be used as supplements.

The determination of accurate and meaningful DRIs is particularly difficult in the elderly population. Whereas the majority of young adults are healthy, the majority of elderly persons have one or more chronic diseases or disabilities that affect nutrient uptake and utilization and at the same time use multiple medications to treat chronic diseases. If nutritional recommendations are to be made not only for healthy elderly persons, but also for sub-groups with different health limitations, this vastly increases the complexity of formulating accurate recommendations. Moreover, the objective of DRIs may change with adult age, with increasing focus on maintaining current health rather than preventing deficiency or future disease. For example, a recommendation to consume a low saturated fat diet to prevent later coronary heart disease may be inappropriate for 85-year-old men and women, who often find it hard to consume enough food to maintain weight. Finally, the 'elderly' are not one group. Currently, DRIs provide specific recommendations for individuals aged 51–70 and >70 years, which assumes that all individuals over the age of 70 years are metabolically equivalent with regard to their nutrient needs. This is certainly not the case for several nutrients, and individuals in the age

range 70–80 years should be judged differently from those aged 80–90 years or older.

With these considerations in mind, this article focuses on the effects of age on the body's ability to use different nutrients. When an increase in the intake of a particular nutrient is needed to achieve the same circulating level of the nutrient in the body or the same level of adequacy, as judged by a particular enzymatic activity, this is taken as evidence of an increase in requirements. A more advanced treatment of nutritional requirements in the elderly must await the collection of data more sophisticated than is currently available.

Energy Requirements

Current recommendations on dietary energy intake define expected average amounts of dietary energy required for sustaining normal metabolic processes, together with desirable or expected levels of physical activity in healthy individuals. In weight-stable adults, energy requirements are equal to total energy expenditure since body energy stores remain approximately constant. Current dietary guidelines also note that not more than 30% of dietary energy should be supplied by fat, and only 10% or less supplied from saturated fat. This recommendation applies to adults of all ages. A further general consideration concerning energy requirements is that body weight should ideally be maintained within the body mass index (BMI, weight in kilograms divided by the square of the height in meters) range of 20–25 $kg\,m^{-2}$.

Age, body weight, and the level of physical activity are the primary determinants of energy requirements for body weight maintenance in adults of all ages. Concerning the effects of age, the older the person, the lower are the energy requirements. For body mass, the larger the body mass, the greater are the energy needs of the body. Height is an important determinant of body mass since taller persons tend to weigh more than shorter persons. Physical activity is also an important determinant of energy requirements. Table 1 shows the recommended energy requirements of adult men and women of typical weight expressed as 'PAL' (physical activity level) units, which are energy requirements divided by the estimated 'basal metabolic rate' (the minimum expenditure of the body when lying supine at rest at least 12 h after the last meal). PAL units are given for light, moderate, and heavy levels of activity, and the basal metabolic rate can be calculated using the equations at the bottom of Table 1.

As predicted by the US National Academy of Sciences recommendation, elderly adults typically have substantially decreased energy requirements relative to young adults by 1255–2510 kJ per day (300–600 kcal per day) (Table 2). This is thought to be for two main reasons: (1) basal metabolism decreases with age, owing to a reduced amount of lean tissue (the actively metabolizing component of the body) as well as a decrease in the amount of metabolic activity per unit of lean tissue; (2) although not inevitable, the capacity for physical activity is typically decreased in older persons in concert with increased body fat mass.

The estimated energy needs given in Tables 1 and 2 have been challenged as somewhat inaccurate. This is

Table 1 Estimated energy requirements by physical activity level

PAL	*PAL units*[b]	*Energy needs at 65 years (kJ per day)*[a]	
		Man (75 kg)	*Woman (60 kg)*
Light activity	1.50	10 615	8 025
Moderate activity	1.65	11 678	8 828
Heavy activity	2.00	14 154	10 698
Estimated BMR of men (kJ per day)[c]			
Age 18–30	BMR = (64.0 × weight in kg) + 2841		
30–60	BMR = (48.5 × weight in kg) + 3678		
> 60	BMR = (56.5 × weight in kg) + 2038		
Estimated BMR of women (kJ per day)[c]			
Age 18–30	BMR = (61.5 × weight in kg) + 2075		
30–60	BMR = (36.4 × weight in kg) + 3469		
> 60	BMR = (43.9 × weight in kg) + 2494		

[a] 1 kJ ≈ 0.239 kcal.
[b] Physical activity level (PAL) = basal metabolic rate (BMR) multiplied by activity factor.

Table 2 Effects of age on estimated energy requirements[a]

Age group (years)	*Body weight (kg)*	*PAL units*[b]	*Estimated energy needs (kJ per day)*[c]
Men			
19–24	72	1.67	12 134
25–50	79	1.60	12 134
51+	77	1.50	9 623
Women			
19–24	58	1.60	9 205
25–50	63	1.55	9 205
51+	65	1.50	7 950

[a] Based on values obtained from National Research Council, Subcommittee on the 10th Edition of the RDAs, Food and Nutrition Board, Commission on Life Sciences (1989) *Recommended Dietary Allowances*, 10th edn. Washington, DC: National Academy Press, with permission.
[b] Physical activity level (PAL) = basal metabolic rate (BMR) multiplied by activity factor.
[c] 1 kJ ≈ 0.239 kcal.

because, based on research using doubly labeled water to measure energy requirements (published after the most recent recommendations were released), they appear to underestimate the usual energy needs of healthy men and women. The underestimation has been suggested to be due to an underestimate of the energy expenditure associated with normal daily living. In a summary of recent energy requirement studies in elderly persons, the measured PAL value of older men and women averaged 1.65, compared with the suggested recommendation of 1.51. This change would mean that the energy requirements of older men and women with typical body weights would average 10 539 kJ (2519 kcal) and 8828 kJ (2110 kcal) per day, respectively. Like the recommended dietary allowances, however, the new research confirms a substantial decrease in caloric requirements with age.

Protein Requirements

The 1985 FAO/WHO Committee on Energy and Protein requirements defines the protein requirements of an adult as 'the lowest level of dietary protein intake that will balance losses of nitrogen from the body in persons maintaining energy balance at modest levels of physical activity'. Nitrogen balance is determined in metabolic studies as the difference between measured nitrogen intake (from dietary protein which is about 16% nitrogen by weight) and nitrogen losses. The major routes of nitrogen loss – in urine and feces – are measured, and miscellaneous nitrogen losses, including those in hair, skin, sweat, and breath ammonia, are assumed to be equal to 8 mg per kilogram of body weight. Based on this nitrogen balance methodology, it is estimated that the mean requirement for good quality protein in adults is 0.6 g per kilogram of body weight, and the recommended safe protein intake (to reflect individual variability in requirements) is 0.75–0.80 g per kilogram of body weight.

No change in protein requirements with age is currently recommended, because of the limited and conflicting information in the literature at the time the most recent recommendations were developed. However, it was recognized in the recommendations that values of 0.75 and 0.80 g per kilogram of body weight provide for higher intakes of protein per unit of lean tissue in older individuals, because of the reduced amount of lean tissue in this group. Thus, even if elderly persons have an increased requirement for protein relative to their amount of lean tissue, this may be accommodated already within the current RDAs.

Recent studies have raised the question of whether the current recommendations may underestimate usual protein needs in elderly persons. In a review and reanalysis of previous studies, protein requirements of elderly persons appeared to be increased to > 1.0 g per kilogram of body weight per day. However, this tentative observation was based on potentially inaccurate assumptions including that miscellaneous nitrogen losses from the body are the same in young and elderly subjects (when they are probably lower in the elderly), and that an equilibration period of only 5 days is sufficient to bring elderly persons into nitrogen balance when protein intake is adequate. Another study found that protein requirements were unchanged in healthy elderly women, compared with younger women, and reduced in elderly men. This controversy over whether the need for dietary protein is increased in the elderly cannot be resolved without further investigation.

Vitamin Requirements

RDAs and DRIs for vitamins in adults are shown in Table 3. Different approaches were taken to determine these estimated vitamin requirements in adults, including depletion–repletion studies conducted in a metabolic ward, measurement of intakes required to maintain constant body stores, and the activity of enzymes requiring vitamins as cofactors. In studies used to determine 1989 RDAs, there was a consistent emphasis on the prevention of clinical or biochemical deficiency as well as consideration of usual dietary intakes, rather than long-term prevention of chronic disease. Although an attempt was made to set the 1997, 1998, and 2000 DRIs at levels designed to reduce the risk of chronic disease, the DRI committees judged that, except for calcium and fluoride, the available scientific evidence was too weak to allow reduction of disease risk to be used as a criteria for setting recommendations. The RDA values listed are derived by adding two standard deviations to the estimated average requirements. The DRI values for vitamin D and biotin, however, are based simply on the observed mean nutrient intakes that appear to sustain a population's normal nutritional status.

The recommendations given in Table 3 are, for the most part, the same for young and older adults – again defined as less than and greater than 51 years of age. The exceptions are vitamin D requirements, which are set at a higher level in older persons based on evidence suggesting that the capacity of human skin to synthesize vitamin D decreases with age, and vitamin B_6 requirements, which are also higher in older persons based on a small number of studies suggesting that the level of vitamin B_6 required to normalize cofactor-dependent enzyme function and excretion levels increases with age.

Table 3 Recommended daily vitamin needs (1989 RDAs except as indicated)

Vitamin	*Younger adults*		*Older adults*		
	Male	*Female*	*Male*	*Female*	*Probable bias in older subjects*
Vitamin A (μg RE)	1000	800	1000	800	Too high
Vitamin D (μg)[a]	5	5	10–15	10–15	Probably OK
Vitamin E (mg-αTE)[b]	15	15	15	15	Probably OK
Vitamin K (μg)	80	65	80	65	?
Vitamin C (mg)[b]	90	75	90	75	Too low
Thiamin (mg)[c]	1.2	1.1	1.2	1.1	Probably OK
Riboflavin (mg)[c]	1.3	1.1	1.3	1.1	Probably OK
Niacin (mg NE)[c,d]	16	14	16	14	?
Vitamin B_6 (mg)[c]	1.3	1.3	1.7	1.5	Too low
Folate (μg DFE)[c,e]	400	400	400	400	Too low
Vitamin B_{12} (μg)[c]	2.4	2.4	2.4	2.4	Too low
Biotin (μg)[c]	30	30	30	30	?
Pantothenic acid (mg)[c]	5	5	5	5	?
Choline (mg)[c]	550	425	550	425	?

[a]1997 DRI range for older adults: the lower value is DRI for 51–70 years; the higher value is DRI for >70 years.
[b]2000 DRI.
[c]1998 DRI.
[d]As niacin equivalents (NE). 1 mg of niacin = 60 mg of tryptophan.
[e]As dietary folate equivalents (DFE). 1 μg of food folate = 0.6 μg of folic acid (from fortified food or supplement) consumed with food = 0.5 μg of synthetic (supplemental) folic acid taken on an empty stomach.

There has been increasing recognition, however, that current RDAs for other vitamins may not be accurate for elderly individuals. In particular, and as summarized in Table 3, there is evidence that DRIs for vitamins C, B_{12}, and folate may be too low and that the RDA for vitamin A may be too high. There is also evidence that the DRI for vitamin B_6 may be inappropriately low as well.

Vitamin C

Vitamin C has three main roles in human metabolism – enyzme cofactor, chemical reductant, and antioxidant. Although the 2000 DRI for vitamin C is increased compared with the previous RDA value, recent research has provided evidence that the currently recommended intake of vitamin C may still be too low for all age groups, including elderly persons. For the same vitamin C intake, elderly persons have lower circulating levels compared with young adults, perhaps because of either impaired absorption of vitamin C from the gut or impaired reabsorption from the kidney. Recent studies examining vitamin C bioavailability, urinary excretion, and steady-state plasma vitamin C concentration as a function of dose suggest that the recommended vitamin C intake should be increased from 90 mg (for men) and 75 mg (for women) to 120 mg per day. Although preliminary studies indicate that even higher doses of vitamin C may prevent low-density lipoprotein oxidation, may improve wound healing, and are inversely correlated with blood pressure in elderly persons, results are inconsistent and further research is needed.

Vitamin B_{12}

Vitamin B_{12} is used in the body as a cofactor for several essential enzymatic reactions, including methionine synthesis and methylmalonyl-CoA mutase. Vitamin B_{12} requirements have been suggested to be increased in elderly persons, on the grounds that 2–3% of individuals over 60 years of age have pernicious anemia (a degenerative autoimmune condition of the stomach) and 10–30% have type B chronic atrophic gastritis (related to nonautoimmune 'environmental' conditions). These conditions result in either impaired intrinsic factor protein or acid and pepsin secretion by the stomach, respectively, which in turn reduces absorption of vitamin B_{12} from the diet. Vitamin B_{12} deficiency may be the one major undetected vitamin deficiency in the elderly population and has been suggested as being responsible for a proportion of the dementia cases among the elderly population. The 1998 DRI committee suggests that older individuals meet their vitamin B_{12} requirement through the use of vitamin supplements or fortified foods, because the absorption of the crystalline form of vitamin B_{12} is not influenced by atrophic gastritis. In older individuals with pernicious anemia, monthly B_{12} injections or daily ingestion of megadose B_{12} supplements ($400 \times$ DRI), allowing absorption by passive diffusion, are other means of normalizing B_{12} status.

Folate

Folate functions as a cofactor for enzymes involved in amino acid metabolism and nucleic acid synthesis. Recently, folate has received attention for its role in homocysteine metabolism and cardiovascular disease (CVD) risk. Excess levels of homocysteine in the blood have been implicated as a CVD risk factor; folate, along with vitamins B_6 and B_{12}, is involved in converting homocysteine to methionine, a harmless amino acid metabolite. In the elderly, studies have shown that folate intakes of at least 500 μg per day, along with a similar amount of vitamin B_{12}, may reduce blood homocysteine levels by as much as one-third. Fortification of grain products and breakfast cereals with folate (140 μg per 100 g) was begun in the USA in 1996 primarily to reduce the risk of prenatal neural tube defects. Recent studies suggest that fortification has also resulted in a substantial improvement in folate status in older adults as well; however, it is unclear whether the current level of fortification will have a significant effect on rates of CVD in the elderly population.

Vitamin B_6

Vitamin B_6 is a cofactor for a large number of enzymes used in the metabolism of amino acids and related compounds. A vitamin B_6 depletion–repletion study showed that vitamin intakes equivalent to a mean of 1.96 mg per day for elderly men and 1.90 mg per day for elderly women were needed to return urinary xanthurenic acid excretion to normal following a tryptophan load (one test for B_6 deficiency), thus indicating that current DRIs may be too low for this age group. This evidence was also consistent with the previous observation that many elderly persons show evidence of marginal biochemical vitamin B_6 deficiency.

Vitamin A

Vitamin A is required for a wide range of metabolic reactions in the body and in particular is used in the differentiation of epithelial cells, support of reproduction, and maintenance of the visual system. Concerning the possibility that the RDA for vitamin A may be too high and should be reduced, studies have indicated that elderly persons have decreased clearance of vitamin A (approximately 50% less than younger adults) by hepatic and other peripheral tissues. This finding helps to explain the observations that elderly persons have normal liver storage of vitamin A despite decreased vitamin A intakes, and that the use of vitamin A supplements by elderly persons is associated with increased circulating indicators of vitamin A overload (high fasting plasma retinyl esters).

Mineral Requirements

RDAs and DRIs for minerals in adults are shown in Table 4. As with the vitamin recommendations, different approaches were taken to determine these estimated mineral requirements in adults, including balance studies and summation of expected mineral needs based on metabolic demands and rates of absorption. The RDA values listed are best estimates of the safe intake for the whole adult population, i.e., the mean requirement plus 2 SD; the DRI values for phosphorus and magnesium are estimated in a similar fashion. The DRIs for calcium and fluoride, however, are based simply on the average nutrient intakes of healthy population groups. The recommendations given in Table 4 are the same for young and older adults, with the exception of iron requirements in older women, which are proposed to be lower on the grounds that iron losses are reduced following menopause, and calcium requirements in older men and

Table 4 Recommended daily mineral needs (1989 RDAs except as indicated)

Mineral	*Younger adults*		*Older adults*		
	Male	*Female*	*Male*	*Female*	*Probable bias in older subjects*
Calcium (mg)[a]	1000	1000	1200	1200	Too low
Phosphorus (mg)[a]	700	700	700	700	?
Magnesium (mg)[a]	420	320	420	320	Probably OK
Iron (mg)	10	15	10	10	Probably OK
Zinc (mg)	15	12	15	12	Probably OK
Iodine (μg)	150	150	150	150	?
Selenium (μg)[b]	55	55	55	55	Probably OK
Copper (mg)	1.5–3.0	1.5–3.0	1.5–3.0	1.5–3.0	Probably OK
Maganese (mg)	2–5	2–5	2–5	2–5	?
Fluoride (mg)[a]	3.8	3.1	3.8	3.1	?
Chromium (μg)	50–200	50–200	50–200	50–200	Too high?
Molybdenum (μg)	75–250	75–250	75–250	75–250	?

[a]1997 DRI.
[b]2000 DRI.

women, which are higher on the grounds that higher intakes ensure a maximal skeletal calcium retention.

Calcium

Based on increased recognition that the 1989 RDA for calcium may be too low, the 1997 DRI was set at 1200 mg per day for men and women 51 years of age and older. This value may still be too low for optimal calcium retention in individuals older than 65 years of age, but there are also issues of nutrient–nutrient interactions when considering an amount greater than 1200 mg per day. Calcium is the primary mineral in bone and teeth and is extremely important for the elderly, because the age-associated bone demineralization that commonly occurs in elderly persons is accelerated when calcium intake is low and leads to increased risks of bone fracture and tooth loss. Aging is associated with a decreased ability to absorb dietary calcium and also a decreased ability to increase the fractional rate of absorption when calcium intake is low. Calcium supplementation (for example using calcium citrate malate, which is better absorbed than calcium carbonate in postmenopausal women) has been shown to prevent age-associated bone loss both in women with initially low calcium intakes and perhaps also in those with intakes in the normal range.

Chromium

Chromium mediates the hormonal effects of insulin and so is needed for a wide range of metabolic functions including maintaining glucose and lipid status. Chromium requirements for older persons are difficult to determine, owing to the scarcity of accurate measures of both chromium status and the chromium content of foods. However, based on limited available intake data, it has been estimated that approximately 12.5 MJ (3000 kcal) of a typical diet would have to be eaten to obtain the minimum estimated safe and adequate daily dietary intake (from 1989 RDAs) of chromium of 50 μg. Such an intake is rare in elderly persons, and at the same time, balance studies have shown that chromium balance can be achieved with dietary intakes less than 50 μg. These findings, coupled with the observation that chromium deficiency is extremely rare in adults of any age, suggest that the current recommended intake may be unnecessarily high for elderly adults.

Fluid Requirements

Water is by far the largest constituent of the body, accounting for between 50 and 80% of the body mass. It is needed for a variety of essential purposes including regulation of cell volume, nutrient transport, waste removal, and temperature regulation. Water is lost from the body in urine, feces, and 'insensibly', i.e., in sweat and transepidermal routes, and so must be replaced. To replace essential water losses, water needs to be consumed at an estimated rate of 0.24–0.36 ml kJ^{-1} (1–1.5 ml $kcal^{-1}$) of energy expended. Thus, an elderly person with an energy requirement of 9200 kJ per day (2200 kcal per day) will need 2.2–3.3 l per day of water. As shown in Figure 1, approximately half of this water intake usually comes from consumed liquids, and the remainder comes from water contained in food and the metabolic water derived from the oxidation of macronutrients in the body.

Water intake is a particular concern in elderly persons. This is not because water requirements are higher in this group (in general, requirements are not higher unless urine concentrating ability is decreased) but because the ability to sense a need for water appears to be blunted in older individuals, with the consequence that they do not feel thirsty when they should and so are at risk of dehydration from inadequate fluid intake. This is particularly true when water requirements are increased – for example, in hot dry weather and when the body temperature is increased during a fever. For this reason, elderly persons should be given the advice that they should not rely on thirst to determine when they drink but instead should have a meal and snack plan that routinely incorporates one or more drinks.

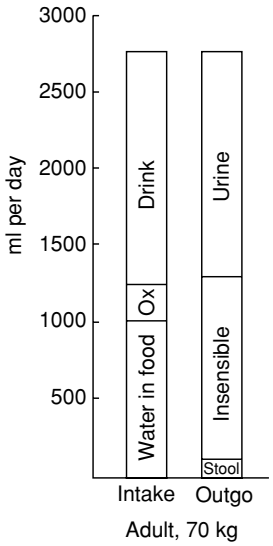

Figure 1 Routes and approximate magnitude of water intake and loss without sweating. Ox, oxidation. Adapted from *Recommended Dietary Allowances* (1989) 10th edn. © National Academy of Sciences. Washington, DC: National Academy Press, with permission.

Appropriate Food Choices for the Elderly

Elderly persons have substantially inadequate intakes of many of the micronutrients, as judged by the adequacy of reported dietary intake in a number of national surveys. This finding may be due, in part, to the inaccuracy of many types of dietary records, especially in elderly persons. However, corroborating evidence from studies of circulating nutrient levels and enzymatic tests of biochemical deficiency suggest that micronutrient inadequacies are widespread in the elderly population. Decreased energy requirements, a reduced ability to accurately regulate food intake, and social factors all contribute to the poor dietary intake of elderly persons. This, coupled with an equivalent or even increased requirement for micronutrients, necessitates a very different dietary pattern in elderly persons with increased emphasis on consumption of fruits, vegetables, legumes, fish, lean meat, low-fat dairy products, and whole grains and decreased intake of highly processed foods with a relative deficiency of micronutrients. Recently, a modified food guide pyramid for healthy individuals aged 70 years and older was developed by Tufts University scientists, placing greater emphasis on the consumption of nutrient-dense foods, high-fiber foods, and water. The modified pyramid also encourages the use of calcium, vitamin D and vitamin B_{12} supplements. While dietary supplements remain a viable alternative to the provision of micronutrients to the elderly population, this should not be a preferred option because supplements do not yet replace the wide range of biologically active food constituents, many of which will probably come to be recognized as playing important roles in the prevention of chronic disease.

AGITATION

K Niranjan, University of Reading, Reading, UK
A A P de Alwis, University of Moratuwa, Moratuwa, Sri Lanka

Background

Food materials – whether individual or prepared meals – are invariably 'multicomponent' systems. Agitation is both a means of rendering food systems more homogeneous and a means of dispersing further components into existing food systems. Agitation can be used to bring about physical and chemical changes in the system. Under the influence of shear and extensional forces generated by agitation, the rates of heat and mass transfer can be improved during processing. Agitation also enhances the rates of biochemical reactions by insuring that reactants and enzymes are brought into intimate contact. Typical applications of agitation in food processing are (1) blending of soluble solids and liquids, (2) dispersing flavorings, preservatives, colorings, and dressings, (3) disintegrating and comminuting animal and vegetable matter, (4) hydrolyzing and reconstituting dried substances, (5) reducing agglomerates, (6) emulsification, and (7) aeration or de-aeration.

The principles of agitation as applied to food processes, as well as associated problems, are discussed here. In addition, the common types of agitation systems used for different applications are illustrated.

The *characteristic features* of food agitation and associated problems are as follows:

1. Food systems cover a whole spectrum of materials, from dry free-flowing materials through thin and viscous liquids to slurries, pastes and doughs. Agitation of these materials involves many complex interfaces and free surfaces.
2. Flow properties of the components and those of the mixture at any stage during mixing are both very complex and time-dependent. This is further complicated in situations that involve simultaneous chemical reactions.
3. The shear stress generated by an agitator is very important in a food system: processes for making fine dispersions and emulsions need a very high shear, whereas others, such as mixing nuts and chocolates or whole fruit into yogurt, need a low shear.
4. Many food products contain particles of different sizes, some of which are fragile, and these particles may have to be dispersed into viscous liquids such as sauce. Agitation of such systems, to produce uniform product composition, is very difficult.
5. Segregation of particles often occurs when blended products are discharged from mixing vessels. During the production of chilli con carne, for example, beans that have been dispersed uniformly by the agitator aggregate during discharge. This can cause valve blockage, as well as inconsistencies in the packaged product. It is not uncommon to observe significantly higher coefficients of variation between packs than between samples taken from the mixer.
6. Mixing of food materials can involve the addition of high-value components, in very small amounts, into bulk materials. This process is particularly difficult when mixing into dry solids, as well as in the production of dough and batters.
7. It is also difficult to monitor and control the extent of mixing in many food systems, since the end point of agitation occurs some time after agitation has ceased. This is typical of processes involving gas inclusion, crystallization, and texturization.
8. A wide variety of agitating systems are available for use in food materials. Regardless of the size or shape of the mixer, its design features must insure hygiene, as well as provide for in-place cleaning and, possibly, sterile operation. Most equipment is therefore available in crevice-free, polished stainless steel. (*See* **Plant Design**: Designing for Hygienic Operation.)

The principles of agitation can be best illustrated by considering mixing phenomena in a single liquid phase.

Agitation of Liquids

Agitation of liquids can be discussed using stirred-tank agitators as examples, since these devices are not only fairly well understood but also widely used. A stirred-tank system consists of an impeller mounted on a shaft; the impeller rotates, immersed in a liquid contained in the tank. Mixing and dispersion are accomplished by dissipating mechanical energy through the impeller. Figure 1 shows the configuration of a typical stirred-tank system: the dimensions given in the figure are often considered to be 'standard', since most design information is available only for this geometric configuration; however, this configuration is not necessarily the best for any given application. When the height of liquid in a vessel is

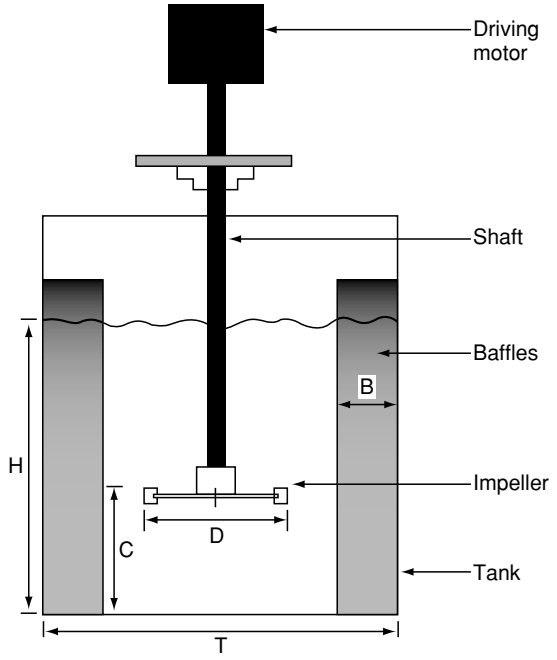

Figure 1 Configuration of a standard agitated, cylindrical stirred tank of diameter *T*, fitted with four baffles, each of width *B*. (Two baffles fitted diametrically opposite each other are shown in the figure; the remaining are fitted along the perpendicular diameter.) Standard ratios: H/T; $D/T=1/3$; $B/T=1/10$; and $C/T=1/3$. greater than 1.5 times its diameter, it is advisable to use more than one impeller, generally fitted on the same shaft. Most mixing vessels used for low-viscosity liquids (less than 1 Pa s) are fitted with baffles which prevent the formation of a vortex[1]. Baffles also help to establish top-to-bottom circulation of fluid, which moves the fluid to all parts of the vessel. In viscous liquids, unbaffled tanks can be used, since gross vortices are not readily formed.

Mechanically agitated devices are useful for mixing liquids of any viscosity up to 750 Pa s, depending on the size and shape of the impeller. Impellers are often classified according to the direction in which they discharge liquid. The disc turbine, shown in Figure 2a, is a *radial-flow* impeller, since it discharges liquid in the radial direction as it rotates (see Figure 3a). However, a propeller (Figure 2b) is an *axial-flow* impeller (see Figure 3b). Pitched-bladed turbines (Figure 2c) and most of the recently developed impellers, such as the hydrofoil (Figure 2d) and the convex-bladed mixed-flow impeller (Figure 2e), are known as *mixed-flow* impellers, since they develop flows that have components of significant strengths in radial as well as axial directions. Figure 3c shows the flow pattern generated by a mixed-flow impeller.

The above-mentioned impellers are often used in vessels conforming to the standard geometry described in Figure 1. While dealing with viscous Newtonian liquids, or with nonNewtonian systems, which

[1]Vortex is a swirling motion produced when an axially mounted agitator, regardless of type, is used to stir a low-viscosity liquid in an unbaffled vessel. The centrifugal force acting on the rotating liquid raises the level of the liquid at the wall and lowers it at the shaft. Sine the resulting liquid flow is predominantly tangential, mixing is very poor.

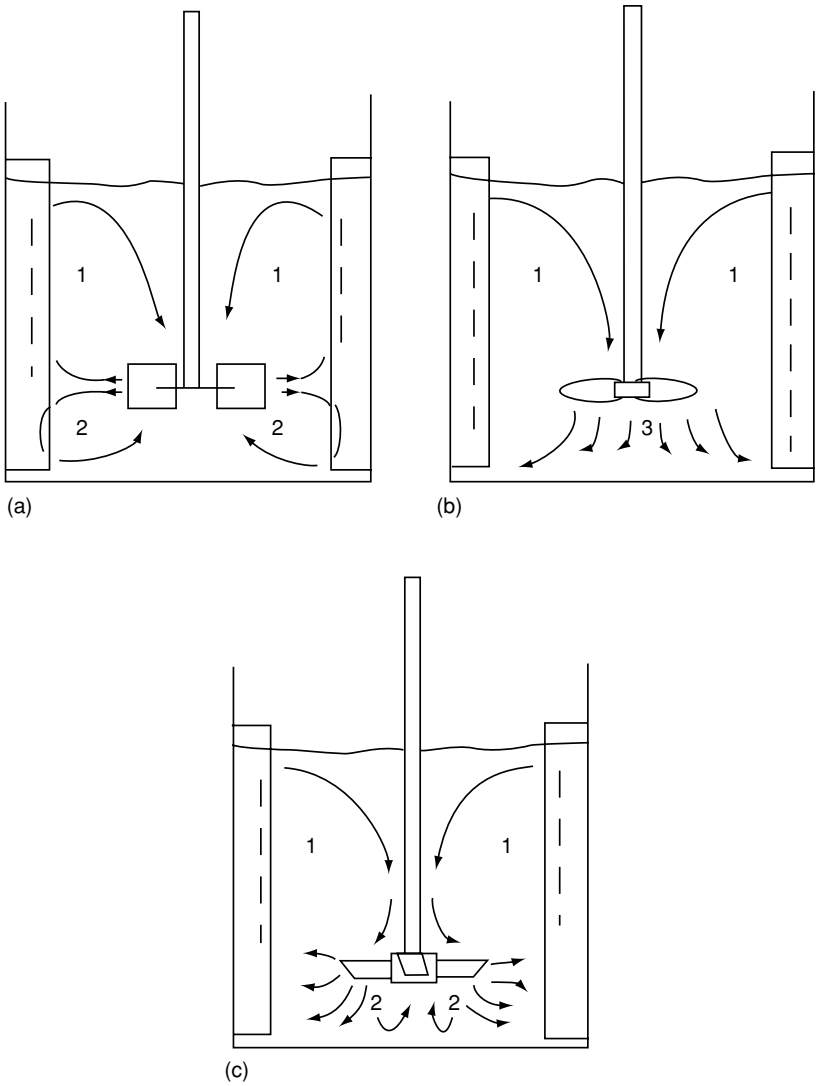

Figure 3 Flow patterns with different impellers: (a) radial-flow; (b) axial-flow; (c) mixed-flow. (1) Upper loop; (2) lower loop; (3) discharged liquid jet. are more prevalent in the food industry, the impeller sizes are much larger, and stirrers that have a close clearance between the impeller body and the vessel walls are used. In pseudoplastic systems (fluids exhibiting lower viscosity at higher shear rate), anchor impellers (Figure 2f) are often used. Helical ribbons (Figure 2g) are also used for high-viscosity liquids, as well as for suspensions. These impellers sweep through a larger volume of the mixing vessel and facilitate heat transfer between the liquid and the vessel walls. For mixing applications involving paste-like materials (effective viscosity > 1000 Pa s), Z or Sigma blade agitators (Figure 2h) are used. Figure 4 shows an agitator selection chart based on the effective viscosity of the material to be mixed.

Flow Pattern in Mixing Vessels

The liquid flow pattern generated by a rotating impeller can be either laminar (streamline) or turbulent, depending on the value of the Reynolds number, defined for Newtonian liquids as follows:

$$N_{\mathrm{Re}} = (D^2 N \rho)/\mu. \qquad (1)$$

Here, D is the impeller diameter (m); N is the rotational speed (Hz); ρ is the liquid density (kg m^{-3}) and μ is its viscosity (Pa s). Flow is laminar when N_{Re} is < 10 and it is fully turbulent when N_{Re} is > 10 000. In between these two values, the flow is considered to be in the transition regime. For non-Newtonian fluids, the same definition of N_{Re} is valid, except that the

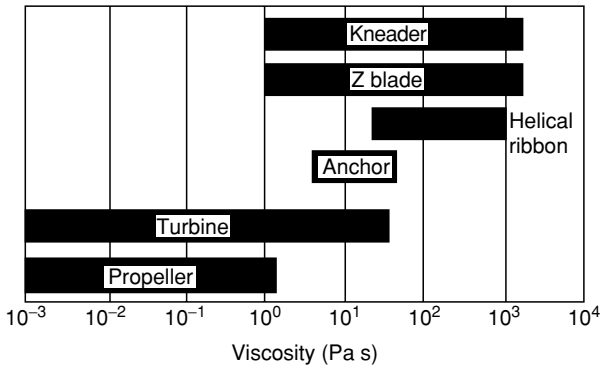

Figure 4 Agitator selection chart based on the viscosity of the material to be stirred. Reproduced from Agitation and Agitator Design, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

denominator is replaced by an 'effective viscosity'. For example, in the case of pseudoplastic liquids following the power law constitutive equation $\tau = k\dot{\gamma}^n$ (where τ is the shear stress, $\dot{\gamma}$ is the shear rate, k is known as the consistency index, and n is known as the power law exponent), the effective viscosity is given by $\mu_{\text{eff}} = k\dot{\gamma}^{n-1}$. It is customary to express $\dot{\gamma}$ in terms of an 'average shear rate' in the agitated vessel, which is known to be proportional to the rotational speed. Thus $\dot{\gamma} = \beta N$, where β is a constant depending on the type of the impeller (β usually takes a value around 10 for most common impellers; see Uhl and Gray 1966). Therefore the effective viscosity of pseudoplastic fluids in an agitated vessel can be expressed as $\mu_{\text{eff}} = k(\beta N)^{n-1}$. With this value of μ_{eff}, the Reynolds number for pseudoplastic fluids can be defined as

$$N_{\text{Re}} = D^2 N\rho / k(\beta N)^{n-1}. \qquad (2)$$

Just as in the case of Newtonian liquids, it is now possible to determine whether the flow pattern in a pseudoplastic fluid is laminar or turbulent or in the transition regime during agitation.

Power Consumption of Impellers

The power consumed by impellers is a very important parameter because it determines the operating cost of running the mixer. For Newtonian liquids, it is related to fluid density and viscosity, rotational speed and impeller diameter. The relationship is graphically expressed by plotting power number (given by $N_{\text{Po}} = P/(\rho N^3 D^5)$, where P is the power drawn by the impeller) against the Reynolds number, N_{Re} (see Figure 5). For any given impeller, the power number decreases with Reynolds number for low values of N_{Re}; for higher values, it is independent of N_{Re}. It may also be noted that, for a given impeller and for low values of N_{Re}, there is no difference in the N_{Po} versus N_{Re} relationship between baffled and unbaffled vessels. However, for high N_{Re} values, baffled vessels consume significantly higher power. Similar relationships between N_{Po} and N_{Re} are also valid for nonNewtonian fluids, provided that the effective viscosity is appropriately defined. Typically, to blend two low-viscosity liquids ($\mu < 0.1$ Pa s), a power dissipation of $0.2\,\text{kW m}^{-3}$ is required; for high-viscosity liquids, the specific power dissipation could be 10 times higher.

Blending of Miscible Substances into Liquids

The *degree of mixing* is a very important indicator of the extent of homogeneity achieved during blending operations. The performance of an agitator is often characterized by the time and energy required to attain a given degree of mixing. In practice, a relatively low, but known, volume of a miscible tracer is added to the contents of the mixer and the time required for the tracer concentration in the mixer to attain 95% of its final estimated concentration is measured; this is known as mixing time. Allowable limits are often placed on the composition variances of blended products. Other statistical methods are also available to describe product uniformity, which can be used for controlling the operation, as well as for testing mixing equipment.

Blending of solute with nonNewtonian liquids (or to result in the formation of nonNewtonian solutions) could pose special problems. *Bingham plastic* fluids (fluids exhibiting shear only when the applied stress exceeds a threshold value known as *yield stress*), when agitated by small impellers, tend to form a cavern around the impeller, where the shear stress is high; there is little or no agitation in the regions remote from the impeller. A different kind of problem can be encountered with certain *viscoelastic* substances, such as those having a consistency similar to a thick sauce or jelly: these substances develop 'normal forces' as a result of elastic properties, in addition to the usual shear forces caused by viscous effects. The normal forces oppose the formation of vortices, and, instead of the liquid level falling around the rotating shaft as described earlier, it rises and climbs up the shaft. The phenomenon is known as the *Weissenberg effect*.

Agitation Equipment for Single-phase Systems

Apart from the impeller-agitated systems described above, various other types of agitating devices are also available. Most of these devices can be operated either batchwise or continuously.

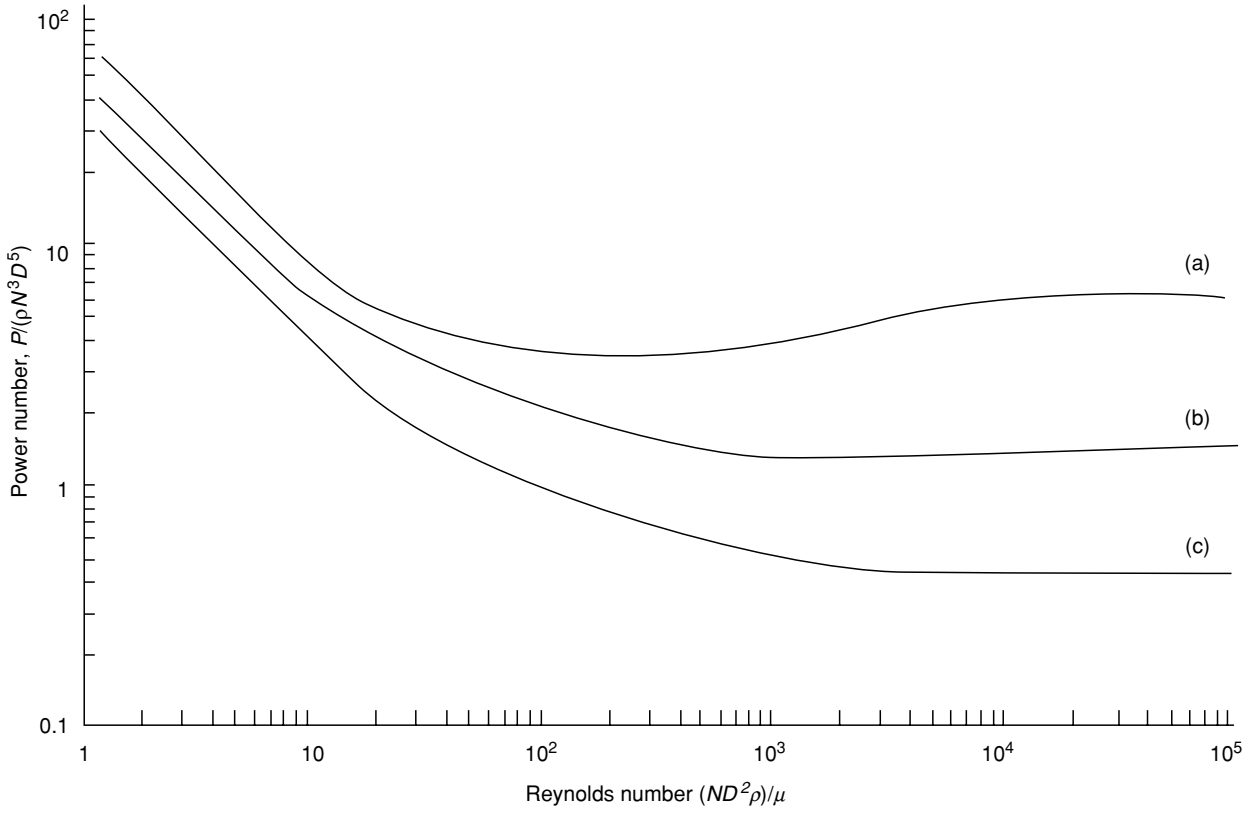

Figure 5 Reynolds number versus power number for some typical impellers – (a) six-bladed turbine, (b) pitched-bladed turbine, (c) propeller – in standard baffle tanks. Reproduced from Agitation and Agitator Design, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

When a blending operation demands or needs only low specific power dissipation levels (e.g., the blending of miscible liquids), a jet mixer can be used. In this device, a continuous recycle of the contents of a vessel is established by an external pump. The stream discharged by the pump re-enters the vessel with sufficient kinetic energy to cause mixing.

Motionless mixers or *static mixers* are a relatively recent development for continuous mixing, especially of viscous liquids. In this type of device, liquid is continuously pumped through conduits fitted with stationary mixing elements. These elements, which are available in various shapes, continuously interchange fluid elements between the walls and the centre of the conduits. The power consumption for agitating action in such devices is simply the power delivered by the pump to the fluid, in order to transport it across the length of the conduit.

Multiphase Agitation

Most practical situations relevant to the food industry involve agitation of several phases, e.g., dispersion of an immiscible liquid into another to form an emulsion, dispersion of air into liquids and pastes, and the mixing of powders (which always involves air and solid phases), pastes and suspensions. The mechanisms of multiphase mixing, as well as the equipment used, are complex, and these areas ought to be the focus of present and future research.

Liquid–Liquid Agitation

Immiscible liquids are agitated for either of the following purposes:

1. To produce a uniform droplet dispersion of one phase (known as the *dispersed* phase) into another (referred to as the *continuous* phase), which would be stable over a period of time, sufficient to allow, for example, mass transfer to occur (as in the case of liquid–liquid extraction); the dispersion is subsequently separated by spontaneous coalescence.
2. Alternatively, and more often, to produce dispersions that are stable over a very long period of time. Such dispersions, known as emulsions, are the most common end products of many agitated liquid–liquid systems. Mayonnaise, salad creams,

can greasing emulsions, and confectionery fillings are all examples of this type of product.

Principles The properties of liquid–liquid dispersions (including emulsions) are related to droplet size distribution, volume fraction of dispersed phase, interfacial tension, and attractive and repulsive forces between droplets. In the production of emulsions, coalescence suppressing agents known as emulsifiers are invariably added; these act by lowering the interfacial tension. Liquid–liquid dispersions are primarily produced by turbulent eddies in the continuous phase, which shear the other phase into droplets. The power dissipated through the agitating device is responsible for the creation of turbulent eddies in the continuous phase. The maximum droplet diameter produced is known to be proportional to the following term:

$$d_{\max} \propto \frac{\sigma^{0.6}}{\rho_c^{0.2}(P/V)^{0.4}},$$

where σ is the interfacial tension, ρ_c is the density of the continuous phase, and P/V is the power dissipated per unit volume of the dispersion.

Practice Mass transfer operations such as liquid–liquid extractions are usually carried out in impeller-agitated vessels; a disc turbine is often the preferred choice for this purpose. Alternatively, spray and packed columns can also be used.

Emulsification is probably the most complicated mixing operation, since the nature of the final product varies greatly in character depending on the method of preparation. The order of addition of the components, as well as the rate at which they are added, can significantly affect emulsion quality. In a typical batch process, an immersion emulsifier is lowered into the aqueous phase (in the case of oil–water emulsions). The various components are drawn into the working head, subjected to very high shear to form the dispersion, and finally the emulsion is expelled. Such devices are described as 'dispersion units.' Different designs of working heads are available, and these can simply be fitted to the end of the frame; care must be taken to select the most appropriate head for any given operation. Emulsification can also be accomplished using in-line static mixers of the type shown in Figure 6. (*See* **Emulsifiers**: Organic Emulsifiers.)

Liquid–Solid Agitation

The agitation of liquid–solid mixtures is carried out in a variety of situations. Dissolving solids into liquids is generally not difficult when the solids are readily soluble, e.g., salt and sugar in water. However, the role of agitation is crucial in dissolving substances such as carboxymethylcellulose, alginates, and gums. In such cases, the rate of dissolution is slow, owing to the low solubility of these substances. The kinetics of this process is further complicated by variations in suspension rheological properties occurring as dissolution progresses. Care must be taken, especially in continuous processes, to provide adequate residence time for dissolution as well as for chemical reactions (e.g., hydrolysis) to occur. In all such situations, it is important to insure that liquids are in a well-agitated state before commencing solid addition. When reconstituting substances such as milk and dried egg powder, the rate of powder addition is important: if the powder is added too quickly, it tends to agglomerate, thus prolonging process times.

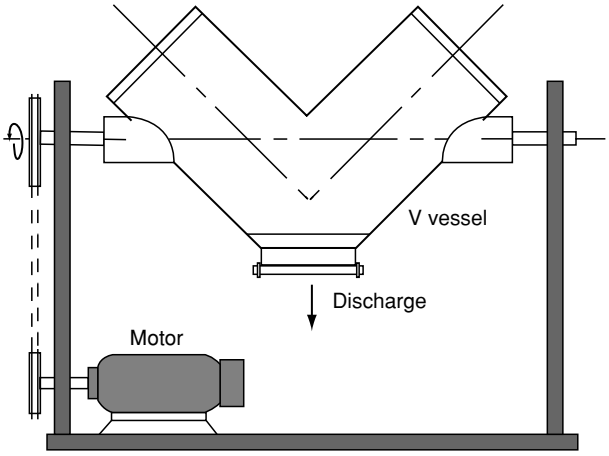

Figure 6 V-shaped tumbler mixer for solid–solid mixing. Reproduced from Agitation and Agitator Design, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

The main difficulty with operations such as dispersing flavorings, spices, coloring, or preservatives is that the quantities to be dispersed are very small in relation to the bulk. In such situations, it is advisable, where possible, to prepare a concentrated dispersion first, and then to mix it with the bulk.

Agitation accompanied by disintegration and comminution of substances such as meat, fruits, and vegetables may be necessary in the manufacture of sauces, ketchups, and infant foods. For each process, a dispersion unit fitted with an appropriate working head, may be used.

In addition to the aforementioned situations, solid–liquid agitation may also be encountered during fermentations (e.g., suspensions of cell cultures and growth media), in holding vessels used as premixers, and in crystallizers. In these situations, the main

objectives of agitation are to keep solids in suspension and to disperse them uniformly so that any draw-off would have an identical solid concentration. Impeller-agitated devices, described earlier, are generally useful for these purposes; propellers, in particular, are known to be efficient for suspending solids in low-viscosity liquids. For a given impeller and solid–liquid system, there is a minimum rotational speed below which the impeller does not produce sufficient 'lift force' to suspend the solids. The threshold rotational speed, in general, depends on the size, shape and density of the solid particles, the solid concentration, the density and viscosity of the liquid, and the geometry of the mixing vessel. In food systems, the density difference between the particles to be suspended and the liquid phase is generally not high. It follows that the minimum rotational speed for solid suspension is not high. Nevertheless, it is quite problematic to ensure homogeneity after the particles have been suspended, especially when the particles are sensitive to collision and high shear. While information on threshold suspension speeds is readily available, the number of studies on the homogeneity of such dispersions in mixing vessels is very limited.

Air–Liquid Agitation

During the agitation of food products, it is generally desirable to exclude air, since entrained air can cause spoilage during storage. However, there are certain situations where aeration is desirable: aerobic fermentations generally demand a continuous supply of air; processes such as cream whipping and ice-cream preparation involve air inclusion. Both aeration and deaeration are therefore important to food processing.

Aeration, whether desirable or not, can occur from the surface of an impeller-agitated vessel. The action of the impeller induces circulation and turbulence in the liquid. When strong eddies are generated at the surface, air is entrained from the head-space to form bubbles, which are then dragged into the bulk by circulation currents. These bubbles are stabilized by surface-active agents that are invariably present in food systems, and the two phases coexist. It has been noted that surface aeration occurs above a minimum impeller speed, and it is possible to estimate its value for a variety of systems. If aeration is detrimental to product storage, then either the impeller speed should be less than the minimum speed for surface aeration, or agitation should be followed by de-aeration.

Aerobic fermenters invariably need a continuous supply of air to sustain microbial growth. The main effect of sparging air into an impeller-agitated tank is to lower its power consumption. The reduction in power is a consequence of the formation of stable air cavities behind the impeller blades; the extent of the reduction depends on the size and shape of the cavities. At a given impeller speed, an increase in air flow rate results in an increase in cavity size. However, the cavity size cannot increase indefinitely: once the cavities have grown to their maximum size at a given flow rate, further increases in air flow rate cause some of the excess air to bypass the cavities and hence the impeller blades. The cavities, in certain cases, may also coalesce. As a consequence, the impeller virtually stops pumping, and the phenomenon is described as 'impeller flooding.' An impeller-agitated fermenter operates well away from the flooding point. In practise, the disc turbine of **Figure 2a** is the preferred impeller used in aerobic fermentation, mainly owing to dispersion ability. This impeller, however, suffers from certain drawbacks: it is a high-shear impeller, and therefore causes shear damage to certain substances, its power consumption is very high, and, more importantly, a large fraction of the supplied power is dissipated in a relatively low volume fraction of the vessel. These disadvantages have been found to be critical to several processes, and there is an attempt to use alternative devices, such as the hydrofoil impeller of **Figure 2d**.

Agitation of Particulate Material

Particle mixing is an extensive food processing operation used for mixing materials that include flour, sugar, dried milk, salt, flavoring materials, cereal flakes, etc. Wide differences among properties such as particle size, shape, density, and surface characteristics (e.g., frictional and electrostatic), make particle mixing a difficult and a complex operation. The process can be further complicated in food systems by a high moisture content, friability, complex flow properties, and agglomeration or segregation. The desired end point of solid-phase mixing is the attainment of a truly random distribution.

The following differences between mixing in particulate systems and fluid systems have been recognized:

1. There is no particulate motion equivalent to molecular diffusive transport in liquids and gases. Thus, when two miscible liquids or gases are in contact with each other, complete mixing eventually occurs. However, blending of particulate materials cannot occur without some input from external energy.
2. Unlike fluids, mixing of particles is reversible, i.e., mixed solids, on storage, tend to segregate, primarily because of size differences; even marginal differences of 15–20% can cause 'unmixing.' Differences in other properties, such as density and

shape, can only accelerate the process of unmixing. It has been recognized that, in general, heavier, smaller, or smoother and rounder particles tend to percolate and sink through lighter, larger or jagged particles.

3. Mixing in liquids and gases is far more intimate than in solids. The ultimate mixing elements of a particulate mixture have a coarser texture, and are of a poorer quality.

Particulate materials may be broadly classified into two groups: (1) free-flowing or cohesionless powders and (2) cohesive powders. Cohesionless powders are mixed by convective transport, surface mixing and/or interparticle percolation; mixing and segregation occur simultaneously. Particles in cohesive powders move in clusters.

Mixers used for solids are normally batch type. Solid mixers can be broadly classified as: (1) tumbler mixers, (2) convective mixers, and (3) hopper mixers. A V-shaped tumbler mixer is shown in Figure 6. The vessel is typically filled to about half its volumetric capacity and is rotated on an axis between bearings, thus causing the particles to tumble and roll over each other. In the case of convective mixers, the mixing vessels are stationary, and the solids are agitated by impeller blades, usually of a ribbon or screw type. Cohesionless powders can also be mixed by discharging a mixture of the components through hoppers. Radial and axial mixing is achieved by returning the discharged material to the top of the hopper and repeating the process until the solids are completely homogeneous.

Mixing of Doughs and Batters

Dough and batter, used in the making of bakery products, are formed by a series of agitation-induced interactions of such diverse components as water, flour, lipids, enzymes, salt, sweeteners, yeast, air, and oxidizing and reducing agents. When classified on the basis of the desired agitating action, most bakery products fall into two broad categories, *extensible doughs*, such as those used to make bread or puff pastry, and *flowable* or *friable mixtures*, used in the preparation of cake batters, icings, etc. (*See* **Bread**: Dough Mixing and Testing Operations.)

Mixing of doughs is more complex and energy-intensive. Although continuous processes are now being developed, mixing of doughs is invariably carried out batchwise in one or many stages. Single-stage mixing is mainly adopted by smaller bakeries, and it aims to complete dough development within its duration. However, in a two-stage process, the initial stage has a shorter duration, and it accomplishes blending and flour hydration (or hydration of the gluten proteins). Dough development and strengthening of the gluten network occurs more gradually during the second stage, promoted by repeated folding and stretching action caused by the mixer. An undesirable effect of the intense shearing action, especially in high-speed mixers, is the rapid increase in dough temperature. Provision for simultaneous cooling therefore exists in most mixers. Careful control of the process is necessary to obtain a dough structure optimum for baking purposes: at the right end point, the dough has maximum consistency or minimum mobility; it appears smooth with a dry surface, and its elastic character is optimized. The end point is reached when the dough starts to pull away from the mixer walls. Overmixed dough, however, is sticky and difficult to handle, and its surface possesses a characteristic sheen.

The agitator in a dough mixer is mounted either on a horizontal shaft or on a vertical shaft. Vertical shafts generally rotate about a fixed axis; in some cases, planetary motion is also superimposed. In either case, there is a close clearance between the agitating blades and the mixing vessel, in order to eliminate stagnant regions and build-up of sticky material on the wall.

AIR CLASSIFICATION

Contents

Principles of Operation

P Fedec, POS Pilot Plant Corporation, Saskatoon, Saskatchewan, Canada

Background

In simplistic terms, air classification is a means of using air to effect a dry separation of objects having certain characteristics. These characteristics include physical properties such as size, shape, density, and physicochemical nature. Air classification is an operation that applies the technology to fractionation of nonhomogenous particles, suspended in an air stream, into classes of fairly uniform size based on a common criterion of density or mass. Whereas some segregation of light and heavy particles can be achieved by aspiration where airflow patterns are generated by only a vacuum, true air classification makes use of airflow induced through centrifugal motion with the assistance of a vacuum. Generally, air classifiers will segregate a heterogeneous particulate into two subclasses, one primarily below a targeted particle size (fine fraction) and the remainder above this size (coarse fraction). Air classification becomes a possible alternative when ordinary sieving fails to effect separation below 40 μm. Applications of air classification in the food industry separate particulates in the range of 2–60 μm, seldom exceeding 100 μm.

Factors Affecting Classification

In the ideal case, classification can be best achieved if the particles are uniform and homogeneous, spherical and smooth, and dry and easily dispersible. Practically, very few finely granulated mixtures exhibit these ideal properties. Other features such as particle geometry can affect the tragectory of particles in an air stream. Classification is also affected if some of the particles are porous, allowing fine particles to hide within the pores of the coarser particles.

Dispersibility is a key issue during classification. Materials containing moisture or oil, or exhibiting hygroscopic tendencies, are likely to agglomerate and resist classification. To minimize these effects, pre-classification techniques need to be considered, which may include additional grinding, vacuum drying, extraction by solvent, blending, dispersion, or deagglomeration.

The cell structure of food materials is one of the most important factors for the mechanical separation or dry processing. Application has primarily been in protein and starch separations of legume and cereal flours. Within the cell, the protein forms a matrix in which the starch granules are embedded. During comminution, the breakdown of this matrix into wedge protein or granular protein (and its size or homogeneity) is important and will affect the efficiency of classification (Figure 1). The cell matrix must shatter easily, and in addition, the protein matrix must disintegrate readily. If compound starch granules are present, they must remain intact. A significant number of particles (e.g., starch granules) must be above the selected cut point. Typically, impact milling is the comminution of choice.

Three particle-related factors of primary importance in achieving separation include: particle density, shape, and size. The difference between density of starch (1500 kg m^{-3}) and protein (1300 kg m^{-3}) is too small for density to have a significant role. Shape plays some role; in particular, starch granules flattened by impact milling exhibit increased air drag and unfortunately may concentrate in the fine fraction. Experience has shown that particle size is the predominating influence on the quality of air classification.

The particle size of the starting material is an important factor in that, generally, the particle must

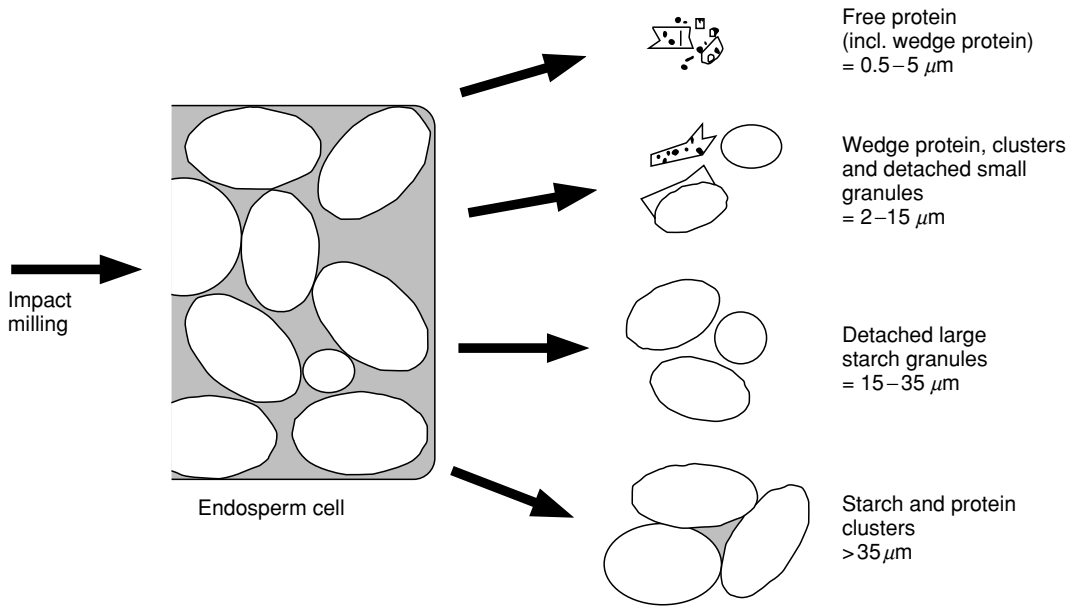

Figure 1 Conceptualized presentation of endosperm cells subjected to milling and subsequent fragmentation.

be less than 100 μm and preferably lower, with a significant number being below the selected cut size. For example, if the granular and wedge protein can be pulverized into aggregates of 2–10 μm in size, while the starch particles remain intact and are in the range of 15–45 μm, separation is possible (Figure 1). Some wedge protein of larger size will spill over into the coarse particle cut, and some small granules will spill into the protein or fine fraction. Products that do not have a significant difference in the sizes of components are not suitable candidates for air classification.

The moisture content of grains and legumes affects the ability to disintegrate the cell contents and dislodge the protein from the starch. Practice suggests that the moisture content for satisfactory comminution preceding air classification should be around 8%. Moisture contents above this value do not lead to an ideal size reduction, but a moisture below 6% can lead to starch granule fragmentation and subsequent spill-over into the fine fraction.

No well-documented research has been carried out on the influence of fat content of the starting material on air classification, but in general, fat contents have to be kept low in order to achieve dispersion in the centrifugal zone and minimize bridging in and around rotors, vanes, and passage-ways. Generally, a 1–2% fat content is the limit, although some results have indicated that flours having up to 7% fat are separable by some classifier models, but prolonged operating times with sustained quality of separation have not been established.

Sharpness of classification is affected by the feed rate, and generally, as rates are elevated above optimal, the sharpness decreases.

Air-classifier Operations

Air-classifier operation is influenced by air-flow dynamics on suspended/dispersed particles of typically less than 100 μm. The term 'cut size' is used in conjunction with discussing the segregation of the two fractions.

If a predetermined particle size were selected (e.g., typically 15 μm in flour applications), a theoretical ideal classification would permit a subdivision of a mixed particle feed stock into two fractions: a fine fraction below the predetermined size and a coarse fraction above it. Figure 2a depicts such a segregation of fine (shaded) and coarse (clear) fractions.

Under practical conditions, such a sharp separation cannot be achieved, and the separation is more realistically observed as shown by the curves in Figure 2b. A single 'cut size' is not achieved; rather, there is a range of particle sizes present in both the fines and coarse fractions, and these overlap in the region of a nominal cut size. The less the overlap, the better is the separation efficiency.

The two major forces affecting air classification are the drag or frictional force exerted on the particle by the air flow and an inertial force exerted by the accelerated motion of the particles. The latter is generally achieved by a centrifugal field or rotational air flow through use of a rotor. A typical example of forces

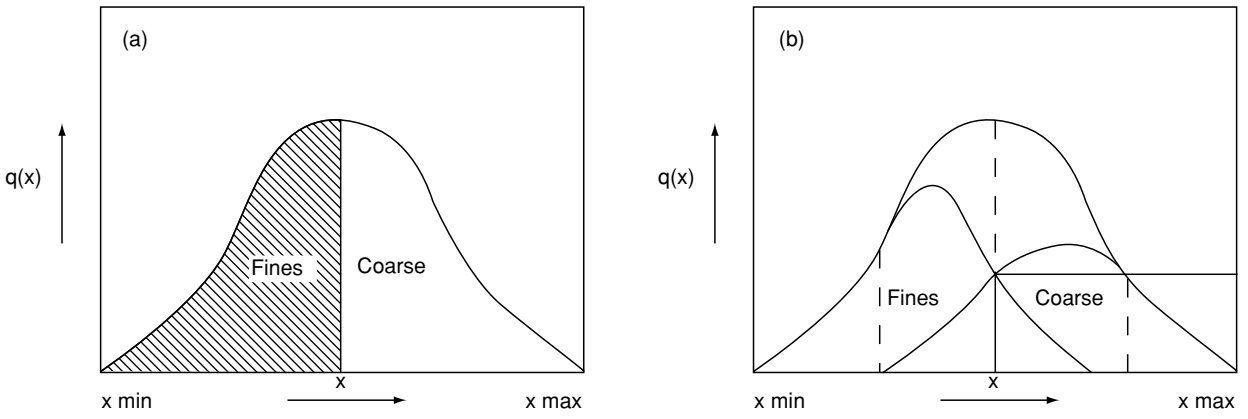

Figure 2 Classification phenomena: (a) an ideal classification; (b) a real classification. Adapted from de Silva SR (1983) Developments in air classifier theory and practice. In: *Institution of Chemical Engineers (Gr. Br.) Symposium Series*, vol. 69, pp. 387–410, with permission.

acting within a classifier is shown in Figure 3. A particle ('G') of a certain diameter and density is exposed to two opposing forces, the centrifugal force (F) produced by a rotating assembly and frictional force (R) produced by an air flow. Additional and more complex mathematical models can be found in articles by Vose and de Silva. As the air flows inwards in a spiral path, particles entrained in the flow are subjected to the opposing forces F and R. Larger particles are dominated by the mass-dependent centrifugal force, whereas small particles are influenced by the frictional force. When the forces are equal, a cut point or particle of a definite size can be established. The cut size can be adjusted by manipulating these forces within the classifier.

Design Styles of Air Classifiers

Many air-classifier variations are on the market. They can be subdivided into types based on their principles of operation. Some of the common types are detailed below.

Gravity Principle

This is the simplest design, has no moving parts, and consists of a zigzag-shaped classifying channel with internal baffling. It is generally used for gross separations, often for dissimilar materials that may be difficult to separate by simple separation techniques such as screening.

Free Vortex Principle

Air classification is achieved by adjusting a set of louvers located at the periphery of the classifying zone, which allows the superimposed radial air flow to enter the zone at an angle. Typical of this group are designs such as Pallmann Galaxy and Alpine Mikroplex. The latter (Figure 4) has been used in a large number of research studies, and significant data have been published. This design incorporates a rotor on a horizontal axis, resulting in a vertical plane of centrifugal force, whereas most others use a horizontal plane that favors greater throughput but with a reduced precision in cut size. The Mikroplex MPS model has been discontinued, but many are still in industrial operation. Feed rates vary from 50 to 5000 $kg\,h^{-1}$, depending on the model size. Classifiers manufactured by Larox operate on the same principle, but the peripheral vanes are not adjustable. The cut size is adjusted by manipulating the air flow produced by a blower.

Forced Vortex Principle

The force is provided by means of a turbine or rotor that disperses the particles into an air stream applied by a suction fan. Variations in equipment design then use air streams to select fine or coarse particles. The Bauer Centri-Sonic was typical of this design and was used commercially for cake flour separation as well as much research, but its precision honeycomb rotor was costly to manufacture, and the equipment has been discontinued. A new breed of classifier, often referred to as the turbine classifier, is now being utilized for fine powder separation (3–150 μm). These may incorporate single or multiple turbine classifier wheels in either vertical or horizontal configuration. The MikroPul Micron Separator illustrates this concept (Figure 5). Other manufacturers using this principle include Hosokawa Micron, ABB Raymond, and Alpine ATP series classifiers, as well as those manufactured by Nisshin, Sturtevant, and Matter and Partner.

Additional but less popular classifier designs used mixed vortex, countercurrent, cocurrent, or crossflow principles. Some are experimental, and others have not been applied to the food industry.

Combined Mill/classifier Units

In the food applications area, no appreciable technological changes to classifier design have been made in

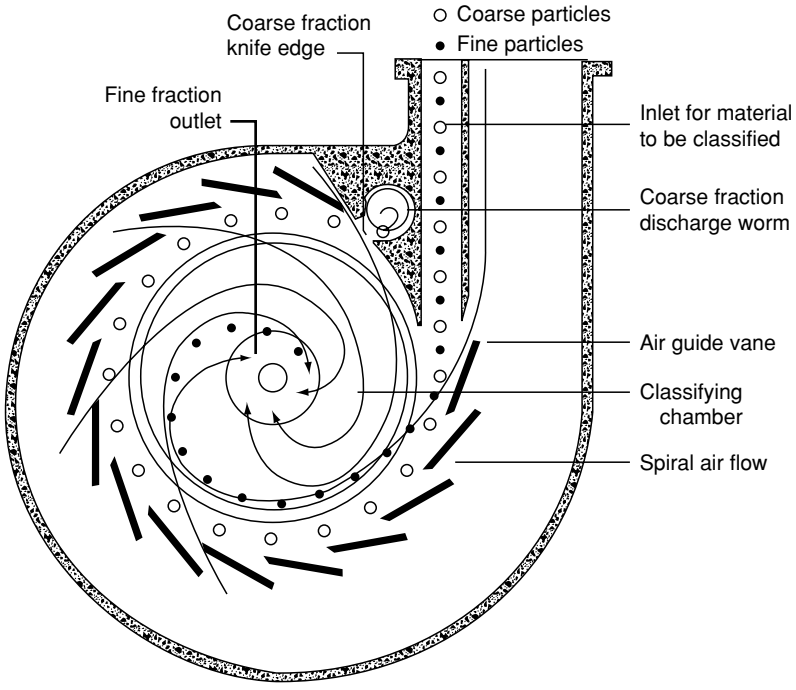

Figure 4 Frontal cross-section view of a Mikroplex MP spiral classifier. ○, coarse particles; ●, fine particles. From Hosokawa Micron International Inc. Catalogue 31/6e. Summit, NJ with permission.

recent years, primarily because the profit margins are low in this industry, thus providing little incentive for spending resources on further development and refinement.

To reduce operating costs, interest has focused on equipment that combines the required fine grinding with classification. One such unit is the Mikropul ACM Air Classifier Mill. The basic operation includes a high-speed impact mill through which an air stream is drawn containing the raw material. The product/air mixture enters the milling chamber, after which the product is then accelerated by the rotor towards peripheral guide vanes into the classification zone. Here, the particles are acted upon by centrifugal force in a centripetal airstream, and lower-mass fine particles are separated and conveyed out of the mill to a collector. The coarse particles are directed back to the grinding zone for further size reduction. The rotor speed and air flow are adjusted to maximize mill performance in a given application.

Plant System Designs

The typical installation consists of a centrifugal fan generating a vacuum draw to a baghouse collector. An additional scrubber for fine particulates may be included after the baghouse filter, and some designs use an optional cyclone ahead of the baghouse collector. The fines separated by the classifier are drawn into the collector, whereas the coarse particles are usually rejected by one of several ways, either in an auger system, in an air stream to a cyclone, or within a cyclone built into the classifier. The classifier may be fed from a silo of premilled material or may be directly coupled to a fine grinding mill. This direct coupling method has received criticism in that changes in material composition or particle size, owing to stratification, affect the classifier cut fraction and thereby the final product composition, especially if the latter is being packaged directly from the process line. Ancillary equipment includes rotary air

locks for the collectors, filter assemblies, discharge devices, blow-out relief doors, monitoring and control devices, blowers, silencing devices, and pulse jet filter cleaning apparatus.

Some operating facilities, in particular for legumes, have used a double milling, double classification design sequence, where the initial mill is followed by a classifier, the coarse fraction remilled and reclassified, thereby yielding a final coarse fraction and two fine fractions that are generally pooled. This plan strives to increase the quantity recovered as fines, although their quality may be compromised, and to improve the purity of the coarse fraction.

Safety factors that should be considered in an installation include dust inhalation, noise hazard, vibration, and dangers of explosion from fine dusts, which are ignitable under certain conditions.

Operating Conditions

In addition to the features of the feed material as given by the composition, nature of particles, product uniformity, and premilling influences, the variation of cut point, and, subsequently, the quality/content of the separated fractions can be manipulated by classifier variables such as the rotational speed of the rotor or disintegrator, the amount of air flow through the classifying chamber and the velocity of the air flow (both can be altered by either adjusting air intake or the external booster fan), degree or angle of vane setting, which deflects flow, and finally the rate of feed delivered to the classifier. These options vary in both availability and degree of adjustment, depending on the manufacturer of the equipment. Some classifiers allow for easy adjustment of fineness from an external position while the unit is operating, whereas others can be adjusted only after partial disassembly (i.e., such as alteration or adjustment of numbers or sizes of selection plates). However, with proper manipulation of these parameters, the classifier can produce a quality separation of high efficiency and yield.

Supplemental options are available for special applications whereby water cooling may be applied to the outside cone of certain separators to satisfy the needs of the cooling product (prior to packaging) that has developed a temperature rise during the milling and classification sequence.

When selecting systems for an application, there is no substitute for actually trying out a system on the materials intended for classification. Most manufacturers maintain laboratory and pilot plant test facilities, where various types and sizes of classifiers may be tested for separation efficiencies. Some independent contract research centers are also able to conduct exploration and demonstration testing.

Uses in the Food Industry

P Fedec, POS Pilot Plant Corporation, Saskatoon, Saskatchewan, Canada

Background

Air classification is a technology that is based on physical principles, and therefore, the use of chemicals is precluded, and protein denaturation is avoided, as is the formation of artifacts. This dry treatment also avoids the production of polluting effluents and minimizes or obviates drying costs. Two of its negative aspects are that there may be a retention of antinutritional or undesirable components in one or both fractions, and neither of the

fractions produced is 'pure' when compared to those obtained through conventional wet processing; hence, applications for products produced often need to be developed.

Application to Grain Legumes

Considerable research work on the milling and classification of nonoleaginous, starchy legume seeds has been carried out in Canada at the National Research council Prairie Regional laboratory and the University of Saskatchewan, both in Saskatoon. Although a wide number of species were studied for their potential to commercialization, the focus on field peas led to the adoption of this dry separation process by industry. Similar procedures were adopted in France for the production of fababean protein concentrate. Other centers that have also explored fine grinding and air classification in legumes include the Agricultural and Food Research Council Food Research Center and the University of Reading in the UK, the Technical University of Denmark, the Michigan State University in the USA, and the Korean Food Research Institute. Most researchers have employed pin mills for fine grinding of the seed, and a majority have focused on using the Alpine Mikroplex MPS series classifiers, although Alpine Zig Zag and Bauer Centri-Sonic series were also used. Recently, studies have shown that the use of jet air mills has given flour grinds having a mean particle size of $< 40\,\mu m$, which has improved separation of flour into protein and starch fractions.

A flow diagram for the process developed at the Canadian Prairie Regional Laboratory and applied to legumes is shown in Figure 1. Researchers have found that the milling of the seed is of overriding importance to the air-classification process. Efficient size reduction in the initial milled flour should lead to improved separation of the protein and starch components. Examining Figure 1, whole or dehulled seeds are finely ground in a pin mill and the resulting flour classified in a spiral air stream classifier, set to a predetermined cut point, resulting in the production of a fine (protein) fraction (F) and a coarse (starch) fraction (C). After the first pass, some protein bodies still remain attached to the starch granule surface, and some agglomerates remain, having starch granules embedded in a protein matrix. A second milling of the starch fraction disrupts these complexes further, and a second classification generates additional protein (G), albeit at a reduced yield and protein cont ent, and a final starch fraction (E) with low levels of protein.

In a typical example, the two-run process on field peas generated a combined protein fraction of 34.1% yield and a protein content of 56.6% (Figure 1). For fababeans, a protein fraction of 37.2% yield and a protein content of 68.1% was produced. Starch fractions contained 6–7% residual protein. Repeated pin milling and air classification studies show that the starch fraction can be further purified, but even after four runs, the residual protein is still around 3% for field peas. It follows that little is to be gained from a process based on more than two runs, and, depending on economics, it may be sufficient to use only a single-run procedure.

A comprehensive review of the published data would be beyond this article. However, to give the reader an overview of what may be achieved/expected from various legume flours, a summary table (Table 1) has been prepared. By way of caution, it should be noted that the data are drawn from a range of classifier types and operating parameters on starting flours with varying initial protein levels prepared by employing a wide assortment of grinding mills from seed with varying moisture contents. The data are presented as min–max ranges recorded in the literature. All data shown are based on a single impact milling followed by a single air classification, generally using dehulled seeds.

Low fine fraction yields have a correspondingly higher level of protein content as well as a higher protein level in the coarse (starch) fraction. As the yield of fines increases, the protein content of the fine fraction decreases, and the quantity of the coarse fraction will show a decrease. The protein content in the coarse fraction will decrease, and correspondingly, the starch proportion will increase. In all cases, the recovery of protein into the fine fraction is not as efficient as the recovery of the starch into the coarse fraction.

The initial protein content of the legume flour has an influence on the classification result. At the same yield or split ratio, higher protein levels in the starting flour will result in a higher protein content in the fines fraction. Alternatively, if the protein content in the fines fraction is kept constant, a higher yield of that fraction can be expected. Finely milled, defatted soybean meal has been added to Table 1 for comparative purposes and serves to indicate that, unless there is a high proportion of relatively large and uniform starch granules, a shift of protein cannot be accomplished, despite achieving a separation into two fractions.

Comparing the legumes, good separation may be expected with faba, lima, mung, navy, Great Northern beans, lentils, peas, and cowpeas. Especially high protein concentrates have been achieved from finely ground fababean flour. Chickpeas are a poor candidate for air classification, presumably because of the

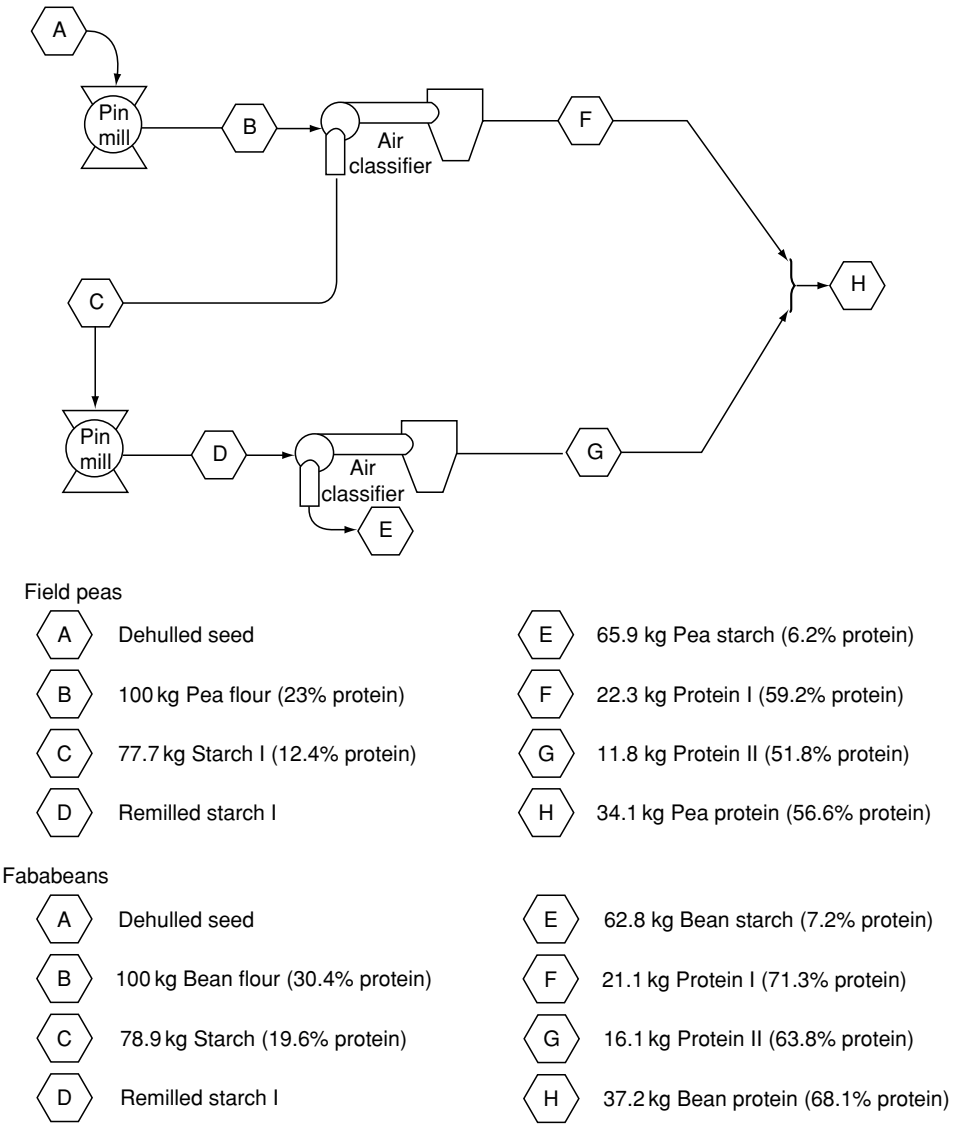

Figure 1 Double-pass milling and air classification sequence for legumes. Adapted from Tyler RT, Youngs CG and Sosulski FW (1981) Air classification of legumes. I. Separation efficiency, yield and composition of the starch and protein fractions. *Cereal Chemistry* 58: 144–148, with permission.

higher oil content in the flour and a high proportion of small starch granules.

The separation efficiency (i.e., the percentage of total protein recovered in the fine fraction or the percentage of total starch recovered in the coarse fraction) is dependent upon moisture at the time the legumes are milled. In peas, an increase in moisture to 14% from 10% reduces the separation efficiency by 20%. As the seed moisture decreases, there is a decrease in the starch yield, in the protein content of the starch fraction and in the protein content of the protein fraction. However, there is an increase in the yield of the protein fraction as well as the protein separation efficiency. It has been suggested that a moisture range of 8–10% is ideal for an impact-milling, air-classification process operation in legumes.

The effect of seed maturity on air classification suggests that the presence of immature seeds, even at high levels, has little effect on subsequent milling and classification. There is concern that green and shrunken seeds may make dehulling difficult and translate to high fiber levels in the starch fraction.

The protein content of the starting flour, and initially of the seed supply prior to milling, has a significant effect on fractionation. In a study of widely varying protein content pea flours, it was noted that the percentage protein in all air-classified fractions

[a]On a percentage dry-weight basis.
[b]Data are shown as a range of reported values from assorted classifier types and settings.

was positively correlated to the percentage protein in the flour, whereas lipid and cell wall material was negatively correlated. Starch and protein separating efficiencies generally increase with increasing protein content. An unpublished rule of thumb has been applied to evaluating the potential of legume seed for air classification. If the flour is finely milled and a 33% fines fraction yield is sought, the protein content of that fraction is apt to be 2–2.5 times the initial protein value of the flour. To insure uniform products by air classification technology, it is suggested that, in any particular legume being processed, the seed falls within a narrow range of protein content.

Shifting of other components also occurs as a result of air classification. In terms of fiber material present in the flour, the hull fiber tends to segregate into the coarse fraction and the cell wall fiber into the fine fraction. Dehulling may enhance the efficiency of the process somewhat and may be a prerequisite if colored hulls are present. If the coarse (starch) fraction is of lesser importance, dehulling need not be practiced as it only has a small effect on the crude fiber content of the protein fraction.

Legume flours containing α-galactosides, especially raffinose, manninotriose, stachyose, and verbascose, generally show the protein fraction to be 40–90% higher in these components than the initial flour, while the starch fractions become depleted. Legumes with trypsin inhibitors, hemagglutinating factors, saponins, phytic acid, vicine, and convicine will exhibit elevated concentrations of these components in the protein fractions.

The protein fraction from legumes also tends to be enriched in ash and lipid, the latter having undesirable ramifications in storage of the concentrate. The lipids likely occur as a result of the presence of a lipid-rich coating on the protein bodies.

Protein concentrates prepared by air classification may be used as emulsifiers or supplements in meat products and patties, beverages, bread, noodles, and spaghetti. Cowpea flour fractionated into enriched protein and starch concentrates has been applied to produce emulsifiers and starch jellies. There may be a requirement to inactivate some of the antinutritional factors. The starch fractions are increasingly being utilized in the paper industry, especially carbonless paper. Some use of pea starch was made in ore refining, but this has been sporadic. Nevertheless, peas have shown the greatest potential for commercial application of air-classification technology. There are few major nutritional or technological problems except for the 'pea flavor' and, in some cases, a darker green color in some end products. The main obstacles to success in classification stem back to basic agronomics, the guarantee of a year-round supply at a competitive price and of high quality, and establishment of markets for the products.

Application to Cereal Grains

Wheat Flour

The earliest work in application of air classification techniques to food products began in several United States labs (Peoria, Illinois and Manhattan, Kansas) with protein-shifting in wheat flours. Classification has generally been less efficient than in legume flours because of the high proportion of small starch granules that cannot be readily separated from the fine protein particles. Approximately 81% of the granules fall below 7.5 μm, the quantity by weight represented

in those fractions being equal to 4, 3, and 93%, respectively. In some studies, protein fractions having up to 40–50% protein (but yields of only 1.5%) were generated accompanied by a 20–30% protein fraction (< 15 μm) at a yield of 11–25%. Although this fraction could be used to enhance the protein content of foods, commercial use has not occurred. The starch fraction can be further processed by water extraction to remove the protein generating purified starch for food (e.g., puddings and thickeners) and industrial applications.

To obtain a protein-rich flour, a separation cut point of 15 μm is usually sufficient, especially in soft wheat. Two separations may be required, however, to obtain a low-protein starch fraction. As an example, 10.8% protein content soft wheat flour can be fractionated into three cuts: < 15, 15–35, and 35 μm, with yields of 12, 43, and 45% having 19.5, 7.1, and 12.0% protein content, respectively. In a single operation, a 20% yield of 21–22% protein fine fraction and an 80% yield of a coarse fraction having 7.5–8% protein can be achieved from soft wheat flour of around 10.5% initial protein.

Using soft wheat flour, air-classification methods have generated a very fine subfraction that is light, fluffy, and high in protein and total dietary fiber. Applications requiring such high-gluten flour are found in the bagel industry.

The protein-rich fractions generated from wheat can be used as the basis for preparation of protein isolates, or the high-protein fraction can be added to low-protein base flours to improve the dough and baking characteristics. This enhancement is due to the nature of the protein components present and the alteration of starch and ash components during air classification. As in legumes, the soluble sugars are also concentrated into the high protein fraction.

To improve the efficiency of fine grinding and subsequent air classification, it has been suggested that a treatment of 0.1–1.0% sulfurous acid be applied for several hours as an aid in loosening the starch protein complex. Sorghum subjected to such treatment has shown increased yields of protein-rich and starch-rich fractions.

Miscellaneous Cereal Flours

Barley, and especially dehulled malted barley, lends itself to successful separation by air classification. Dehulled malted seed with 11.5% protein can be impact-milled and classified into a high-protein, low-fiber fraction with 26–27% protein content and a starch portion of about 9.5% protein. The split ratio is in the range of 16/84. Regular dehulled barley with 15% protein has up to 40% protein in the fine fraction with a 17.5% yield. The benefits of such application may be in a defibered starchy malt or barley flour or a high-starch malt flour that may be used in rapidly brewed malt drinks. Applications for generating starch have shown that up to three passes have been used in some programs, thereby yielding fractions rich in large granule starch (77–78% starch), which, upon subjecting to wet extraction, produce an almost pure large-granule starch with a higher extraction efficiency than conventional extraction processes.

Similarly, high-fiber byproduct streams from the milling of rye have been impact-milled and reclassified to yield fractions that have enhanced soluble and dietary fiber levels.

β-Glucan-enriched Flours

Nonconventional use of the air-classification technique has been applied to oats for the purpose of generating a β-glucan rich bran fraction. More recently, focus has also turned to barley flour. Instead of classifying finely ground flour, oat groats have been coarsely milled and then subjected to air classification in order to produce a high-bran coarse fraction and a fine flour fraction. The bran fraction can serve as an enriched fiber source for cereal applications or as a starting material for the isolation of β-glucan concentrates. Other researchers have defatted the oat flour prior to air classification and noted that the coarse fraction (> 30 μm) had a β-glucan content of about 17% for a 30% yield. Inactivation of enzymes would be a prerequisite for the preparation of β-glucan fractions by wet extraction. Preparation of barley fractions (2–4% yield) has shown β-glucan values of 15–18%. Numerous researchers have confirmed these results with various waxy and nonwaxy barleys.

Other Minor Uses

Cottonseed proteins are rarely used in edible foods because of pigment glands containing gossypol. Air classification has been shown to produce an edible protein fraction if there is minimal pigment gland damage during the milling of extracted flakes. Yields of 35–40% protein-rich fractions with up to 65% protein and meeting food and drug directorate standards are possible.

Finely ground soybean hulls have been air-classified into fine and coarse fractions with enriched fiber. Application of this fraction in frying batters reduces oil absorption. Substitution of wheat flour by 20% in cakes increases volume and acceptability. The protein fraction from the soybean hulls may yield increased quantities of trypsin inhibitor with anticarcinogenic properties.

Utilization of rapeseed and canola meals could be enhanced if crude fiber levels could be reduced by on-half or less. Small protein shifts of 11–17% have been achieved in roughly 50/50 splits, but in spite of the fiber being shifted into the coarse fraction, the two end products are not sufficiently improved to warrant commercialization.

Although rice protein has a high nutritional value, attempts at recovery of this protein by air classification have failed to demonstrate any significant protein shifting. Air classification of defatted finely ground rice bran has provided a high-protein bran fraction of a 50% yield and 23% protein content from an initial 19.4% protein level in the flour. Unfortunately, the ash content of the protein-enriched fraction is also increased, rendering the product unsuitable for direct food use.

Potato granules produced by spray drying from a wet milling process have been successfully classified. Granules with about 10% protein have been classified into a 15/85 fine:coarse ratio having 38 and 3.1% protein, respectively. Assuming that the economics of spray drying is favorable, the protein fraction can provide a source of nondenatured protein concentrate for food applications.

Other miscellaneous applications of air-classification principles to food products include the production of fine confectioners sugar ($< 5\,\mu$m) and fine cocoa powder ($< 75\,\mu$m), the latter being used to make top-quality, smooth chocolate products. Recent investigations have shown a possible means of generating flax lignan involving the use of hull material removed from flaxseed by pearling then subjected to classification yielding a fraction rich in lignan and water-soluble fiber. The lignan can be extracted sequentially and used in the nutraceutical industry.

The combined air-classifier mills have recently found some applications in the food industry, including milk powder, sugar, alginates, gelatine, wheat gluten and flour, cocoa powder, casein, and starches.

Air-classification techniques applied to finely ground flours have produced a wide range of protein/starch-rich fractions and with variable degrees of success. The process is advantageous in that drying and effluent disposal costs for wet plants are reduced or excluded, a significant factor from an environmental viewpoint. There is also some flexibility for the processor to vary the resulting flours to suit the end-user. Increases in capital and operating costs for the operation must be considered in light of these benefits.

ALCOHOL

Contents

Properties and Determination

A T Bakalinsky and M H Penner, Oregon State University, Corvallis, OR, USA

Introduction

The earliest written records indicate that alcohol (ethanol or ethyl alcohol) has been enjoyed in the human diet for thousands of years. In spite of past and present prohibitions among some groups, an impressive number and variety of alcoholic beverages have been developed, refined, and extolled in an extensive and rich literature. While the discovery of alcohol was undoubtedly accidental, its microbial origin was only established some 120 years ago through the work of Louis Pasteur. Microbial physiologists have since shown that alcohol formed through different fermentative pathways in various microbial species always serves the same purpose: regeneration of an oxidized cofactor, usually the oxidized form of nicotinamide adenine dinucleotide (NAD^+).

Major classes of alcoholic beverages include primary products of alcoholic fermentations (beer and wine), products of mixed alcoholic–lactic acid fermentations, and since the discovery of distillation – known to the Chinese at least 3000 years ago and to the ancient Egyptians even earlier – distilled and fortified beverages. Because alcohol is an excellent extractant, exhibits low toxicity, and possesses antimicrobial activity, it also enjoys wide use as a solvent for food ingredients such as spices and flavors. (*See* **Lactic Acid Bacteria**.)

Physical and Sensory Properties

Ethanol is a clear, colorless, flammable liquid miscible with water and many organic solvents in all ratios. It is hygroscopic and relatively nontoxic, exhibiting an oral LD_{50} in rats of 13.7 g kg^{-1} (grams of ethanol per kilogram of body weight required to kill 50% of the animals). When ethanol is added to water, a rise in temperature due to the heat of solvation occurs with a consequent increase in volume. When the mixture cools to the original temperature, the volume decreases, becoming slightly less than the sum of the initial water and ethanol volumes. Maximum contraction occurs at a molar ratio of eight parts of water to one part of ethanol. At a pressure of 101.3 kPa, a mixture of 95.6% ethanol and 4.4% water on a mass basis forms a constant-boiling-point mixture called an azeotrope. In practice, this means that the concentration of ethanol cannot be increased beyond 95.6%, by simple distillation. Some important physical properties of ethanol are listed in Table 1.

Ethanol has a slightly sweet taste and a characteristic aroma. The aroma threshold determined in one study ranged from 4 to 5 mg of ethanol per 100 ml of

Table 1 Physical properties of ethanol

Formula	CH_3CH_2OH
Molecular weight (Da)	46.07
Boiling point (°C)	78.32
Freezing point (°C)	−114.1
Density, d_4^{20} (g ml^{-1})	0.7893
Refractive index, n_D^{20}	1.361
Viscosity at 20 °C (cP)	1.17
Dielectric constant at 20 °C	25.7
Heat of fusion (J g^{-1})	104.6
Heat of vaporization at 78.32 °C (J g^{-1})	839.31

total aqueous solution. At high concentrations, it causes a burning sensation in the mouth. It moderates the taste of acids, as shown by the greater tartness of dealcoholized wines relative to the same untreated wines. It is said to impart 'body,' which may be due to the fact that at room temperature it is more viscous than water. Addition of sugar to an ethanol–water solution increases the threshold for ethanol, indicating that sugar masks its taste and/or aroma.

Sources of Alcohol

The natural source of alcohol is fermentation which has been defined as the oxidation of organic compounds (generally carbohydrates) in the absence of external electron acceptors. Pasteur called it 'life without air.' Microorganisms ferment in order to obtain the energy necessary for growth and reproduction and alcohol is one of several possible fermentation products. In most countries, use of alcohol in beverages is restricted to that made by fermentation. The vast amount of alcohol used industrially as a solvent and substrate in chemical syntheses is made synthetically from ethylene. The amount derived from the fermentation of agricultural products is largely dependent on economic considerations, e.g., alcohol produced by fermentation is used as a substitute for petrol in Brazil.

Alcoholic Beverages

All alcoholic beverages are derived either directly or indirectly from fermented products. As indicated in Table 2, the major groups are fermented beverages, products of mixed alcoholic–lactic acid fermentations, beverages made by distillation and by fortification. Fruits containing high sugar concentrations at maturity and nutrients at levels sufficient to support growth of fermenting yeasts, primarily *Saccharomyces cerevisiae*, have traditionally been the raw materials from which wines are made. Grapes are unusual in that they contain sufficiently high levels of sugars, nutrients, and acids to produce wines that are microbiologically stable.

Table 2 Major classes of alcoholic beverages

Fermented
Beer
Wine
Sake
Mixed alcoholic–lactic acid fermentation
Kefir
Koumiss
Distilled
Whiskies, vodka
Rum
Brandy
Tequila
Liqueurs
Fortified
Port
Sherry
Vermouth

Beer and sake are produced from barley (other grains are possible sources) and rice, respectively. Unlike wines, these beverages are derived from carbohydrates that are not initially fermentable. Conversion of carbohydrates into fermentable sugars requires the action of amylases produced by barley in the case of beer, and by the fungus *Aspergillus oryzae* during sake production. Kefir and koumiss are examples of beverages produced by the fermentation of cows' and mares' milk, respectively, by a mixture of lactic acid bacteria and lactose-fermenting yeasts. Although almost unknown in some western countries, kefir and koumiss continue to enjoy great popularity in eastern Europe. (*See* **Beers**: History and Types; **Fermented Milks**: Other Relevant Products.)

Distilled beverages are derived from fermented grains and potatoes (whiskies and vodka), sugar cane byproducts (rum), fruits (brandies), and other plants such as mezcal (tequila). Liqueurs are distilled beverages that have been flavored and sweetened. Fortified beverages require the addition of alcohol during production, generally in the form of brandy. Special fruit preserves are fortified to assure preservation. The intact fruits, usually cherries, are steeped in brandy for a period of months prior to consumption. (*See* **Brandy and Cognac**: Armagnac, Brandy, and Cognac and their Manufacture; **Rum**; **Whisky, Whiskey, and Bourbon**: Products and Manufacture.)

Use as a Preservative

Ethanol is not particularly toxic. As a sole agent of preservation in beverages, minimum concentrations ranging from 18 to 21% by volume are required to assure microbiological stability. Table wines which contain significantly less alcohol are stable because of additional factors: their natural high acidity, low pH, high content of phenolic compounds, and lack of sugar. The toxicity of ethanol towards microorganisms is due to a number of effects. At very high concentrations, as in flavor extracts, ethanol acts as a desiccant and protein denaturant. At lower concentrations, 10–20% by volume, the toxicity is believed to result primarily from interactions with cell membranes. In the yeast *S. cerevisiae*, ethanol has been shown to inhibit several solute transport systems. In the presence of sugar, the toxicity of ethanol is enhanced. This explains the stability of a class of sweet

dessert wines which contain several percent sugar and only 7–10% ethanol.

Analysis

Several methods are available for quantitative measurement of ethanol. Some are based on ethanol-specific chemical reactions, such as dichromate and enzyme-catalyzed oxidation. Others are based on selected physical properties of the product or sample which are functions of its ethanol content, such as boiling point or relative density. Often, separation of the ethanol from other compounds by chromatography, distillation, or other means is required prior to quantification. The choice of method depends on the need for accuracy and precision, analysis time, potential for interfering substances, and expense. (*See* **Chromatography**: Principles.)

With respect to interfering substances, it is worth noting that methanol is a minor but potentially toxic constituent of distilled beverages derived from fruits. It is formed from hydrolysis of methoxylated fruit pectin and does not interfere with enzymatic or chromatographic methods of ethanol analysis.

Boiling Point Determinations (Ebulliometry)

Boiling point depression is probably the most commonly used measure of ethanol in liquid systems. The method is based on Raoult's law of partial pressures. Under ideal conditions, the law states that the total pressure above a mixture of two miscible liquids is equal to the sum of their partial pressures, and that the partial pressure of each component is directly proportional to its mole fraction in the mixture. Stated mathematically:

$$P_T = P_A + P_B = P_A^0 X_A + P_B^0 X_B \qquad (1)$$

where P_T is the total pressure above a solution of liquids A and B, P_A is the partial pressure of component A, P_B is the partial pressure of component B, P_A^0 is the vapor pressure of component A above pure liquid A, X_A is the mole fraction of component A in the mixture, P_B^0 is the vapor pressure of component B above pure liquid B, and X_B is the mole fraction of component B in the mixture. Ethanol–water mixtures have boiling points ranging from slightly less than 78.32 °C (100% ethanol) to 100 °C (0% ethanol) at 101.3 kPa pressure. The ethanol–water azeotropic mixture (95.6% ethanol, w/w) boils at 78.2 °C. Deviations from Raoult's law are exhibited by mixtures of nonideal liquids, in which significant molecular interactions occur between components. Ethanol–water mixtures are examples of nonideal systems because ethanol exhibits significant hydrophilic character. Generally, the boiling point of pure water is measured in addition to that of the sample and tabulated ethanol content–boiling point data are adjusted accordingly, to account for variations in atmospheric pressure. To prevent significant evaporative loss of ethanol during boiling and measurement, ebulliometers are fitted with a small condenser, and readings are taken shortly after a constant temperature is attained.

Boiling point measurements require relatively large samples – up to 50 ml – which limits their utility. Their accuracy is reduced in the presence of high concentrations of other dissolved solutes. Since ebulliometers are simple devices, relatively inexpensive, and sufficiently accurate for production purposes, small wineries have used them extensively.

Relative Density Measurements (Hydrometry)

Relative density (specific gravity) is the ratio of the density of a solution to the density of a reference solution (usually water at 4 °C). Relative densities of aqueous solutions are dependent on the concentration of dissolved solutes. Two general approaches are used to obtain relative densities.

The first is to measure the mass of known volumes of sample and standard reference solutions. This is accomplished by use of a pycnometer, a small, relatively lightweight flask of known volume. Since specific volume is temperature-dependent, the pycnometer is immersed in a water bath maintained at a standard temperature. The mass of the sample and reference solutions is then determined on an analytical balance and compared to tabulated standard values. The relative density of aqueous ethanol solutions reflects the concentration of ethanol, assuming it is the only (or major) dissolved solute.

The second general approach is based on Archimedes' principle, which holds that an object immersed in a liquid appears to lose an amount of mass equivalent to the mass of liquid it displaces. The Westphal balance illustrates this principle. Its design is similar to that of an equal-arm, two-pan balance. At one end, a tube of known volume and weight is immersed in a reference solution and the beam is balanced by addition of weights to compensate for the buoyancy of the liquid. The procedure is repeated by immersion in the unknown liquid sample. In this manner, a relative density is determined. A more commonly used device, based on the same principle, is the hydrometer. Hydrometers are glass instruments with narrow, calibrated stems much like a thermometer at the top, but with much expanded bottom halves that are weighted with lead to insure that they float upright. When the hydrometer is placed in a liquid sample, it sinks to a depth that results in displacement of a volume of liquid equal to its weight. The alcohol

content is read from the calibrated stem at the point where it intersects the liquid surface. Hydrometers designed for alcohol measurement are standardized for use at a specific temperature and calibrated either in percent alcohol (v/v), or °proof, where °proof = 2 × % ethanol (v/v). Correction tables are available for measurements taken at nonstandard temperatures. Hydrometers are accurate over a limited range of alcohol concentrations. Consequently, a set of instruments may be required to cover the range of interest.

Since the relative density of a solution depends on the concentration of all dissolved solutes, it is often necessary to separate the ethanol from the other solutes. To accomplish this, the ethanol contained in a specified volume of product is separated by distillation. The distillate is diluted to a known volume with water, and the relative density of the resulting solution is measured. In fermented beverages, the concentration of other volatiles that codistill is significant from a sensory perspective, but is very low compared to that of ethanol and does not significantly affect the relative density. In some beverages, such as bourbon whiskey, the concentration of soluble solids other than ethanol is sufficiently low to permit direct measurement of relative density without need for distillation.

The international Association of Official Analytical Chemists (AOAC) has approved methods based on specific gravity for determination of ethanol in distilled beverages, beers, and wines. The methods require relatively large samples, and are somewhat tedious due to the need for distillation and strict temperature control. However, the equipment is relatively inexpensive and readily available, and precise results can be expected from a skilled technician.

Enzymatic Determination

The enzymatic analysis of ethanol is generally based on the reaction catalyzed by alcohol dehydrogenase. As shown in eqn (2), the oxidation of ethanol by NAD^+ yields acetaldehyde and NADH.

$$\underset{\text{Ethanol}}{CH_3CH_2OH} + NAD^+ \rightarrow \underset{\text{Acetaldehyde}}{CH_3CHO} + NADH + H^+ \qquad (2)$$

The reaction is monitored photometrically at 340 nm since NAD has no significant absorbance at this wavelength in the oxidized form (NAD^+), but has a molar extinction coefficient of $6.23 \times 10^3\,l\,mol^{-1}\,cm^{-1}$ when reduced (NADH). Primary alcohols other than ethanol can interfere, but this is rarely a problem in foods. Determination of ethanol concentration requires that conditions be adjusted such that the equilibrium is shifted toward acetaldehyde formation. One approach is to trap the aldehyde as it forms by reaction with semicarbazide. Another is to carry out the reaction at alkaline pH. A third is to couple the reaction with a second enzyme, aldehyde dehydrogenase, which converts the acetaldehyde to acetic acid. In the latter case, 2 mol of NADH are formed per mole of ethanol. (*See* **Enzymes**: Uses in Analysis.)

Enzyme assays have high sensitivity relative to other methods and good accuracy due to the specificity of the reaction. Often, samples require treatment such as dilution, pH adjustment, or decolorization prior to analysis. Material needs for this type of assay are simple: volumetric glassware, a photometer, and reasonable temperature control. A recurring expense is the enzyme itself, which must be stored and handled appropriately.

Dichromate Oxidation

Chemical oxidation may be used to quantify the amount of ethanol in a sample. In the dichromate procedure, the quantity of dichromate required to oxidize ethanol to acetic acid is measured. In complex beverages, the ethanol is usually separated from potentially interfering compounds by distillation. The ethanol in the ethanol–water distillate is then oxidized with a known excess of dichromate in the presence of sulfuric acid. Residual dichromate is then reduced by ferrous ammonium sulfate in a standard oxidation–reduction titration. A useful end-point indicator is 1,10-*o*-phenanthroline-ferrous sulfate, which turns brownish purple from blue-green. Potassium dichromate is available in sufficient purity to be used as a primary standard. Ferrous ammonium sulfate may be used as an approximate standard, but solutions that are not fresh must be standardized against dichromate.

The dichromate oxidation method for the measurement of alcohol in wines has been approved by the AOAC. The method is appropriate for routine analyses only when the reagents are standardized regularly.

Refractive Index

The refractive index (RI) of a medium is dependent on its chemical composition, since under controlled conditions composition dictates its electrical and magnetic properties. The RI of a sample is defined as the ratio of the speed of light in a vacuum to its speed in the sample medium. Consequently, RI values are always greater than one. The RI of aqueous ethanol solutions can be measured directly to indicate ethanol concentration. When interfering compounds are present, the RI of a distillate can be measured. Since the RI of a liquid is temperature-sensitive, measurements

taken at nonstandard temperatures must be corrected by use of conversion tables.

The AOAC has approved RI-based methods for determining ethanol in beers and wines. For wines, the measurement is made on the distillate. Measured RI values for beer are used in conjunction with specific gravity measurements to calculate ethanol content.

Chromatography

Chromatography is based on the separation of sample components due to their differing affinities within a stationary–mobile-phase system. A successful chromatographic run results in separation of the analyte of interest from all sample components that would otherwise interfere with its analysis. The separated analyte may then be quantified by one of several detectors. The ethanol in most samples can be readily separated by chromatography. Since ethanol is volatile, direct measurement by gas chromatography (GC) is possible. Several commercial vendors have columns specifically designed for determining the ethanol content of beverages. Simple, 2-m packed columns are commonly used. Depending on the sample, it is often beneficial to carry out a simple pretreatment to extend the life of the column by removing nonvolatile components. Ethanol exiting a GC column is commonly quantified with a flame ionization detector or by thermal conductivity. Ethanol separations using high-pressure liquid chromatography (HPLC) are also possible. An advantage of HPLC over GC is the possibility of simultaneous determination of certain nonvolatile sample components. Commercial HPLC columns for ethanol analysis are available. Chromatographic methods, which are expensive, are widely used in analytical laboratories because of their specificity, increasingly simple operation, and potential for automation. (*See* **Chromatography**: High-performance Liquid Chromatography; Gas Chromatography.)

Metabolism, Beneficial Effects, and Toxicology

C H Halsted, University of California, Davis, CA, USA

Background

Alcohol is both a food that provides 29.7 kJ g^{-1} (7.1 kcal g^{-1}), accounting for 5.6% of energy in the American diet, and a drug with potential for intoxication, addiction, and damage to several organ systems. In the USA, alcohol is consumed to some extent by at least two-thirds of the population, and an estimated 5–10% consume alcohol in excess and are at risk for addiction, liver disease, cardiomyopathy, pancreatic disease, and neurological defects. The overall mortality from alcoholism in the USA is about 100 000 deaths per year, about half due to accidents related to intoxication, and the remainder mainly due to chronic alcoholic liver disease and its consequences.

Metabolism of Alcohol

Unlike most other drugs, alcohol is completely metabolized after ingestion at a rate of 10–15 g h^{-1}, and its energy content is not stored in the body. Alcohol diffuses across all cell membrances, and after equilibration, its concentration is similar in all aqueous compartments. After the human ingestion of 50 g of alcohol, its concentration in the stomach reaches

Table 1 Alcohol metabolizing enzymes

Enzyme	K_m *(mM)*	*Related effects*
Gastric cytosolic alcohol dehydrogenase	500	'First pass'; 30% in men, 10% in women
Liver cytosolic alcohol dehydrogenase (one to two drinks)	2	Increased NADH/NAD ratio promotes fatty acid synthesis leading to fatty liver, preferential oxidation of ethanol over lipid, and reduced gluconeogenesis, lactic acidosis, and hyperuricemia
Liver microsomal CYP2E1 (more than two drinks)	20	Increased NADPH/NADP ratio consumes energy and increases metabolism of many other drugs and vitamin A; increased acetaldehyde inhibits mitochondrial functions and stimulates lipid peroxidation and collagen synthesis

$\sim 1\,\text{mol}\,\text{l}^{-1}$ ($4.2\,\text{g}\,\text{dl}^{-1}$), decreasing by one-half in the upper intestine and equilibrating with the blood alcohol level in the distal intestine. 'First pass' metabolism is achieved in the stomach by gastric alcohol dehydrogenase, an enzyme located in parietal cells with K_m 500 mM that accounts for $\sim 30\%$ of total alcohol metabolism in men and $\sim 10\%$ of alcohol metabolism in women. This gender difference in gastric metabolism partly explains the lower tolerance of women for alcohol. Subsequently, alcohol is metabolized entirely in liver cells by two enzyme systems: cytoplasmic alcohol dehydrogenase and a specific and inducible microsomal cytochrome P450 enzyme, known as CYP2E1 (Table 1). Hepatic alcohol dehydrogenase with K_m 2 mM metabolizes alcohol at blood levels consistent with moderate drinking. During the oxidation of alcohol by this reaction, NAD is reduced to NADH while producing acetaldehyde and subsequently net energy through the production of ATP. However, the increased ratio of NADH to NAD is associated with increased fatty acid and triglyceride synthesis, reduced gluconeogenesis, enhanced lactate production, and reduced urinary excretion of uric acid. The potential clinical consequences of these metabolic side effects include transient fatty liver, hypertriglyceridemia, hypoglycemia, acidosis, and gout. On the other hand, CYP2E1 with a K_m of 20 mM accounts for the metabolism of higher alcohol levels as seen with chronic excessive alcohol use. Alcohol oxidation by CYP2E1 is energy-wasteful by utilizing NADPH at a 2:1 molar ratio while producing greater amounts of acetaldehyde without generation of ATP. Increased intrahepatic acetaldehyde blocks mitochondrial respiration thereby enhancing the accumulation of fat in the liver, increases catecholamine release while promoting ketoacidosis, and, by enhancing lipid peroxidation and collagen synthesis, contributes to the development of alcoholic hepatitis and cirrhosis. The induction of CYP2E1 by frequent alcohol consumption generates a free radical that can trigger oxidative liver injury, accounts for alcohol tolerance in habitual users, and is associated with induction of other microsomal enzymes that accelerate the metabolism of drugs such as acetaminophin, barbiturates, and coumadin, and the catabolism of vitamin A.

Risks Versus Benefits of Alcohol Consumption

The risks or benefits of alcohol consumption are based on quantitative estimates of the numbers of drinks per day, where one drink of 360 ml of beer, 120 ml of wine, or 40 ml of spirits provides ~ 15 g of alcohol. By these standards, 'moderate drinking' is defined as one to two drinks (15–30 g of alcohol) per day or seven to 14 drinks per week on average, and excessive drinking that increases disease risk is defined as more than two to three drinks (30–45 g of alcohol) per day for men and more than one or two drinks (15–30 g of alcohol) per day for women. Excessive drinking may occur through habituation or addiction, and in cultures where wine is consumed daily as a component of the diet (Table 2).

A variety of studies from many developed countries established a J-shaped curve for mortality risk from alcohol consumption, wherein the lowest mortality occurs at consumption of one or two drinks per day compared with abstinence or to the consumption of more than two drinks per day. Thus, the term 'moderate alcohol consumption' is used to define consumption with clinical benefit and no increased mortality risk. Comparing all causes of mortality, the moderate drinking level is somewhat less for women at one to two drinks per day than in men at two to three drinks per day. When all the causes of mortality are taken into account, it appears that the benefit of moderate drinking is confined to the prevention of coronary heart disease and ischemic strokes, both together of which account for the majority of deaths in the USA. Above the level of moderation, i.e., at more than two to three drinks per day, alcohol consumption associates with life-threatening trauma, hemorrhagic strokes,

Table 2 Benefits and risks of alcohol consumption

Benefits (one to two drinks per day)	Protection against ischemic cardiovascular disease
	Improved lipoprotein profile
	Increased tissue plasminogen activator
	Wine flavonoids decrease LDL oxidation, platelet adhesiveness
Risks (more than three drinks per day)	Hypertension
	Cardiomyopathy
	Hemorrhagic stroke
	Pancreatitis
	Anemia
	Neurologic disorders
	Cancer of esophagus, breast, colon
	Alcoholic liver disease
	Malnutrition

hypertension, esophageal, breast and colorectal cancers, acute and chronic pancreatitis, malnutrition, and alcoholic liver disease.

Interest in the cardiovascular protective effects of alcohol stemmed from the French report of the paradoxical improved mortality among wine-drinkers in the Mediterranean provinces compared with residents of northeastern provinces, in spite of the similar content of high-fat foods in the diet and overall alcohol consumption. A subsequent *in vitro* study at the University of California Davis demonstrated that the oxidation of low-density lipoprotein could be prevented by coincubation with phenolic compounds extracted from red wine, suggesting that the improved cardiovascular risk of French red wine-drinkers was related to these nonalcoholic compounds. The principal flavonoid of red wine is catechin, which is also present in nonfermented grape juice. The biological availability of catechin for human subjects is similar in red wine to that in dealcoholized red wine, but a greater amount of catechin may be extracted from fermented grapes during wine-making than from nonfermented grape juice. A long-term prospective Danish study of residents of Copenhagen concluded that the lowest mortality rates occur in wine-drinkers, with the highest mortality in consumers of liquor. A study from Northern California concluded that the improved mortality in wine-drinkers related to their healthy dietary lifestyle, and that red and white wine provided equal protection.

There are several explanations for the cardioprotective effects of moderate alcohol consumption, in particular the effects of red wine. Moderate consumption of all types of alcoholic beverages has a positive effect on the circulating lipoprotein profile, principally by elevating the levels of high-density lipoprotein. Furthermore, moderate alcohol consumption by women results in modest reductions in low-density lipoprotein levels and increases Apo A-1 but decreases Apo B lipoproteins. Whereas serum triglycerides increase in male alcohol consumers, they may decrease in postmenopausal women drinkers. Moderate alcohol consumption also benefits the clotting process by increasing levels of tissue plasminogen activator. In addition to the benefit of wine flavonoids in reducing the oxidation of low-density lipoprotein, they also improve the clotting risk by reducing platelet adhesiveness.

Alcohol Toxicity

With the exception of traffic fatalities that may occur after consumption of an intoxicating dose of alcohol pending timing after the last drink, the deleterious effects of alcohol consumption are limited to those who consume excessive amounts of alcohol (on average, more than two to three drinks per day) on a chronic basis. The clinical risks of alcohol toxicity increase in proportion to increasing average daily amount of alcohol and duration of excessive alcohol consumption. In many instances, the development of these clinical syndromes is modulated by nutrient deficiency, and in the case of pancreatic insufficiency and alcoholic liver disease, the clinical syndromes can contribute to malnutrition.

Clinical Effects of Alcohol Toxicity

Excessive alcohol consumption contributes to increased risks of alcoholic liver disease, cardiomyopathy, chronic pancreatitis and insufficiency, nutritional anemia, certain cancers, abnormal energy metabolism, and malnutrition that is more pronounced after the development of alcoholic liver disease. Abnormal nutrient availability and metabolism play a role in all of these clinical complications of chronic alcoholism (Table 3).

Increased cancer risks Increased risk of cancer of the oropharynx and esophagus is directly related to the amount and duration of alcoholism, is tripled in heavy smokers, and may be related in part to abnormal carcinogen metabolism secondary to zinc and vitamin A deficiency. The incidence of breast cancer is increased in women who drink, in part due to enhanced estrogen secretion, and particularly in women who consume inadequate folate in their diets. Colorectal cancer risk is increased in excessive drinkers of both sexes and is related to both alcohol toxicity and low folate status.

Table 3 Clinical toxic effects of alcohol

Cancers of oropharynx, esophagus, breast and colon (see folate)
Cardiac risk
Arrhythmias: 'holiday heart syndrome'
Cardiomyopathy: low-output failure
Wet beri-beri: high-output failure (see thiamin)
Anemia due to iron, folate, and/or pyridoxine deficiencies
Pancreatitis and pancreatic insufficiency with malabsorption of fat and fat-soluble vitamins
Alcoholic liver disease
Fatty liver: reversible
Alcoholic hepatitis: inflammation, steatonecrosis
Alcoholic cirrhosis: portal hypertension with risk of ascites, renal failure, ruptured esophageal varices, and hepatic encephalopathy
Neurological disorders:
Wernicke–Korsokoff syndrome (see thiamin)
Peripheral neuropathy (see thiamin, pyridoxine)
Intoxication: trauma, automobile accidents
Alcohol withdrawal syndromes

Cardiac risks Alcoholics are at increased risk for three different clinical cardiac complications. The 'holiday heart syndrome' refers to potentially lethal arrhythmias secondary to the excessive consumption of alcohol over a short period of time. Alcoholic cardiomyopathy is caused by the toxic effects of alcohol and/or acetaldehyde or increased circulating fatty acids on mitochondrial respiration in cardiac muscle cells, and results in low-output left-sided heart failure. 'Wet beriberi' represents high-output heart failure secondary to thiamin deficiency in chronic alcoholism and, since thiamin is integral to many carbohydrate and ketoacid reactions, may be triggered or exacerbated by acute fall in thiamin stores following the administration of intravenous glucose in severely malnourished alcoholics.

Pancreatitis and pancreatic insufficiency Chronic alcoholism is the leading cause of acute and recurrent attacks of pancreatitis in developed countries, resulting in anatomic distortion and progressive destruction of the pancreas. Loss of more than 90% of pancreatic function results in pancreatic insufficiency, a condition characterized by glucose intolerance due to destruction of pancreatic beta cells and to decreased production of pancreatic digestive enzymes, resulting in malabsorption of dietary protein, lipid, and lipid-soluble vitamins A, D, E, and K. The net clinical picture is that of late-onset chronic steatorrhea (diarrhea due to excessive unabsorbed fat in the stool), with malnutrition, diabetes, and signs of fat-soluble vitamin deficiencies.

Anemia Anemia is common in chronic alcoholism due to frequent episodes of bleeding from alcohol-associated gastritis or bleeding esophageal varices and to nutritional causes. A study of more than one hundred anemic chronic alcoholics admitted to a large urban hospital found mixed and combined causes, including iron deficiency consistent with episodic blood loss in about one-quarter, megaloblastic bone marrow consistent with folate deficiency in one-third, and sideroblastic bone marrow changes consistent with pyridoxine deficiency in one-quarter of the patients.

Neurological effects of excessive alcohol The neurological effects of alcohol consumption can be categorized as those related directly to alcohol, those that are related to alcoholic liver disease, and those that are secondary to the effects of alcohol consumption on specific micronutrients. The direct toxic effects of excessive alcohol consumption on the brain include intoxication, coma, head injury, and withdrawal syndromes. Intoxication is associated with lowered inhibition, euphoria, poor memory and judgment, and decreased reaction time, which is the principal cause of motor vehicle accidents and other alcohol-related trauma. About half of all motor vehicle accidents involve innocent or intoxicated pedestrians. Legal intoxication in most localities in the USA occurs at blood levels above $0.08\,\mathrm{g\,dl^{-1}}$ or $0.019\,\mathrm{mol\,l^{-1}}$. Severe intoxication resulting in coma and death can occur at levels above $0.4\,\mathrm{g\,dl^{-1}}$ or $0.095\,\mathrm{mol\,l^{-1}}$. Intoxication is often the background for falls that can result in head injury, such as subdural hematoma, that, if unrecognized, can lead to progressive loss of consciousness and death. Alcohol withdrawal syndromes occur after prolonged consumption of excessive amounts of alcohol, usually in binge drinkers who are forced through illness or other circumstances to abruptly stop drinking. The several potential signs of alcohol withdrawal depend upon the length of time after the last drink and are all characterized by hyperexcitability. For example, tremulousness occurs within hours, a general seizure may occur within the first 24 h, and delirium tremens with auditory or visual hallucinations may occur 2–5 days after the last drink. These withdrawal syndromes can be forestalled by reinstitution of alcohol and gradual lowering of intake or by specific anti-anxiety benzodiazepine drugs.

Hepatic encephalopathy represents a disturbance in consciousness that occurs in patients with end-stage alcoholic liver disease. This syndrome is caused by nitrogenous substances, in particular ammonia, that originate through intestinal bacterial digestion of protein, bypass their hepatic site of metabolism due to liver scarring and diversion of blood flow from the portal-splanchnic circulation to the systemic circulation, and then cross the blood–brain barrier

into the brain. Elevations in blood ammonia levels typically occur in patients with severe cirrhosis of the liver after ingestion of excessive animal protein or after acute intestinal bleeding. If untreated, the stages of consciousness proceed from normal to confusion to somnolence to coma to death. Treatment consists of avoidance of excessive dietary animal protein, prevention or prompt treatment of intestinal bleeding, and administration of substances that reduce ammonia levels in the intestine.

Neurologic disorders that are based on micronutrient deficiencies include the Wernicke–Korsokoff syndrome of thiamin deficiency and peripheral neuropathies of thiamin or pyridoxine deficiency, and are described separately below.

Alcoholic liver disease The risk of developing alcoholic liver disease is dependent upon the amount and duration of alcohol consumed. While alcoholic fatty liver is common and reversible with abstinence, alcoholic hepatitis or inflammation of the liver with steatonecrosis of hepatocytes carries a significant mortality and is the precursor of chronic scarring or cirrhosis of the liver. Both alcoholic hepatitis and cirrhosis can result in portal hypertension, which is associated with diversion of portal-splanchnic blood flow through collateral veins to the systemic circulation, and is characterized clinically by increased risk of abdominal fluid accumulation known as ascites, renal failure, acute hemorrhage from esophageal varices, and hepatic encephalopathy.

Retrospective European and American population studies found that the chronic consumption of at least six drinks per day was the threshold for developing alcoholic cirrhosis over time, whereas the statistical risk of developing cirrhosis develops with as little as three drinks per day. A German study of well-to-do corporate executives found a direct relationship between the amount and duration of alcohol consumption and the incidence of cirrhosis by liver biopsy, such that the average daily consumption of 160 g of alcohol (11 drinks, equivalent to 440 ml or a pint of whiskey) over 15 years resulted in a 50% likelihood of cirrhosis. Worldwide, the mortality from alcoholic liver disease increases in direct proportion to the national per capita consumption of alcohol, with the greatest number of cirrhosis-related deaths occurring in Russia and eastern European countries, followed by countries with a high daily cultural wine consumption such as France and Italy. These statistics, together with results from alcohol-fed animal models, support the notion that the pathogenesis of alcoholic liver disease is related mainly to the toxic effects of alcohol and its acetaldehyde metabolite that trigger oxidative and cytokine responses. These responses result in hepatic inflammation, hepatocellular necrosis, collagen production, and cirrhosis. More recent data point to an important role of abnormal hepatic methionine metabolism during excessive alcohol consumption – in particular, decreased hepatic *S*-adenosylmethionine – that is associated with abnormal antioxidative mechanisms and altered hepatocellular DNA metabolism associated with necrosis and apoptosis of hepatocytes.

Nutrient Deficiencies

While alcoholic liver disease is mainly due to the toxicity of alcohol, its presence has profound effects on nutrient metabolism (Table 4). There are essentially three overall etiologies of malnutrition in chronic alcoholism: decreased dietary intake due to anorexia and/or economic deprivation combined with alcohol addiction, decreased intestinal absorption, and abnormal nutrient metabolism with increased nutrient excretion in the bile or urine. With the exception of beer as a source of folate, alcoholic beverages are essentially devoid of micronutrients and of protein, carbohydrate, and lipid sources of energy. Abnormal nutrient absorption of dietary energy from fat and of soluble vitamins is magnified by pancreatic insufficiency due to decreased pancreatic lipase secretion and by alcoholic liver disease due to decreased secretion of bile acids that are required for the micellar solubilization of dietary lipids.

Thiamin Chronic alcoholism is the principal cause of thiamin deficiency in the developed world, and low serum levels of thiamin have been described in 80% of patients with alcoholic liver disease. The etiologies of thiamin deficiency include poor diet and intestinal

Table 4 Micronutrient deficiences associated with chronic alcoholism

Micronutrient	*Deficiency signs*
Thiamin	Wernicke–Korsokoff syndrome
	Peripheral neuropathy
Folate	Macrocytic anemia
	Diarrhea
	Colon and breast cancer
	Hyperhomocysteinemia
Pyridoxine	Peripheral neuropathy
	Sideroblastic anemia
Vitamin A	Night blindness
	Increased cancer risk
Vitamin D	Osteoporosis
Zinc	Night blindness
	Abnormal taste
	Hypogonadism
	Abnormal cellular immunity
Iron	Microcytic anemia

malabsorption secondary to alcohol inhibition of the Na, K-ATPase pump in the basolateral membrane of the intestinal epithelial absorbing enterocytes. The clinical features of the Wernicke–Korsokoff syndrome of thiamin deficiency include progressive cerebral, thalamic, and cerebellar defects that result in cognitive defects, ophthalmoplegia, and a wide-based gait. The Korsokoff syndrome refers to irreversible confabulation, confusion, and profound loss of recent memory. Chronic alcoholics are also prone to develop wet or dry beriberi. Wet beriberi is one of the cardiomyopathies of chronic alcoholism, is characterized by high-output cardiac failure, and can be precipitated by intravenous administration of glucose to severely malnourished patients, with marginal thiamin stores. Dry beriberi represents progressive peripheral neuropathy mainly of the lower extremities and may be associated with painful hypersensitivity of the plantar surfaces of the feet that makes walking difficult.

Folate deficiency and abnormal methionine metabolism Folate deficiency occurs in about 50% of patients with alcoholic liver disease and results from combinations of poor diet, malabsorption secondary to alcohol inhibition of the intestinal reduced folate carrier, abnormal hepatobiliary metabolism, increased urine excretion, and acetaldehyde-triggered oxidation of the folate molecule. While macrocytic anemia is the overt clinical sign of folate deficiency induced by chronic excessive alcohol ingestion, more subtle signs include chronic diarrhea due to abnormal enterocyte function and hyperhomocysteinemia when more than two alcoholic drinks are consumed per day. The combined effects of folate deficiency and chronic alcohol intake may contribute to abnormal hepatic methionine and DNA metabolism. Studies in animal models found that chronic exposure to alcohol impairs the activities of methionine synthase and methyl adenosyl transferase, resulting in hyperhomocysteinemia and *S*-adenosylmethionine deficiency, which in turn impairs the synthesis of the antioxidant glutathione and contributes to the development of alcoholic liver disease. As indicated, impaired DNA metabolism may account for the increased risk for colon and breast cancer found in excessive alcohol consumers with dietary inadequacy of folate.

Vitamin B_{12} The standard Schilling test for vitamin B_{12} absorption is abnormal in chronic alcoholic patients secondary to low uptake of the vitamin by the absorbing ileal enterocytes. However, whereas hepatic levels of vitamin B_{12} are low in patients with alcoholic liver disease, serum vitamin B_{12} levels are typically normal or elevated in chronic alcoholism and correlate with changes in serum enzymes that reflect alcoholic liver injury. This dichotomy may relate to failure of liver uptake and/or increased release of vitamin B_{12} and its analogs from damaged hepatocytes. Owing to the metabolic interaction of vitamin B_{12} and folate in the methionine synthase reaction, the clinical effects of liver vitamin B_{12} deficiency cannot be readily distinguished from those of folate deficiency. Thus, the degree to which liver vitamin B_{12} deficiency contributes to macrocytic anemia and hyperhomocysteinemia in chronic alcoholic patients with liver disease has not been established.

Pyridoxine Pyridoxine, or vitamin B_6, deficiency in chronic alcoholism results from poor diet and the effects of the alcohol metabolite acetaldehyde on hepatic pyridoxal phosphate that releases it from its protein binder and enhances its urinary excretion. The effects of pyridoxine deficiency include sideroblastic anemia, peripheral neuropathy, and a relative decrease in serum alanine transaminase activity that results in decreased ratio of this hepatic enzyme compared with aspartate transaminase during the development of alcoholic liver disease.

Vitamin A While serum levels are unreliable, hepatic vitamin A deficiency, according to measurements in liver biopsies, increases in relationship to the severity of alcoholic liver disease and is essentially universal in alcoholic cirrhosis. The causes of vitamin A deficiency include malabsorption secondary to decreased secretion of pancreatic lipase and of bile acids and increased catabolism due to alcohol induction of microsomal enzymes that convert retinol to polar metabolites that are rapidly excreted in bile, as well as enhanced metabolism of retinol to retinaldehyde by alcohol dehydrogenase. The effects of vitamin A deficiency in chronic alcoholics include decreased dark visual adaptation, which may enhance the risk of automobile accidents, and abnormal epithelial cell turnover, which may enhance the risk of esophageal cancer. Chronic alcoholics have an increased risk of vitamin A toxicity during supplementation of vitamin A at relatively low levels (e.g., 5000 IU per day), resulting in more rapid progression of alcoholic liver injury. Supplementation of chronic alcoholics with β-carotene contributes to a similar deleterious effect on the liver as well as an enhanced risk of lung cancer when smoking is combined with excessive alcohol consumption.

Vitamin D and metabolic bone disease Chronic alcoholics frequently have low circulating levels of 25-hydroxy vitamin D, especially following the development of alcoholic liver disease. The potential

causes of vitamin D deficiency in alcoholic liver disease include poor diet, decreased sun exposure, decreased intestinal absorption secondary to inadequate bile secretion, decreased hepatic 25-hydroxylation, and increased degradation by alcohol induced microsomal enzymes. Vitamin D deficiency is compounded by decreased calcium absorption as a pathway to decreased bone accretion. However, moderate alcohol consumption may be protective against bone disease, since alcohol use also raises estrogen levels in women and is associated with decreased secretion of parathyroid hormone.

Zinc Low serum zinc levels are common in chronic alcoholics and are low in about 50% of liver specimens obtained at all stages of alcoholic liver disease. Zinc deficiency is caused by inadequate dietary ingestion of zinc-rich proteins, decreased production of zinc-rich pancreatic enzymes, abnormal transport through absorbing enterocytes, and enhanced urine excretion due to decreased binding to serum albumin. Among alcoholics, zinc deficiency contributes to night blindness since zinc is a cofactor for retinol dehydrogenase, impaired alcohol metabolism due to decreased activity of gastric alcohol dehydrogenase, altered taste that may contribute to anorexia, decreased testosterone production and hypogonadism that may contribute to osteoporosis, and altered cellular immune function contributing to enhanced infection risk.

Iron Iron deficiency in chronic alcoholic patients is due to frequent episodes of gastrointestinal bleeding, and was found in about one-quarter of consecutive anemic patients admitted to a large urban hospital. The causes of bleeding among alcohol consumers include acute gastritis, esophageal tears due to retching and vomiting (Mallory–Weiss syndrome), and episodic ruptured esophageal varices. Contrary to popular opinion, the incidence of peptic ulcer is no greater in alcoholics than in nonconsumers of alcohol.

Energy Metabolism in Chronic Alcoholism

Alcohol consumers may be severely malnourished, at normal weight, or obese. In moderate drinkers, alcohol-induced thermogenesis accounts for 15% of alcohol metabolism, and preprandial alcohol consumption increases the amount of nonalcohol calories consumed in a meal. However, other studies have shown that women moderate drinkers may become underweight due to the substitution of alcohol calories for carbohydrate. Among excessive alcohol drinkers, the substitution of alcohol for nonalcohol calories decreases body weight due to the energy consuming effect of alcohol metabolism by inducible hepatic microsomal CYP2E1. Conversely, weight gain and obesity may occur when alcohol is added to a typical high-fat diet, potentially due to promotion of fat storage that results from the inhibitory effect of alcohol on oxidation of lipids in the liver (Table 5).

Effects of Alcoholic Liver Disease on Energy and Protein Metabolism

Extensive multicenter clinical studies have established the universality of protein calorie malnutrition in patients with alcoholic hepatitis and cirrhosis (Table 6). Several studies that used anthropometric techniques found that body fat stores were decreased in derelict chronic alcoholics, whereas those who developed alcoholic liver disease had a significant depletion of skeletal muscle as well. Protein calorie malnutrition scores based on anthropometry, urinary creatinine excretion, serum albumin, transferrin, and retinol bound protein, and anergy by skin testing correlated with disease severity and mortality in over 500 male patients with alcoholic liver disease. Retrospective studies showed that malnourished excessive alcohol consumers limit their intakes of nonalcohol calories, whereas prospective studies of hospitalized patients with alcoholic liver disease found significant anorexia with voluntary consumption of less than half the diet offering, which correlated with disease severity and was predictive of mortality risk. On the basis of measured lean body mass or body cell mass, resting energy expenditure by indirect calorimetry is either normal, low, or high in patients with alcoholic cirrhosis. Stable and abstinent cirrhotics tend to have a normal or low energy expenditure if muscle and visceral protein stores are normal or decreased. However, patients with active

Table 5 Energy metabolism during alcohol consumption

	Moderate drinkers	*Excessive drinkers*
Increase in body weight	Appetite stimulation or disinhibition	Increase in fat stores through inhibition of lipid oxidation
Decrease in body weight	Substitution of alcohol for carbohydrate in diet (women)	Substitution of alcohol for nonalcohol calories Energy wasting of CYP2E1 metabolism

Table 6 Effect of alcoholic liver disease on energy and protein metabolism

Protein calorie malnutrition	Universal in advanced liver disease
	Decreased dietary intake due to anorexia
	Increased protein catabolism in active disease
Abnormal energy metabolism	Active disease: hypermetabolic
	Inactive disease or stable cirrhosis
	Normal or hypometabolic
	Prefer fatty acids as fuel source
	Decreased glycogen storage
	Fat malabsorption due to low pancreatic enzyme and bile secretion
Nutritional support	Improves nutritional status
	Not proven to alter the course of disease

alcoholic hepatitis tend to have increased energy expenditure, insulin resistance, and increased urinary excretion of total nitrogen and creatinine, consistent with ongoing inflammatory processes in the liver. Malnourished nonhospitalized patients with stable cirrhosis have normal carbohydrate metabolism but decreased glycogen stores with a greater tendency to utilize fatty acids as a fuel source. Many clinical trials have approached the question of whether improving protein calorie malnutrition by oral, enteral, or parenteral nutrition support will reduce the morbidity and mortality from alcoholic liver disease. Although most trials have found an improvement in parameters of malnutrition, none have shown that correction of malnutrition by nutritional support alters the course of this disease. However, a recent European multicenter clinical trial showed that provision of oral *S*-adenosylmethionine for 2 years decreased the mortality from active alcoholic liver disease by one half.

Alcohol Consumption

A Sierksma and K F A M Hulshof, TNO Nutrition and Food Research, The Netherlands
D E Grobbee, University Medical Center Utrecht, Utrecht, The Netherlands
H F J Hendriks, TNO Nutrition and Food Research, The Netherlands

Background

Alcohol-containing beverages play a prominent role in many societies. For centuries, alcohol (ethanol) formed a part of our diet. Even in the first Bible, wine consumption and drunkenness are mentioned. In the early middle ages, alcoholic beverages (beer) became of great importance as there was a lack of clean drinking water.

Abundant epidemiological and clinical evidence shows that there is a J-shaped relationship between alcohol intake and total mortality, with increases in death from cirrhosis, accidents, cancer, and cerebrovascular disease in heavier drinkers (Figure 1).

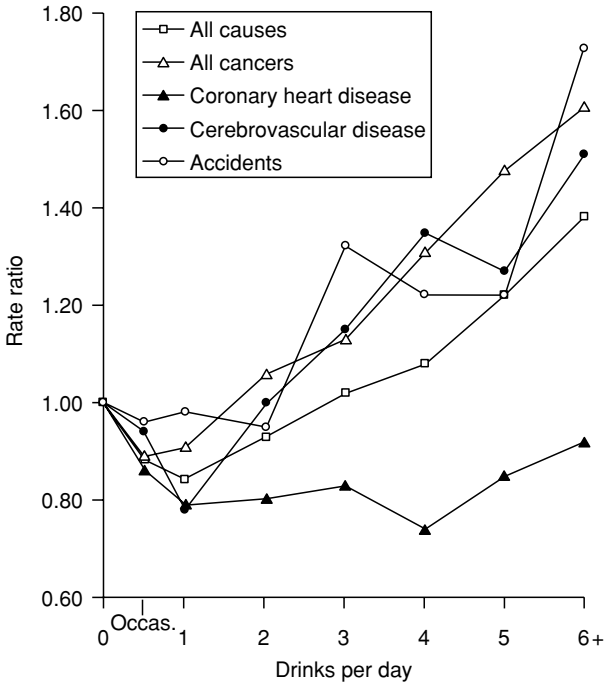

Figure 1 Relationship between alcohol intake and total mortality and death from cirrhosis, accidents, cancer, coronary heart disease, and cerebrovascular disease. From Boffetta P and Garfinkel L (1990) Alcohol drinking and mortality among men enrolled in an American Cancer Society prospective study. *Epidemiology* 1: 342–348, with permission.

Alcohol is consumed according to various patterns. It is becoming increasingly clear that certain drinking patterns may have widely varying effects on health and may lead to social problems. This chapter discusses various aspects of alcohol consumption. First, data on trends in alcohol consumption are given, drinking patterns and their health effects are presented, followed by an overview of the most frequently used methods for the assessment of alcohol intake and their suitability for different purposes. Then, the terms 'moderate and excessive drinking' and 'standard drink' are discussed, and finally, different alcohol control policies and their effectiveness are summarized.

Trends in Alcohol Consumption

Historical Trends

Economic changes, such as those brought about by depression and war, cause fluctuations in the per-capita alcohol consumption. During World War I and II, alcohol consumption was low, and in the mid-1970s after the OPEC oil crisis, per-capita alcohol consumption declined in some countries. In other countries, such a decline occurred in the early 1980s, when unemployment increased, and income stopped rising. Table 1 shows the total alcohol consumption per inhabitant in various developed countries in 1973, 1983, and 1999. Developing countries show increases in alcohol consumption, but these countries still have lower rates of consumption than those in Europe and North America.

Table 1 Total alcohol consumption per liter of pure alcohol per capita in various countries in 1973, 1983, and 1999

Country	*1973*	*1983*	*1999*
Australia	8.6	9.5	7.5
Austria	12.2	10.2	9.3
Canada	7.2	8.2	6.3
Denmark	8.4	10.4	9.5
Finland	5.6	6.4	7.3

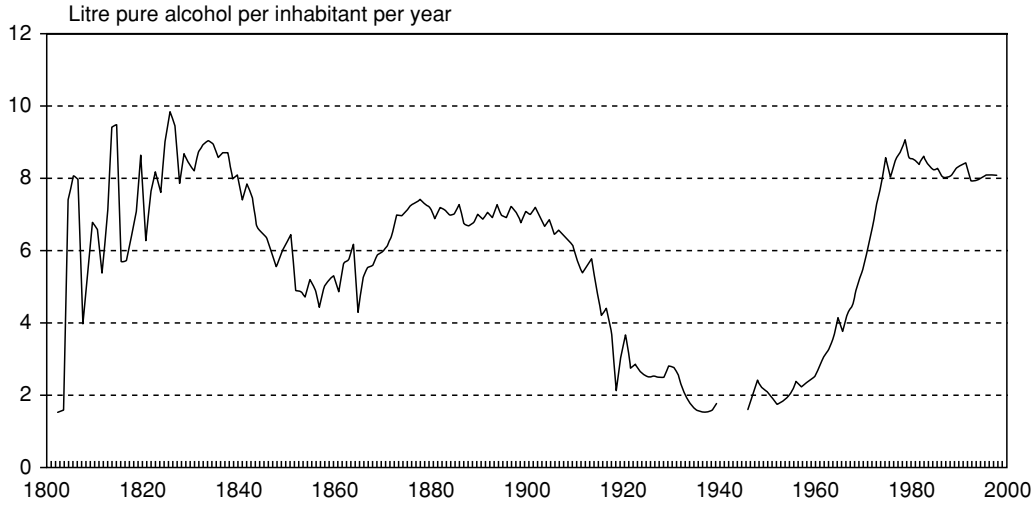

Figure 2 Alcohol consumption in The Netherlands (liters of pure alcohol per inhabitant per year) since 1820. From Statistics Netherlands, with permission.

In The Netherlands, alcohol consumption has been quite stable since 1979, with an average intake of 8 l of pure alcohol per inhabitant per year (Figure 2). The Dutch National Food Consumption Survey over the last 10 years showed that the proportion of alcohol users increased among those aged 13–16 and 16–19 years and that alcohol consumption increased among males aged 16–19 and 19–22 years. Above these age groups, alcohol consumption is somewhat decreased.

Beverage Preference

Wine is the predominant beverage in Mediterranean and Latin American societies. In these regions, wine is commonly consumed with meals. Spirits are the beverages of choice in Nordic and some Eastern European countries, where the drinking pattern is characterized by a low overall consumption and binge-drinking. Beer is the beverage of choice in many parts of Europe, North America, and Australia. In these countries, beer is mainly drunk in leisure time and usually not with a meal. Wine-drinking has become more popular in beer-drinking countries, and beer-drinking in wine-drinking countries. In spirit-drinking countries, both beer and wine consumption have become popular. So differences in beverage preference among preference appear to diminish over time. Table 2 shows the recent consumption figures for alcoholic beverages in various countries.

Table 2 Consumption by beverage type per liter per capita in various countries in 1999

Country	*Spirits*[a]	*Beer*	*Wine*
Australia	3.9	91.2	19.3
Austria	4.0	108.9	30.9
Canada	5.1	68.0	8.9

Drinking Patterns

Drinking patterns refer to several aspects of drinking behavior, including the quantity and frequency of consumption, personal characteristics of the drinkers, types of beverage consumed, temporal variations in drinking, settings where drinking takes place, and the activities associated with drinking. These patterns are important determinants of both the positive and negative consequences of drinking.

Quantity and Frequency

The importance of quantity follows from extensive epidemiological research. Light to moderate alcohol consumption is associated with a reduced risk for coronary heart disease, as well as for ischemic stroke

and possibly for type 2 diabetes. Epidemiological and physiological data are in favor of a causal relationship. Proposed protective mechanisms include the stimulation of high-density lipoprotein (HDL)-mediated processes and improvement of hemostatic processes and vascular wall functioning. Excessive alcohol consumption and alcohol abuse may lead to alcoholism or alcohol dependence, with negative effect on almost all parts of the body, including the liver, brain, pancreas, cerebrovascular system, and immune system, and are also associated with premature death.

Both the average amount of alcohol consumed and how drinkers decide to spread the consumption of alcohol over the hours and situations available for drinking are important. Although very little is known about the effects of drinking frequency, intuitively, it seems clear that variations in frequency may have widely varying effects on health and social problems. Binge-drinking, for example, is associated with intoxication, hangover, and injuries.

Individual Characteristics

Drinking is generally associated with particular personal characteristics, like genetics, personality traits, age, gender, and religion.

Genetics Alcohol dependence is a result of an interaction between biological and environmental factors. Twin and adoption studies have shown that there is a genetic factor in the etiology of alcohol dependence, but the exact mechanism of transmission is not known.

Up to about 50% of some Asian groups have inherited deficiencies of the enzyme aldehyde (acetyldehyde) dehydrogenase, inducing relatively high blood levels of acetaldehyde, which causes symptoms such as flushing, nausea, vomiting, palpitations, and hypertension. Deficiency of this enzyme deters the individual from drinking alcohol and reduces the risk of alcohol dependence. About 5–10% of the British and German populations and up to 20% of the Swiss population are reported to have atypical forms of the enzyme alcohol dehydrogenase, which causes more rapid elimination of alcohol.

Personality traits Personality traits such as chronic anxiety, a sense of inferiority, self-indulgent tendencies, antisocial personality disorder, aggressive and impulsive personality, particularly in adolescents, and borderline personality have been linked with alcohol abuse.

Age Young people are more likely to abuse alcohol than older people. They have higher risks of incurring such complications associated with acute intoxication such as accidents, violence, and alcohol poisoning. Physical changes in older people, like increased susceptibility to the depressant effects of alcohol, decreased rates of alcohol catabolism in the liver and decreased percentage of body water, tend to limit excessive alcohol consumption.

Gender Use, abuse, and dependence of alcohol are much more common in males than in females. Social disapproval or prohibition tends to restrict alcohol consumption by females, but it may also promote a different pattern of use, such as drinking at home or in private. The lower percentage of body water and the slower metabolism of alcohol in women may influence the use of alcohol by women and may also be a reason for the increased risk of alcohol problems. Females tend to start abusive drinking much later in life than males and probably also develop alcohol problems later. The inverse association between moderate alcohol consumption and coronary heart disease has been documented in both men and women. Benefits for women are mostly associated with lower quantities of alcohol and appear to be most pronounced in postmenopausal women. This is not surprising since this age group, like men over the age of 50, has a marked increase in cardiovascular risk.

Religion Religion and religiosity are among the most powerful predictors of drinking. The vast majority of persons in Muslim countries abstain from alcohol. Also, among Mormons, Adventists, and various other religious communities, alcohol drinking is not allowed. In countries where drinking is relatively common, attendance at religious services is a powerful predictor of whether and how much a person drinks.

Beverage Type

Some reports have suggested that the type of beverage may be important in coronary heart disease risk. Red wine has received much attention as a potential contributor of antioxidant activity, because of its natural antioxidant compounds, i.e., polyphenols. However, observational and experimental studies on the consumption of beer, wine, and spirits in relation to the risk of coronary heart disease indicate that moderate consumption of all three alcohol-containing beverages is linked with a lower risk. Thus, a substantial portion of the benefit is connected with the alcohol component, rather than with specific non-alcohol components present in the different types of beverages.

Temporal Variations

Drinking is strongly related to leisure time, which is why drinking generally tends to be greatest during nonworking hours and at weekends. Temporal patterns of drinking vary considerably in different cultures and social groups. The term 'alcohol culture' has been used to denote similarities between particular aspects of drinking patterns in different countries. 'Dry' and 'wet' drinking cultures refer to the relatively low or high social acceptance of drinking. In 'wet' cultures, like the Mediterranean area and Latin American societies, drinking with meals and during the day is a common pattern. In 'drier' Northern European cultures, drinking during the day is less accepted and less common. It has been argued that drinking problems are manifested differently in 'dry' cultures: fewer people incur problems, but those who do suffer more severe individual consequences.

Settings and Activities

Another dimension of drinking patterns concerns the settings and activities associated with drinking. Drinking may occur in connection with social or religious rituals or may be related to particular work activities. Drinking can take place in private homes, with or without a meal, or in public places, such as bars, cafés, restaurants, or beer gardens.

Drinking alcoholic beverages leads to a rapid increase in blood alcohol concentration (BAC). After reaching a maximum value, the BAC returns slowly to the base level. The course of the alcohol concentration with time depends on drinking conditions such as the dose and concentration of the alcoholic beverage consumed and whether alcohol is consumed with or without a meal. Studies have shown that BACs after moderate alcohol consumption together with a meal remained half as high as those with moderate alcohol consumption without a meal.

Assessment of Alcohol Consumption

It is very difficult to assess alcohol intake accurately. Although alcohol is part of the normal diet, it is not considered a normal food constituent. It has a highly symbolic value, and its consumption is influenced by cultural differences and social norms.

Methods for determining alcohol intake can be divided into nonintrusive and intrusive estimates. Nonintrusive estimates such as sales figures and collateral reports are less threatening and more objective, because respondents are not aware of them. Intrusive estimates are based on self-reports or biological markers. Unfortunately, a 'gold standard' for alcohol intake assessment is lacking.

Sales Figures

To determine alcohol availability in a population, per-capita sales figures can be used. However, these do not provide information about alcohol consumption in certain groups or individuals. Another drawback is that sales reports do not include untaxed alcohol (duty-free shops), home-brewed alcohol, and export sale.

Self-reports

Methods based on self-reports include face-to-face or telephone interviews, self-administered questionnaires, and diaries. Most of these self-reports can be applied very easily and are relatively cheap. Self-reports are suitable for use in small studies and in large-scale surveys for epidemiological research and can provide beverage-specific information. The quality of the data collected is determined by the order and structure of the questions asked and by the mode of the report and characteristics of the respondent, such as age and culture.

Questions about drinking are threatening and may easily yield socially desirable answers. In population surveys, the average extent of underestimation of alcohol intake can vary between 29 and 83% of the actual intake. When the degree of underestimation is not linked to the actual level of intake, it will not affect the conclusions, and only the quantitative definition of moderate or optimal level of alcohol use will be unrealistic. However, some studies indicate that heavy drinkers underestimate their alcohol intake more than light drinkers do, and in this case, conclusions about dose–response relationships are unreliable. Underestimation may be partly prevented by an anonymous questionnaire. The memory capacity of the respondents may be a limiting factor as well. Common errors in assessing alcohol intake in surveys include selection bias, nonresponse, incomplete time sampling, under- or overestimation of portion size, and recall bias.

Collateral Reports

Collateral reports are provided by a significant 'other person' (e.g., a spouse or friend). The accuracy of these reports is affected by the subject's daily routine making behavior more or less predictable and the frequency of contact between the subject and the collateral. Collateral reports are often used as a reference method.

Biological Markers

The advantage of biological markers is that they are an objective measurement of intake, not affected by socially desirable answers or interviewer effects.

However, they are not suitable for assessing actual level of intake, drinking patterns, or beverage preferences. They can only be used to rank individuals according to their intake. Table 3 gives an overview of the biological markers of alcohol presented in the literature, their purpose and estimated sensitivity (proportion of positives that are correctly identified by the test), and their specificity (proportion of negatives that are correctly identified by the test).

Biological markers of alcohol use are not suitable for assessing habitual low or moderate drinking levels: they can only be used for clinical studies of alcoholics to monitor change in drinking patterns of patients or to check abstinence.

Alcohol Consumption: Moderate and Excessive

Moderate and Excessive Drinking

The literature contains widely different applications of the term 'moderate.' A comparison of average daily amounts defined as light, moderate, and heavy in a sample of recent publications shows that the lower limit of moderate alcohol intakes ranges from 4.5 to 50 g per day, and the upper limit ranges from about 24 to 80 g per day. Table 4 shows some recommendations on drinking levels published by governments or learned bodies.

On a population basis, for the average adult man, the optimal level may be in the range of 10–19 g of alcohol per day, and the noninjurious level may be approximately 30–40 g per day. For a woman, these levels may be < 10 g per day and approximately 10–20 g per day. However, the individual differences in body size, age, and special situations that can increase the degree of risk (pregnancy, driving, diseases, and medications) should also be taken into account.

Light and frequent drinking is suggested to be beneficial, whereas large amounts drunk infrequently are harmful with respect to coronary heart disease.

What is a 'Standard Drink'?

Research outcomes are often confusing when moderate and excessive drinking are expressed in 'standard drinks.' The term 'standard drink' was originally intended to apply to drinks of 'standard' strengths. However, the alcohol content varies among different beers, wines, and distilled spirits, and interpretations differ across countries as to how much alcohol there is in a standard drink (see Table 4). There may also be differences in the standard serving sizes within a given country, depending on the type of beverage served, so the amount of alcohol may be different between the different beverages. Another problem is a lack of uniformity in the definition in which the alcohol content is measured – grams versus ounces of ethanol, American versus British fluid ounces, or measures of alcohol content as a percentage by weight or by volume. The size of drinks poured in serving establishments may not be the same as that defined by the standard drink, and there are significant levels of alcoholic beverage consumption in homes and other private settings where drinks are rarely measured in standard units. These wide discrepancies and variations make any form of international comparison

Table 3 Characteristics of biological markers of alcohol use

Marker	*Purpose*	*Estimated sensitivity (sens.) and specificity (spec.)*
Ethanol in serum, breath, or urine	Recent intake (2–6 h)	Sens. 25% Spec. 100%
Methanol in body fluids or breath	Recent (5–15 h) and chronic intake	Higher sensitivity than ethanol
MCV of erythrocytes	Chronic intake	Sens. 35% Spec. 40–90%
Erythrocyte acetaldehyde in plasma	Recent intake (several days)	Low sensitivity
Transferases (GGT, ASAT, ALAT) in serum	Chronic intake, screening	GGT: sens. 45%, spec. 75% ASAT and ALAT: lower than for GGT
5-Hydroxytryptophol in urine	Recent intake (6–15 h)	Sens. 70% Spec. 95%
HDL in serum	Recent and chronic, moderate and high intake	Sens. 30%
FAEE in serum	Recent intake (24 h)	Higher sensitivity than ethanol
CDT in serum	Chronic excessive intake, screening	Sens. 75% Spec. 90%
AANB in serum	Chronic intake, monitoring	Low sensitivity

AANB, α-amino-*N*-butyric acid; ALAT, alanine aminotransferase; ASAT, aspartate aminotransferase; CDT, carbohydrate-deficient transferrin; FAEE, fatty acid ethyl esters; GGT, γ-glutamyltransferase; HDL, high-density lipoprotein. MCV, mean corpuscular volume.

of drinks and consumption data difficult, so assessment and comparison of data from many countries would be greatly facilitated by the uniform expression of alcohol intakes and by the adoption of a uniform international definition of a standard drink.

Alcohol Control Policies

In order to reduce the prevalence of alcohol-related problems, many countries apply control measures that affect the availability and/or the price of alcoholic drinks. In addition, governments may use public health campaigns and alcohol advertising as instruments to diminish the prevalence of alcohol-related problems. Alcohol control policies may be directed at reducing the average alcohol consumption among the total population (public health approach) or at reducing the number of heavy users or drinking in high-risk situations (high-risk approach). Alcohol control measures are more effective as public support is higher, and so education of the public and possibly self-regulation by the alcohol industry may be important contributory measures.

Price

Taxation of alcoholic beverages is essentially for the purpose of raising revenue. It is not generally regarded as a primary tool for controlling consumption, although it is used as such in some countries. In most countries, alcoholic drinks are perceived to be luxury items and, as such, candidates for taxation. Alcoholic drinks are price-elastic, which means that the demand is sensitive to price changes. This is the main reason for the argument that taxation should be used to reduce consumption. However, it has been found that elasticity values relating to different regions, different periods, and different types of alcohol vary considerably.

More important is the effect of price increases on different types of consumers. Some claim that heavy drinkers are at least as responsive to price increases than light-to-moderate consumers. Others claim that heavy drinkers reduce their consumption much more than other drinkers after excise duties are increased.

Advertising and Alcohol Availability

A commonly held assumption is that alcohol advertising increases alcohol consumption. The main objective of advertising is to persuade customers to continue to enjoy, or to switch their preference to, the brand being advertised. Several studies have demonstrated that advertising does not increase consumption. Also, restrictions on advertising do not automatically result in a decline in total alcohol consumption.

It has been suggested that there is an association between hours of sale and outlet density, and the consumption of alcohol, but some studies show no

Table 5 Minimum drinking and purchasing age laws in various countries

such association. Prohibition of alcohol has been shown to be an ineffective and even counterproductive measure. Although the alcoholic cirrhosis mortality and other alcohol problems may decrease, it might not produce positive results in public health terms as, for example, organized crime increased in the United States after complete alcohol ban.

Drinking Age Limits

Drinking age laws cover a broad spectrum of behaviors concerned with where, when, and under what circumstances alcoholic beverages can be purchased and consumed. Some countries focus their legislation on both a minimum legal drinking age and a minimum age at which beverage alcohol can be purchased, and these ages may be different. Other countries do not address a minimum age for consumption. Table 5 shows some minimum drinking and purchasing age laws. Both consumption and purchasing laws in most countries are set at 18. The national laws generally apply to drinking age limits for venues outside the home, such as taverns, bars, restaurants, nightclubs, and similar establishments. The UK is the only country that legislates a minimum consumption age in the home (from age 5 with parental consent).

Effectiveness of Alcohol Control Policies

Price policy may be an effective means of reducing alcohol consumption and alcohol-related problems as long as increases in price keep up with or outstrip rises in income. However, the effectiveness may depend very much on the population group affected and on socio-economic and demographic factors. Also, stable political and economic conditions as well as appropriate law enforcement and administrative systems are prerequisites for success.

ALKALOIDS

Contents

Properties and Determination

M Wink, University of Heidelberg, Heidelberg, Germany

Background

Plants produce a wide variety of secondary metabolites, many of which function as allelochemicals or signal compounds to attract pollinating insects and seed- or fruit-dispersing animals. Their main function is chemical defense against herbivores, microrganisms, or competing plants. Over 13 000 nitrogen-containing secondary metabolites have been described so far in plants. Alkaloids contribute over 12 000 compounds, followed by amines, nonprotein amino acids, cyanogenic glycosides, and glucosinolates.

Definition

The definition of alkaloids has changed throughout the years. Formerly, this class of secondary compounds was restricted to plant bases with a heterocyclic nitrogen atom. Exocyclic nitrogen bases were termed 'pseudoalkaloids.' Other definitions demanded that the skeleton of alkaloids should derive from amino acids or that these bases have explicit pharmacological activities. At present, alkaloids are defined in a more pragmatic way; they include all nitrogen-containing natural products that are not otherwise classified as peptides, nonprotein amino acids, amines, cyanogenic glycosides, glucosinolates, cofactors, phytohormones, or primary metabolites (such as purine and pyrimidine bases). Even a number of antibiotics produced by bacteria or fungi are therefore included in the group of alkaloids.

Occurrence

Alkaloids have been detected in about 15% of plants, bacteria, fungi, and even in animals. Within the plant kingdom, they occur in primitive groups such as *Lycopodium* or *Equisetum*, in gymnosperms and angiosperms. In higher plants (angiosperms) some families contain more alkaloid-containing taxa than

others. Such alkaloid-rich' taxa include Papaveraceae, Berberidaceae, Fabaceae, Boraginaceae, Apocynaceae, Asclepiadaceae, Asteraceae, Liliaceae, Gnetaceae, Ranunculaceae, Rubiaceae, Solanaceae, and Rutaceae. Also, several food plants and food items may contain alkaloids (Table 1).

It has been speculated that alkaloids evolved early in evolution and were already present at the time (*c.* 200 million years ago) when the angiosperms began to radiate. In general, specific alkaloid types are restricted to particular systematic units and are therefore of some importance for the systematics, taxonomy, and phylogeny of plants. For example, benzylisoquinoline alkaloids are typical for Papaveraceae, Berberidaceae, and Ranunculaceae, which seem to be phylogenetically related. Other alkaloids occur in phylogenetically unrelated plant families. Ergot alkaloids occur in fungi (*Claviceps*) but also in members of the Convolvulaceae; quinolizidine alkaloids are typical for some Fabaceae, but have also been detected in Berberidaceae (*Caulophyllum*, *Leontice*). It has been speculated that the genes encoding enzymes leading to the main quinolizidine alkaloid skeleton are distributed much more widely in the plant kingdom, but are normally switched off. Alternatively, convergent evolution and horizontal gene transfer have been suggested.

Isolation and Detection

Alkaloids form free bases in alkaline solutions. The free base is usually lipophilic and mostly insoluble in water but soluble in organic solvents (ethanol, methanol, diethylether, methylene chloride). At higher hydrogen ion concentrations (i.e., pH < 7), alkaloids occur in a protonated state and are usually

Table 1 Alkaloids present in food plants, beverages, stimulants, or hallucinogens

Substance	*Occurrence*	*Activity*
Alkaloids in food		
Solanine and other steroid alkaloids	Solanum (potato, tomato)	Membrane disruption, Neuroreceptor interaction, mutagenicity
Pyrrolizidine alkaloids	*Symphytum* (comfrey); honey (if bees have visited PA plants)	DNA and protein alkylation; mutagenicity, cancer
Cycasin	Cycas, other cycads	Mutagenicity
Ergotalkaloids	*Claviceps purpurea*	Neuroreceptor interaction; vasoconstriction; uterus contraction
Saxitoxin	Algae; ends up in food chain (molluscs; fish)	neurotoxin (Na^+ channel)
Lupanine and other quinolizidine alkaloids	*Lupinus*; other genistoids	Interaction with AChR[a], Na^+, K^+ channels
Pelletierine	*Punica granatum*	Interaction with AChR
Alkaloids in beverages		
Caffeine, theophylline, theobromine	*Coffea, Thea, Paullinia, Ilex paraguarensis*	Stimulant
Quinine	*Cinchona succirubra*	Bitter tonic; neuroreceptor and ion channel interaction; central stimulant
Ephedrine and related compounds	*Ephedra*; *Catha edulis*	
Alkaloids as stimulants and hallucinogens		
Morphine	*Papaver somniferum*, opium	Hallucinogen
N-Methyltryptamine	Fungi, plants	Central stimulant
N, *N*-dimethyltryptamine, 5-methoxy-*N*, *N*-dimethyltryptamine	Mimosaceae: Anadenanthera (syn. Piptadenia), *Mimosa hostilis*; Myristicaceae: *Virola*; Malpighiaceae: *Banisteriopsis*, Poaceae: *Phalaris*	Central stimulant, hallucinogen
Serotonin	Fungi (*Amanita*); stinging hairs of *Urtica*, *Laportea*, *Jatropha urens*, *Mucuna pruriens*; seeds and fruits	
Bufotenine	Fungi (*Amanita*); animal poisons (*Cnidaria*, spider, scorpions, wasps, toads)	
Psilocybin, psilocin	Fungi (*Psilocybe*, *Stropharia*, *Conocybe*, *Panaeolus*, *Gymnophilus*, *Psathyrella*, etc.)	
Mescalin	*Lophophora williamsii*; other cacti	Hallucinogen
Harmalin and other β-carboline alkaloids	*Peganum harmala*, *Banisteriopsis caapi*	Hallucinogen
Cocaine		Hallucinogen
Arecoline	Nuts of Areca palm	Stimulant

[a]AChR, acetylcholine receptor.

soluble in water but insoluble in apolar organic solvents. The different solubilities are useful to isolate and purify alkaloids. In the laboratory, alkaloids are often solubilized from plant material by dissolving them in acidic solutions (e.g., 0.5 M HCl). Treatment of this solution with organic solvents will remove nonalkaloidal substances. The solutions are brought to pH > 12 in the next step and extracted with CH_2Cl_2, ethylacetate, or ethylether to yield free alkaloids.

Plant extracts are often analyzed by thin-layer chromatography (TLC) as a first screening to find out whether alkaloids are present or not. A number of reagents give typical color reactions, such as Dragendorff's, Mayer's reagent, etc. Because alkaloids are typically present in complex mixtures consisting of two to five main and up to 20–50 minor alkaloids, TLC does not have sufficient separation capacities. Better methods are high-performance liquid chromatography (HPLC) and capillary gas–liquid chromatography (GLC). The latter method is extremely useful because it has a strong separation power and is very sensitive and selective if a nitrogen-specific detector is used. Furthermore, GLC can be directly coupled with a mass spectrometer, allowing mass spectra to be obtained, even from very minor components. Since many alkaloids have been analyzed by mass spectrometry, already a large collection of mass spectra is available, making it possible to identify many of the known alkaloids unambiguously. Usually, mass spectra are recorded in the electron impact (EI) mode, which promotes fragmentation. If information on the molecular ions is needed (which can be elusive in EI-MS), other MS techniques, such as chemical ionization (CI), field desorption (FD), or fast-atom bombardment (FAB) are the methods of choice.

HPLC tends to be less sensitive and of lower separation capacity than capillary GLC. However, modern photodiode array detectors are very helpful to identify known metabolites by UV-VIS spectroscopy. Today, also, HPLC and capillary electrophoresis can be coupled to a mass spectrometer, thus widening the use of MS for the analysis of natural products.

In addition, HPLC has a major advantage in that it is possible to isolate a compound in milligram quantities that allow structural elucidation by nuclear magnetic resonance (^1H, ^{13}C). Nuclear magnetic resonance is the method of choice if unknown structures are to be elucidated, whereas mass spectrometry is extremely useful for identifying previously described substances or substances that are slightly different to known compounds.

If small quantities (femtogram or nanogram amounts) of known alkaloids need to be detected routinely, immunological procedures such as radioimmunoassays (RIA) or enzyme immunoassays (EIA, ELISA) should be appropriate. In order to obtain specific antibodies, the alkaloid in question has to be coupled chemically to a large protein, such as albumin, usually by some sort of spacers (e.g., succinic acid).

Biosynthesis

The skeleton of most alkaloids is derived from amino acids (Figure 1, Table 2), although moieties from other pathways, such as terpenoids, are often combined. In addition, in a number of alkaloids (e.g., steroid alkaloids), the nitrogen (deriving from glutamine or other NH_2 sources) is added near the end of a biosynthetic pathway, i.e., the alkaloid skeleton does not stem from amino acids. Biosynthetic pathways have been worked out in detail for a few alkaloids.

Accumulation and Storage

Although the exact site of alkaloid formation in a plant cell has been elucidated for a few species only, it is certainly correct to assume that most compounds are synthesized in the cytoplasm. Membrane-enclosed vesicles have been implied in the biosynthesis of berberine. Not only is the chloroplast the site of photosynthesis and related processes, but it also harbors a number of biosynthetic pathways, such as those for fatty acids and amino acids. In addition, quinolizidine alkaloids (QA) are synthesized in the chloroplast stroma; thus, both the alkaloid and its amino acid precursor, L-lysine, share the same compartment. QA formation is regulated by light and displays a diurnal rhythm. Light regulation seems to be triggered by (1) lysine availability (it is also made during the day), (2) the change in stromal hydrogen ion concentration to pH 8 (enzymes of QA formation have a pH optimum at pH 8), and (3) the reduction of QA enzymes by thioredoxin (reduced thioredoxin is generated under illumination).

Alkaloids are not formed in the extracellular space or in the vacuole. The storage of high concentrations of alkaloids is a prerequisite for their allelochemical roles as defense compounds. Since these concentrations would interfere with the normal metabolisms, the allelochemicals are safely stored in the vacuole (Table 3) of often specialized cells or tissues (such as epidermis). The vacuole of these alkaloid-accumulating cells has been termed the 'toxic' or 'defense' compartment. A number of plants produce latex, which, in addition to its gluing properties (think of insect mandibles!), often contains defense chemicals, such as alkaloids (morphine and related

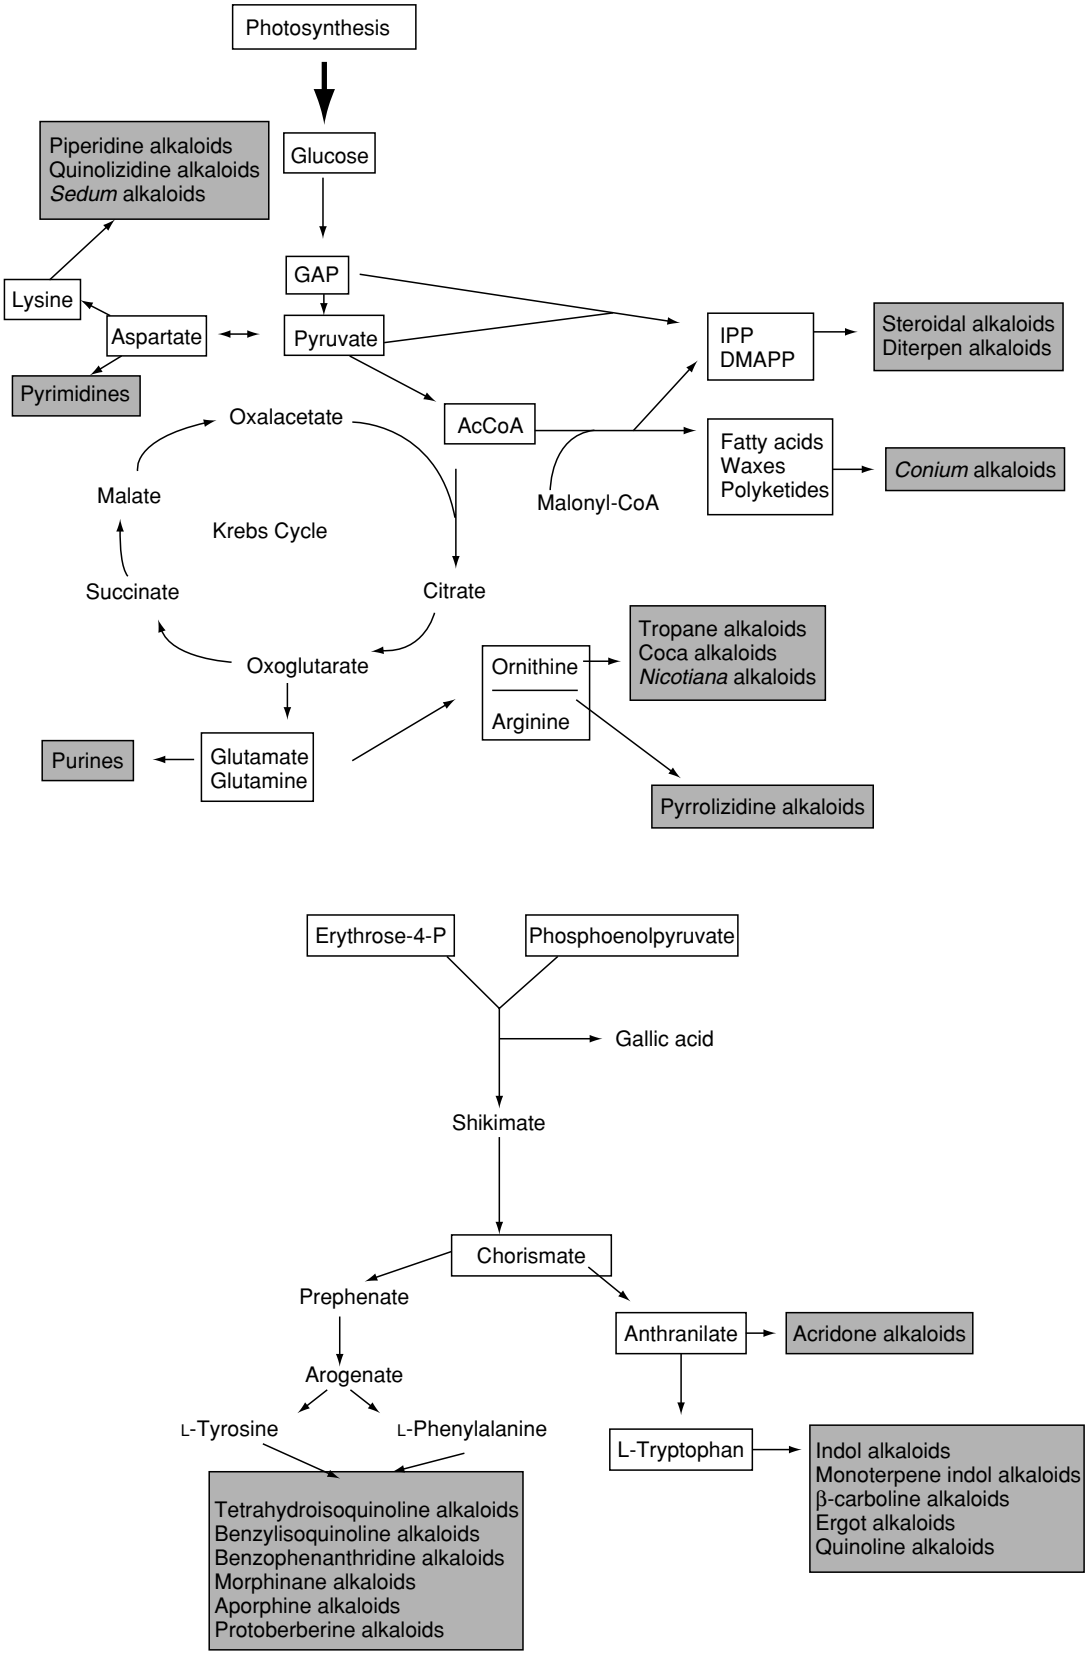

Figure 1 Schematic overview of biosynthetic pathways leading to different groups of alkaloids.

Table 2 Examples for important alkaloids and their biosynthetic precursors

Amino acid	*Alkaloid*	*Main occurrences*	*Example structure*
Lysine	Quinolizidine alkaloids	Fabaceae	Lupanine, sparteine, cytisine
	Lycopodium alkaloids	Lycopodiaceae	Lycopodine
	Piperidine alkaloids	Punicaceae, Crassulaceae	Pelletierine, sedamine
Ornithine	Tropane alkaloids	Solanaceae, Erythroxylaceae	Hyoscyamine, cocaine
	Pyrrolizidine alkaloids	Asteraceae, Boraginaceae, Fabaceae	Senecionine, heliotrine
	Nicotiana alkaloids	Solanaceae	Nicotine, anabasine
Tryptophan	Monoterpene indol alkaloids	Apocynaceae, Aslepiadaceae ...	Strychnine, vincamine, Yohimbine, ajmalicine ...
	Simple indole alkaloids	Fabaceae	Physostigmine
	Quinoline alkaloids	Rubiaceae, Cornaceae	Quinine, cinchonine, camptothecine
	Ergot alkaloids	*Claviceps*, Convolvulaceae	Ergotamine, lysergic acid
	β-carboline alkaloids	Loganiaceae, Zygophyllaceae	Harman, harmaline
Phenylalanine/tyrosine	*Ephedra* alkaloids	Ephedraceae	Ephedrine
	Tetrahydro-isoquinoline alkaloids	Rubiaceae	Emetine
	Benzylisoquinoline alkaloids	Papaveraceae, Berberidaceae	Papaverine
	Benzophenanthridine alkaloids	Papaveraceae	Sanguinarine
	Protoberberine alkaloids	Berberidaceae, Papaveraceae	Berberine
	Morphinane alkaloids	Papaveraceae	Morphine, codeine
	Aporphine alkaloids	Monimiaceae	Boldine
	Phenylethyl-isoquinoline alkaloids	Colchicaceae	Colchicine
	Aristolochia alkaloids	Aristolochiaceae	Aristolochic acid
Anthranilic acid	*Ruta* alkaloids	Rutaceae	Skimmianine, dictamine

Berberine	*Chelidonium*
Morphine and other morphinane alkaloids	*Papaver*

benzylisoquinoline alkaloids in Papaveraceae; protoberberine and benzophenanthridine alkaloids in *Chelidonium*; lobeline and other piperidine alkaloids in *Lobelia*) and terpenoids (e.g., phorbole esters). The alkaloids are selectively sequestered in small (diameter < 1 μm) latex vesicles and reach local concentrations of up to 1 M.

Storage in the vacuole or in vesicles demands that alkaloids pass the tonoplast and accumulate within the vacuole against a concentration gradient. For the passage across the tonoplast, three mechanisms are plausible:

- simple diffusion (takes place in case of lipophilic alkaloids, e.g., nicotine, ajmalicine, vinblastine, colchicine);
- carrier-mediated transport (in case of polar and charged alkaloids, which is the rule for most alkaloids under physiological conditions, e.g., hyoscyamine, lupanine, reticuline, scoulerine, senecionine);
- membrane fusion (in case of alkaloids that are formed in vesicle-enclosed compartments, e.g., berberine).

Because alkaloids are sequestered against a concentration gradient in the vacuole or in latex vesicles, the driving force of uphill accumulation needs to be determined. In some instances, vesicles or vacuoles contain alkaloid binding or complexing compounds. For example, latex vesicles of *Chelidonium majus* contain between 500 and 1200 mM chelidonic acid, which binds or complexes berberine and benzophenanthridine alkaloids. It has been shown experimentally that chelidonic acid acts as a trapping agent that causes the apparent uphill transport resulting in alkaloid concentrations in vesicles of 500–1200 mM. Protonation, organic acids, and specific peptides may constitute other trapping mechanisms. There is some evidence that amino acids and some ions are transported into the vacuole with aid transporters that are fueled by proton–substrate antiport mechanisms.

Protons are enriched in the vacuole, which generally has hydrogen ion concentrations of 0.001–1 mM (=pH 6–3), by proton-translocating ATPases and pyrophosphatases. In analogy, it has been assumed (supported by experimental evidence) that carrier transport of alkaloids is achieved by a proton–alkaloid antiport mechanism or with the aid of ABC transporters.

Whereas a few alkaloids are formed ubiquitously in all plant organs, organ- or even tissue-specific formation seems to be more common (Table 4). Since most eukaryotic genes are regulated in a cell-, tissue-, and organ-specific manner, genes of alkaloid formation seem to be no exception. The corresponding promotors are presumed to be regulated by respective regulatory proteins. This conclusion is important for the interpretation of results obtained with cell suspension cultures. Whereas alkaloid formation is active in differentiated systems (root or shoot cultures), it is usually reduced, or even absent, in undifferentiated suspension cultured cells. It is likely that the corresponding alkaloid genes are just 'switched off.' The production of berberine and sanguinarine in cell cultures seems to be more the exception than the rule.

Alkaloids are stored predominantly in tissues that are important for survival and reproduction, which include actively growing young tissues, root and stem bark, flowers (especially seeds), seedlings, and photosynthetically active tissues. Alkaloid contents in storing organs can be quite high, reaching up to 10% of dry weight in some instances, which is important if the alkaloids are to function as effective defense compounds. In several herbaceous plants, alkaloids are stored in epidermal and subepidermal tissues (e.g. cocaine, colchicine, aconitine, steroidal alkaloids, nicotine, veratrine, buxine, and coniine), which have to ward off small enemies (insects, microorganisms) in the first place. In lupins and broom, quinolizidine alkaloid concentrations are up to 200 mM in epidermal tissue, whereas mesophyl tissue has values below 5 mM. Some plants possess typical alkaloid-storing cells, called 'idioblasts.' These idioblasts have been detected in *Corydalis* (for corydaline), *Sanguinaria* (for sanguinarine), *Ruta* (for rutacridones), *Catharanthus* (for indole alkaloids), and *Macleaya* (for protopine). Short- and long-distance transport are often required to reach these sites of accumulation.

Alkaloid patterns usually vary between the site of synthesis and the sites of accumulation, since a number of secondary substitutions may take place in the latter tissues, or transport may be selective, distributing differing cocktails. In addition, alkaloid profiles of seeds and seedlings often differ from those of the mature plant. Both patterns and concentrations usually change during the development of plants and the annual cycle. In general, alkaloid levels are markedly reduced in senescing tissues, so that shedded leaves are often nearly alkaloid-free. Alkaloid formation and storage may be influenced by environmental stress, such as wounding or infection.

Transport and Turnover

A number of alkaloids are synthesized and stored in all parts of plants, whereas others are restricted to a particular organ. Alternatively, alkaloids are synthesized but accumulated in many organs, which usually demands long-distance transport. Theoretically, this transport could procede sym- or apoplastically. However, utilization of established transport routes, such as xylem or phloem, seems to be more common. Because it is technically difficult to sample and analyze xylem and phloem sap, only a limited number of appropriate data are available (Table 5). Besides long-distance transport, short-distance and intracellular transport need to be reviewed. In general, alkaloids are synthesized in the cytosol or in membrane-enclosed vesicles (endoplasmic reticulum, mitochondria, chloroplasts), but are accumulated and sequestered in the vacuole.

In general, alkaloids are not end products of metabolism but can be degraded, which seems to be

Hyoscyamine	X		*Atropa*
Scopolamine	X		*Datura*, *Hyosycamus*
Swainsonine		X	*Astragalus*

plausible because nitrogen is a limited nutrient for plants. As discussed previously, alkaloids stored in seeds are partly degraded during germination and seedling development, and their nitrogen is probably used for the synthesis of amino acids. Degradative pathways have not been worked out yet.

In addition to this developmentally specific recycling, there is evidence that a number of alkaloids are turned over all the time, with half-lives of between 2 and 48 h. Examples are nicotine, QAs, and tropane alkaloids. Alkaloid turnover is often quite substantial in cell cultures: *Lupinus* callus cultures are even able to live on the QA sparteine as a sole nitrogen source for more than 6 months.

How can we explain this phenomenon? A number of alkaloids are allelochemicals and affect molecular targets such as receptors of neurotransmitters (tropanes, nicotine, etc.). For this interaction, a correct stereochemical configuration is required. Because alkaloids may oxidize or give rise to racemic mixtures spontaneously, a continuous turnover would make sure that a sufficient concentration of active compounds is always available, similar to the situation of protein turnover.

Functions

Although several alkaloids and other secondary metabolites have been used by mankind for thousands of years as dyes (e.g., indigo, shikonine), flavors (e.g., vanillin, capsaicin, mustard oils), fragrances (e.g., rose oil, lavender oil, and other essential oils), stimulants (e.g., caffeine, nicotine, ephedrine), hallucinogens (e.g., morphine, cocaine, mescaline, hyoscyamine, scopolamine, tetrahydrocannabinol), insecticides (e.g., nicotine, piperine, pyrethrin), vertebrate and human poisons (e.g., coniine, strychnine, aconitine) and even therapeutic agents (e.g., atropine, quinine, codeine, cardenolides, etc.), their putative functions have been discussed controversially.

Alkaloid biology is tightly connected with the basic physiology of plants. Many of the features described before would make no sense if these compounds did not have a vital function for the producer. As a common theme, it has been observed that plants that produce seeds rich in energy supplies (carbohydrates, lipids, proteins) concomitantly accumulate potent chemical defense compounds, often alkaloids, nonprotein amino acids, cyanogenic glycosides, glucosinolates, protease inhibitors, lectins, or other toxalbumins. Their presence in seeds can be mutually exclusive, i.e., legume seeds store either alkaloids (e.g., quinolizidines, pyrrolizidines) or nonprotein amino acids, but not both at the same time. During germination, the breakdown of nutrient reserves is a general procedure and usually includes the nitrogenous defense compounds. They serve a double purpose, i.e., that of N-storage and protection. They are thus degradable and toxic N-storage compounds.

The main function is obviously that of chemical defense against herbivores (insects, other arthropods, and vertebrates), which can be deduced from the fact that many alkaloid have a high affinity for receptors of neurotransmitters that are present only in animals. In some instances, alkaloids play a role (additionally) in the antimicrobial defense (against bacteria, fungi, viruses) and even in the interaction between plants (allelopathy).

Alkaloids are certainly multipurpose compounds that, depending on the situation, may be active in more than one environmental interaction. For example: QAs are certainly the most important defense chemical in Fabaceae against insects and other herbivores, but they also influence bacteria, fungi, viruses, and even the germination of other plants. In addition, they are employed as degradable N-transport and N-storage compounds.

Alkaloids repel or deter the feeding of many animals (many have a bitter or pungent taste to humans and other vertebrates) or are toxic if ingested. In microorganisms and competing plants, a reduction of growth and antibiosis are usually the visible effects of alkaloid intoxication. How are these diverse effects being achieved? Although most compounds have not been studied in full detail, an impressive number of cellular and molecular targets have been identified that are selectively inhibited or modulated by alkaloids. As a consequence of such interactions, organ malfunctions (heart, lung, liver, kidney, CNS disorders) result that may impair reproduction and fertility in animals and other organisms, or simply kill them.

Because many alkaloids have been shaped during evolution by 'molecular modeling,' many of them are

used by humans as medicinal compounds; allelochemicals may have positive effects if used at non-toxic concentrations.

Presence at the Right Concentration at the Right Time and Place

To be effective, alkaloids need to be present at the right time, site, and concentration. Alkaloid metabolism and biochemistry seem to have been optimized and coordinated in most systems to fulfill this prerequisite. An interesting variation can be seen in some plants, where alkaloid formation is enhanced by wounding or microbial attack, i.e., in case of emergency, the production of defense compounds is stimulated.

How effective are alkaloidal defenses? In lupins, which normally produce high amounts of QAs, mutants have been selected (so-called sweet lupins) that accumulate only trace amounts of alkaloids. When both alkaloid-rich and low-alkaloid lupins are planted in the field without any fences and phytoprotectives, a dramatic effect can often be seen (Figure 2). Whereas the low-alkaloid lupins were selectively grazed or infested by herbivores, their alkaloid-rich counterparts remained almost undisturbed. More experimental data are certainly needed, but the defensive role of alkaloids seems to be beyond doubt.

Similar to the situation in sweet lupins, in which plant breeders have eliminated the alkaloid trait, also in other crop plants, secondary metabolites, which had evolved to serve as defense compounds, have been bred away or strongly decreased. As a consequence, many crop plants have lost their original resistance to pests and herbivores. Man-made chemistry (i.e., synthetic pesticides) has to be used if these crop plants have to be cultured.

Exceptions to the Rule – Adaptations of Specialists

No defense is absolute. Whereas chemical defense works against the majority of potential enemies, usually a few specialists have evolved during evolution that have become specialized in the toxin-protected ecological niche. This phenomenon can be clearly seen in many insects, which are often highly host-plant-specific. Some of these insects take up the dietary alkaloids, store, and exploit them for their own chemical defense or that of their offspring.

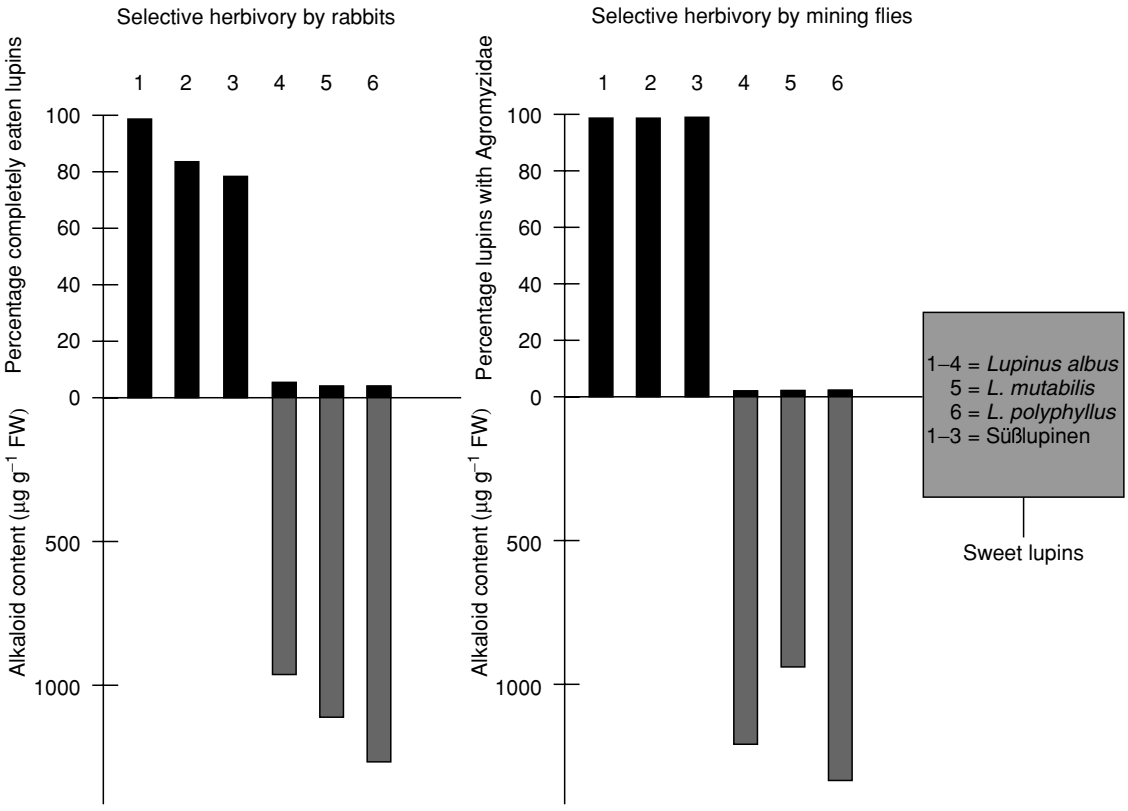

Figure 2 Selective advantage of alkaloids in lupins against herbivores (rabbits, mining flies). Lupins without alkaloids suffer heavily from herbivory, whereas alkaloid-rich lupins are widely protected.

Others additionally transform the alkaloids into pheromones or utilize them as morphogens. Well-studied examples have been published for pyrrolizidine and QAs. Vertebrate herbivores (humans included) have effective liver enzymes that can detoxify xenobiotics. Often, substances become hydroxylated, conjugated, and then excreted via the feces or the kidney and urine.

Background

Apparently, most alkaloids play an important role in the ecology of plants or animals. They serve as defense chemicals against herbivores and predators. To a lesser degree they protect against bacteria, fungi, and viruses or provide a means for plant–plant interactions. To be effective defense chemicals, alkaloids must closely interact with specific targets in herbivores, predators, microorganisms, or competing plants, i.e., they must either inhibit or otherwise deregulate important processes that are vital for these organisms. For this purpose the molecular shape of alkaloids has apparently been optimized during a million years of evolution in a process which could be termed 'evolutionary molecular modeling.'

While the structures of more than 12 000 individual alkaloids have been reported, rather limited knowledge is available for most of them in terms of biological activities and functions. In this chapter the modes of action of the better known alkaloids, especially those found in food plants, are summarized and discussed, considering interactions with organs or complete organisms first and then molecular targets. These interactions are the base for understanding the toxic or antinutritional effects that are observed if humans or animals have ingested alkaloids with their diet.

Toxic and Pharmacological Effects at the Organ Level

Many alkaloids are known for their toxic or adverse effects on animals (**Table 1**). In many cases, only the toxicity of an alkaloid has been reported evidencing substantial interactions, but the exact mode of action has not yet been elucidated or is rather complex, involving several molecular targets and organs.

In medicine, alkaloids are employed as local anesthetics, as narcotics, analgesics, as cardiac, uterine and respiratory stimulants, or to raise blood pressure, dilate pupils, and to relax skeletal muscles (**Table 2**). The use of alkaloids as narcotics and hallucinogens causes major social problems.

Ultimately, the toxic and pharmacological effects (**Tables 1** and **2**) observed must be the result of interactions of alkaloids with molecular targets present in or on cells.

Central Nervous System and Neuromuscular Junctions

A remarkable number of alkaloids interfere with the metabolism and activity of neurotransmitters in the brain and nerve cells. A disturbance of metabolism or binding of neurotransmitters and related signal pathways impairs learning and memory, sensory faculties (smell, vision, or hearing), and coordination of bodily functions, or produces euphoric or hallucinogenic effects.

Muscle activity (skeletal, heart, etc.) is controlled by acetylcholine (Ach) and norepinephrine (noradrenaline). Any inhibition or overstimulation of neurotransmitter-regulated ion channels will severely influence muscular activity and thus the mobility or organ function (such as heart, lungs, gut). When there is inhibition, muscles will relax; when there is overstimulation, they will be tense or in tetanus, leading to a general paralysis and/or respiratory failure (which is the effect of many of the more toxic alkaloids). Alkaloids which activate (so-called parasympathomimetics) or inhibit (parasympatholytics) neuromuscular action are tabulated in Table 3. These compounds are usually considered to be strong poisons (Table 1).

Inhibition of the Digestive Process

Food uptake can be reduced by pungent or bitter taste in the first instance. The next step can be the induction of vomiting, which is a common reaction to the ingestion of a number of alkaloids; the alkaloid emetine already implies this activity in its name! Causing diarrhea, or the opposite, constipation, would be another activity which negatively influences the digestive system. Many intoxications with alkaloid-containing plants have diarrhea as one of the symptoms. Another way to interfere would be the inhibition of digestive enzymes or of transport proteins for amino acids, sugars, or lipids.

Modulation of Liver and Kidney Function

Nutrients and xenobiotics (such as secondary metabolites) are transported to the liver after resorption in

Table 2 Pharmacological and medicinal properties of alkaloids

Type	*Alkaloid*	*Activity*
Poison	Pyrrolizidine alkaloids (from *Senecio*, *Heliotropium*, *Crotalaria*)	Conversion to DNA and protein alkylating agent in liver Causing liver cirrhosis, mutations, cancer
	Ergot alkaloids (from *Claviceps purpureus*)	Cause vasoconstrictions, hallucinogenic effects, gangrenic limps; disease named ergotism
	Aconitine (*Aconitum*)	Local anesthetic, general paralytic effect
Analgesics	Morphine (*Papaver somniferum*)	Very effective painkiller (used since ancient times); addictive properties
	Codeine (*Papaver*)	Pain and cough depression
	Cocaine (*Erythroxylon coca*)	Local anesthetic
Cardiac stimulants	Quinidine (*Cinchona* spp.)	Antiarrhythmic properties at heart auricle
	Sparteine (*Cytisus scoparius*)	Antiarrhythmic properties
	Ajmaline (*Rauwolfia serpentina*)	Antiarrhythmic properties at ventricle
Respiratory stimulant	Nicotine (*Nicotina*), cytisine (*Laburnum*)	Stimulation of respiration is followed by respiratory depression, asphyxia or even respiratory failure
	Lobeline (*Lobelia* spp.)	Stimulant; used in bronchial asthma
	Coniine (*Conium maculatum*)	Used as a potent poison in antiquity (Socrates)
Constriction of blood vessels	Ergot alkaloids (*Claviceps purpurea*)	Used in obstetrics
	Ephedrine (*Ephedra* spp.)	Employed in the treatment of bronchial asthma, cold, sinusitis
	Scopolamine (*Hyoscyamus, Atropa, Datura*)	Dilatator of vessels
Muscle relaxant	Tubocurarine (*Chondodendron tomentosum*)	Block nAChR*; used in surgery
	Hyoscyamine (atropine, *Hyoscyamus, Atropa, Datura*)	Antispasmodic at smooth muscles (gastrointestine, bladder)
	Papaverine (*Papaver somniferum*)	Smooth-muscle relaxant
Antiparasitic and antimicrobial activity	Berberine (*Berberis, Mahonia*)	Intercalates DNA and inhibits parasites and microorganisms
	Emetine (*Cephaelis acuminata*)	Intestinal amoebiasis, emetic drug
	Boldine (*Peumus boldo*)	Anthelmintic activity
	Quinine (*Cinchona succirubra*)	Antimalarial
Antiinflammatory activity	Colchicine (*Colchicum autumnale*)	Treatment of acute gout, recurrent gout
Eye treatments	Physostigmine (*Physostigma venenosum*)	Reduces intraocular pressure (glaucoma)
	Pilocarpine (*Pilocarpus jaborandi*)	Miotic used in the treatment of open-angle glaucoma
Cytostatic treatment	Taxol (*Taxus brevifolia*)	Treatment of breast and ovary carcinoma; other malignancies
	Vinblastine, vincristine (*Catharanthus roseus*)	Treatment of lymphomas and other tumors

*nAChR, nicotinic acetylcholine receptor.

the intestine. In the liver the metabolism of carbohydrates, amino acids, and lipids and the subsequent synthesis of proteins and glycogen takes place. The liver is also the main site for the detoxification of xenobiotics. Lipophilic compounds, which are easily resorbed from the diet, are often hydroxylated and then conjugated with a polar, hydrophilic molecule, such as glucuronic acid, sulfate, or an amino acid. These conjugates are exported via the blood to the kidney for elimination via the urine. Both organ systems are affected by a variety of secondary metabolites: pyrrolizidine alkaloids are activated during the detoxification process and are converted into potent carcinogens, causing liver cancer. Many other metabolic inhibitors, discussed below, are also liver toxins.

Many alkaloids are known for their diuretic activity. Increased diuresis would also mean an increased elimination of water and essential ions. Since Na^+ ions are already limited in plant food, long-term exposure to diuresis-inducing compounds would reduce the fitness of a herbivore substantially.

Disturbance of Reproduction

Quite a number of allelochemicals are known to influence the reproductive system of animals, which will ultimately reduce their numbers (and fitness as a species). Antihormonal effects could be achieved by mimicking the structure of sexual hormones, such as coumarins which dimerize to dicoumarols, or isoflavones. The next target is the gestation process itself.

Table 3 Examples of alkaloids which bind to neurotransmitter receptors and neurotransmitter-degrading enzymes

Target	*Ligand*	*Alkaloid*	*Occurrence*
Acetylcholine receptors			
Nicotinic receptor	Acetylcholine	Nicotine	*Nicotiana, Duboisia*
		C-toxiferine	*Strychnos*
		Tubocurarine	*Chondodendron*
		Coniine	*Conium*
		Cytisine and other QA	Several legumes
		Lobeline	*Lobelia*
		Anabasine	*Anabasis, Nicotiana*
Muscarinic receptor	Acetylcholine	Hyoscyamine (atropine)	*Atropa, Hyoscyamus, Datura, Mandragora*
		Scopolamine	Several Solanaceae
		Arecoline	*Areca*
		Pilocarpine	*Pilocarpus*
		Muscarine	*Amanita, Inocybe, Clitocybe*, other fungi
		Sparteine and other QA	Several legumes
Adrenergic receptors	Norepinephrine(noradrenaline)/ (adrenaline) epinephrine	Ergot alkaloids	*Claviceps*
		Yohimbine	*Pausinystalia, Aspidosperma*
		Rauwolscine	*Rauwolfia*
		Corynanthine	*Rauwolfia*
		Norlaudanosoline	Papaveraceae
		Ephedrine, norephedrine	*Ephedra*
Serotonin receptor	Serotonin	Ergot alkaloids	*Claviceps*
		Psilocin, psilocybine	*Psilocybe*, other fungi
		N,N-dimethyltryptamine	Several plants and toads
		Bufotenine	*Virola, Anadenanthera*
		β-carboline alkaloids	*Banisteriopsis, Peganum*
		Mescaline	*Lophophora*, other cacti
Dopamine receptor	Dopamine	Ergot alkaloids	*Claviceps*
		Bulbocapnine	*Corydalis*
GABA receptor	GABA	Bicuculline	*Dicentra cucullaria* and other *Corydalis* species
		Muscimol	*Amanita*
		β-carboline alkaloids	*Peganum, Banisteriopsis*
Adenosine receptor	Adenosine	Caffeine	*Coffea, Camellia, Ilex, Paullinia*
		Theophylline, theobromine	*Theobroma*
Glycine receptor	Glycine	Brucine	*Strychnos*
		Strychnine	*Strychnos*
Opioid receptor	Endorphins	Morphine	*Papaver somniferum*
Acetylcholine esterase	Acetylcholine	Physostigmine (eserine)	Physostigma venenosum
		Berberine	Several Papaveraceae
		Coptisine	Several Papaveraceae
		Galanthamine	Several Amaryllidaceae
		Solanine and other steroid alkaloids	*Solanum*
		Huperzine A	*Huperzia serrata*
Monoamine oxidase (MAO)	Norepinephrine, dopamine, serotonin, histamine	Harmaline, harmine	*Peganum*
		Salsolinol	Chenopodiaceae
		Ephedrine	*Ephedra*
Catechol-*O*-methyltransferase	Norepinephrine, epinephrine, dopamine	Tetrahydroisoquinoline	Papaveraceae

QA, quinolizidine analogs; GABA, γ-aminobutyric acid.

As outlined below, a number of alkaloids are mutagenic and lead to malformation of the offspring or directly to the death of the embryo. The last step would be premature abortion of the embryo. This dramatic activity has been reported for a number of allelochemicals, including many mono- and sesquiterpenes and alkaloids. Some alkaloids achieve this by the induction of uterine contraction, as do the ergot and lupin alkaloids.

Molecular Targets of Alkaloids

In the following a number of important cellular molecular targets (Figure 1) have been addressed

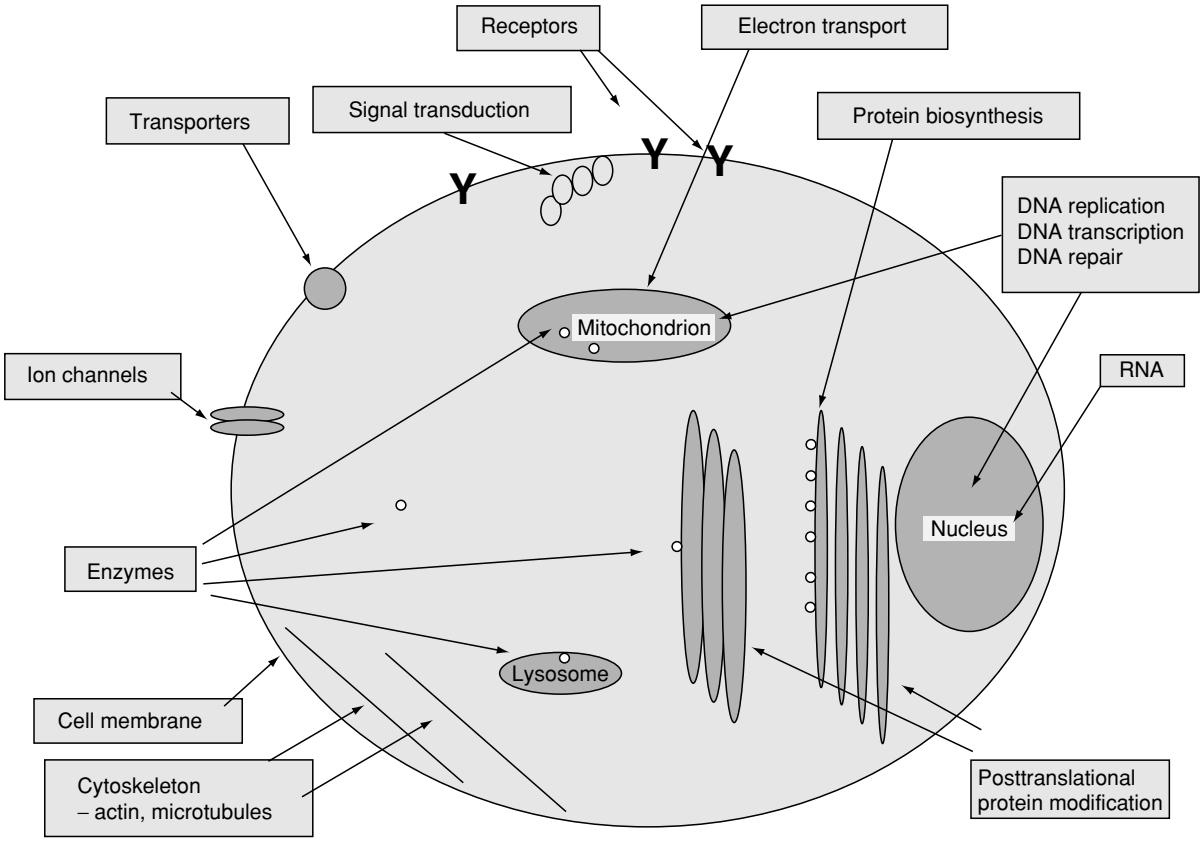

Figure 1 Molecular targets of animal cells that are affected by alkaloids.

which are often affected by alkaloids and other plant toxins.

Biomembranes, membrane transport, and neuronal signal transduction

Cells can only operate effectively if their biomembranes (cytoplasmic membrane, internal membranes) are intact. Biomembranes are almost impermeable for ions and polar molecules. As an exchange of these molecules must take place between cells and organs, specific membrane proteins, which can be ion channels, pores, or carrier proteins, mediate the controlled flux of these compounds across biomembranes. The biomembranes and the complex transport systems are targets of many natural products.

Steroidal alkaloids, such as solanine and tomatine, which are present in many members of the Solanaceae (including potatoes and tomatoes), can form complexes with the cholesterol present in biomembranes. While the steroidal moiety 'dives' into the lipophilic interior of the membrane and interacts with the structurally similar cholesterol, the hydrophilic side chain remains outside and binds to external sugar receptors. Since phospholipids are in a continuous motion, a tension easily builds up which leads to membrane disruption; transient 'holes' occur in the biomembrane, rendering the cell leaky. A similar mechanism has been postulated for saponins, a widely distributed group of natural products, to which the steroidal alkaloids may be assigned. Steroidal alkaloids can also interact with other targets, such as neuroreceptors or even with DNA; malformations have been observed in animal embryos after having been exposed to *Solanum* alkaloids.

Communication between cells is especially important for nerve cells. Signal transduction in the central nervous system and in neuromuscular junctions is mediated by receptor proteins residing in the membrane which are directly or indirectly coupled with ion channels. The neurotransmitters involved include, among others, norepinephrine (noradrenaline), epinephrine (adrenaline), serotonin, dopamine, histamine, glycine, γ-aminobutyric acid (GABA), glutamate, and acetylcholine (ACh).

Neuroreceptors can be ligand-gated channels, i.e., a receptor which is part of an ion-channel complex. When the neurotransmitter binds, a conformational change induces the opening of a Na^+/K^+ channel for

microseconds, allowing Na^+ ions (the external concentration is about 145 mmol l^{-1}) to enter the cell following a concentration gradient (the internal Na^+ concentration is between 5 and 15 mmol l^{-1}). The ligand quickly dissociates from the receptor and, in the case of ACh, is hydrolyzed by ACh esterase (Figure 2). Glutamate (*N*-methyl-D-aspartate, NMDA) and GABA receptors are also ligand-gated ion channels.

More abundant are G-protein-coupled neuroreceptors. A prominent one is the muscarinic ACh receptor; norepinephrine, serotonin, and dopamine receptors also belong to this type. When ACh binds, the receptor changes its conformation, inducing a conformational change in an adjacent G-protein molecule. Its α-subunit dissociates and then activates the enzyme adenylyl cyclase, which in turn produces cyclic adenosine monophosphate (cAMP) from adenosine triphosphate (ATP). The cAMP molecule, a second messenger, activates protein kinases or Ca^{2+} channels directly.

Quite a number of alkaloids are known whose structures are more or less similar to those of endogenous neurotransmitters. They can function therefore as structural analogs. In addition, several plants produce compounds which are identical to animal neurotransmitters, such as ACh and histamine in stinging hairs of *Urtica*, or serotonin and dopamine in several species. Targets can be:

- the receptor itself through inhibition or overstimulation (Table 3)
- the enzymes which deactivate neurotransmitters after they have bound to a receptor (Table 3)
- transport processes, which are important for the uptake of neurotransmitters into the presynapse or their storage in synaptic vesicles (Table 4) or
- enzymes involved in the biosynthesis of a neurotransmitter.

The stimulation of neurotransmitter-activated ion channels leads to a rapid influx of Na^+ ions, which in turn activates voltage-gated Na^+ and K^+ channels, which are essential for further signal transduction. These Na^+ and K^+ channels constitute another important target for alkaloids (Table 5).

Table 4 Alkaloids as inhibitors of neurotransmitter uptake (transport into presynapse or into vesicles)

Transporter	*Alkaloid*	*Occurrence*
Norepinephrine	Reserpine	*Rauwolfia*
(noradrenaline)	Ephedrine	*Ephedra*
Biogenic amines	Tetrahydro-β-carboline	*Peganum*
	Salsolinol	*Salsola*
	Tetrahydroisoquinoline	Papaveraceae
	Tetrahydropalmatine	Berberidaceae
Dopamine	Cocaine	*Erythroxylum*

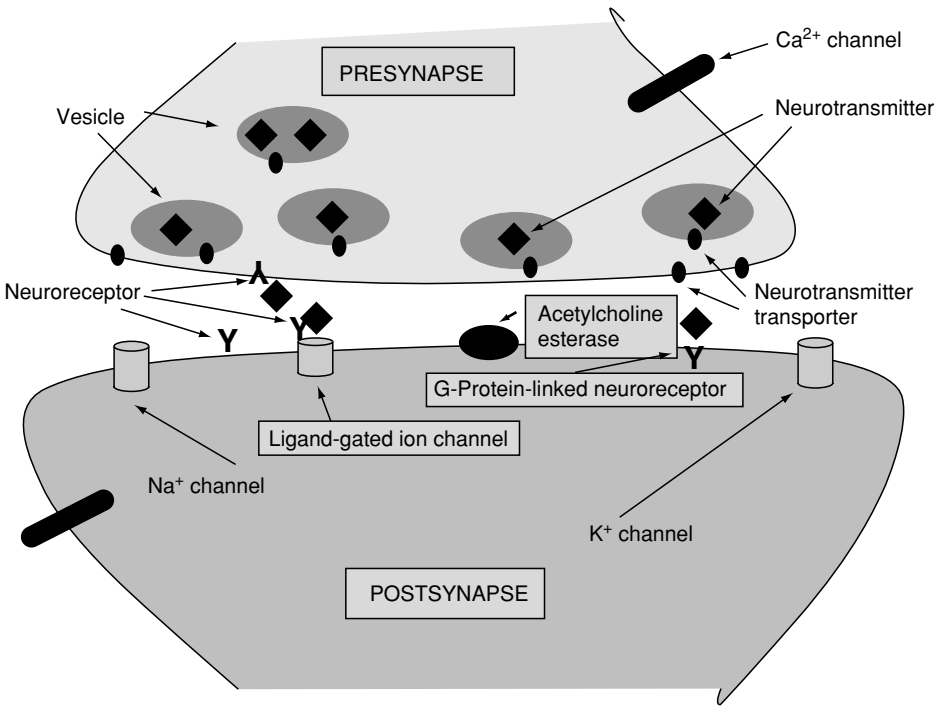

Figure 2 Signal transduction in excitable synapses.

Cells carefully control ion concentrations inside and outside of the cells with the help of specific ion channels (e.g., Na^+, K^+, Ca^{2+}, and Cl^- channels) and of active Na^+, K^+ or Ca^{2+} pumps, such as Na^+, K^+-ATPase and Ca^{2+}-ATPase. Ion gradients and ion fluxes mediated by these channels and pumps are the main elements in the active transport processes, in neuronal and neuromuscular signaling. Cardiac glycosides are potent and well-known inhibitors of Na^+, K^+-ATPase found in plants, some insects, and in the skin of certain toads. A few alkaloids such as harmaline, nitidine, sanguinarine, capsaicine, cassaine, and solenopsine (from ants) inhibit Na^+, K^+-ATPase.

Whereas receptor/ion channel interactions represent the initial part of many signal pathways, key enzymes which produce or inactivate second messengers or amplify the signal can be important targets further down the pathway (Table 6). These enzymes include:

- adenylyl cyclase (making cAMP),
- phosphodiesterase (inactivating cAMP),
- phospholipase (releasing arachidonic acid or inositol phosphates) or
- several protein kinases, such as protein kinase C (which is activated by phorbol esters and the alkaloid chelerythrine) or tyrosine kinase (activating other regulatory proteins or ion channels)

Because these targets are almost exclusively found in animals but absent in plants, the development of active compounds directed to these targets appears to be advantageous for the plants producing them. They can store these compounds without risk of being intoxicated by their own toxins.

Table 5 Alkaloids as modulators of Na^+, K^+, and Ca^{2+} channels

Alkaloid	*Occurence (genera)*	*Action*
Na^+ and K^+ channels		
Aconitine[a]	*Aconitum*	Activation
Ajmaline[a]	*Rauwolfia*	Inhibition
Batrachotoxin[a]	Frogs (Dendrobatidae)	Activation
Harmalin	*Peganum*	Inhibition
Protoveratrine A, B[a]	*Veratrum*	Activation
Quinidine[a]	*Cinchona*	Inhibition
Quinine	*Cinchona*	Inhibition

DNA/RNA

The genetic information of most organisms is mainly encoded in DNA. Since the integrity of DNA is important for the structure and function of rRNAs, proteins and enzymes which are important for metabolism, structure and development of an organism, DNA is a highly vulnerable target. It is not surprising that a number of secondary metabolites became selected during evolution which interact with DNA or DNA-processing enzymes. Some alkaloids are known to bind or to intercalate with DNA (Table 7). Many of these molecules are planar, hydrophobic molecules which fit between the planar stacks of AT and GC base pairs. Other alkaloids act on the level of DNA- and RNA-polymerases and DNA topoisomerases, thus impairing the process of replication and transcription.

The effects of DNA-binding or intercalating compounds can be mutations, which may result in malformations of newborn animals or in the initiation of cancer. When anabasine, coniine, or anagyrine is administered to pregnant cows or sheep, a large proportion of the offspring develop malformations of the

		amanitin	*Amanita*

legs – so-called 'crooked calf disease.' Some alkaloids of the monocot *Veratrum*, such as jervine and cyclopamine cause the formation of a large central eye, the cyclopean eye, which was probably known to the ancient Greeks and thus led to the mythical figure of the cyclops.

Other alkaloids are known as carcinogens, such as aristolochic acid from *Aristolochia* and pyrrolizidine alkaloids (PA) which are produced by approximately 3% of the higher plants, especially within the families of Asteraceae and Boraginaceae. Aristolochic acid has a nitro group which can be transformed into reactive intermediates in the intestine. If resorbed, these metabolites can alkylate DNA. Pyrrolizidine alkaloids are not carcinogenic in their native form, but become so when they are 'detoxified' in the liver: PA are usually present in the plant as their *N*-oxides, which are polar compounds that cannot pass biomembranes by simple diffusion. In the intestine, PA-*N*-oxides are reduced by gut bacteria. The free base is then readily taken up by the gut cells and transported to the liver. There, the PA are transformed into alkylating compounds, which covalently bind to DNA and proteins. As a result mutations and cancer can be initiated.

Protein Biosynthesis

Protein biosynthesis is essential for all cells and thus provides another important target. Indeed, a number of alkaloids have been detected which inhibit protein biosynthesis *in vitro*. Emetine from *Cephaelis ipecacuanha* (Rubiaceae) is the most potent plant constituent. Other alkaloids with the same ability include harringtonine, homoharringtonine, cryptopleurine, tubulosine, hemanthamine, lycorine, narciclasine, pretazettine, pseudolycorine, tylocrepine, and tylopherine. Several alkaloids which inhibit protein biosynthesis and are also DNA intercalating substances can induce apoptosis in cells.

Electron Chains and Other Enzyme Activities

The respiratory chain and ATP synthesis in mitochondria or photophosphorylation in chloroplasts demand the controlled flux of electrons. These targets seem to be attacked by nicotine, sanguinarine, ellipticine, gramine, alpinigenine, capsaicine, and a few other alkaloids. A multitude of enzymes exist in animal cells and several alkaloids have been reported that interfere with at least one of them.

A recently discovered group of alkaloids are the polyhydroxyalkaloids, such as swainsonine or castanospermine, which inhibit hydrolytic enzymes, such as glucosidase, galactosidase, trehalase (trehalose is a sugar found in some beetle cocoons and fungi which is hydrolyzed by trehalase) and mannosidase selectively.

Cytoskeleton

Microtubules, which are important for cellular movements, vesicle transport in neurons, or the separation of chromosomes during cell division, are composed of tubulin subunits. Movements and some transport processes are mediated through either the rapid assembly or disassembly of microtubules. The assembly of microtubules is inhibited by colchicine, and dimeric indole alkaloids vinblastine and vincristine (important for chemotherapy of certain cancers). These alkaloids thus interrupt cell division. The diterpene alkaloid taxol (used in the treatment of ovarian and breast cancer) affects microtubules in the opposite way; the polymerization of tubulin is enhanced by taxol. As a consequence taxol-induced microtubules are very stable and dividing cells are arrested in the metaphase.

Cell stability, phagocytosis, cell–cell interactions, and cell movements are also controlled by actin filaments, which are rapidly assembled or disassembled from action monomers. Cytochalasin B and latrunculin B bind to the plus end of a growing actin filament, preventing the addition of actin monomers there. Another alkaloid, phalloidin, produced by the fatally poisonous toadstool *Amanita phalloides*, stabilizes actin filaments and inhibits their depolymerization.

Mechanisms of Allelochemical Activities in Antiviral, Antimicrobial, and Phytotoxic Interactions

Circumstantial evidence indicates that some alkaloids protect the producing plant against viruses, bacteria, fungi, and competing plants. A number of antimicrobial alkaloids such as sanguinarine, quinine, or berberine intercalate with viral and microbial DNA or bind to it. These compounds may thus inhibit processes such as DNA replication and RNA transcription which are vital for the microorganisms. Protein biosynthesis in ribosomes is another vulnerable target, attacked by emetine. The stability of biomembranes can be disturbed by steroidal alkaloids and tetrandine. Other targets may be electron chains or just metabolically important enzymes. Phytotoxic properties or germination inhibition, which can be observed in plant–plant interactions, can also proceed via the above-mentioned mechanisms. But interactions with growth hormones and their metabolism must also be considered.

Target specificity of alkaloids

In general, the interactions of a particular alkaloid with a molecular target (as described above) suggest a high degree of specificity. A closer look, however, shows that many alkaloids interfere with more than one target. The phenomenon will be explained for two groups of alkaloids: ergot alkaloids and quinolizide alkaloids (QA).

Ergot Alkaloids

Ergot alkaloids, such as ergotamine, ergometrine, or ergoclavine, are produced by fungi of the genus *Claviceps* which lives in close contact with many grasses (family Poaceae) such as the cereal *Hordeum vulgare*. These alkaloids can modulate several receptors of neurotransmitters, such as dopamine, serotonin, and norepinephrine. As a consequence. the pharmacological action of ergot alkaloids is rather broad, ranging from vasoconstriction and uterus contraction to hallucinations. We can explain these activities through structure similarities between the alkaloid and the different neurotransmitters.

Quinolizidine Alkaloids

QA, such as lupanine, sparteine, or cytisine, are produced by lupins and many members of the Leguminosae. They are bitter for many animals (and plants producing them are therefore avoided as food). If ingested, QA exhibit a broad level of toxicity: they interact with ACh receptors (AChR) as agonists. QA, like many other alkaloids, occur as complex mixtures in plants. Some QA preferentially bind to the nicotinic AChR, whereas others tend more to bind to the muscarinic AChR. Some QA exhibit a prominent cross-reactivity. Additionally, QA such as lupanine and sparteine inhibit Na^+ and K^+ channels, thus blocking the signal transduction in nerve cells at a second critical point. A few particular QA, such as anagyrine, cytisine, and the bipiperidine alkaloid ammodendrine (which cooccurs with QA in many plants), are mutagenic and lead to malformations (see above).

If we accept the hypothesis that alkaloids were developed as chemical defense compounds through a process of 'evolutionary molecular modeling' the 'cross-reactivity' described makes sense: any compound which can interfere with more than one target or with more than one group of adverse organisms is likely to be more effective and thus has a better survival value in general than a more selective allelochemical. In addition, herbivores will try to develop tolerance to or resistance against the dietary toxins. If more than one target is affected by a defense chemical the chances of a herbivore developing specific resistances concomitantly are much smaller than in single-target situations. In conclusion, we can say that Nature has obviously tried 'to catch as many flies with one clap as possible' in the selection of alkaloids during evolution. (*See* **Trypsin**

ALLERGENS

E N C Mills, Institute of Food Research, Norwich, UK
A S Tatham, University of Bristol, Bristol, UK

Introduction

This encyclopedia entry describes the nature of food allergens involved in IgE-mediated allergy, their nomenclature, and the properties of proteins thought to predispose them to becoming allergenic. Current knowledge of food allergens of plant and animal origin is summarized, and the role that cross-reacting IgE epitopes play in the relationship between pollen and latex allergy and allergies to certain fruits and vegetables is discussed. The impact of postharvest treatments and food processing on allergen activity is described, together with the problems posed to food allergic individuals by 'hidden' allergenic ingredients and those that result from cross-contamination in the factory and catering outlets.

What is an Allergen?

During the course of normal immune functioning, the body produces a number of different forms, or isotypes, of immunoglobulins such as IgA, IgG, IgM, and IgE, which bind to 'nonself' molecules. These include molecules found in microbial pathogens, parasites, environmental agents such as pollen and dietary proteins. However, in the allergic disease classified as a *Type I hypersensitivity reaction*, this antibody repertoire is altered, and the body synthesizes larger quantities of IgE, an antibody type normally produced only in response to parasitic infections. As yet, we do not understand the mechanisms whereby particular allergens elicit an IgE rather than the normal IgG response in certain individuals. This IgE is directed towards target molecules, which are usually proteinaceous in nature and are known as allergens. IgE can become associated with mast cells, and on binding multivalent allergen, it becomes 'cross-linked' at the mast cell membrane, triggering the

release of immune mediators, such as histamine, which actually cause the symptoms associated with allergic reactions. (*See* **Food Intolerance**: Food Allergies for more information.)

The sites on a protein that are recognized by an antibody are known as epitopes and can be either linear or conformational. In the former, only the primary sequence of a polypeptide is involved in antibody recognition, but in conformational epitopes, the three-dimensional structure of a protein is important. Thus, a number of segments of the polypeptide chain that may be quite distant in the amino acid sequence of a protein are brought together spatially as a consequence of its tertiary and quaternary structure, to form an epitope. Most epitopes are thought to be conformational in nature and are particularly difficult to define in relation to food allergens where processing can have such a disruptive effect on native protein structure (see below).

Allergen Nomenclature

The World Health Organization and the International Union of Immunological Societies produce an official list of allergens, which are designated by the Allergen Nomenclature subcommittee. Allergens included in this listing must induce IgE-mediated (atopic) allergy in humans with a prevalence of IgE reactivity above 5%. An allergen is termed major if it is recognized by IgE from at least 50% of a cohort of allergic individuals but does not carry any connotation of allergenic potency; allergens are otherwise termed 'minor.' The allergen designation is then based on the Latin name of the species from which it originates and is composed of the first three letters of the genus, followed by the first letter of the species finishing with an arabic number, e.g., *Ara h 1* relates to an allergen from *Arachis hypogea* (peanuts).

Types of Food Allergens

There appear to be around eight foods, including those of both plant and animal origin, that are responsible for causing the majority of food allergies, namely peanuts and tree nuts, wheat, soya, cows' milk, egg, shellfish, and fish. The geographical distribution of these allergies reflects patterns of food consumption with, for example, buckwheat allergy being much more common in the Far East, where they are staple foods, than is the case in Western countries. The distribution of allergies also differs across Europe, with reactions to fish and shellfish being higher in Mediterranean countries, where fish consumption is higher.

In addition to foods that sensitize individuals directly (probably via the gastrointestinal tract), there is a group of fruit and vegetable allergies that arise from the presence of cross-reactive epitopes in the allergens. Thus, individuals who become sensitized to pollen are more likely to develop IgE, which recognizes homologous proteins present in fresh fruits and vegetables. Around 70% of individuals who develop birch pollen allergy with IgE towards the pollen protein *Bet v 1*, develop allergies to apples and other fruits of the *Rosacea* because the anti-*Bet v 1* IgE reacts with fruit homologs such as the apple protein *Mal d 1*. Similarly, many of those who develop allergy to latex have IgE, which recognizes the chitin-binding domain of the hevein polypeptides that make up the rubber latex network. An almost identical domain is found in a group of enzymes, the class I chitinases, found in a number of fruits including avocado, chestnut, and banana, which the anti-latex IgE recognizes. As a consequence of this cross-reactivity, individuals with latex allergy frequently suffer from allergic reactions on consuming these fruits (**Figure 1**.)

Protein Properties and Allergenicity

Two factors that are thought to contribute to the allergenic potential of food proteins are their resistance to the effects of thermal processing used in food preparation (discussed below) and breakdown by digestive enzymes in the gastrointestinal tract. The stability of a number of allergenic proteins to pepsin, including those from peanuts, soya, and cows' milk, has been compared with that of nonallergenic proteins. It was found that all the allergens either remained undigested or gave stable fragments that persisted for 8–60 min (depending upon the allergen), whereas the nonallergens were completely digested after less than 15 s. As peptides are required to have a molecular weight of greater than 3000 Da in order to stimulate an immune response, large stable

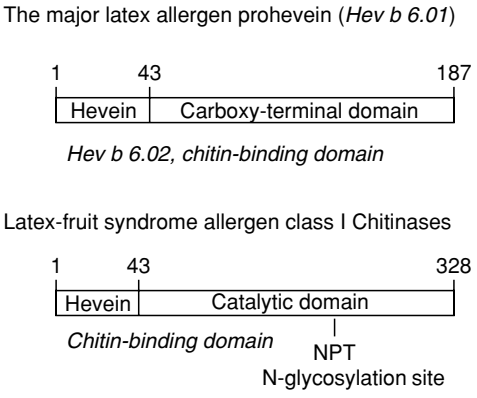

Figure 1 Presence of conserved hevein domains in latex and the class I chitinases of fruits responsible for many latex–fruit cross-reactive allergies.

fragments, as well as intact proteins, have the potential to act as sensitizers. Similarly, such large fragments may be able to cross-link mast cell IgE, leading to histamine release. Whilst the bulk of food proteins are broken down into immunologically inactive fragments, very small proportions (milligram amounts) of material, which are still immunologically important, may escape digestion. Circumstantial evidence that food proteins can resist digestion and cross the gut barrier is offered by the presence of antibodies to a wide range of food proteins in the circulation of normal individuals. The presence of proteins, such as ovalbumin in the blood of individuals after consumption of egg, also supports the premise that intact proteins, albeit in small quantities, can enter the body. However, although the nature of the transported proteins has not been clearly defined, a large proportion of cow's milk allergic patients have specific IgE, which recognizes proteolyzed β-Lg, some of which reacts better with the hydrolyzed protein than the intact form. Thus, the resistance of allergens to the effects of the digestive process plays an important role in determining the allergenic potency of food proteins.

Allergens of Plant Origin

Many plant food allergens are pathogen-related (PR) proteins, which are produced by the plant as a defense against pathogenic microorganisms, insects, and invertebrate pests. They have been classified into a number of families on the basis of sequence similarities or enzymic properties and are receiving attention from plant breeders, as a tool for GM crops, because of their protective activities against agricultural pests. However, they are cross-reactive allergens in fruits, vegetables, and pollen. Allergens, other than PR proteins, are inhibitors of proteases and α-amylases, profilins (actin-binding proteins), seed-storage proteins (albumins, globulins, and prolamins), proteases and lectins (agglutinins). These are summarized in Table 1.

Fruit and Vegetables

Fruit allergy is increasing and is often associated with birch- and grass pollinosis, as well as latex–fruit syndrome. Oral allergy syndrome is a manifestation of food allergy, where certain foods cause itching or hives when they touch the lips and mouth. Fruit and vegetables are often responsible for this reaction, owing to pollen cross-reactivity, and many fruit allergens are PR proteins.

Allergens homologous to the major birch pollen allergen *Bet v 1* (PR group 10), are found in apple *Mal d 1*, cherry *Pru av 1*, apricot *Pru ar 1*, pear *Pyr c 1*, carrot *Dau c 1*, and celery *Api g 1*, but may trigger responses to many other fruits and vegetables. By contrast, in areas free of birch, the major allergens in patients sensitized to Rosaceae fruits are lipid transfer proteins (LTP, PR group 14), 9-kDa proteins that often have antifungal and antibacterial activities. LTP allergens characterized include apple *Mal d 3* and peach *Pru p 3*, but homologous proteins are found in a range of plant-derived foods (vegetables, nuts, and seeds), and as a consequence, LTPs have been described as panallergens.

Class-I chitinases (PR group 3) are a group of carbohydrases active against the exoskeletons of insects and the cell walls of fungi. They are widely distributed in plants and are also termed panallergens, with characterized allergens including those from avocado (*Prs a 1*) and banana (*Mus p 1.2*). Wound-induced chitinases (Win) have been extracted from virus-infected leaves (PR group 4) and have been reported in turnip, tomato, and potato. Another group of carbohydrases, the glucanases (PR group 2), are active against fungal cell walls, have been isolated from latex, and are recognized by IgE from food-allergic patients with hypersensitivity to banana, potato, and tomato. Lastly, thaumatin-like proteins (PR group 5) are another group of allergens that have antifungal and/or antibacterial activity, allergens having been characterized in apple (*Mal d 2*) and cherry (*Pru a 2*).

NonPR protein allergens include the profilins, originally identified from birch pollen, *Bet v2*, which are now recognized as cross-reactive plant allergens in a wide range of fruits, vegetables, nuts, and seeds. Thiol proteases (proteolytic enzymes) have also been identified as allergens in kiwi *Act c 1*, papaya, fig, pineapple, and soybean. Patatin, a storage protein from potato, has also been shown to be an allergen in raw potato and cross-react with the latex allergen, *Hev v 7*.

Tree Nut and Peanuts

Nut allergy is the most common form of food allergy and the most common cause of death by anaphylaxis. The major allergens are 2S albumins and the 7S and 11/12S globulins. In peanut, three of the major allergens are major storage proteins: *Ara h 1* is the 7S globulin, conarachin, a vicilin-like glycoprotein; *Ara h 2* is a 2S albumin; and *Ara h 3*, is a subunit of the legumin-like 11S globulin, arachin. The IgE binding epitopes of *Ara h 1* and *2* have been determined and mutagenized to alter their activity. Brazil nut contains a 2S storage protein allergen, *Ber e 1*; a major allergen is a 2S albumin with a high methionine content. Related 2S albumins are found in walnut, *Jug r 1*, which also contains a 7S globulin allergen, *Jug r 2*. In addition to storage protein allergens, chestnut contains an endochitinase allergen *Cas s 1*, and

Seeds				
Barley	Inhibitor	*Hor v 1*	15 000	Glycosylated α-amylase inhibitor
	Inhibitor	CMb	16 000	Glycosylated subunit of barley tetrameric α-amylase inhibitor
Castor bean	2S albumin	*Ric c 1*	10 000	Storage protein
Lentil	Vicilin	Len c 1	45-50,0000	Storage protein
Maize	LTP	*Zea m 14*	9 000	Antifungal and antibacterial activity (PR-14)
Mustard	2S albumin	*Bra j 1*	14 000	Storage protein
	2S albumin	*Sin a 1*	14 000	Storage protein
Rice		*RAP*	14 800	Rice allergenic protein
Rye	Inhibitor	*Sec c 1*	14 000	α-Amylase/trypsin inhibitor
Sesame	2S albumin	*Ses i 1*	10 000	Storage protein
	Vicilin	Ses i 3	60,0000	Storage protein
Soybean	Cys protease (inactive)	*Gly m 1*	7 000	Function
		Gly m 2	8 000	Unknown
	Profilin	*Gly m 3*	14 000	Actin (cytoskeleton)-binding protein
Wheat	Inhibitor	*CM16**	16 000	Glycosylated subunit of wheat tetrameric α-amylase inhibitor
	Prolamin	γ-gliadin	30-50,0000	Storage protein of glutenin

peanuts a profilin, *Ara h 5*. Other nuts, such as cashew, hazelnut, pecan, and pine nuts are known to be allergenic, and contain storage globulin, 2S albumin and LTP allergens.

Seeds

Seed allergens are predominantly nonPR-type proteins, comprising storage proteins, proteases and α-amylase inhibitors. Wheat and related cereals, barley and rye, contain a range of allergens including the prolamins (alcohol soluble storage proteins), which are responsible for food-dependent exercise-induced anaphylaxis and atopic dermatitis; the same proteins are active in celiac disease and dermatitis herpetiformis. Inhibitors of proteases and α-amylases protect the seed from microorganisms and insect pests, characterized allergens including the 12–15-kDa proteins and inhibit α-amylases or trypsin and are both inhalant allergens (e.g., baker's asthma) and food allergens. Those with the highest activity are glycosylated subunits of tetrameric α-amylase inhibitors from wheat (CM16) and its homologs from barley (CMb) and BMAI-1 and rye *Sec c 1*, similar proteins being found in rice. The major allergens in rice are α-amylase and trypsin inhibitors, and in buckwheat, the major allergen is another trypsin inhibitor. Peroxidases in wheat and barley (PR group 9) of 36 kDa have been identified as allergens in baker's asthma.

The major allergens in yellow mustard *Sin a 1* and oriental mustard *Bra j 1*, castor bean, cottonseed, chickpea, oilseed rape *BnIII*, and sunflower SFA8 are 2S albumins (apart from sunflower, which consists of a single polypeptide chain), and they consist of two polypeptide chains linked via disulfide bonds. In soybean, the two major storage globulins, β-conglycinin and glycinin, are major allergens; other allergens are profilin *Gly m 3* and a papain-related thiol protease *Gly m Bd28*.

Allergens of Animal Origin

Egg

The allergens primarily originate from egg white, the major allergens being ovomucoid (*Gal d 1*) and ovalbumin (*Gal d 2*), which constitute 10 and 50% of white proteins, respectively. Both proteins are heavily glycosylated with 25% of the mass of ovomucoid comprising carbohydrate. However, in ovomucoid, the IgE epitopes are clustered in seven regions of the protein sequence and do not encompass glycosylation sites. Whilst IgE epitopes of ovomucoid appear to be conformational in newly acquired sensitivities to egg, linear epitopes are more important in long-standing egg allergy. The IgE epitopes of ovalbumin are also resistant to enzymic digestion and denaturation, and seven IgE-binding regions have been identified, which tend to cluster at the N- and C-terminal regions of the protein. Ovalbumin has also been found in an immunologically active form in the blood of human subjects following consumption of raw egg. Two minor allergens, ovotransferrin (*Gal d 3*) and lysozyme (*Gal d 4*), have also been identified in egg white. In general, cooking has been found to reduce the allergenic activity of egg.

Cows' Milk

Allergens are found in both the whey and casein fractions, the most common allergens being β-lactoglobulin and α-casein, although other IgE-reactive proteins have been identified (Table 2). β-Lactoglobulin is highly resistant to proteolysis and is taken up in an intact form by the gut in experimental systems, with the major IgE epitopes having been in four main regions located on the more mobile surface loops of the protein. The caseins also appear to contain thermostable epitopes, with IgE binding being located in around seven different regions of the protein.

Fish

The major allergen in fish is the muscle protein parvalbumin (*Gad c 1*), which belongs to a group of such proteins unique to fish and amphibians. Whilst it has only been characterized in depth for cod and salmon, parvalbumin is conserved across fish species, a factor responsible for the cross-reactive nature of allergens in cod, salmon, mackerel, herring, and plaice, amongst many other fish species. It acts as a calcium buffer protein in fast muscle, binding the Ca^{2+} ions in a calcium-binding motif known as an EF-hand. *Gad c 1* has been shown to bind IgE in five regions evenly distributed along the length of the protein, one of which encompassed one of the Ca^{2+}-binding sites. Like other calcium-binding proteins, *Gad c 1* is heat-stable, with the holo-form being both more IgE-reactive and more heat-stable than the apo form.

Shellfish and Seafood

Tropomyosin, a heat-stable muscle protein, is the major allergen in shellfish and seafood, with highly homologous proteins being found in the commonly edible crustaceans. These homologies are responsible for the cross-reactive allergies observed between various types of seafood including shrimps, lobsters, crab, squib, and abalone, and inhalant insect allergens, such as those from cockroaches. Two main linear IgE-binding sites have been identified in the shrimp allergen, *Pen i 1*, one in the N-terminus, which

Table 2 Major food allergens of animal origin

Food	*Allergen*	*Allergen designation*	*Molecular weight*	*Function and stability*
Hen's egg	Ovomucoid	*Gal d 1*	28 000	Protein source with protease inhibitor

		Tod p 1 (squid)	34 000	
		Hal m1 (abalone)	38 000	
			49 000	
Meat	Serum albumin	*Bos d 6* (beef)	68 000	Fatty-acid-binding protein
		Bos d 7 (beef)	150 000	Immunoglobulin

showed no homology with vertebrate tropomyosin, and another in the C-terminal region. The first two residues of the C-terminal epitope appear to be crucial for IgE binding and are not found in vertebrate tropomyosin. As a consequence of the lack of homology in the IgE epitopes, there is no cross-reactivity between IgE from shell-fish allergic individuals and animal muscle tropomyosins. In addition to being found in cooked meat, the allergen also leaches into cooking water.

Meat

Meat allergy is rare, the major allergens having been identified as serum albumins and IgG, both of which are also minor milk allergens. However, unlike shellfish, muscle proteins such as tropomyosin do not appear to be involved. Processing has been found to reduce the allergenic activity of meat allergens, with more severe processes, such as sterilization, causing the greatest reduction.

Factors Altering the IgE reactivity of Food Allergens

Postharvest treatments and processing can potentially alter the IgE reactivity of allergens by altering the levels of allergens present in raw materials and altering IgE-epitope presentation.

Effects of Raw Material and Postharvest Handling

A number of plant protein allergens belong to multigene families, where a number of isoforms differing in only a few amino acid residues may be present. In addition, the levels of different isoforms may vary between cultivars. These changes have been demonstrated to make a difference particularly with regard to the apple allergen *Mal d 1*, where the IgE reactivity of certain cultivars is demonstrably higher than others. Furthermore, one variant, *Mal d 1a*, has a higher IgE-binding capacity than another variant *Mal d 1b*, which differs by only 15 amino acid residues. Allergen levels appear to increase in apples following harvest and during storage at 4 °C over 130 days, probably because of their association with the ripening process, and the fact that they are 'PR' proteins and hence synthesized in response to environmental stress. Storage under modified atmospheres can reduce these increases in allergen levels, as might be anticipated from its ability to delay fruit ripening.

Effects of Processing

There are several food proteins that do not adopt a compact globular three-dimensional structure, but are highly mobile, adopting an ensemble of conformations. These include the γ-gliadin from wheat and caseins from milk. The IgE epitopes on such proteins

are likely to be linear and hence less affected by thermal treatments than those on globular proteins. In contrast, globular proteins undergo a marked denaturation at around 50–60 °C, which is accompanied by a loss of tertiary and secondary structure and is usually followed by aggregation.

Cross-reactive allergens, such as those involved in the pollen–fruit and latex–fruit allergy syndromes, are generally destroyed by cooking, and hence the allergic reactions are confined to raw produce. In addition, heating has been found to reduce the allergenicity of beef and purified bovine allergens. However, many other food allergens are remarkably heat-stable, particularly those originating from plant seeds, which are involved in sensitization via the gastrointestinal tract. This is illustrated by Figure 2, which shows the differential scanning calorimetry (DSC) thermogram for glycinin, indicating that the main thermal transition for this protein is around 90 °C. There is also evidence that, whilst many of highly disulfide bonded plant proteins unfold on heating, they are able to refold on cooling to an almost native structure. Hence, many allergenic proteins may be able to retain both linear and conformational epitopes following processing, allowing an IgE-mediated reaction towards the native and processed protein. However, the unfolding and subsequent aggregation processes that occur in many food proteins offer the possibility of introducing new epitope sites. This applies to many allergens, including those from soya, egg, and shellfish meat, which form aggregates on heating that become incorporated into heat-set gel networks. Thus, allergic IgE binding to roasted nuts has been shown to be 90 times greater than that observed towards raw peanuts, indicating that processing does introduce additional IgE binding sites. The technical difficulties of working with large aggregated protein systems has meant that the characterization of such processing-induced epitopes has been difficult.

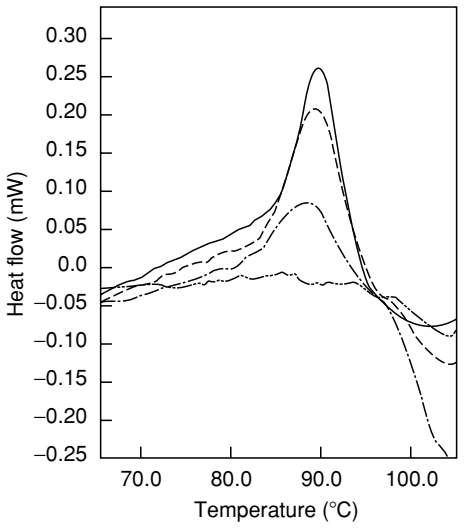

Figure 2 Thermostability of the soya allergen, glycinin, as determined by DSC. Native protein (——); after treatment at 70 °C, 10 min (–); 80 °C, 10 min (-·-·-) and 90 °C, 10 min (-···-···-).

Carbohydrate residues on glycoproteins have also been implicated as thermostable IgE epitopes, although some workers have shown that their removal does not affect IgE reactivity. Furthermore, because of their sparse nature in some allergens, they do not offer the polyvalency necessary IgE cross-linking on mast cells and subsequent histamine release. Whilst they have not been well characterized, there is now evidence that Maillard browning adducts formed following severe heat treatments contribute to the allergenic activity of roasted nuts such as peanuts and pecan nuts. It appears that Maillard modified peanut allergens *Ara h 1* and *Ara h 2* become cross-linked to form high-molecular-weight aggregates that bind IgE more effectively than unmodified allergens and are also more resistant to gastric digestion. The role that other thermally induced modification, such as lactosylation of milk proteins, may play in altering the allergenic activity of products, including severely heat-treated milks, has yet to be characterized in detail.

Problems of 'Hidden' Allergens

Those individuals who suffer from severe forms of food allergy, such as anaphylaxis, can have reactions triggered by very small amounts (as little as 100 μg) of an allergen present in a food. Indeed, traces of nuts found in processed oils and carry-over of allergens on utensils used for serving foods can be enough to cause an allergic reaction. Proteins are widely used as functional ingredients in foods, with soya flours being routinely included in bread and bakery products as an improver, whereas other soya ingredients are used in soups and sauces as well as meat products such as sausages. Similarly, caseinates and whey protein isolates are used in a range of products such as sauces, cakes, and confectionery.

Another difficulty is presented by the uncertainty relating to accidental contamination, where processing lines are shared between products utilizing different ingredients. This is particularly problematic for confectionery, where tree nuts and peanuts are a favored ingredient and has led to labeling of products with the warning 'may contain nuts.' Indeed, surveys have shown that a large proportion of chocolate confectionery is contaminated with hazelnut proteins, probably as a result of cross-contamination in

factories during manufacture. One of the consequences of this for the allergic consumer is that allergenic proteins are hidden as ingredients in manufactured products. Accidental exposure to allergens is a frequent occurrence, and epidemiological studies have shown that around 50% of peanut-allergic individuals have a reaction at least once a year as a consequence of accidental exposure.

In order to address concerns over inadvertent contamination of raw materials by allergenic nuts and seeds, methodologies have been developed for detecting allergens in raw materials and finished products. The favored method of analysis is immunoassay, particularly the form known as enzyme-linked immunosorbent assay (ELISA). In general, the approach adopted has been to develop either a polyclonal or a monoclonal antibody preparation that is specific for a major allergen present in a food stuff, such as *Ara h 1* from peanuts. Whilst it is possible to develop sensitive calibration curves for allergens in buffer, difficulties can be encountered when analyzing foodstuffs, where the presence of fats and polyphenol components found in products such as chocolate can reduce assay sensitivity by 10-fold. Nevertheless, such assays have been developed for a range of allergenic proteins, including milk proteins, hazelnuts, and peanuts, and are available for manufacturers, retailers, and other analysts to detect allergen contamination. Another exciting new development is the application of highly sensitive mass spectrometry methods to allergen analysis, which has the potential to offer a second orthogonal method of analysis to immunoassay, as is desirable for purposes of enforcing labeling regulations and hazard control procedures.

ALMONDS

D E Kester and A A Kader, University of California Davis, Davis, CA, USA
S Cunningham, Blue Diamond Almond Growers, Sacramento, CA, USA

Introduction

The almond is the major commercial tree nut crop of the world. This importance has been achieved by the very large increase in acreage and production in California during the past 25 years. This article reviews the areas of production, principal cultivars, important uses, and methods of handling and storage.

The Crop and its Importance

Global Distribution

The cultivated sweet almond (*Prunus dulcis* Miller (D. A. Webb) syn. *P. amygdalus* Batsch) originated from within the wild species known originally as

Amygdalus communis L. which grew on the lower slopes of mountains in central Asia. About 30 related almond species have been described occupying specific ecological niches in the arid steppes, mountains, and deserts of central and south-western Asia and southern Europe.

The geographical range of the cultivated almond corresponds to the three stages of cultural evolution: (1) Asiatic (south-west and central Asia); (2) Mediterranean (countries bordering both sides of the Mediterranean sea); and (3) Californian (central valleys of California, parts of Australia, central Chile, and areas of South Africa).

Almonds are adapted to Mediterranean, steppe, and desert climates characterized by mild, rainy winters and hot, dry summers. Although they have traditionally been grown with other arid tree and vine crops, such as olive, pistachio, and grape, almond trees respond so well to supplementary irrigation, fertilizers, good soil, disease, and insect control and other intensive culture methods that yields can be increased five-to 10-fold over the traditional culture practiced for centuries.

Commercial Importance

Since 1950, almonds have become the most important world tree nut crop, with present annual production of approximately $350–400 \times 10^6$ kg ($800–900 \times 10^6$ lb). In any given year, California produces about 70% of the world's supply of almonds (**Figure 1**), with most of the balance coming from Mediterranean countries (Spain, Italy, Greece, Portugal, Morocco, Tunisia, Canary Islands, France). Almonds are also grown, often in primitive culture, as local crops in Iran, Israel, Afghanistan, Pakistan, south-eastern Russia, north-west India, Syria, Turkey, and Iraq.

Cultivars

Older botanical literature described two botanical varieties as *Prunus amygdalus* var. *dulcis*, the sweet almond, and *P. amygdalus* var. *amara*, the bitter almond. In reality, bitter and sweet kerneled trees exist side by side in seedling populations with the same parents; the difference is apparently due to a single dominant gene. Some of the more primitive almond-growing areas (e.g., in Asia and Morocco) still grow almond trees as seedling populations (wild or cultivated).

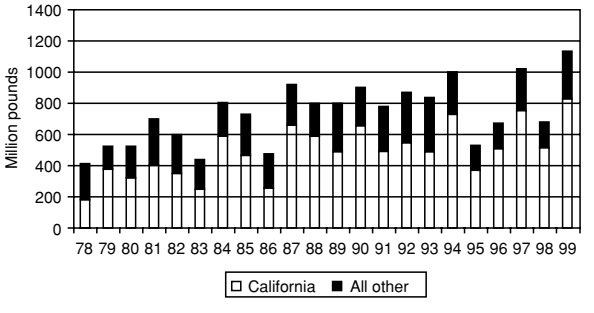

Figure 1 Almonds produced in California in comparison to world production.

Modern orchards grow selected cultivars, which are clones that are vegetatively propagated by budding or grafting upon specific rootstocks. Rootstocks include almond and peach seedlings, as well as certain plums and peach × almond hybrids. Historically, many cultivars were apparently identified when superior individual trees were selected to replace 'bitter' trees within seedling orchards. In recent years, controlled breeding has created cultivars with special qualities. Use of genetic engineering methods will augment genetic improvement.

Although many cultivars exist in the world, a limited number have dominated industrial and local use within specific production areas. Cultivars are selected for performance in the orchard. Flowers on most current cultivars are self-incompatible, so that two or more cultivars that bloom at nearly the same time need to be planted together, preferably in adjoining rows. Hives of honeybees are placed within the orchard to effect cross-pollination. Combinations of cultivars are also chosen to facilitate an economical harvest. Other cultivar characteristics of importance include yield, tree habit, disease and insect resistance, ease of harvest and processing, and other specific characteristics. Nuts of different cultivars vary from very hard-shelled to soft- and paper-shelled. Cultivars are also chosen for their marketing potential, and specific marketing classes have evolved.

California Nonpareil accounts for around 44% of the production. Kernels are uniform in shape, relatively flat, smooth, attractive in appearance, easy to blanch, and are versatile in processing and utilization. The nut has a thin, papery shell which is easy to remove without damaging the kernel. This shell is subject to worm and bird damage. The cultivar is subject to a genetic variant referred to as noninfectious bud failure which is controlled through selection and management of propagation sources.

Mission (Texas) is an old cultivar which produces small, round, plump nuts. Kernels have a relatively strong almond flavor owing to higher levels of amygdalin. The pellicle is difficult to remove during blanching. The shell is hard and protective of worm damage. Padre is a similar cultivar, the kernels of which can be combined with Mission. Peerless is grown to a limited amount as a pollinator of

Nonpareil. The shell is hard and the nuts are sold primarily in the shell.

Ne Plus Ultra has a large, elongated kernel, blooms early, and cross-pollinates Nonpareil. The cultivar is gradually becoming obsolete in California, but orchards still exist and it represents 3% of the total crop.

In the mid-1960s, Merced and Thompson were planted to replace Ne Plus Ultra, Peerless, and Mission. Similarly shaped and blanchable kernels of these and later introduced cultivars have been mixed and marketed under the name California. Other cultivars of this group include Price, Fritz, Monterey, and others.

Carmel became popular in the mid-1970s and is the second most important cultivar in new plantings (18% of almond acreage in 1996). Sonora was introduced in the mid-1970s and is becoming popular as an early-blooming pollinator for Nonpareil. Sonora has large, elongated nuts and is sometimes marketed with Carmel.

Additional cultivars that have recently been planted in California include Butte, Livingston, LeGrand, Mono, and Ruby. Their nuts are grouped either as Mission or California marketing classes.

Spain Marcona and Desmayo are the most important cultivars in Spain, each accounting for about 25% of Spanish production. Marcona has large, heart-shaped, flat, high-quality kernels which blanch easily. Desmayo produces large, elongated, flat kernels, the pellicle of which is thin and can be readily removed after roasting by rubbing between the fingers. Many other cultivars exist in specific production areas of Spain but their kernels are usually mixed together for marketing.

Italy Most of the older areas (Puglia, Sicily, and Sardinia) are reducing production. Kernels of the many cultivars are mixed together for marketing. The main cultivars in newer orchards include Tuono, Felipo Ceo, and Genco, which are self-fertile.

France New, late-blooming, high-yielding, vigorous cultivars derived from breeding programs are being planted not only in France but other countries of the Mediterranean area. These cultivars include Ferragnes and Ferraduel, kernels of which are marketed together with those from other cultivars.

Morphology and Anatomy

Fruit

The almond fruit is known botanically as a drupe, which is composed of three basic parts: (1) exocarp (skin), which in almond is pubescent; (2) mesocarp, which is fleshy and becomes the hull; (3) endocarp (shell). This overall structure is the same as stone fruits, such as peaches, plums, and apricots, but differs in that the almond mesocarp does not enlarge into fruit, but dehisces (splits) at maturity and dries. The hull is an important feed for livestock.

Seed

The almond kernel is the seed which develops from the ovules. Although two ovules are present in the flower, only one normally develops to produce a single kernel. The seed is edible because it lacks amygdalin, the bitter compound in many seeds. The seed consists of the embryo (also referred to as the meat), surrounded by seed coats or testae (also referred to as the pellicle and sometimes the skin). The embryo consists of the hypocotyl root axis with growing points for roots and shoots which appear upon germination, and two massive cotyledons, which are storage organs and contain the high-energy compounds characteristic of almond.

Almond kernels of different cultivars have characteristic sizes, shapes, appearances, thickness of pellicle and, to some extent, flavor. Double kernels result when two kernels develop within the same nutshell. Twin kernels result when two or more embryos develop within the same pellicle.

Harvesting, Handling, and Storage

Harvesting

Almond nuts should be harvested as soon as possible after maturation to avoid quality losses and to minimize problems with fungal attack and insect infestation. Indices used to determine maturity stage and optimum harvest dates for almonds include hull dehiscence (splitting), separation of the hull from the shell, decrease of the fruit removal force, and drying of hulls and kernels. Almond harvesting in California is by machines. Almonds are shaken from the tree to the ground by various kinds of shakers. After about a week of drying, the nuts are raked into rows and picked up by mechanical harvesters. They are then transported in bulk to hulling machines which separate the hull from the in-shell product.

Postharvest Handling

Dehydration of the kernel begins while the nut is still on the tree. Further drying takes place after the nuts are knocked to the ground. Under rainy and/or cool weather conditions, heated-air dehydrators may be used to reduce moisture content to 7% or less. Most almonds sold commercially range from 4% to 5% in

moisture. Dried almonds are transported in bulk to processing plants where they are stored in bins, silos, or other bulk-storage containers for a few weeks to several months before final processing and preparation for market.

In-shell almonds are fumigated with methyl bromide or aluminum or magnesium phosphide, which are lethal to all insect life stages. Residues are monitored to insure that levels in finished products are below legal limits. (*See* **Fumigants**.)

Alternatively, almonds can be kept in a controlled atmosphere of 0.5% oxygen and about 10% carbon dioxide (balance nitrogen) to control insects. The nuts can be frozen for insect control at home, or for small-scale operations. (*See* **Controlled-atmosphere Storage**: Applications for Bulk Storage of Foodstuffs.)

Storage

Compared to other nuts, almonds and almond products have a long life. This is attributable in part to their low moisture, the presence of relatively low levels of polyunsaturated fatty acids, and high tocopherol levels.

Raw almonds should be stored at 0–5 °C, and 65–70% relative humidity (RH), to minimize deterioration during storage. Prolonged exposure to direct sunlight causes the skins to darken and reduces shelf-life. Since almonds readily absorb odors, they should never be exposed to pungent odors from onions, fresh fruits, fish, cheeses, paint, chemicals, or other products.

Both the maintenance of quality and safety of almond and the extension of storage life depend upon the initial moisture content, the RH and temperature of storage, and the exclusion of oxygen and insect pests. (*See* **Storage Stability**: Parameters Affecting Storage Stability.)

The Food and Drug Administration (FDA) regulations for tree nuts define a safe moisture level (i.e., moisture content which will not support fungal growth) as a water activity level that does not exceed 0.70 at 25 °C. This is equal to a moisture content of about 7%. The optimum range for unroasted almonds is 4–6% moisture. The equilibrium moisture of almonds ranges from 3.8 to 5.0% at 30% RH and from 8.1 to 10% at 75% RH at 5 °C.

The relationship between moisture content and equilibrium relative humidity (ERH) is temperature-dependent. From 20% to 80% ERH (for any given moisture content), ERH rises approximately 3% for every rise in temperature of 10 °C. At a given RH, air will contain more water vapor at a high temperature than at a low temperature. Temperatures between 0 °C and 5 °C are recommended for almonds; the lower temperatures allow longer storage life (up to a year).

Low oxygen (0.5% or lower) atmospheres are beneficial for keeping flavor quality, delaying rancidity, and controlling stored products against insects. Exclusion of oxygen is usually achieved by vacuum packaging or replacement with nitrogen in storage facilities and transport vehicles. The storage life of raw almonds can be extended up to 2 years under low-oxygen atmosphere at 0 °C. (*See* **Chilled Storage**: Packaging Under Vacuum.)

Quality and Safety Factors

Important appearance factors for almonds marketed in the shell include shell integrity, suture opening, and shell color. Kernel defects include damage from insects, mold and mechanical injury, gum, callus growth, shriveling and doubling. Kernels are graded for size. Quality criteria used in the grade standards include freedom from dust particles and other foreign materials, and uniformity of shape and color.

Textural factors, including crispness and firmness, are influenced by moisture content. Thus, roasted almonds are usually more crisp than raw almonds.

Flavor quality depends upon sweetness, oiliness, intensity of almond flavor, and absence of off-flavors resulting from rancidity, staleness, or other causes. A problem called concealed damage, which appears as internal darkening and poor flavor after roasting, is related to wet conditions and high temperatures during temporary storage following harvest.

Safety factors relate primarily to the potential contamination of almonds with mycotoxins, especially aflatoxin produced by the fungus *Aspergillus flavus*. Contamination can occur in the orchard or during postharvest handling if recommended handling and storage procedures are not followed. Elimination of nuts exhibiting any symptoms of fungal contamination is an integral part of market preparation. (*See* **Mycotoxins**: Occurrence and Determination.)

Residues of pesticides used to control the major insect pest, navel orange worm (*Anyelois transitella* Walk), have been reduced by 40% during the last 10 years. This reduction was made possible through such integrated pest management procedures as orchard sanitation, maintaining natural predator balance, and prompt harvest. (*See* **Pesticides and Herbicides**: Residue Determination.)

Propylene oxide, the only sterilant approved for nuts, is generally effective against bacteria, but less effective against yeasts and molds. The nuts are treated in a specially designed vacuum chamber. After treatment, a series of air washes under vacuum removes traces of the remaining gas. Each chamber load then enters a postconditioning staging area until cleared for both residue level and microbial load.

Propylene oxide-treated products are recommended when raw almonds are incorporated into dairy products, such as cheese or yogurt, or in high-moisture foods, or used for other microbially sensitive applications.

Composition and Nutritional Quality

The chemical composition related to nutritive value is summarized in Table 1.

Nuts are a healthy snack if eaten in moderation. Almonds and other nuts are good sources of protein, essential fatty acids, fiber, vitamin E, and minerals. Most of the fat in almonds is monounsaturated. This may be partly responsible for the association observed between frequent nut consumption and reduced risk of coronary heart disease.

Market Forms

Almonds are eaten alone as snacks and are included in many processed foods to enhance their appeal. The wide variety of foods includes sweets, health foods, baked goods, cereals, icecream, dry mixes, garnishes for food entrées, and packaged snacks.

Table 1 Chemical composition and nutritive value of almonds (per 100 g edible part)

Component	*Mean*

Almonds may be used directly as a whole nut, or it may be appropriate for them to be chopped, diced, sliced, split, halved, slivered, or cube-cut. They are available in an array of kernel sizes as segregated by round and slot-holed screens which separate according to kernel width and thickness. There is also a wide range of smaller-sized products, such as flakes, slivers, and meals. The variety of shapes, sizes, and colors available makes almonds appropriate ingredients for many different foods.

The largest usage category is confectionery. Many premium confectionery products are enhanced by the combination of chocolate and almonds. Almonds enhance the flavor and acceptability of confections by lowering the sweetness of the finished piece, by adding crunch, enhancing the nutritional value, and adding sales appeal.

Manufacturing

Roasting

The flavor of most almond varieties is quite mild before they are roasted. The strong flavor and crunchy texture desired in most applications are developed by roasting. Most almonds added to chocolate are roasted almonds. Almonds may be roasted by hot air or in hot oil. Almonds roasted in oil may pick up some of the flavor of the roasting oil. Dry-roasted almonds usually possess the same roasted flavor, a somewhat harder texture, and slightly lower moisture (below 2%).

The amount of oil absorbed by almonds in oil roasting is minimal, usually 3–4%, roughly equal to the amount of moisture driven off by roasting. This small amount of oil has a minimal impact on the fat content of the final product. The degree of roast in a given application is determined by experimentation and/or sensory testing.

Blanching

Blanching is the process of soaking the almonds briefly in hot water, then slipping the skins from the kernels using rollers.

Blanched almonds have a milder flavor and softer texture than unblanched almonds. The only cultivar which is not blanchable is Mission. Blanched almonds are preferred in applications where the brown skin may come loose upon cooking, or a light nut is desired.

Almond Butter

Almond butter is made by grinding (dry) roasted almonds with other ingredients, such as salt, sugar, and stabilizer. The predominant flavor of almond

butter is that of roasted almonds. Almond butter is similar to peanut butter in appearance, with a slightly oilier texture. It is used in a wide variety of food applications.

Almond Paste and Marzipan

Almond paste and marzipan have long been used in baked goods, pastries, and confections, particularly in Europe. Marzipan is traditionally shaped into figures for holidays and in some countries is enclosed in chocolate. Almond paste is among the oldest of confections and is made by grinding raw blanched almonds with sugar.

Extending Shelf-life

The package as well as the moisture, temperature, and RH of the surrounding environment must be considered in predicting shelf-life of products using almonds. With higher moisture and RH in the surrounding environment, the shelf-life is usually shorter.

As a general rule, blanching reduces shelf stability by about 25–50%. Any cutting, such as slicing and dicing, has a similar effect. Roasting accelerates deterioration, and roasted nuts should be packaged to exclude oxygen. When properly packaged in cans, foil, or glass under vacuum or nitrogen-flushed, both dry-roasted and oil-roasted almonds can last a year or longer at room temperature. Dry-roasted almonds tend to have a longer shelf-life than oil-roasted almonds. The quality and stability of oil-roasted almonds depend upon the type and quality of roasting oil. Finely ground products, such as almond paste and almond butter, have a long shelf-life (>1 year) because the particles pack tightly together, excluding oxygen.

Roasted almonds in oxygen-free packaging have a shelf-life of 1–2 years at room temperature. If longer storage is desired, or if harsh storage conditions exist, treatment with antioxidants should be considered. A variety of natural and artificial antioxidants can contribute to a two- to threefold improvement in shelf-life. The ideal package for almonds excludes both moisture and oxygen. Shelf-life in some packages may be improved by the addition of oxygen and/or moisture scavenger packets. (*See* **Antioxidants**: Natural Antioxidants; Synthetic Antioxidants.)

ALUMINUM (ALUMINIUM)

Contents

Properties and Determination

G R Boaventura and J G Dórea, Universidade de Brasília, Brasília, Brazil

Introduction

Aluminum (Al) is a white metal, which has low density, and is ductile and malleable. It is stable in the presence of atmospheric air, and does not react with water. It is easily dissolved in most acidic media liberating hydrogen. The naturally occurring isotope 27 is found with 100% abundance. Three more isotopes – 26, 28, and 29 – can be obtained artificially. Its physical and chemical characteristics are shown in Table 1.

Al is considered one of the most commonly occurring elements in nature. It is found in combination with other elements. After oxygen and silicon it is the most abundant element on the earth crust, comprising 7.5% of its mass. The main ores containing Al include bauxite (AlO(OH)), corundum (Al_2O_3), spinel, and silicates. It is largely used in construction, the metallurgic industry, aviation, maritime equipment, food industry, packaging, and the chemical and pharmaceutical industry.

Al can occur in the metallic particulate form, and also complexed with organic compounds. In foods, including water, it occurs mostly in particulate form, exchangeable Al, nonexchangeable organic, and inorganic Al. In biological samples, Al is normally present in the $\mu g\,g^{-1}$ to $mg\,g^{-1}$ concentration range.

Due to Al abundance on the earth crust (natural), and the many ways it is used (synthetic), people are exposed to Al contamination. Furthermore, as it is frequently used in the food industry as well as in products employed in water treatment, there is increasing interest in its toxic effect on humans. Additionally, industrial activity that causes acid rain increases the availability of Al in the environment.

Because of its low absorption in the human intestine, Al is still considered as nontoxic. However, it is recognized that Al can be toxic to plants, laboratory animals, and humans, depending on the level and chemical form. Absorption, retention, and excretion of Al depend on Al chemical complexes formed with biological ligands. The study and identification of such complexes are treated separately as metal speciation: because of specific techniques of separation and identification, this is beyond the scope of this article.

Table 1 Physicochemical characteristics of aluminum

Symbol	Al
Atomic number	13
Atomic mass	26.98
Melting point	660.45 °C
Boiling point	2520 °C
Density	2.7 g cm^{-3}
Atomic volume	9.99 cm^3
Ionization potential	5.98 eV
Electrode potential (ε^0)	1.66 V
Electronegativity	1.5

Analytical Methods for Al Determination

There are numerous analytical techniques that can be used for Al determination, both traditional and novel. The choice of analytical method is determined by the type of sample and the expected concentration of Al. A typical range of concentrations expected in biological samples is illustrated in Table 2.

Due to the abundance of Al on the earth crust, the first challenge is reducing environmental contamination as this may be an important source of systematic error in sample preparation. Therefore, it is important to consider an Al-free environment, with high-purity water and reagents.

Sample Preparation

Biological samples, especially human, like blood, urine, saliva, and feces, must be handled with extreme caution. In these cases it must be considered that they can be infected with transmissible diseases. Blood samples must always be collected by qualified personnel.

Table 2 Typical concentrations of aluminum in different environments

	Typical concentration (mg kg^{-1})
Marine plants	60
Land plants	500
Soils	71 000
Crustal average	81 300
Granite rocks	74 300
Open sea water	< 0.001
Lake water	0.010–0.5
River water	0.01–40
Groundwater	0.01
Milk	0.02
Cows' liver	0.01–0.05
Beef muscle	0.02–0.06
Human blood	< 1.6–5 mg l^{-1} × 10^{-3}
Orange juice	0.1–0.6
Wine	0.3–2
Potatoes	0.1
Tea leaves	400–1000
Beech leaves	37–163
Beech seeds	6–13

Table 3 Typical concentrations of aluminum in reagents and laboratory glassware

Reagents	*Aluminum (ng ml^{-1})*
Distilled water	
Tin still	0.8
Polypropylene still	0.3
Quartz still	3
Deionized water	0.06
Nitric acid, reagent grade	10
Nitric acid, subboiling	0.9
HCl, high-purity, commercial	100
HCl, subboiling quartz still	0.8

During sample preparation, metal utensils commonly used in handling food are a source of aluminum contamination and should be avoided at all stages. Decomposition of solid samples for total Al is simple, and as with other metals can be done with NaOH fusion, *aqua regia* (HCl:HNO_3) inorganic acids (H_2SO_4, HNO_3, and HCl). For fractionation of Al compounds, exchange resins are employed as required by the nature of the Al complex. In acidic decomposed samples or effluent from exchange resins, Al can be determined by any method suited for the expected concentration. Traditional analytical methods can be used for high aluminum concentrations, using oxine and other specific reagents.

Certified Reference Materials

Reference materials or certified reference materials are essential tools for quality control of analytical results. These materials are accompanied by a certificate of the concentrations of one or more elements by a specified procedure. The commercially available Standard Reference Material (SRM) of the National Institute of Standards and Technology (NIST) of the USA for Al in nonfat bovine liver, corn kernel, bovine muscle, rice flour, egg powders, and others are suitable for most food and nutrition Al determinations.

Purity of Reagent and Quality Control of Sample Acquisition and Storage

In ultratrace Al determination, conventional apparatus and reagents are considered to be far from satisfactory. The most used material sample storage and reagent solution is Teflon (a registered trademark of DuPont de Nemours and Co. Inc. USA) and quartz glass. In these materials the Al contamination levels are very low. Environmental contamination depends on the particulate level of Al in that particular environment. The Al concentration in water, reagents, and other materials generally used in analytical laboratories are presented in Table 3.

Satisfactory Al concentrations in reagents used in Al determination can be obtained by purification. Most water purification equipment available commercially is satisfactory. There is also equipment for acid purification and a simple subboiling apparatus has been proposed that can be assembled in a well-equipped analytical laboratory. Two Teflon bottles joined by a Teflon joint, where one is heated and the other serves as an acid-purified collector, can be used to purify HNO_3, HF, and HCl.

Instruments

The instrumental techniques most commonly used in trace Al determination are spectrofluorometry, molecular spectrometry, atomic absorption spectrometry (AAS) with flame (FAAS) and with graphite furnace (GFAAS), inductively coupled plasma–atomic emission spectrometry (ICP-AES), inductively coupled plasma–mass spectrometry (ICP-MS), X-ray fluorescence spectrometry (XRS), and instrumental neutron activation analysis (INAA).

Molecular Spectrophotometry/Colorimetry

Spectrophotometric (ultraviolet and visible) techniques can be used for sample solutions with concentrations above 0.1 mg l^{-1}. In this technique Al is reacted with a chromogen, usually aurintricarboxilate (aluminon), criocromocianin R, oxine, or alizarin red. Although this technique uses a low-cost instrument, it involves a laborious procedure. There are also interfering substances that can react with chromogen.

Spectrofluorimetry

Compared to other colorimetric methods, fluorimetry offers more sensibility with three orders of magnitude in its detection limit. As with colorimetric methods in general, fluorometry requires the formation of fluorescent complexes: usually Pantochrome dark blue R is used. In chemically complex matrices its selectivity is low and produces low yields. In blood samples fluorescence with 2-hydro-1-naphthaldehyde-*p*-methoxybenzoyl hydrogen has been used. Samples are read at 475 nm with a detection limit of $0.13 \times 10^{-1}\,\mathrm{mg\,l^{-1}}$.

Atomic Absorption Spectrophotometry

The direct determination of Al by AAS is based on the radiation of free atoms with a minimum of interference. The determination is accomplished in the atomized state of the mineral after nebulizing liquid samples. Al is determined at 309.3 nm, using a hollow cathode lamp (HCL) or an electrodeless discharge lamp (EDL) in N_2O/acetylene reducing (rich red) flame. The EDL provides a greater light output and longer life than HCL. In concentrated samples it is possible to use wavelengths of less sensibility, such as 396.2, 237.3, 257.5, and 256.8 nm, where sensitivity can reach $6.0\,\mathrm{mg\,l^{-1}}$. The air/acetylene flame is not recommended because aluminum oxide hinders the acceptable limits of detection for most applications. The partial ionization of Al can be suppressed by adding lanthanum nitrate or potassium chloride in concentrations ranging between 1 and $2\,\mathrm{mg\,l^{-1}}$ in all samples, including blanks and standards. The presence of silicates, nickel, cobalt, chromium, and manganese can decrease sensitivity. Background correction must be used in samples with a high concentration of salts. Sensitivity is in the order of $1\,\mathrm{mg\,l^{-1}}$ with a detection limit of $0.03\,\mathrm{mg\,l^{-1}}$ and good work range within $10–100\,\mathrm{mg\,l^{-1}}$.

In most matrices the use of N_2O/acetylene flame limits the use of AAS for Al determination. However, flameless electrothermal atomization in a graphite furnace (GFAAS) enhances the application of AAS for low Al concentrations. The detection limit in this procedure can reach $0.00003\,\mathrm{mg\,l^{-1}}$ compared to $0.06\,\mathrm{mg\,l^{-1}}$ in N_2O/acetylene flame at 309.27 nm.

Flameless electrothermal atomization can be used in liquid samples that have been predigested or directly in solid samples of biological materials. Although high in sensitivity, the procedure requires analytical skills and longer handling time, which renders it difficult for large numbers of routine analysis. Constant instrument calibration also requires analytical skills.

Compared with other techniques for the same degree of sensitivity, like ICP-MS the GFAAS is considered to be simple, effective, and reliable with a much lower operational cost.

Inductively Coupled Plasma Atomic Emission Spectrometry

In the last 20 years there has been an increase in the use of ICP-AES. Several factors have contributed to its increasing preference over flame AAS. As a source of atomic excitation the plasma has a greater capacity. Advantages include the possibility of multielemental analysis, less interference, mostly of spectral nature, and good sensitivity.

When multielemental analysis is considered there are some operational parameters to be planned. The choices of combination of concentration of the elements in question, its variability and expected range of concentrations can pose a challenge to an experienced analyst.

The use of ICP-AES in food and nutrition is of particular interest, especially when considering multielemental determinations. With advances in microprocessors the complexity of multielement determination has been reduced. The use of simultaneous or sequential spectrometers has greatly improved the routine analysis of matrices containing trace amounts or highly concentrated elements.

Interference in ICP-AES is only found in spectral lines. However, these are fewer and easily solved. In the case of Al there are alternative lines and program designs for instrument operation that take into consideration the concentration of Al. The wavelength at 308.25 nm is the most used and is almost free of interference. For the determination of trace amounts of Al in the wavelengths at 167.08 nm in UV or optic vacuum, spectral interference can be further reduced.

The typical Al detection limit by ICP-AES using a Meinhard nebulizer is $0.08\,\mathrm{mg\,l^{-1}}$ and $0.00033\,\mathrm{mg\,l^{-1}}$ using an ultrasonic nebulizer at 308.215 nm. In biological fluids or tissues where Al concentrations can be low, i.e., less than $0.03\,\mathrm{mg7\,ml^{-1}}$, samples have to be preconcentrated and/or extracted.

Inductively Coupled Plasma Mass Spectrometry (ICP-MS)

ICP-MS combine two established analytical source (ICP and MS) in this relatively new analytical tool. Although one advantage of ICP-MS is the simplicity of the spectra, an overlap of spectra can happen, thus hindering some of its applications. In the determination of Al, both Mg and molecular N cause interference. Background interference is usually related

UV, ultraviolet; AAS, atomic absorption spectrometry; GFAAS, graphite furnace atomic absorption spectrometry; XRS, X-ray fluorescence spectrometry; ICP-AES, inductively coupled plasma–atomic emission spectrometry; ICP-MS, inductively coupled plasma-mass spectrometry; INAA, instrumental neutron activation analysis.

to ArO^+, Cl^+, ClO_2^+, NO_3^+ and isotope analytes which originate from impurities of argon-gas used as a plasma source. Elements with charge can form oxides of the type metal–O^+ and others with double charge metal–OH^+ can cause serious spectral interference.

Limits of detection are reported in the order of $0.003\,mg\,l^{-1}$, and sensitivity is between GFAAS and flame AAS, ICP-AES and INAA. The high cost of equipment, maintenance, and operation is still restricting its use.

INAA is a powerful multielement technique determining trace elements in a variety of sample matrices. The samples are irradiated in a neutron flux inside a nuclear reactor and the energy of the γ-ray peaks forms a spectrum that is used to identify the analyte. However, one of its limitations is the appropriate handling of radioactive materials and chemical interference. ^{28}Al has a half-life of 2.2 min and its decomposition products for complexes with both Si and P. In an ideal matrix, the INAA detection limits for Al are between 1 p.p.b. and 1 p.p.m, which for many biological samples may require sample preconcentration. The INAA determination of Al in food and nutrition samples is rare because of costs and operational difficulties in sample irradiation.

Conclusion

Aluminum determination in biological samples can be accomplished by all available instrumental techniques. Its application in food and nutrition will depend on the availability of instruments. In view of its abundance in the environment, the interest in its determination can range from trace concentrations to relatively large amounts. Although almost any technique is suitable for Al determination in large concentrations there are sample analyses that would require a certain degree of suitability and judgement will depend on the analyst's skill and resources. Although AAS is relatively available in most analytical laboratories, its use in food analysis is suitable for concentrations greater than $mg\,l^{-1}$ because of its limit of detection (Table 4). For trace concentrations of Al, AAS is only possible when coupled with graphite furnace. The versatility of multielement determination offered by ICP-AES is becoming attractive in food and nutrition studies. The limitations of ICP-AES are of the same nature as AAS for trace concentrations of Al but in the case of ICP coupled with MS, very low limits of detection with precision and accuracy are possible. For routine analysis, ICP-AES is superior in speed and operational simplicity to AAS.

Toxicology

J L Domingo, Rovira i Virgili University School of Medicine, 43201 Reus, Spain

Introduction

The following aspects concerning aluminum toxicology are covered in this article: essentiality and major sources of aluminum exposure in humans, aluminum in drinking water, aluminum metabolism, experimental toxicity including mutagenicity, carcinogenicity, developmental and neurobehavioral toxicity, and human toxicity. The potential role of aluminum in the pathogenesis of Alzheimer's disease is also reviewed. Finally, the prevention and treatment of aluminum accumulation and toxicity are briefly discussed.

Essentiality of Aluminum

Aluminum is the third most abundant element in the earth's crust and it is also ubiquitous in nature. Although biological systems have probably evolved in the presence of high aluminum concentrations, no essential role has been established for this element in living systems. In general terms, the few available data on the essentiality of aluminum are so limited and controversial that it seems that this element is not essential for growth, reproduction, or survival of humans and animals. In spite of the increased number of spontaneous abortions, depressed growth, and decreased life expectancy reported as signs of aluminum deficiency in goats at an apparent deficient concentration in diet of 162 $\mu g\,Al\,kg^{-1}$, nutritional research has been unable to define a deficiency state associated with minimal aluminum intake. Also, until recently aluminum was considered to be an innocuous element.

Sources of Aluminum Exposure

Dietary Exposure

For the general population, most aluminum exposure occurs through the diet. Aluminum in the food supply comes from natural sources including water, food additives, and contamination by aluminum utensils and containers. However, the intake of aluminum from foods has been reported to be less than 1% of that consumed by individuals ingesting aluminum-containing medications such as antacids or phosphorus-binding gels.

While most unprocessed foods, excepting some herbs and tea leaves, contain less than 5 $\mu g\,Al\,g^{-1}$, food additives are probably the major source of dietary aluminum. Sodium aluminum phosphate is the main aluminum compound used in foods. The acidic forms of this compound are commonly added to cake mixes, frozen doughs, pancake mixes, and self-raising flours to react with sodium bicarbonate and leaven these products when they are moistened. Moreover, the alkaline forms of sodium aluminum phosphate are widely used as additives in processed cheeses and cheese foods. In turn, aluminum potassium sulfate is an additive used to clarify sugar as a firming agent and as a vehicle for bleaching agents. Athough this additive is considered safe, in larger quantities it can interfere with the body's retention of phosphorus. Lastly, the aluminum silicates are commonly used as anticaking agents in salt, nondairy creamers, and other dry, powdered products. (*See* **Emulsifiers**: Uses in Processed Foods; **Leavening Agents**.)

One of the most recent surveys on the dietary exposure of aluminum has been carried out in the UK. In that survey, exposure estimates of aluminum for mean (12 $mg\,day^{-1}$) and upper-range (29 $mg\,day^{-1}$) adult consumers were lower than the PTWI (provisional tolerable weekly intake) of 420 $mg\,week^{-1}$ (equivalent to 60 $mg\,day^{-1}$) for a 60-kg adult set by the Joint Expert Committee on Food Additives (JECFA) of the Food and Agriculture Organization of the United Nations and the World Health Organization International Program on Chemical Safety. The higher aluminum concentrations were found in the miscellaneous cereals group, which might reflect the use of aluminum-containing additives in some bakery products. Dietary exposure estimates of aluminum in that survey were similar to those from other countries. In a study carried out in the USA in 1993, dietary exposures of aluminum ranged from 0.7 $mg\,day^{-1}$ for 6–11-month-old infants to 11.5 $mg\,day^{-1}$ for 14–16 year-old males, while average intakes for adult men and women were 8–9 and 7 $mg\,day^{-1}$, respectively. The major contributors to daily intake of aluminum were foods with aluminum-containing food additives, e.g., grain products and processed cheese. Dietary exposures from Italian Total Diet studies were found to range between 2.3 and 6.3 $mg\,day^{-1}$. Finally, in a study conducted in Japan between 1990 and 1995, the median aluminum intake from diet was found to be 2.5 $mg\,day^{-1}$.

Aluminum in Drinking Water

In addition to the naturally occurring aluminum in raw waters, aluminum-based coagulants such as aluminum sulfate (alum) or polyaluminum chloride are often added for water treatment. Although the

treatment of surface water with alum has been in operation for over 100 years all over the world, the use of aluminum-based coagulants for the removal of particulate, colloidal, and dissolved substances from the water often leads to higher aluminum concentrations in the treated water than in the raw water itself. The maximum allowable concentration of aluminum in drinking water established by the former European Economic Community (now European Union) is $0.2\,mg\,l^{-1}$, while the US Environmental Protection Agency promulgated a secondary maximum contaminated level range of 0.05–$0.2\,mg\,l^{-1}$ of aluminum in drinking water. In turn, the World Health Organization has proposed $0.2\,mg\,l^{-1}$ as a guideline value. These values are not based on any assessment of risks to health, but they provide a compromise between the use of aluminum salts in water treatment and discoloration of distributed water.

Other Contributors of Aluminum to Human Diet

In addition to food containing natural aluminum or additives containing aluminum, the intake of aluminum through diet can also be increased from contact of food with containers, cookware, utensils, cans, and foil wrappings. Although the amount of aluminum ingested as a result of preparing food in aluminum cookware (pans, pots, kettles, trays, and foil) does not appear to be of significance in comparison with the amount consumed from other sources, in some cases release of aluminum from aluminum utensils has been found to be remarkable if used frequently. In relation to this, it has been demonstrated that increased concentrations of complexing ions (organic acids, fluoride ion, OH^-, etc.) significantly enhance the release of aluminum from cooking utensils.

One of the possible routes through which aluminum can enter humans can be foods packed in aluminum containers, e.g., aluminum cans. Aluminum cans are now widely used for packaging of different types of food products, e.g., soft drinks, beers, fruit juices, and mineral water. In general, the aluminum content of beverages from aluminum cans has been found to be higher than that from glass containers. However, recent studies have shown that beers or soft drinks packaged in aluminum cans are an insignificant source of dietary aluminum intake – 0.4 and 1.3%, respectively – of the tolerable daily intake according to the JECFA.

Pharmaceutical Products

Aluminum compounds have been widely used in various nonprescription drugs. They include some antacids, buffered aspirins, antidiarrheal products, douches, and hemorrhoidal medications. Aluminum compounds are also used as adjuvant in vaccines. However, due to some doubts in relation to the potential role of aluminum in some neurological disorders, in recent years some companies are removing aluminum from some of their pharmaceutical products. Among the aluminum compounds currently used in nonprescription antacids, aluminum hydroxide has been by far the most common. Although aluminum hydroxide is considered safe its use should be restricted in subjects with chronic renal insufficiency and probably also during pregnancy. On the other hand, various substances administered intravenously, such as albumin, calcium salts, and phosphate salts, have been reported to contain significant quantities of aluminum. Moreover, aluminum is a known contaminant of total parenteral nutrition solutions. In 1990, the US Food and Drug Administration recommended that aluminum concentrations in parenteral feedings not exceed $25\,\mu g\,l^{-1}$.

Infant Formulae

In recent years, several studies have determined the concentrations of aluminum in infant formulae and compared with those found in human milk and cows' milk. The lowest mean aluminum concentrations have been observed in human milk (9.2–$23.4\,\mu g\,l^{-1}$), while the highest values corresponded to infant formulae, which differed markedly among manufacturers (mean, $551\,\mu g\,l^{-1}$; range, 302–$1149\,\mu g\,l^{-1}$). It has been reported that infants consuming milks containing more than $300\,\mu g\,Al\,l^{-1}$ had raised plasma aluminum concentrations. Although some researchers suggested that this might indicate the maximum intake tolerated by these infants, there is not a general agreement about it.

Aluminum in Soils and Plants

Aluminum is one of the most abundant elements in soil. Natural acidification processes result in increasing solubility of aluminum and, as soils become moderately acidic (pH < 5.5), aluminum begins to appear as the exchangeable cation which dominates in the lower mineral horizons. Concentrations of soluble and exchangeable aluminum in acid soils may reach many micrograms per gram of soil and can be toxic to plants. Aluminum toxicity in agricultural plants is a major problem that has been acknowledged at least since 1918. Worldwide, it has been estimated that 40% of arable soils and perhaps about 70% of potential new lands that can be brought under cultivation are acidic enough to have an aluminum toxicity problem. Apart from the Al^{3+} cation, aluminum has also the potential to form various hydroxy-aluminum and polynuclear species in solution. While the

available evidences suggest that the Al^{3+} cation is phytotoxic, it is unclear whether other hydroxy-aluminum species are also toxic. In contrast, anionic aluminum species in solution are considered not to be toxic. On the other hand, a significant correlation between low pH and high aluminum concentration has also been found in acidified fresh water where this element may reach levels of 0.3–1.6 mmol l^{-1} and cause serious metabolic derangement in some water plants.

Absorption, Distribution, and Excretion of Aluminum

Absorption

Among the potential routes of aluminum absorption in humans, only absorption via the gastrointestinal tract has received adequate consideration in scientific research. Despite significant effort, it is still not known how aluminum is absorbed across the gastrointestinal tract. Although some aluminum absorption may occur in the stomach, the majority of aluminum absorption is expected to occur in the intestine. It is believed that intestinal absorption of aluminum includes both paracellular passage routes along enterocytes and through tight junctions by passive processes and transcellular passage routes through the enterocyte, involving passive, facilitated, and active transport processes. On average, about 0.1–0.3% of the aluminum daily intake is absorbed. However, this figure is based in part on the assumption that urinary excretion represents absorption, which does not take into account tissue distribution, as dicussed below. In a recent study in rats using ^{26}Al, aluminum absorption was 0.97% of the dose.

The efficiency of aluminum absorption is also dependent on a variety of other factors. Two important dietary factors affecting absorption of aluminum are organic and inorganic anions. It has been demonstrated that the concurrent ingestion of aluminum compounds and some frequent organic constituents of the diet such as ascorbic, citric, and lactic acid among others (gluconic, malic, oxalic, and tartaric acids) significantly raised the gastrointestinal absorption of aluminum. The reaction of gastric acid with these organic chelators solubilizes aluminum cations, resulting in the equilibrium formation of a soluble complex of aluminum which, by preventing reprecipitation, results in aluminum absorption. Because of the propensity of uremic patients to retain aluminum even if not given oral aluminum compounds, in order to prevent the potential aluminum accumulation and toxicity it is important to carry out a careful surveillance of the diet of patients with chronic renal failure. In contrast to the effects of the dietary organic acids, concurrent ingestion of aluminum compounds with fluoride or silicon significantly reduces aluminum absorption.

Distribution

It has been estimated that the total aluminum load for healthy subjects is 30–50 mg, with about 50% present in skeleton and 25% in lungs. However, studies in rats and mice have shown that aluminum accumulated in tissues as: bone > spleen > kidney $\simeq$ liver > brain. Recently, it was shown that the aluminum burden in liver, kidneys, and spleen of rats was higher in old than in young or adult animals, whereas brain aluminum levels were higher in young than in adult or old rats. The finding of higher aluminum concentrations in brain of young rats can be particularly significant in relation to the controversial role of aluminum in some neurodegenerative diseases.

Excretion

In general, it is accepted that aluminum is mainly excreted in the urine and to a lesser extent in the bile. The susceptibility of patients with renal insufficiency to aluminum toxicity demonstrates the importance of the kidneys as excretory organs following aluminum ingestion. However, it has also been shown that biliary secretion of oral doses of aluminum occurs rapidly after ingestion and probably reflects a response by the liver to increased aluminum loads brought via the portal circulation. Although studies in rats have suggested that the liver is capable of secreting small amounts of absorbed dietary aluminum into bile, the kidneys become the primary excretory organs for aluminum when the liver's secretory capacity is surpassed after ingestion of pharmacological doses of aluminum. However, the occurrence and possible mechanisms of the cellular and tissue excretion of aluminum are almost completely unresolved.

Experimental Toxicity of Aluminum

Acute Toxicity

The intraperitoneal median lethal dose (i.p. LD_{50}) for aluminum nitrate nonahydrate was reported to be between 327 and 901 mg kg^{-1} in rats, and between 320 and 1587 mg kg^{-1} in mice, whereas the reported oral LD_{50} values in rats ranged from 260 to 4280 mg kg^{-1} depending on rat strain, sex, age, and period of observation. The LD_{50} of aluminum sulfate in mice was 1400 mg kg^{-1} injected intraperitoneally and 6200 mg kg^{-1} when given orally. The LD_{50} of aluminum chloride following oral administration

Table 1 Acute toxicity of aluminum compounds given orally and intraperitoneally to rats and mice

	LD_{50} (for Al^{3+})			
	Rats		Mice	
Test compound	Oral	Intraperitoneal	Oral	Intraperitoneal
$Al(NO_3)_3.9H_2O$	261 (223–305)	65 (50–83)	286 (234–346)	133 (104–201)

$AlBr_3$	162 (127–205)	82 (66–103)	164 (129–209)	108 (84–138)

Median lethal dose LD_{50} (14 days) in mg kg^{-1}; 95% confidence limits in parentheses.

was 380 mg kg^{-1} in mice, 400 mg kg^{-1} in guinea-pigs, and 400 mg kg^{-1} in rabbits. The LD_{50} values of some aluminum compounds in rats and mice expressed in mg Al^{3+} kg^{-1} are summarized in Table 1. Decreased locomotor activity, piloerection, weight loss, and decreased food and water consumption are the most notable physical signs appearing after acute aluminum intoxication.

Neurotoxicity

It is well established that, regardless of the host, the route of administration, or the speciation, aluminum is a potent neurotoxicant. In susceptible species, aluminum induces cytoskeletal changes in which neurofilaments accumulate in neuronal cell bodies and proximal axonal enlargement. By contrast, neurobehavioral studies of aluminum in rodents have generally not produced robust or consistent results. Thus, while some investigations showed a correlation between elevated brain levels of aluminum with alterations in a variety of behaviors in rats and mice, other studies did not find significant differences in most of the behavioral tests performed in the rat following aluminum exposure. Recently, it has been shown that concurrent oral aluminum exposure and restraint stress enhances aluminum concentrations in the brain and cerebellum of mice, which can be of special interest taking into account the potential role of aluminum in some serious neurological disorders.

Reproductive and Developmental Toxicity

The gonadotoxic effect of aluminum in rats, guinea-pigs, and rabbits was found to be weak following chronic aluminum exposure, while spertamozoa were only affected at the highest aluminum doses tested. When male mice were intraperitoneally exposed to aluminum nonahydrate for 4 weeks before mating with untreated females, the 'no observable adverse effect level' (NOAEL) was 50 mg kg^{-1} day^{-1}. As most oral aluminum is not absorbed from the gastrointestinal tract, and taking into account that in individuals with normal renal function most aluminum ingested is excreted into urine, it was concluded that there is a remarkable safety margin for any adverse reproductive effects in humans due to aluminum ingestion under the intended conditions of use.

On the other hand, it is well established that parenteral exposure to aluminum during pregnancy can cause a developmental syndrome in mammals that includes resorptions and deaths, skeletal, and soft-tissue abnormalities, and growth retardation. However, until recently there was little concern about embryo/fetal consequences of aluminum ingestion because bioavailability was considered low. Nowadays, it is well demonstrated that aluminum may be a developmental toxin depending on the route of exposure and/or the solubility of the aluminum compound administered. Aluminum chloride was found to be embryotoxic and teratogenic when given parenterally at high doses to rats and mice, whereas teratogenic effects of aluminum were also reported in rats given high oral doses of aluminum nitrate that induced concomitant maternal toxicity. In contrast, maternal and embryo/fetal toxicity were not observed when high doses of aluminum hydroxide, the most common aluminum compound given therapeutically, were given by gavage to pregnant mice and rats during organogenesis. However, some signs of maternal and developmental toxicity were found in mice when aluminum hydroxide was given concurrently with citric or lactic acids. In spite of these results, it seems evident that pregnant women are not currently exposed to aluminum doses that can cause adverse effects on health. Moreover, recent studies have shown that maternal stress is not an additional real risk for women consuming current quantities of aluminum during pregnancy.

Carcinogenicity and Mutagenicity

Animal studies have failed to demonstrate carcinogenicity attributable to aluminum powder, aluminum hydroxide, aluminum oxide, or aluminum phosphate administered by various routes to rats, rabbits, mice, and guinea-pigs. Aluminum fibers were not carcinogenic following i.p. injection to rats, whereas

sarcomas were produced at the site of injection of aluminum-dextran in mice. However, since subcutaneous injection of aluminum-dextran is a rather irrelevant model to assess aluminum carcinogenicity, the significance of the positive results appears questionable. (*See* **Carcinogens**: Carcinogenic Substances in Food: Mechanisms.)

Since aluminum and aluminum compounds are not carcinogenic, or even show some antitumor activity in laboratory animals, the negative results in most short-term *in vitro* and *in vivo* mutagenic assays (except some experiments in plants) are not surprising. (*See* **Mutagens**.)

According to experimental data together with certain epidemiological evidence, it can be concluded that aluminum and its salts do not constitute a carcinogenic or mutagenic hazard except, perhaps, in cases of extremely high exposure.

Miscellaneous

No significant aluminum toxicity was observed when aluminum nitrate nonahydrate was given orally to rats at 375, 750 or 1500 mg per kg of body weight per day for 1 month or over a period of 100 days at 360, 720, and 3600 mg per kg body weight per day. However, it has been suggested that oral aluminum exposure may both stimulate and suppress the immune system, depending on the exposure level and the physiological state of the animal and the immune response assessed. Recent studies in rats have shown a slight stimulation of some immune functions in the rats at aluminum plasma concentrations normally found in healthy humans ($< 10\,\text{ng ml}^{-1}$).

Aluminum Toxicity in Humans

Dialysis Encephalopathy Syndrome

Although the possible human toxicity of aluminum has been a matter of controversy for over 100 years, the spectrum of clinical aluminum toxicity has expanded gradually since its initial description as the cause of dialysis dementia. In the 1970s, Alfrey *et al*. suggested that dialysis encephalopathy, previously a uniformly fatal neurological syndrome, resulted from aluminum intoxication. Based on additional biochemical and epidemiological data, this supposition was confirmed, and now it is quite accepted that aluminum is the cause of the dialysis encephalopathy syndrome, the main neurotoxic condition of aluminum. This syndrome includes a mild or severe speech disorder, hallucinations, twitching, myoclonus, seizures, mental changes and typical electroencephalogram abnormalities. Moreover, there is little doubt that aluminum can also cause bone disease and anemia in dialysis patients. Individuals with dialysis osteomalacia typically present with severe symptoms of axial skeletal pain, proximal muscular weakness, and fractures of the ribs, among other symptoms. In turn, aluminum has also been implicated as the cause of a microcytic, hypochromic anemia in patients with chronic renal failure. These disorders can result from introduction of aluminum directly into the blood stream via high aluminum-dialysate or consumption of large oral doses of aluminum-containing phosphate binders. The lack of urine production, which is the major route for aluminum excretion, contributes to the problems in these patients. While the health threat from diffusate fluids was significantly reduced by the recommendation that the diffusate contains less than 10 μg of aluminum per liter, ingesting aluminum-containing phosphate binders is still a matter of concern for uremic patients.

On the other hand, several reports have described aluminum accumulation and toxicity in individuals without chronic renal failure but with iatrogenic exposure to aluminum. These include preterm infants, largely fed intravenously, patients on total parenteral nutrition, subjects with severe burns, individuals receiving alum irrigation in the urinary bladder to prevent bleeding, and patients undergoing cranial bone reconstruction with aluminum containing bone cement.

Occupational Exposure

Occupational exposure to aluminum occurs not only in the primary refining of this metal but also in user industries (e.g., aircraft, automotive, metal products). Aluminum welding is also an important exposure vehicle. Although there are only a few studies on the influence of occupational exposure to aluminum on a worker's cognitive performance, a diverse range of cognitive deficits, including visuomotor or visuospatial problems, attention deficits, impaired verbal or visual memory and learning, and problems with 'concept formation' have been reported. Recent investigations have also corroborated that exposure to aluminum is associated with detrimental effects on certain cognitive functions, with deficits in memory attention, and visuomotor and visuospatial abilities.

For biological monitoring, urinary aluminum appears to be a more sensitive index to current exposure than serum levels. Workers with occupational exposure to aluminum have shown statistically significant increases in urinary aluminum/creatinine ratios in association with borderline changes in serum aluminum values. The mean aluminum concentrations in a healthy nonexposed population who

did not use antacid drugs were 0.06 μmol l^{-1} (range 0.02–0.13 μmol l^{-1}) in serum, and 0.33 μmol l^{-1} (range 0.07–0.82 μmol l^{-1}) in urine, with the upper reference limit for aluminum being 0.1 μmol l^{-1} in serum and 0.6 μmol l^{-1} in urine.

Aluminum and Alzheimer's Disease

Although there are still many unanswered questions, there are strong indications that aluminum may be one of the factors resulting in Alzheimer's disease and perhaps other neurodegenerative disorders, including amyotrophic lateral sclerosis. Aluminum has been detected in both senile plaques and neurofibrillary tangle-bearing neurons in the brains of people with Alzheimer's disease. Several epidemiological studies have shown increased risks for Alzheimer's disease in populations exposed to elevated aluminum concentrations in public drinking water supplies. However, a recent study indicated that any relation at aluminum levels below 0.2 mg l^{-1} is weak. Other independent lines of evidence supporting the hypothesis that aluminum might play a role in the pathogenesis of Alzheimer's disease are: (1) studies on the effects of intracranial aluminum on the cognitive and memory performance of animals; (2) data showing that in laboratory experiments aluminum aggregates Aβ, phosphorylates some sites on tau, the principal subunit of Alzheimer's disease tangles and assembles, *in vitro*, Alzheimer's disease hyperphosphorylated tau into paired helical filaments which are indistinguishable from those of Alzheimer's disease; and (3) the slowing of the progress of the disease with the use of desferrioxamine (or deferoxamine), an aluminum chelating agent that removes aluminum from the body.

Almost certainly Alzheimer's disease can result from many factors, genetic and environmental, or a combination of both. Although the participation of aluminum cannot be discarded, it seems very unlikely that a single environmental factor such as aluminum can constitute a sufficient explanation. A possible interpretation is that aluminum, which is definitely neurotoxic, may have a dementing effect independent of the pathological processes associated with Alzheimer's disease. In contrast to genetic risk factors for which preventive measures cannot yet be instituted in the foreseeable future, human exposure to aluminum, especially in the aging population, could probably be reduced. It would, perhaps, contribute to reducing the incidence of at least some forms of dementia.

Treatment of Aluminum Overload

Reduction of aluminum accumulation and toxicity may benefit a variety of patient populations which have different treatment needs. Prevention is the most important issue to avoid aluminum overload. Because of the propensity of uremic patients to retain aluminum, prevention is of special interest for these subjects. In relation to it, a careful surveillance of the diet of these patients (citrate, ascorbate, lactate, etc.) is recommended. Moreover, sodium bicarbonate and calcium carbonate or calcium acetate are adequate substitutes for Shol's solution and calcium citrate, respectively.

Aluminum mobilization and removal are essential in patients with aluminum toxicity. Currently, the most effective treatment to remove aluminum from the body is parenteral administration of desferrioxamine, an aluminum chelator. In recent years, a number of experimental studies have shown that oral administration of the chelating agent deferiprone (L1) could be an alternative drug to desferrioxamine for aluminum mobilization. However, the potential use of deferiprone for aluminum removal in humans is still controversial.

AMARANTH

R Bressani, Instituto de Investígaciones, Universidad del Valle de Guatemala, Guatemala

Background

Amaranth, a legacy of the Aztecs, Mayas, and Incas, continues to be an underexploited plant with a promising economic value due to the variety of uses it can have and the benefits it can provide to producers, processors, and consumers. Present interests have developed because the plant offers leaves of a high nutritional quality when used as a vegetable, because the grains have a high protein content and quality, and because the whole plant offers a highly acceptable forage. The amaranth plant is also attractive since it adapts itself to a large number of environments, grows with vigor, produces large amounts of biomass, and resists drought, heat, and pests. Less attractive features of the plant include leaves that tend to accumulate nitrate and oxalates, and a very small grain size, which necessitates a large labor force when harvesting. With only a relative small research effort, a strong knowledge base is being constructed and is beginning to reveal the economic value and nutritional benefits of this ancient legacy crop.

Origin and Distribution

The Amaranthacea comprise over 60 genera, which include around 800 species of dicotyledonous, herbaceous plants, of either annual or perennial growth. There are three species of the genus *Amaranthus* that produce relatively large inflorescences with often more than 50 000 edible seeds per plant. These are *A. hypochondriacus* from Mexico, *A. cruentus* from Guatemala and *A. caudatus* from Peru and other Andean countries. Vegetable amaranths grow very well in the hot, humid regions of Africa, South-east Asia, Southern China, and India; they are represented by various amaranth species, such as *A. tricolor*, *A. dubius*, *A. cruentus*, *A. edulis*, *A. retroflexus*, *A. viridis*, and *A. hybridus*. Grain amaranth was an important crop for the preHispanic, New World civilizations. Its presence goes back some 4000 years BC in the Tehuacan Valley in Mexico, also the most likely site for the origin of maize. Its use is said to have been highly associated with religious festivities, which were forbidden by the Spanish conquerors and resulted in the elimination of the crop. Its production declined to small and insignificant levels, but it did not disappear. From Mesoamerica and the Andean region, grain amaranth was apparently carried as a weed, ornamental, or grain to other parts of the world. At present, there are three major germ plasm collections: (1) USDA Plant Introduction Center, Ames, Iowa, US; (2) Universidad del Cuzco, Cuzco, Peru; (3) National Bureau of Plant Genetic Resources, Shimla, India.

Classification

Amaranth is a dicotyledonous plant, not a grass like most cereals, which are monocotyledonous; rather, it is a pseudocereal. Amaranth shows an extreme botanical plasticity in adaptation that contributes to difficulties and confusion in its taxonomy. It is classified by means of flower structure, the form and proportion of leaves and inflorescence. These highly variable characters also allow for a high hybridization frequency, and assure the availability of a large germ plasm reserve.

Plant Description

Amaranths are broad-leafed plants that can grow to about 1.5–3.0 m high. The plant has a variable growth pattern in the type and number of branches, all of which end with a small seed head, sometimes maturing at the same time as the main seed head. Leaf shape varies from lanceolate to ovate to elliptic. Leaf number and size show great variability within and between species. The leaves, stems, and flowers of amaranth can be green, gold, reddish purple, or various shades. The seed head, some 50–60 cm high, varies from pendulous to spiked, and seed color is usually black, gold, or cream.

Amaranths, like many cereals and grasses, carry out photosynthesis by the C_4 pathway, which uses carbon dioxide very efficiently by fixing it in the chloroplasts of specialized cells surrounding the leaf vascular bundles. This characteristic is also responsible for lower water losses by transpiration in association with the stomata. C_4 plants also have the capacity to photosynthesize at high rates at high temperatures, and through osmotic adjustment, the amaranth plants can tolerate some degree of lack of water without wilting.

Grain Description

It has been found that the main amaranth inflorescence may produce 49–89 g of grain (50 000–100 000 seeds). The grain is very small, lenticular in shape, 1–1.5 mm in diameter, and weighs 0.6–1.3 mg per seed, with the structure shown in Figure 1. The germ, which is circular in shape, encircles the perisperm in one plane, and represents, together with the seed coat, around 25–26% of the weight of the seed, as obtained by milling techniques. This fraction is relatively rich in fat and protein. The perisperm represents 68–78% of the weight of the grain. In cereal grains, such as maize, the seed coat plus germ represent around 16–18% of the weight of the kernel, with the endosperm representing about 65%.

Production

Grain

Production depends on many variables, such as agronomic practices, plant density per hectare, method of harvest in which seed shattering is important, uniformity of grain maturation, and the type of seed head. Yields in some localities have ranged from 1.1 to 1.5 t ha^{-1}, but in Mexico, some reports indicate yields of 3.0–5.9 t ha^{-1} Annual production has been estimated at 470×10^6 t per year world-wide. High yields can be obtained through high plant population densities (320 000–360 000 plants per hectare), as well as from the appropriate application of organic and inorganic fertilizers. To increase yield, breeding objectives include the development of early maturing varieties, with a reduced plant height and resistance to lodging with insect and disease tolerance and no seed shattering. Likewise, the size of the seed should be increased.

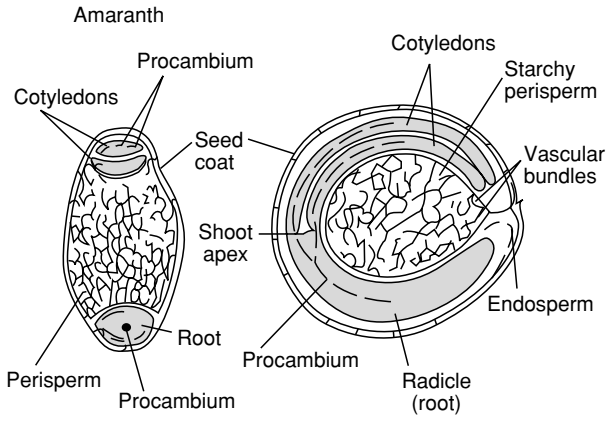

Figure 1 *A. cruentus* seed in (a) cross- and (b) longitudinal sections as viewed in a light microscope, Source: Irving DW, Betschart AA and Saunders RM (1981) Morphological studies on *Amaranthus cruentus*. *Journal of Food Science* 46(4): 1170–1174.

Whole Plant

With respect to vegetable production, yields between 1.4 and 11 t of dry matter per hectare at 4 weeks have been reported. In one study, dry matter yields at 25, 40, and 60 days after emergence were 66.6, 681.8, and 3452.0 kg ha^{-1}, yielding 9.7, 154.3, and 514.7 kg of protein per hectare. Yields of edible leaves are obviously much lower, with values varying from 0.30 to 0.70 t per hectare of dry matter. From a study on 14 varieties, the average dry weight of the whole plant prior to seed harvest, was 208.5 g, of which 40% was represented by the weight of the stems, 26% by the inflorescence, and 34% by the seed.

The amaranth plant may be cultivated as an intercrop with maize to provide a good-quality forage fed fresh or ensilaged to swine and/or to cattle. Alone or combined, it can be dehydrated or pelletized to be used as feed for farm animals.

Vegetable Amaranth

The use of amaranth leaves as a vegetable has been well established in a number of countries. *A. tricolor* is the main vegetable species in Asia, whereas *A. hybridus* and *A. cruentus* predominate in Africa and Latin America. Today, there is probably more amaranth consumed as a vegetable than as grain. The young leaves and the softest sections of the plant are boiled, sometimes in several changes of water, and consumed often mixed with cooked tomatoes and other condiments. Usual forms of consumption include soups, salads, boiled, made into a purée with tomatoes and consumed with cooked root crops or lime-cooked tortillas. The flavor of cooked amaranth leaves and young stems is pleasantly mild and not unlike that of similar greens.

Chemical Composition

The chemical composition of the vegetative part of amaranth is variable, since the content of organic and

Table 1 Chemical composition of amaranth (grams per 100 g)[a]

[a]dwb, dry-weight basis.

inorganic compounds changes as a result of climate, plant nutrition, agricultural practices, physiological stage, species and cultivar type, and position of leaves taken for analysis (Table 1). The moisture content for all species varied from about 70 to 94%, or from 6 to 30% dry matter. On a dry-weight basis (dwb), protein varies from 18 to 38% and total crude lipids from 1.3 to 10.6%. The lipid fraction contains 53.6% non-polar lipids, 33.8% glycolipids, and 12.6% phospholipids. The main fatty acids include linolenic (30–70%) and palmitic (13–14%) as well as oleic and stearic acid (see Table 5).

The variability in crude fiber is also quite large, from 5.4 to 24.6% (dwb). This variability can be explained on the basis of the age of the plant, with old leaves and shoots showing the highest values. Finally, the ash content ranges from 7.6 to 22.2%.

Minerals and Vitamins

The levels of calcium, potassium, and magnesium are quite high, with calcium present in the largest amount (2–3 g%; Table 2). Large quantities of phosphorus are also found, with values ranging from 0.49 to 0.79 g%. There is a relatively high concentration of iron, varying from 0.08 to 0.50 g% (dwb). Other minerals have been reported in smaller amounts.

The amounts of vitamins B_1 and B_2, nicotinic acid, and ascorbic acid are similar to those found in other greens, but the content of β-carotene is as high as, or higher than, that reported for other green vegetables (Table 3).

Other Compounds

Amaranth, like many other fast-growing plants, has a tendency to accumulate nitrates. Reported values range from 0.27 to 0.74% nitrate (dwb) (0.046–0.104% fresh weight; Table 1). There is a significant variation among cultivars, also due to environmental factors, since the same cultivar grown over different years has different values. The stems contain about twice as much nitrate as the leaves on a fresh-weight basis (fwb). The levels of nitrate in amaranth leaves are similar to those found in spinach and chard. Nitrogen fertilizer increases nitrate accumulation in green vegetables, including amaranth. Nitrates seldom cause problems to consumers because of the relatively low concentration and because, upon cooking, they leach out of the vegetable.

Another compound of greater concern is oxalate, which accumulates in leafy vegetables such as amaranths, particularly during dry weather. Oxalate levels are nutritionally important because they can bind essential divalent minerals, particularly calcium,

Table 4 Essential amino acid content of amaranth (milligrams of amino acid per gram of nitrogen)

Essential amino acid	*Vegetable*	*Grain*
Leucine	421 ± 76.5	356 ± 17.6
Isoleucine	327 ± 38.7	226 ± 15.9
Lysine	300 ± 34.9	351 ± 21.4
Methionine	78 ± 43.6	124 ± 17.7
Cysteine	24 ± 8.1	124 ± 6.4
Phenylalanine	314 ± 78.0	270 ± 40.1
Tyrosine	232 ± 48.7	220 ± 32.6
Threonine	356 ± 75.9	238 ± 21.3
Tryptophan	80	76 ± 12.3
Valine	355 ± 31.4	256 ± 14.1

making it nutritionally unavailable. On a dry-weight basis, the oxalate in amaranth ranges from 1.1 to 7.9% (0.20–1.02% fwb); the stems contain significantly lower amounts than the leaves. The variability is a result of both the genetic make-up of the plant and environmental factors. The oxalate in amaranth is bound to sodium, potassium, calcium, and magnesium, but about 40% is free and therefore capable of binding other minerals. During processing in boiling water, oxalates are removed when water is changed, so that an intake of 100 g of cooked amaranth would provide approximately 0.2–1.0 g of oxalic acid. Assuming that 40% of oxalate is free and lost during cooking, the level drops to 0.12–0.6 g, which is nontoxic. Toxic levels for humans have been indicated to be 2–5 g per day. For populations consuming low levels of calcium, some of this mineral would become unavailable because of its complexing affinity to oxalic acid.

Other Uses

Amaranth leaves have been used in the preparation of leaf protein concentrates. These represent 24–36% of the leaf protein and contain 61–80% protein, which is of a light color, almost odorless, and nonbitter. Their essential amino acid content is attractive and high in lysine, but the sulfur amino acid content is low (Table 4).

Nutritional Value

The chemical composition of amaranth leaves shows that they provide a relatively good nutritional value. The iron and β-carotene contents are highly available. Not much information is available on the quality of the protein in amaranth leaves, but they make a very good supplement to maize and rice, either alone or with common beans at levels of up to 5% (dwb), because of their relatively high content of lysine, an amino acid that is lacking in both cereal grains (Figure 2). At this level of supplementation, amaranth leaves can provide substantial levels of vitamins and minerals to cereal/bean diets.

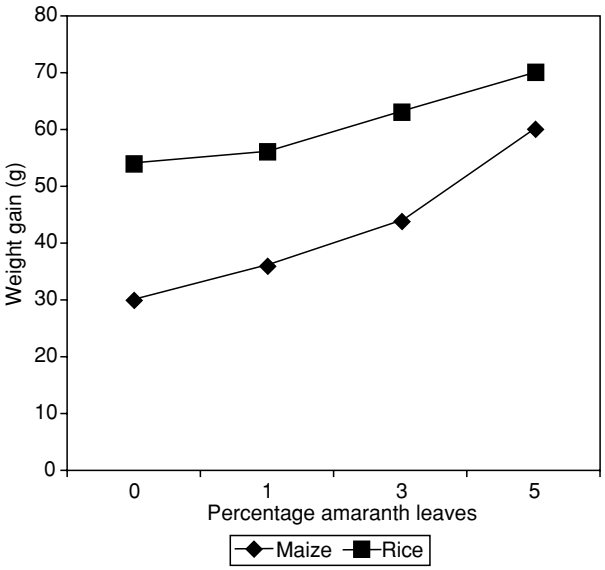

Figure 2 Supplementary effect of amaranth leaves to maize and rice.

Grain Amaranth

Chemical Composition

The gross chemical composition of amaranth grain is shown in Table 1. The crude protein content ranges from 11.8 to 17.6%. The reasons for the large variation amongst the different species are not known. While it may be of a genetic nature, it may also be due to environmental conditions and cultural practices. Nitrogen fertilization of amaranth has not consistently increased the crude protein in the grain.

The variability in total lipid content for all species is 4.8–8.1%. Nutritionally, a high lipid content is of interest for the high energy that grain amaranth can provide in comparison with cereal grains and food legumes.

Dietary fiber data for grain amaranth are lacking. Values for *A. caudatus* have been reported to vary from 7.6 to 16.4%.

The ash concentration is relatively constant among species, and the variability for each element is also small.

Vitamin contents appear to be relatively constant among species. Some of the vitamins, e.g., nicotinic acid, are low in comparison with the nicotinic acid content in cereal grains, which show values about two to three times higher.

Starch is the most abundant chemical component in amaranth grain; the content varies from 48 to 69%. It occurs as very small polygonal or spheric granules (1–3 μm in diameter), and is readily digested by α-amylases. The starch is present mainly as highly branched amylopectin, but some varieties of amaranth grain contain 4.8–7.22% of amylose, a linear starch. Other carbohydrates include sucrose, raffinose, stachyose, and maltose in small but variable amounts. Microgranule starches, like those in amaranth, are being studied for paper coatings, fat substitutes, and biodegradable applications.

Fatty Acids

Amaranth seed oil is rich in the essential fatty acid, linoleic acid, with values ranging from 43.4% in *A. cruentus* to 51.4% in *A. hypochondriacus*. Oleic acid content is second in concentration, with values of 21.3% for *A. hybridus* and 31.9% for *A. cruentus*. Amaranth oil contains 18.6–21.3% palmitic acid. The reported variability suggests differences between species and also differences between varieties of the same species. Other lipid classes include sterols, of which spinasterol is found at around 0.20% of the crude oil. In the unsaponifiable fraction, the isoprenoid, squalene, is found in relatively large amounts, around 6.8%. The total unsaturated fatty acid content is around 77% for amaranth oil (Table 5). (*See* **Fatty Acids**: Dietary Importance.)

Protein

Protein distribution in the grain The endosperm of the grain contains 35.0% of the total grain protein, while the remainder is in the seed coat and germ or embryo. This distribution is quite different from that found in maize, sorghum and rice, wherein the germ contributes between 12.5 and 18.5%, and the endosperm between 81.5 and 87.5% of the total protein of the grain. The physical distribution of the protein in amaranth is responsible for its higher total protein content, as compared with common cereal grains, since the protein concentration in the germ is higher than the concentration in the endospem. (*See* **Protein**: Requirements.)

Table 5 Fatty acid content of amaranth (grams per 100 g)

Fatty acid	*Vegetable*	*Grain*
Myristic acid 14:0	1.1	0.53 ± 0.3
Palmitic acid 16:0	13.3	20.4 ± 2.0
Stearic acid 18:0	4.6	3.5 ± 1.5
Oleic acid 18:1	4.7	26.1 ± 5.6
Linoleic acid 18:2	6.4	48.0 ± 7.3
Linolenic acid 18:3	34.4	1.43 ± 0.8
Arachidonic acid 20:0	0.5	1.6 ± 0.9

Protein fractions in amaranth A few studies have been carried out on amaranth protein fractions. The quantity of albumin was found to vary between 19 and 23%, and that of the globulins between 18 and 21%. The alcohol-soluble prolamines have been found to vary from 2 to 3%, and alkali-soluble glutelin-like proteins from 42 to 46%. Values of around 5–14 g per 100 g of protein have been reported for nonprotein nitrogen. The data available suggest that there are no great differences in the quantity of protein fractions among species or among cultivars. Recently, a purified albumin fraction, 35-kDa monomer, is being used to insert it into potato and rice protein by biotechnological techniques because this albumin fraction has an excellent essential amino acid pattern.

Amino Acids

Table 4 presents average values for all species. Comparison of the essential amino acid content in grain amaranth with the Food and Agriculture Organization/World Health Organization (FAO/WHO) 1973 reference pattern reveals that the most deficient amino acid is leucine. Nevertheless, other amino acids such as valine, isoleucine, and threonine could be limiting. Biological tests, however, have revealed that threonine, rather than leucine, is the most limiting essential amino acid. Amaranth protein is a good source of lysine, tryptophan, and sulfur amino acids. In contrast, cereal grains are deficient in lysine. The essential amino acid balance of grain amaranth protein is significantly better than that of many other proteins of vegetable origin. Since germ proteins are richer sources of essential amino acids (as compared with the storage proteins of the endosperm), the higher proportion of germ proteins in amaranth may explain the higher concentration of lysine in amaranth grain than that in cereal grains. (*See* **Amino Acids**: Properties and Occurrence.)

Antinutritional Factors

As indicated above, amaranth is consumed as a vegetable and as a grain. There are various reports that indicate that both food forms contain antinutritional factors or toxic compounds that could interfere with food uses and limit nutrient utilization. The toxic factors in vegetable and grain amaranth include saponins and phenolic compounds, phytic acid, oxalates and nitrates, protease inhibitors, lectins, alkaloids, and polyphenolics. Appropriate processing, however, has been shown to reduce or eliminate such compounds. (*See* **Plant Antinutritional Factors**: Characteristics.)

Processing

Amaranth grain has been processed by a relatively large number of techniques such as wet and dry cooking, which include atmospheric and pressure cooking, nixtamalization, drum drying, extrusion cooking, and puffing; by biological approaches such as germination, malting, and enzymatic hydrolysis, and by physical means, which include milling, physical fractionation, and starch and protein extraction.

Nutritive Value

Oil

The digestibility of amaranth crude oil varies between 91.7 and 94.1% at the 5% level of addition and between 91.1 and 93.8% at the 10% level. These results are significantly lower than those from refined cottonseed oil at both levels of addition. The lower digestibility is probably caused by the presence of sterols (0.37% total) and unsaponifiable matter (1.4%) in crude amaranth oil; however, no deleterious effects from its consumption have been reported.

Metabolizable Energy of Amaranth Grain

The two main sources of energy in amaranth grain are the carbohydrate fraction and the oil content. The metabolizable energy (ME) of light- and dark-colored *A. cruentus* grain is 11.8 and 11.72 $kJ\,g^{-1}$ (2.81 and 2.79 $kcal\,g^{-1}$), respectively. Heat processing increases the value for both seed colors, with extrusion cooking giving the highest values of 17.72 and 14.11 $kJ\,g^{-1}$ (4.22 and 3.36 $kcal\,g^{-1}$), respectively.

Protein

A number of researchers have uncovered an important conclusion: the protein value (protein efficiency ratio) of the raw amaranth grain does not reflect the amino acid pattern of the protein. Furthermore, amaranth grain processed by wet cooking gives a higher protein quality value than that of the raw grain in all amaranth species. When processed under conditions that do not damage the availability of essential amino acids, its protein quality is very close to that of casein or milk protein. The effect of processing is evident in both the consumption of the diet and the weight gains of test animals. This effect is still unexplained and deserves some research. It has been suggested that the presence of antiphysiological factors that are inactivated by heat may be responsible; well-known antigrowth factors such as trypsin inhibitors, tannins, and lectins are present at low levels in amaranth grain.

Some processes, such as expansion, flaking, and wet cooking, apparently do not affect protein digestibility. However, the product from toasting gives an equal or lower protein digestibility than the raw grain. Table 6 lists the protein quality values of amaranth grain protein and that of other cereal grains. With the exception of quality protein maize, also high in lysine, all other cereal grains have a protein quality below that of amaranth grain.

Table 6 Protein quality of amaranth and various common cereal grains

Grain	*Condition*	*Protein quality (percentage of casein)*

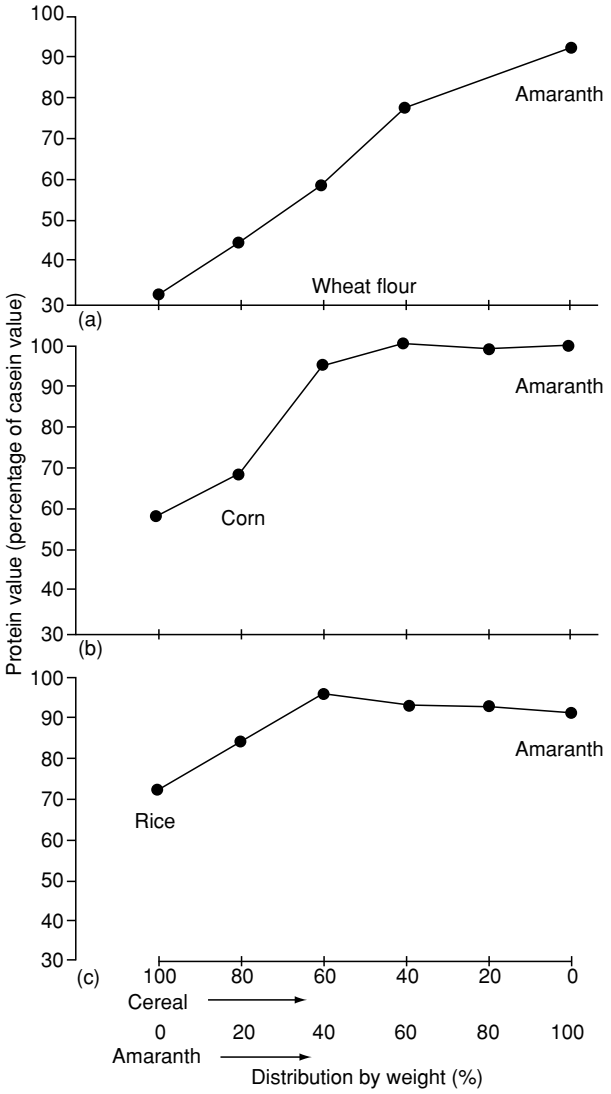

Figure 3 Complementation between amaranth and cereal protein. (a) Wheat flour plus processed amaranth, 10% protein in diet; (b) corn flour plus processed amaranth, 9.0% protein in diet; (c) rice flour plus processed amaranth, 8% protein in diet. Source: Bressani R (1989) The proteins of grain amaranth. *Food Reviews International* 5: 13–38.

Although human studies on grain amaranth protein quality have been conducted, data are not readily available. Some results with adult human subjects indicate that extrusion-cooked grain amaranth has a protein value of 89% relative to the value of cheese, whereas the popped material has a value of 81% of the value of cheese. Digestibility values follow the same order. Table 7 summarizes the protein quality of various protein sources as evaluated in humans. The quality is expressed as the amount of nitrogen ingested from the food protein source needed to obtain nitrogen equilibrium in nitrogen-balance studies. A smaller value indicates a higher protein quality.

In studies with rats, amaranth containing diets reduced cholesterol levels in blood as well as in the liver. In the colon, amaranth diets induced similar changes to those from cellulose feeding, but did not reduce the pH and did not increase cecum surface area. These observations suggest that the soluble and insoluble fiber of grain amaranth behave as that is these fractions of other cereal grains.

Supplementary Value

As a result of its high lysine content, the addition of amaranth grain to cereal flours improves the quality of the mixture (Figure 3). The available data show an increase in protein quality of 62% for wheat flour, 40% for maize, and 25% for rice, from the addition of 30% amaranth flour to 70% of each cereal grain. The high protein quality of amaranth means that it can be used alone or as a fortifier in cereal grain mixtures.

Grain Uses

Popped and parched amaranth are time-honored edible forms of whole amaranth. The methods of preparation have persisted for centuries in Mexico, Peru, and India. In recent research, grain amaranth flour has been tested as a supplement to wheat, maize, and rice flours for use in pastries, baking mixes, pasta products, tortillas, and similar products Likewise, amaranth grain flour has been tested as a component of high-quality protein foods and as a drink in blends with milk and other grain flours. The product possibilities are numerous, but very few have been commercialized. A total of 60 cereal grain foods containing small amounts of amaranth are marketed in the Americas. In Mexico, eight different amaranth grain flours are marketed, with the most popular product being alegria, a mixture of popped amaranth with sugar. Product and market development will be crucial to amaranth's growth in the food chain.

AMINES

M B A Glória, Federal University of Minas Gerais, Belo Horizonte, Minas Gerais, Brazil

Definition, Structure and Synthesis of Amines

It has long been known that certain amines fulfill a number of important metabolic and physiologic functions in living organisms. They are formed during normal metabolic processes and are, therefore, present in foods.

Bioactive or biologically active amines are aliphatic, cyclic, and heterocyclic organic bases of low molecular weight. Most of them have been named after their precursor amino acids, e.g., histamine originates from histidine, tyramine from tyrosine, tryptamine from tryptophan, and so on. However, the names cadaverine and putrescine are associated with decomposition and putrefaction, and spermine and spermidine are related to seminal fluids in which they were first found.

Bioactive amines can be classified on the basis of the number of amine groups, chemical structure, or biosynthesis. According to the number of amine groups, they can be mono-(tyramine, phenylethylamine), di-(histamine, serotonin, tryptamine, putrescine, cadaverine), or polyamines (spermine, spermidine, agmatine). Based on their chemical structure, amines can be aliphatic (putrescine, cadaverine, spermine, spermidine, agmatine), aromatic (tyramine, phenylethylamine) or heterocyclic (histamine, tryptamine, serotonin). They can also be indolamines (serotonin) and imidazolamines (histamine).

According to the biosynthetic pathway, amines are traditionally classified as natural or biogenic. Natural amines – spermine, spermidine, putrescine, and histamine – are formed during *de-novo* biosynthesis (they are produced *in situ* and as required from their precursors). Biogenic amines are formed by bacterial decarboxylation of free amino acids (**Figure 1**). Histamine can be either natural (stored in mast cells or basophils) or biogenic.

Prerequisites for the formation of biogenic amines in foods are the availability of free amino acids, presence of decarboxylase-positive microorganisms, and favorable conditions for bacterial growth and decarboxylase activity. Free amino acids occur as such in foods, but also may be released from proteins as a result of proteolytic activity. Decarboxylase-positive microorganisms may constitute part of the associated population of the food or may be introduced by contamination before, during, and after processing. Several studies have been performed to investigate the production of amines by microorganisms isolated from fish, cheese, meat products, vegetables and alcoholic beverages. Several species of *Escherichia*, *Enterobacter*, *Salmonella*, *Shigella*, and *Proteus* are active biogenic amine formers. Certain species of *Achromobacter*, *Lactobacillus*, *Leuconostoc*, *Pseudomonas*, *Pediococcus*, *Streptococcus*, *Micrococcus*, and *Propionibacterium* are also capable of amine production. In fermented foods, the applied starter cultures also may affect amine production.

Polyamine synthesis is a more complex process, although the first few steps also include decarboxylation reactions. Polyamines are synthesized from their natural precursors – ornithine or arginine and *S*-adenosyl-L-methionine – in different organisms, with putrescine as an obligate intermediate

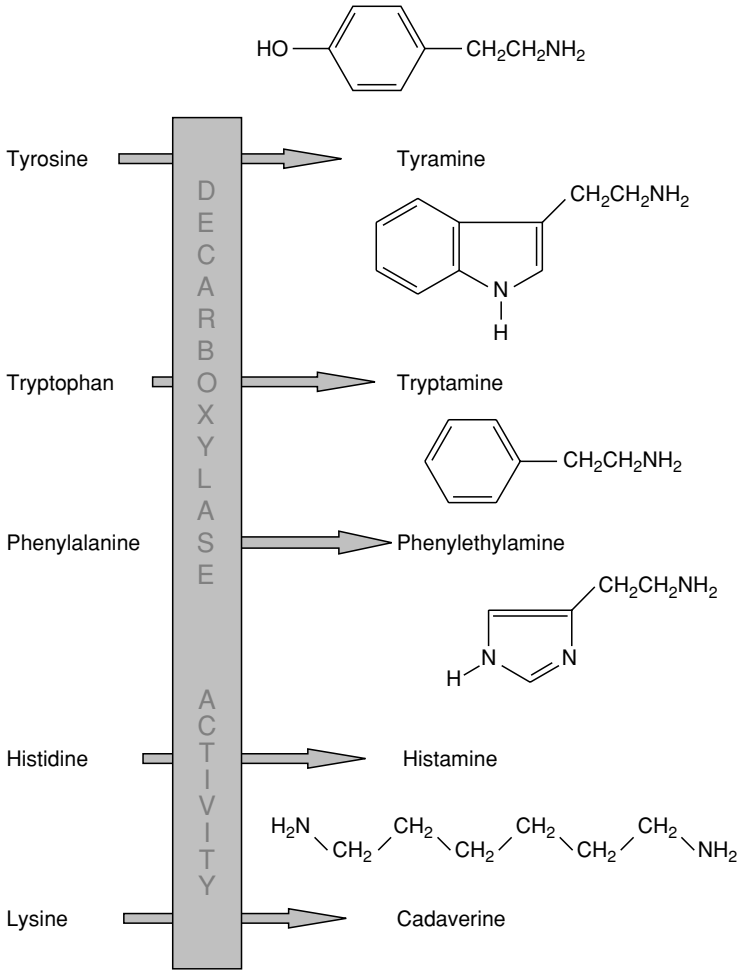

Figure 1 Synthesis of biogenic amines.

(Figure 2). In plants and some microorganisms, an alternative pathway exists to produce putrescine from arginine via agmatine (see dotted lines).

Physiological Importance of Amines

Amines participate in important metabolic and physiological functions in living organisms. Polyamines are essential for cell proliferation, growth, renewal, and metabolism. They are involved in nearly every step of DNA, RNA, and protein synthesis, and regulate the permeability and stability of cellular membranes. Polyamines play indispensable roles in living cells. Therefore, they are important in health and disease. Polyamine requirements are higher in the young during periods of intense growth. In healthy adults, however, these should not be as high, because polyamines are needed only to replace cells and mediate the action of hormones and growth factors. Polyamines are also essential for the maintenance of the high metabolic activity of the normally functioning and healthy gut, repairing the damage caused by deleterious components in food or by bacteria.

Biogenic amines are generally either psychoactive or vasoactive. Psychoactive amines, such as histamine and serotonin, act on the neural transmitters in the central nervous system. Vasoactive amines act directly or indirectly on the vascular system. Pressor amines – tyramine, tryptamine, and phenylethylamine – cause a rise in blood pressure by constricting the vascular system and increasing the heart rate and contraction force. Serotonin is vaso- and broncoconstrictor, reduces the volume and acidity of the gastric juice, has an antidiuretic effect, stimulates smooth muscle, and affects carbohydrate metabolism. Histamine can exert many responses within the body. It can directly stimulate the heart, cause contraction or relaxation of extravascular smooth muscle, stimulate both motor and sensorial neurons, and control gastric secretion. It also mediates primary and immediate symptoms in allergic responses.

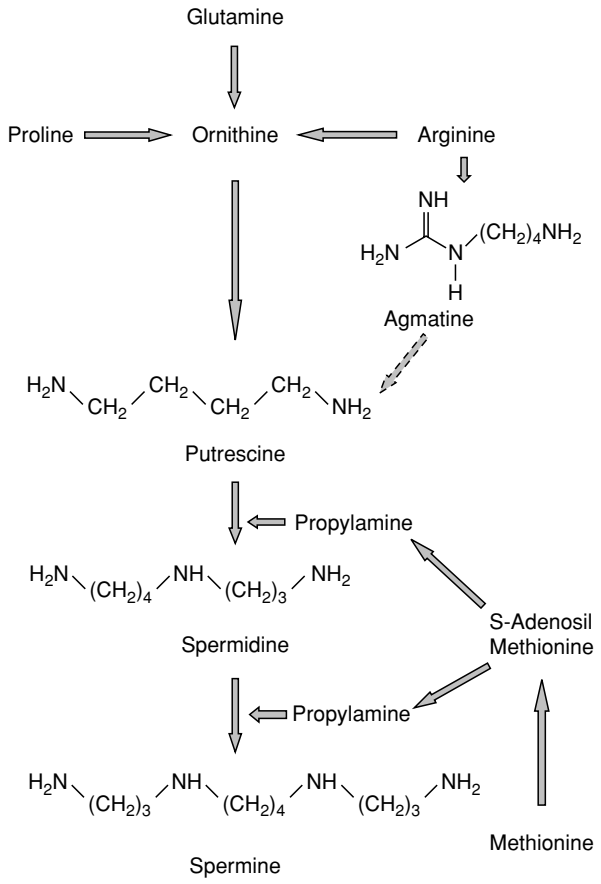

Figure 2 Pathways for the biosynthesis of polyamines.

Toxicology of biologically active amines

Three sources of amines have been identified: biosynthesis *in situ* from amino acids, direct ingestion from the diet, and synthesis and release by the bacterial flora resident in the gastrointestinal tract of the individual. It is now clear that the diet is an important source, supplying a significant part of the polyamines required to sustain normal metabolism.

Because of their biological activity, surplus amines need to be eliminated. Healthy individuals can detoxify amines present in foods by acetylation and oxidation. Biogenic amines are oxidized by monoaminoxidases (MAO; EC 1.4.3.4) and diaminoxidases (DAO; EC 1.4.3.6). Polyamines are usually acetylated first, then oxidized by polyaminoxidases (PAO; EC 1.5.3.11).

Amines in foods do not usually represent any health hazard to individuals, unless excessive amounts are ingested, or the natural mechanism for the catabolism of amines is genetically deficient or impaired by diseases. Individuals with respiratory and coronary problems, hypertension, or vitamin B_{12} deficiency are at risk because they are sensitive to lower amounts of amines. People with gastrointestinal problems (gastritis, irritable bowel syndrome, Crohn's disease, stomach and colonic ulcers) are also at risk because the activity of oxidases in their intestines is usually lower than that in healthy individuals. Patients taking medication that acts as inhibitors of MAO, DAO, and PAO activity also can be affected, as such drugs prevent the catabolism of amines. These MAO and DAO inhibitors are used for the treatment of stress, depression, Alzheimer's and Parkinson's diseases, pulmonary tuberculosis, malaria, panic syndrome, and social phobia. The toxic effect of some amines also can be potentiated by the presence of ethanol and of amines including putrescine, cadaverine, tyramine, tryptamine, 2-phenylethylamine, agmatine, serotonin, spermidine, and spermine. Most of them act by inhibition of amine metabolizing enzymes, whereas spermine causes liberation of endogenous histamine in the intestine.

The toxic effects caused by amines are summarized in Table 1. The most frequent foodborne intoxication caused by amines involves histamine. Histamine intoxication is also referred to as 'scombroid poisoning' because of the association of this illness with the consumption of scombroid fish. The disease manifests several minutes to 3 h after ingestion of the histamine-containing food. At first, a flushing of the face and neck is usually observed, accompanied by a feeling of heat and general discomfort. Often, this is followed by an intense throbbing headache. Other symptoms may be: cardiac palpitations, dizziness, faintness, itching, rapid and weak pulse, and gastrointestinal complaints (abdominal cramps, nausea, diarrhea). In severe cases, bronchospasms, suffocation, and severe respiratory distress are reported. However, the illness usually has a mild character, and symptoms do not last long. In most cases, the illness is not recognized as such. It is also possible that the symptoms are falsely attributed to a food allergy.

In the literature, many cases of food intoxication have been attributed to high histamine levels in foods or to low histamine levels in food containing other amines that can potentiate the toxic effect of histamine. Foods implicated in outbreaks of histamine intoxication include scombroid (tuna, bonito, mackerel, skipjack, herring) and other fish (sardine, anchovy, mahi-mahi), cheese (Gouda, Swiss, Gruyère, Cheddar, Cheshire), sauerkraut, sausage, and red wines.

When foods containing high tyramine levels are ingested, large amounts of nonmetabolized tyramine can reach the blood stream. This causes release of noradrenaline from the sympathetic nervous system,

Table 1 Toxic effects of biologically active amines

Toxic effects	*Amines involved*	*Food associated*	*Symptoms*
Histamine intoxication or scombroid poisoning	Histamine (Toxic effect is potentiated by putrescine, cadaverine, spermine, tryptamine, tyramine, phenylethylamine, ethanol)	Scombroid fish: tuna, bonito, mackerel, skipjack, herring Other fish: sardines, anchovy, mahi-mahi Cheese: Swiss, Gouda, Cheddar, Gruyère, Cheshire Sauerkraut; sausage; wine	Gastrointestinal: nausea, vomiting, diarrhea, cramps Neurological: headache, palpitation, face and neck flushing, burning throat, itching, rapid and weak pulse, dizziness, faintness Hemodynamic: hypotension Cutaneous: rash, urticaria, edema, localized inflammation Severe cases: bronchospasms, suffocation, severe respiratory distress
Tyramine intoxication	Tyramine	Cheese Beer Wine	Headache, fever, increased blood pressure, vomiting, perspiration, pupils and palpebral tissue dilatation, salivation, lacrimation, increased respiration, palpitation, dyspnea
Cheese reaction[a] or hypertensive crisis (associated with patients under MAOI drugs)	Tyramine 2-Phenylethylamine	Cheese: Gouda, Swiss, Gruyère, Cheddar Beer, wine, yeast extract, Pickled herring, dry Sausage, broad beans	Hypertensive crisis, severe headache, cerebral hemorrhage, neuronal sequel, cardiac failure, pulmonary edema, visual alterations, palpitation, nausea, sweat, vomit, muscle contractions, excitation, and mental confusion
Migraine	Tyramine 2-Phenylethylamine Tryptamine Serotonin	Cheese Chocolate Beer Wine	Throbbing headache, migraine attack

[a]MAOI, monoaminoxidase inhibitors.

leading to a variety of physiological reactions. There is an increase in blood pressure by peripheral vasoconstriction and by increasing the cardiac output. Tyramine also can dilate the pupils and the palpebral tissue, cause lacrimation and salivation, and increase respiration.

Ingestion of foods rich in tyramine by individuals under MAO inhibitor drugs treatment results in a dangerous intoxication known as the 'cheese reaction,' so called because most of the cases involved cheese. However, it is not the only type of food incriminated, since cases have also been reported with yeast extracts (marmite), pickled herring, dry sausage, alcoholic beverages, broad beans, etc. The cheese reaction involves a hypertensive crisis, usually accompanied by a severe headache. There can be visual alterations, nausea, vomit, muscle contraction, mental confusion, or excitation. It can lead also to cerebral hemorrhage, neuronal sequel, cardiac failure, and pulmonary edema. Fatal incidents have been reported in the literature.

Several amines, such as tyramine, tryptamine, and phenylethylamine, are considered precipitants of attacks in migraine sufferers.

Even though putrescine and cadaverine have less pharmacological activity than the aromatic amines, after ingestion of very large amounts of these compounds, toxic effects have been observed. Intoxication symptoms reported are hypotension, bradycardia, dyspnea, lockjaw, and paresis of the extremities. However, the most important consequence of these compounds in food is probably the potentiation effect of the toxicity of other amines.

Determination of the exact toxicity threshold of amines is extremely difficult. The toxic dose is dependent on the efficiency of the detoxification mechanism of different individuals. Upper limits of 10 mg of histamine, 10 mg of tyramine, and 3 mg of 2-phenylethylamine in 100 g of foods have been suggested. In the case of alcoholic beverages, the proposed limits are 2–8 mg of histamine and 8 mg of tyramine per liter. Individuals taking MAO inhibitor

drugs should limit tyramine intake to 6 mg per 100 g of foods.

As mentioned before, polyamines play important roles in cellular metabolism and growth. However, the importance of putrescine, spermine, and spermidine in tumor growth is widely recognized, and the inhibition of polyamines biosynthesis in tumor-bearing individuals is a major target of cancer therapy research. A new direction being investigated to inhibit tumor growth is to limit polyamine uptake.

Furthermore, putrescine and cadaverine can be converted to pyrrolidine and piperidine, respectively. These compounds, as well as spermidine, spermine and agmatine, can react with nitrite to form carcinogenic nitrosamines in foods or *in vivo*, in the gastrointestinal tract.

Occurrence of Amines in Foods

Biologically active amines are inherent to living organisms and, therefore, are present in plants, meat, and dairy products. The amount and type of amines in foods depend on the nature and origin of the commodity. However, it can change during processing, fermentation, and storage. It can be affected also by hygienic conditions. Amines are resistant to heat treatment employed in food processing. Based on these findings, amines have been considered good indicators of the freshness, spoilage, and degree of quality of fresh and canned food products.

It is evident that all types of food, whether they originate from plants or animals, contain putrescine and spermidine. In addition to these most common compounds, other amines also may occur naturally. When the food is spoiled by bacteria, the spermine content often decreases, because it can be used as a nitrogen source by some microorganisms. There is also formation and accumulation of different types of biogenic amines.

Much still remains unknown about the concentration of amines in food products. Most data available relate to specific amines, mainly histamine and tyramine in fish, cheese, meat, and alcoholic beverages. A comprehensive study of levels of all amines would be useful from both a toxicological and technological point of view. This is obviously an area deserving further detailed investigation.

Fish

Under normal physiological conditions, fish muscle contains high levels of spermidine and spermine and low levels of histamine and putrescine (Table 2). During storage and deterioration of fish, the levels of spermine and spermidine decrease, levels of putrescine, histamine, and cadaverine increase, and, in some species of fish, the presence of tyramine and tryptamine can be detected also. Based on these findings, a chemical index, calculated by the levels of putrescine, histamine, and cadaverine divided by those of spermine and spermidine, was proposed to evaluate the

Table 2 Mean levels of biologically active amines in different fresh, stored, and deteriorated fish, meat, and meat products

Technol*. 17: 20–23; Halász A, Baráth A, Simon-Sarkadi L and Holzapfel W (1994) Biogenic amines and their production by microorganisms in food. *Trends in Food Science and Technology* 51: 42–49; Silva and Glória (2002) Bioactive amines in chicken breast and thigh after slaughter and during storage at 4 1°C and in chicken-based meat products. *Foods Chemistry* 78: 241–248.

quality of tuna fish. This index was considered adequate to evaluate the quality or freshness of tuna and other types of fish and seafood, among them, salmon, rockfish, snapper, lobster, and shrimp.

Amine formation and build-up in fish normally occur during decomposition or spoilage processes as a result of the liberation of free amino acids through proteolysis together with bacterial production and action of amino acid decarboxylase. Several investigations have demonstrated that storage temperature is a critical factor influencing histamine and other amines formation in fish muscle. The requirement for rapid and uninterrupted refrigeration after catch cannot be overemphasized. The US Food and Drug Administration (FDA) established a guidance level for histamine in fish at the dock or before processing of 5 mg per 100 g. The FDA also states that rapid chilling of fish immediately after catch is the most important strategy to limit histamine formation. The internal temperature of the fish should be brought to 10 °C or below within 6 h of death. Chilling from 10 to 4.4 °C or less should take no longer than 18 h. Any period of time at a temperature above 4 °C significantly reduces the expected safe shelf-life. A maximum average histamine content of 10 mg per 100 g has been established by several countries and communities for acceptance of canned tuna and other fish belonging to the Scombridae and Scomberesocidae families. Because of the potentiating effect of other amines on the toxic effect of histamine, European regulation recommends the use of high-performance liquid chromatography (HPLC) techniques for the determination of the amines.

Scombroid fish, such as tuna, bonito, mackerel, yellowfin, and bluefin, have been involved more frequently in histamine intoxication incidents. Scombroid fish are particularly susceptible to histamine formation, since they contain large amounts of free histidine. However, other fishes have also been implicated, including Scomberesocidae, Pomatomidae, Coryhaenidae, Carangidae, Clupeidae, and Engraulidae. Even though several fish bacteria, either natural or contaminants, are capable of producing histamine, *Morganella morganii*, *Hafnia alvei*, and *Klebsiella pneumoniae* are the only histamine-producing bacteria that have been isolated from fish implicated in outbreaks.

Meat and Meat Products

Putrescine, spermine, and spermidine occur naturally in meat, where they serve as growth factors and are involved in a number of vital processes. Compared with fish, meat contains higher spermine levels. Meat products are also susceptible to proteolysis by enzymes (endogenous or from microbial contaminants), liberation of amino acids, and amine formation by amino acid decarboxylation. Amine levels in different types of fresh and stored meat are listed in Table 2. During storage and putrefaction of pork meat, there is a significant increase in putrescine and cadaverine. A significant correlation has been observed between these amines and total microbial counts.

In poultry, immediately after slaughter, high levels of spermine and spermidine and traces of putrescine have been detected. During storage at 4 °C, there is a decrease in spermine levels, whereas spermidine levels remain constant. The levels of putrescine, cadaverine, histamine, and tyramine increase significantly on the 15th day with higher levels found in breast than in thighs. The amine levels in chicken-based products listed in Table 2 indicate that the ingredients can affect the amine profile. Chicken-based hot dog contains significantly higher spermidine levels than the meat, probably because of the addition of soybean in the formulation. Significantly higher biogenic amine levels have been observed in chicken-based sausages, which could be indicative of the use of low-quality raw material, or of contamination during processing and storage.

Sausages have been implicated in histamine intoxication and hypertensive crisis episodes. Moreover, several reports have shown a wide range and high contents of biogenic amines in sausages. The manufacture of sausages offers favorable conditions for the formation of biogenic amines. The microbial count can be high and the production process lengthy, allowing a certain degree of proteolysis and yielding the amine precursor amino acids. Raw material quality, thawing conditions, ripening temperature and addition of a properly selected starter culture can affect the formation and accumulation of tyramine and histamine and, therefore, are important critical control points in preventing amine formation.

Dairy Products

The polyamine content in milk and dairy products is low, but the biogenic amine levels in cheese can be high. In fact, cheese is one of the foods with the highest amine content. A variety of amines have been found in different types of cheese (Table 3). In general, spermine and spermidine are present at low levels. The levels of other types of amines vary widely. High histamine and tyramine levels have been reported in several types of cheese.

Cheeses represent an ideal environment for amine production. The major factors that affect the formation, accumulation, and type of amines in cheese are the availability of amino acids (and hence proteolysis of cheese) and the presence of microorganisms, either

Table 3 Levels of biologically active amines in different types of cheese

Type of cheese	*Range of amine levels (mg per 100 g)*[a]

[a]nd, not detectable; –, not determined.

From Stratton JE, Hutkins RW and Taylor SL (1991) Biogenic amines in cheese and other fermented foods: a review. *Journal of Food Protection* 54: 460–470; Halász A, Baráth A, Simon-Sarkadi L and Holzapfel W (1994) Biogenic amines and their production by microorganisms in food. *Trends in Food Science and Technology* 51: 42–49; Vale S and Glória MBA (1998) Biogenic amines in Brazilian cheeses. *Food Chemistry* 63(3): 343–348.

added or as a contaminant, capable of decarboxylating amino acids. Several factors may contribute also, such as pH, salt concentration, water activity, ripening temperature and time, storage temperature, bacterial density, and activity of amine catabolic enzymes by means of mono- and diaminoxidase.

The longer the aging process, the higher the biogenic amine content. Amines concentrate on the rind of cheese. Numerous bacteria, both intentional (starter cultures) and adventitious, have been reported as being capable of amine production. *Lactobacillus* spp. play a major role in histamine, tyramine, and putrescine accumulation. *Enterococcus* spp. are notorious tyramine formers. Representatives of the Enterobacteriaceae, even at low densities, can cause cadaverine and putrescine build-up.

Several outbreaks of histamine intoxication have occurred following the consumption of cheese, particularly Swiss and Cheddar, containing high levels of histamine. Migraine headaches have been observed after ingestion of cheese with high levels of tyramine, tryptamine, or phenylethylamine. Hypertensive crisis has been observed after consumption of Swiss, Cheddar, Gouda, and Gruyère cheeses with high tyramine levels. Therefore, susceptible individuals should be advised to consume cheese with a low biogenic amine content. Furthermore, efforts should be made to elucidate amine formation in cheese in order to optimize the technology and secure low amine levels.

Fermented Beverages

Although tyramine and histamine are the major amines investigated in wine and beer, several different amines have been detected. The type and concentration of amines in wines vary widely (Table 4). In general, red wines contain significantly higher amine levels compared with white. Some amines are normal constituents of grapes, with levels varying with variety and degree of ripening as well as with soil type and composition. Among amines detected in grapes, putrescine and spermidine are usually abundant, whereas agmatine, cadaverine, spermine, and histamine have been found in smaller amounts. During wine-making, several amines can be formed and accumulate. Several factors can affect amine formation, including the presence of precursor free amino acids, must treatment, contact time of must and grape skin, initial microbial population present on the fruit, alcohol content, sulfur dioxide concentration, added nutrients, pH, temperature, quantity and type of finings, and bacterial contamination in wineries. A number of researchers have demonstrated that the amine content increases with microbial growth.

The presence of biogenic amines in wines is also of interest from a toxicological point of view. Histamine has been considered the causative agent of physiological distress experienced by individuals following the consumption of red wines. However, reports have demonstrated that tyramine, tryptamine, 2-phenylethylamine, and serotonin may play an important role as well as the simultaneous presence of potentiating compounds in wines, such as ethanol, aldehydes, and polyamines. Upper limits for histamine in wine have been recommended in Germany ($2\,mg\,l^{-1}$), Belgium ($5–6\,mg\,l^{-1}$), France ($8\,mg\,l^{-1}$) and Switzerland ($10\,mg\,l^{-1}$).

Since beer is generally consumed in greater amounts than wine, it has been suggested that beer might be more of a hazard to the consumer. Mainly, raw materials, brewing techniques, and microbial contamination during brewing affect the types and levels of amines in beers. High levels of putrescine, agmatine, spermine, and spermidine and low levels of histamine, tryptamine, 2-phenylethylamine, and cadaverine are usually found in malt. Tyramine, putrescine, spermine, spermidine, and agmatine have been detected in barley. Relatively high levels of tyramine, 2-phenylethylamine, putrescine, spermine,

and spermidine have been detected in hops. However, their contribution to amine levels in beer is not significant, since the amount used is very small. The use of adjunct cereals such as rice has been found to be useful in reducing biogenic amine levels in wort and beer. Beers with a higher acidity usually have higher amine contents.

During beer production, several amines can be formed and accumulate. Tyramine and agmatine can accumulate during mashing and wort boiling, as a result of thermal amino acid decarboxylation and possibly enzymatic activity in the malt. Moreover, amines can be formed during fermentation by contaminating lactic acid bacteria. Therefore, biogenic amines could be associated with hygienic conditions during brewing.

In general, putrescine, agmatine, and spermidine are inherent to beers (Table 4). Large variations in the levels of histamine, tyramine, tryptamine, and cadaverine have been observed. These amines are formed mainly during brewing. Higher total amine levels have been detected in stout and lower in ice beer.

Plant Foods

In plants, putrescine, spermidine, and spermine are implicated in a number of physiological processes, such as cell division, flowering, fruit development, response to stress, and senescence. Polyamines are known to stimulate growth and inhibit ethylene production, and therefore inhibit senescence. Amines are also intermediates in alkaloids synthesis.

The polyamines putrescine, agmatine, spermidine, and spermine are often detected in plants, but spermidine is the prevalent amine, especially in seeds and tissues undergoing growth. In conditions of potassium and magnesium deficiency and high ammonium concentration, putrescine and agmatine can accumulate. Putrescine also builds up in plants subjected to a wide range of stress conditions such as osmotic shock, acidification, high salinity, drought, desiccation, and temperature change.

Phenylethylamine, serotonin, tryptamine, and histamine may be present also in plants, where they have a protective role in deterring predators. Tryptamine and phenylethylamine are precursors of growth substances. These amines have been used as a tool for taxonomic studies. However, microbial contamination can cause increases in the biogenic amine content of fruits and vegetables.

Besides spermidine, putrescine, and agmatine, other types of amines have also been detected in vegetables. Tyramine is present in cabbage, lettuce, chicory, radish, tomato, potato, green onion, spinach, and eggplant. Histamine is found in cabbage, eggplant, tomato, beet, and spinach. Tomato and eggplant also have serotonin and tryptamine. Cadaverine is only found in plants of the Leguminosae family. Sprouts are usually rich in polyamines. High levels of tyramine and histamine have been detected in fermented vegetables such as sauerkraut, table olives, soy sauce, and miso.

Fruits are generally rich in putrescine and spermidine. High amine levels have been found in orange juice (putrescine, tryptamine, tyramine, synephrine), plum (serotonin, tryptamine, tyramine), banana, avocado (serotonin, tyramine), pineapple (serotonin), and raspberry (tyramine).

Other Food Products

Chocolate has been observed to contain high phenylethylamine and serotonin levels. Phenylethylamine is derived from the decarboxylation of phenylalanine during cocoa bean roasting. Mushrooms also contain high levels of phenylethylamine.

There is a clear need for further information on the nature and quantity of amines in food products. There is also a need to understand the effect of production and processing on amine levels, in order to optimize the technology and ensure low amine levels in foods. This will enable food chemists to declare limiting amine concentrations for certain food products. Furthermore, it will allow dietitians to formulate specific diets that are scientifically based, safe, and practical.

Introduction

Amino acids can be defined as organic acid molecules that also carry at least one amino group. If one of the amino groups is attached to the α-carbon (relative to the carboxylic group), the amino acid will be an α-amino acid (**Figure 1**). In addition to the above, various distinguishing groups can be attached to the α-carbon, a feature which is responsible for the rather wide variety of amino acids in nature. The distinguishing groups are given the generic name of 'side chains' ('R-groups'). The most common amino acids are those found in proteins, whose side chains are listed in **Table 1**.

Owing to their chemical nature and structure, amino acids have high melting and boiling points,

are water-soluble, and can readily ionize their carboxylic and amino groups in aqueous solutions. Since these molecules can carry both negative and positive charges, they are called zwitterions or ampholytes; that is, they can migrate to either the cathode or the anode in an electric field. By adjusting the pH of the solution, therefore, a point will come when the opposite charges are equal in magnitude and the

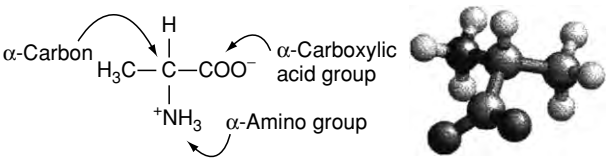

Figure 2 Alanine – a typical α-amino acid.

molecule will not migrate (Figure 2). The amino acid is said to have reached its isoelectric or isoionic point (*p*I). (*See* **pH – Principles and Measurement.**)

Isomerism

With the obvious exception of glycine, all α-amino acids contain at least one asymmetric carbon atom, i.e., their α-carbon atoms are indeed bonded to four different substituent groups. Most amino acids therefore exist in two different spatial arrangements or isomers, whereas isoleucine, threonine, hydroxylysine, and hydroxyproline each have a second asymmetric carbon and thus four stereoisomers.

Standard nomenclature of amino acids is preceded by either a D or an L, indicating whether a structure corresponds to either that of D(+)-glyceraldehyde or L(−)-glyceraldehyde. This designation is the 'absolute configuration' of an amino acid. The relationship between the D and L isomers of glyceraldehyde and alanine can be seen in Figures 3 and 4, respectively.

Since stereoisomers are mirror images of each other and exhibit characteristic angles of rotation for polarized light, nomenclature also includes either a (+) or (−) (formerly *d* or *l*) to indicate that a pure solution of the amino acid would rotate a beam of polarized light clockwise (dextrorotation) or counterclockwise (levorotation), respectively.

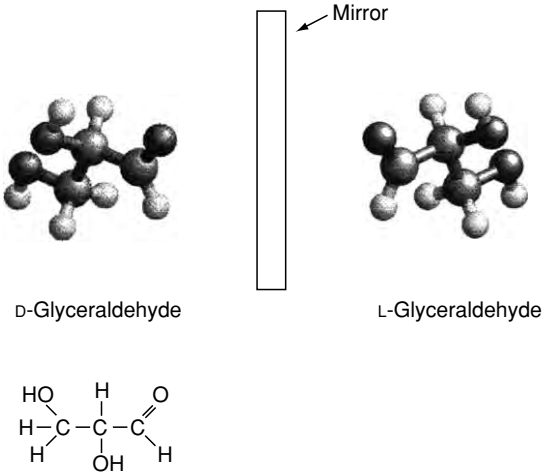

Figure 3 The stereoisomers of glyceraldehyde.

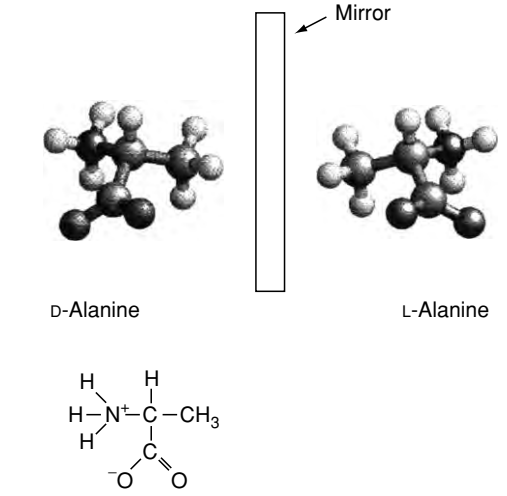

Figure 4 The stereoisomers of alanine.

Amino Acids as Protein Constituents

Over 95% of the amino acids in a food will be encountered in the form of proteins. Proteins are unbranched chains (polypeptides) of L-α-amino (or α-imino) acids linked together by peptide (amide) bonds. Combinations of about 20 amino acids commonly make up the structures of polypeptides. Different sequences made with the same amino acids will spell out different proteins, each sequence corresponding to a different primary structure. The remainder will be found as peptides and free amino acids. (*See* **Protein**: Chemistry.)

Interestingly, only the L isomers of α-amino acids have been found in all proteins. Although D-amino acids are not involved in the metabolism of higher organisms, they can be structural components of cell walls in certain bacteria and part of some peptide antibiotics. L-Amino acids will slowly convert to racemic mixtures of D- and L-amino acids with time or as a result of alkali exposure or considerable heat treatment.

A peptide bond results from the condensation of the α-carboxylic group of one amino acid and the α-amino group of another. Figure 5 shows a dipeptide linkage between two alanine residues.

The peptide bond can be visualized as a plane, in the middle of which lies the amide (C-N) linkage (Figure 6). Two opposite corners of the plane are occupied by the two α-carbons, and each of the remaining two is occupied by an oxygen and a hydrogen atom. The plane is considered a rather rigid structure ($E_{\text{rotation}} = 21\ \text{kcal mol}^{-1}$) due to the tendency of

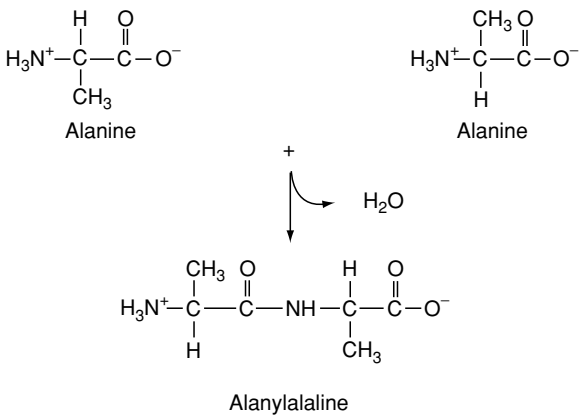

Figure 5 The formation of the peptide bond between two molecules of alanine.

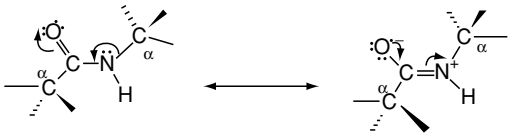

Figure 6 The two structures contributing to the resonance hybrid structure of the peptide bond.

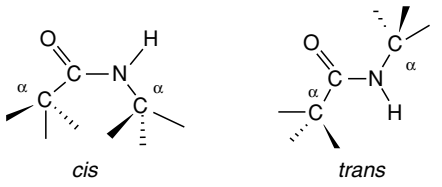

Figure 7 The *cis* and *trans* configurations of the peptide bond.

the electron clouds of the system to remain orbitting, each on a separate side of the plane. Once a free amino acid has been incorporated into a polypeptide or protein, all physical, physicochemical, and chemical properties attributed to the free form are altered.

The peptide bond exists in nature in either the *trans* or *cis* configuration. The *cis* configuration is less common and results from the presence of proline residues (Figure 7).

Imino Acids Found in Proteins

Proteins often contain small amounts of the imino acid L-proline and, more rarely, L-4-hydroxyproline (Hypro). Unlike α-amino acids (with primary amines), the imino acids cannot keep their side chains as far away as possible from those of the neighboring residues, as the *trans* configuration would require. Therefore, the mere presence of a proline (or a hydroxyproline) residue in the sequence introduces a 'kink' or bend in the polypeptide structure (Figure 8).

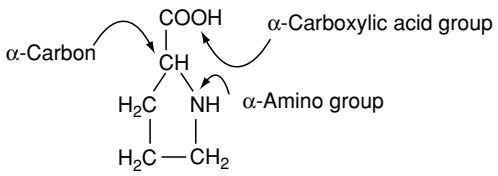

Figure 8 Structure of proline. Note that the α-carbon and 'amino' nitrogen are involved in the side chain, and the amine is thus secondary.

Table 2 The nonessential (dispensible) and essential (indispensible) amino acids for humans

Nonessential	*Essential*
Alanine	Arginine[a]
Asparagine	Histidine[a]
Aspartate	Isoleucine
Cysteine[b]	Leucine
Glutamate	Lysine
Glutamine	Methionine[b]
Glycine	Phenylalanine[c]
Proline	Threonine
Serine	Tryptophan
Tyrosine[c]	Valine

[a]Essential to the young. Not limiting in most foods.
[b, c]Due to one-way interconversions, nutritional evaluation takes into account the pairs.

If the imino acid content of a polypeptide is high (3–10%), then the peptide is likely to fold randomly. If the imino acid residues are repeated regularly along the polypeptide (as is true of collagen, ~23% Pro + Hypro), then the protein is able to fold into a regular structure.

The Classification of Amino Acids

Amino acids can be usefully classified in several ways, depending on their properties. Two common classifications are by their nutritional essentiality to animals and by the polarity of the R-groups at neutral pH (Tables 2 and 3, respectively). As most proteins and amino acids function in aqueous environments at physiological pH, the second criterion is most helpful when considering the function of an amino acid in a protein *in vivo* or in most food systems. Hydrophobic R-groups tend to 'hide' themselves in the interior of folded proteins. Table 1 highlights the structures of the 20 common protein amino acids classified according to their polarity in neutral solutions.

A nutritionally essential amino acid is one that cannot be manufactured, either at all or in sufficient quantities for optimal growth by the body, and

Table 3 Genetic code and some physicochemical properties of the common protein amino acids while in the free form

Amino acid	*Genetic code*	*Solubility ($g\,l^{-1}$)*[a]	*PK_1 (α-COO^-)*	*PK_2 (α-NH_3^+)*	*PK_3*[b]	*PI*
Alanine	GN(N)	167.2	2.34	9.69		6.00
Arginine	AGA/AGG/CG(N)	855.6	2.17	9.04	12.48	10.76

[c]Solubility at 37 °C.

therefore has to be present in the diet. These amino acids are sometimes termed collectively as 'indispensible.' In contrast, nonessential amino acids (indispensible nitrogen) can thus be interconverted in order for the body to meet its needs.

Although the nutritive or biological value of a protein can be measured by its contents of essential amino acids, nonessential amino acids should be regarded as important, as maximal protein efficiency will only be attained if an adequate supply of nonspecific nitrogen is guaranteed in the diet. Besides serving as protein constituents, surplus essential amino acids are used as precursors of other vital metabolites and occasionally as energy. Excess of nonspecific nitrogen, on the other hand, will preferentially be used as energy. (*See* **Amino Acids: Metabolism.**)

Physical, Chemical, and Sensory Properties of Amino Acids Found in Proteins

All amino acids in the pure state are crystalline solids with physical constants much too high for either organic amines or acids of similar structures and molecular weights. They are not volatile, melt at high temperatures, are insoluble in organic solvents, and have low pK values. Their molecular weights range from 75 to 204; average molecular weight is estimated at 110. Therefore, if a protein has a molecular weight of 33 000, one could estimate it contains approximately 300 residues.

Amino Acids Commonly Found in Proteins

Although the following listing refers to those amino acids actually found in proteins, it should be remembered that they also exist in the free form in both vegetable and animal tissues.

Glycine (mol. wt 75.1) The R-group is a single hydrogen atom, making it the smallest amino acid. Because it is the smallest residue, glycine enables a protein to fold into a compact structure. Collagen can fold into a tight triple helix because every third amino acid is glycine. (The uniform sequence of collagen is abbreviated to [-Gly-Pro-X-]$_n$, where X is often hydroxyproline.) The hydrogen atoms attached to the α-carbon atom have too small an influence on the ionization and high degree of polarity of the α-amino/α-carboxylic system. Free glycine is responsible for the sweet taste of shrimp. Its name derives from the same Greek word as glucose (*glycos*).

Alanine (mol. wt 89.1) This is the next simplest amino acid. The side chain of alanine is a methyl group (Figure 2) and performs well in both hydrophobic and hydrophilic environments. Like glycine, this amino acid is found in high concentrations in tightly folded proteins such as keratin and collagen.

Serine (mol. wt 105.1) A hydroxyl group at the end of the side chain makes serine more polar than alanine, yet uncharged at pH 7. Like the other polar,

uncharged amino acids (glycine, threonine, cysteine, tyrosine, asparagine, and glutamine), serine forms hydrogen bonds with water; with sugars it forms glycosidic bonds. Serine is essential for the active sites of enzymes, as in the serine-proteases trypsin and chymotrypsin. (*See* **Enzymes**: Functions and Characteristics.)

Cystine (mol. wt 240.2) and cysteine (mol. wt 121.1) These amino acids have R-groups that contain sulfur either oxidized as a disulfide or reduced as a thiol. Cystine is two molecules of cysteine linked through a disulfide bond (Figure 9). When incorporated into proteins the disulfide bond between cysteine residues effectively 'pins' the protein structure together. The fact that most natural proteins contain disulfide bonds may be a natural mechanism to increase the protein's structure stability under unfavorable conditions and magnify its biochemical function. Intracellular fluids are mildly reducing, favoring cysteine, while the extracellular environment is sufficiently oxidizing to favor cystine. The thiol of cysteine is essential for the catalytic activity of some enzymes, such as papain, and is a prime target for enzyme inactivation by heavy metals and alkylating reagents. Free cystine has low solubility.

Aspartic acid (mol. wt 133.1) This amino acid is normally abbreviated to 'Asp' but if, when it is determined, no distinction is made between aspartic acid and its amide (Asn), it is abbreviated to 'Asx.' Aspartate has an acidic, negatively charged R-group at pH 7. It is electrically neutral at pH 2.98.

Asparagine (mol. wt 132.1) Asparagine is the amide of aspartate. This was the first amino acid to be isolated (1806), from asparagus, the plant from which it derives its name.

Valine (mol. wt 117.1) Valine has a bulky, very hydrophobic side chain. It is an essential amino acid for humans (average adults require 0.7 g day^{-1}) and can be metabolized in the muscle. Valine, leucine, and isoleucine are the branched-chain amino acids.

Leucine (mol. wt 131.2) The side chain of leucine is aliphatic, bulky, and very hydrophobic. It is essential for humans (average adults require 0.98 g day^{-1}) and can be metabolized in the muscle. Leucine, isoleucine, and valine are the branched-chain amino acids.

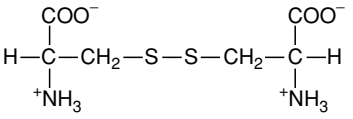

Figure 9 Disulfide bond in a cystine molecule linking two molecules of cysteine.

Isoleucine (mol. wt 131.2) This amino acid is also highly hydrophobic. It has two asymmetric carbon atoms and therefore can exist as any of four isomers. Only one isomer exists in proteins. It is nutritionally essential for humans (average adults require 0.7 g day^{-1}) and can be metabolized by the muscle. Isoleucine, valine, and leucine are the branched-chain amino acids.

Methionine (mol. wt 149.2) Like cysteine, methionine is a sulfur-containing amino acid. The sulfur in methionine can be oxidized, but is unable to form disulfide bonds. The R-group renders methionine quite hydrophobic. In prokaryotic cells a methionine residue is essential for the initiation of protein synthesis. It is nutritionally essential for humans (average adults require Met + Cys 0.91 g day^{-1}) and is limiting in most dietary proteins. It becomes toxic when ingested in excess of 4% of the protein.

Threonine (mol. wt 119.1) This amino acid has a hydroxyl group as part of the side chain, making it polar, yet uncharged at physiological pH. It has two asymmetric carbon atoms and therefore can exist in any of four isomers. Only one form exists in proteins. This was the last of the common amino acids to be identified (1938). It is an essential amino acid for humans (an average person requires 0.49 g day^{-1}).

Glutamine (mol. wt 146.1) The abbreviation for this amino acid is 'Gln' (or 'Q'), but 'Glx' (or 'Z') is used when no distinction can be made between glutamic acid and the corresponding amide glutamine. Glutamine has a polar but uncharged R-group. It is found in large amounts in the gliadin and glutenin fractions of wheat.

Glutamic acid (mol. wt 147.1) This amino acid has a γ-carboxylate group in the side chain. It is therefore found on the surface of proteins. It was discovered in 1908 in edible seaweed, when it was recognized as a flavor potentiator or enhancer. The salt monosodium glutamate (MSG) has a sweet and salty taste at very low concentrations. MSG increases sensitivity to sour and bitter tastes. Other amino acids, such as ibotenic acid and tricholomic acid, have been reported to have similar effects.

Lysine (mol. wt 146.2) A positively charged side chain with a second (ε-)amino group that can form

salt-bridges or react with other residues to form covalent cross-links is found in lysine. These cross-links are important in skin, where they are involved in aging effects. Lysine is known to react with sugars, giving rise to different flavor and color compounds (Maillard reaction). Lysine is an essential amino acid for humans. Cereal proteins are typically low in lysine, while legume proteins are high. The average person requires 0.84 g day^{-1}. (*See* **Browning**: Non-enzymatic.)

Arginine (mol. wt 174.2) This amino acid has a positively charged guanidinium group on the end of the side chain, being a much stronger base than the ε-ammonium group of lysine. Consequently, arginine is 100% protonated with a net charge of +1 at physiological pH. Ammonia intoxication results in children (and cats) if this amino acid is absent from a fasting diet. It is present in high amounts in immature seeds like groundnuts.

Histidine (mol. wt 155.2) A weakly protonated imidazole group is present in the side chain of this amino acid. It is often found in the active sites of enzymes, where it is essential for the catalytic activity. This residue is a primary target for enzyme inactivation by heavy metals and alkylating reagents. Histidine is the only amino acid with significant buffering power near the pH of intracellular fluids and blood. Hemoglobin has a uniquely high content of histidine in order to counteract the effects of excess carbon dioxide. Recommended intake for adults varies from 0.56 to 0.84 g day^{-1}.

Phenylalanine (mol. wt 165.2) This amino acid has an aromatic, nonpolar hydrophobic R-group that makes it ideal for structuring the core of proteins. When present on the surface, it can have a role in substrate recognition or hydrophobic binding of other molecules. Phenylketonuria is a disabling disease that is estimated to occur in 1% of mentally handicapped patients. It is caused by a failure of the liver to metabolize phenylalanine and sufferers must avoid eating foods containing phenylalanine. As natural proteins devoid of phenylalanine are almost nonexistent, feeding phenylketonurics is a technological challenge. Average adults require (Phe + Tyr) 0.98 g day^{-1}.

Tryptophan (mol. wt 204.2) An indole, nonpolar hydrophobic R-group makes this amino acid essential for humans (average adults require 0.25 g day^{-1}). Plant proteins are probably poor in tryptophan due to diversion of the indole group to auxin biosynthesis. Pellagra is now an uncommon disease but may occur in persons subsisting on vegetable proteins that are poor in tryptophan. Symptoms include skin rashes in response to sunlight, diarrhea, severe nervous depression, and partial paralysis. The administration of tryptophan or nicotinic acid reverses these symptoms. (*See* **Niacin**: Physiology.)

Tyrosine (mol. wt 181.2) This amino acid has an aromatic, polar but uncharged side chain (hydroxylated phenylalanine). Tyrosine is an important intermediate in the synthesis of epinephrine, thyroxin, melanin, and biogenic amines. Foods such as chocolate and cheese which is somewhat rich in tyrosine have been suggested to be responsible for some migraine-type headaches. (*See* **Migraine and Diet**.)

Posttranslational Modification of Proteins: Unusual Amino Acids

There exists a number of unusual amino acids, derived from some of the 20 standard protein amino acids. Although a few of these can still be found in the free form (Table 3), the remainder are essential to specific proteins and arise from enzymatic modifications occurring after they have been incorporated into a peptide, as listed below.

Hydroxylation

Hydroxyprolines Proline may be modified to 3-hydroxyproline or 4-hydroxyproline after it has been incorporated into a precursor peptide for collagen. Hydroxylated residues can be further glycosylated.

5-Hydroxylysine 5-Hydroxylysine is another unusual amino acid found in collagen. Hydroxylysine results from the modification of lysine after incorporation into a peptide. Scurvy symptoms occur when hydroxylation does not take place. (*See* **Scurvy**.)

Phosphorylation

The reactivity of tyrosine can be augmented in a peptidic environment. This is illustrated by the fact that tyrosine residues of certain cell proteins are particularly targeted by phosphokinase-phophatase-mediated reactions as an effective way to regulate division, growth, and general cell metabolism in both animals and plants. Epidermal-, platelet- and some insulin like-growth factors (EGF, PDGF, IGF) are examples of proteins that are activated by tyrosine phosphorylation. Mice and human oncogenes can produce tyrosine kinases with uncontrolled phosphorylation activities that lead to leukemia, breast, and prostate cancer.

Carboxylation

γ-Carboxyglutamic acid This amino acid is associated with calcium binding and is found in proteins such as prothrombin, the protein involved in blood clotting, and other proteins in bone tissue.

Methylation

ε-N-Methyllysine This amino acid is abundant in the contractile muscle protein myosin and in cytochrome *c*. (*See* **Exercise**: Muscle.)

Glycosylation

Many proteins have carbohydrate side chains. The sugars (often galactose and glucose) are attached to asparagine, serine, or theonine residues or other hydroxylated amino/imino acid residues. Glycoproteins can form gel structures that influence the water activity and the texture of foods.

Covalent Cross-Linking

Desmosine The structure of desmosine is shown in Figure 10. It is a derivative of lysine and forms a covalent cross-link between polypeptides. It is mainly found in elastin and is relevant to the aging process, as seen in skin. Other cross-links (aldolic) that occur in collagen are associated with meat texture.

Sulfur–Selenium Exchange

Selenocysteine and selenomethionine These are analogs of both cysteine and methionine that result from sulfur–selenium exchange, occurring mostly in plants grown in selenium-rich soils. These amino acids are found in the active site of selenium-dependent enzymes, such as glutathione peroxidase, which are essential for the removal of toxic hydrogen peroxide from cells. (*See* **Selenium**: Physiology.)

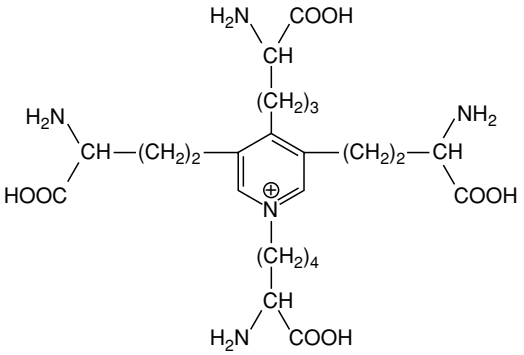

Figure 10 The structure of desmosine.

Occurrence in Foods and Nutritional Implications

All animal foods, such as meat, fish, milk, and eggs, are protein-rich, whereas most plant foods are not. Leguminous seeds, like beans and nuts, where protein and lysine are high, are an exception. These proteins, however, are deficient in the sulfur-containing amino acids, particularly methionine. The proteins found in cereal grains (seeds of maize grain, rice, sorghum), in turn, are deficient in lysine and tryptophan, but not so in methionine. Leafy vegetables are somewhat richer than root vegetables, whereas fruits are very low in protein. The proteins of seeds of pseudocereals like quinoa (*Chenopodium quinoa* Willd.) and amaranthus grain (*Amaranthus* sp.) have amino acid profiles that combine the characteristics of both legumes and cereals. (*See* **Protein**: Food Sources.)

Humans can synthesize only 10 of the 20 amino acids required for protein synthesis. They must obtain the rest from their diet if they are to remain healthy (Table 2). (*See* **Protein**: Synthesis and Turnover.)

Interestingly, the metabolisms of children and adults are slightly different. The growing child has a greater requirement for arginine and histidine than the adult, whereas adults synthesize sufficient arginine for their daily requirement.

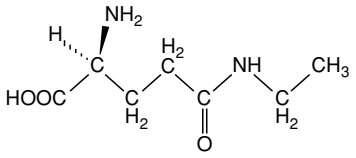
Consistent with food composition data, proteins rather than free amino acids are the main source of dietary nitrogen. Some special diets, however, require the use of predigested proteins or free amino acids. About 75% of amino acid metabolism in normal healthy adults is devoted to protein synthesis. This protein is essential for normal growth, repair, and defense, including the production of active enzymes, plasma protein, muscle creatine and, in females, reproduction and synthesis of milk proteins. The remaining 25% of nitrogen metabolism produces intermediates of the tricarboxylic acid (TCA) cycle, hormones, and neurotransmitters.

Amino acids that are not associated with proteins in a given tissue or food can be collectively called 'nonprotein' amino acids or 'nonprotein' nitrogen. In spite of the fact that nonprotein amino acids are present in relatively small amounts, their importance in food science and nutrition can be significant. Table 3 lists the common protein amino acids, as free species, their solubility, genetic code, *p*K and *p*I values.

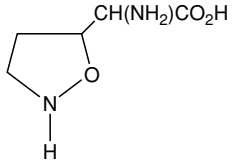
Less common, nonprotein amino acids, some with very peculiar properties, are listed in Table 4. Worthy of mention are theanine, typical of green tea, which has a relaxing effect in humans (Figure 11) and taurine in human milk. Taurine (β-aminoethanesulfonic acid) is an unusual amino acid, normally found in the

Table 4 Natural nonprotein amino acids found in plant and animal tissues

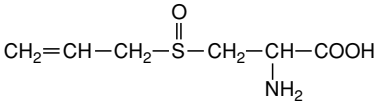
Name	*Occurrence, function, and importance*
β-Alanine (β-aminopropionic acid)	A component of pantothenic acid, coenzyme A, constituent of carnosine and anserine. Also occurs in the free state
L-α-Aminobutyric acid	Normal human urine, animal and plant tissues. Also as a component of the tripeptide ophthalmic acid
β-Aminoisobutyric acid	Human urine and iris bulb in the free state
γ-Aminobutyric acid	Occurs in the free state in several plants, animal tissues, and certain bacteria. Has been found in the brain of mammals, some amphibia, and birds. This amino acid appears to function in the transmission of nerve impulses
α-Aminoadipic acid	Maize, pea and other plants, human urine
α-Aminopimelic acid	Isolated from *Asplenium septentrionale*
O-acetylhomoserine	This amino acid has been isolated from pea plants
O-Phosphohomoserine	Isolated from extracts of *Lactobacillus casei*
L-Azaserine (*O*-diazetoacetil-L-serine)	Isolated from cultures of a strain of *Streptomyces*. This amino acid inhibits the growth of certain experimental tumors
L-Albizzine (L-2-amino-3-ureidopropionic acid)	It has been found in the seeds of *Albizzia julibrissin* and in other species of Mimosaceae
Alliin (*S*-allyl-L-cysteine)	A constituent of garlic. Alliin is enzymatically converted by alliinase to allicin, which exhibits an odor characteristic of garlic
Betaine	A constituent of plant and animal tissues, an intermediate in the metabolism of lipids
L-Baikiain	Rhodesian teak (*Baikiaea plurijuga*)
Canavanine	Soy and jack bean meals and also in a number of other plants
m-Carboxy-L-tyrosine	Seeds of *Reseda odorata* L.
β-Cyano-L-alanine	Seeds of the vetch (*Vicia sativa*)
L-Citrulline	Fish, juice of watermelon, other plants and animal tissues, important intermediate in urea cycle; precursor of arginine
L-Djenkolic acid	Djenkol bean (*Pithecolobium lobatum*, from Java), *Acacia farnesiana*
Dichrostathinic acid	Seeds of *Dichrostachys glomerata*
β,γ-Dihydroxyglutamic acid	Found in lettuce seeds, rhubarb, and other plants
1,3-Dimethylhistidine	Reported in the Australian seaweed *Gracilaria secundata*
2-(β-D-Glucopyranosyl)-4-alanyl-3-isoxazolin-5-one	Found in peas (*Pisum sativum*)
Glycine	In the free form plays an important role in the sweet flavor of shrimp
L-Homoarginine	Seeds of legumes of the genus *Lathyrus* and *Lotus helleri*
L-Homomethionine	Present in cabbage
Homoserine	Peas and other plants
Homocysteine	Found in adrenal extracts
Hypusine	A basic amino acid reported in bovine brain and other mammalian tissues
3-Hydroxypipecolic acid	Halophyte leaves, flowers, and fruits
5-Hydroxy-L-tryptophan	Found (6–10%, fresh weight) in the West African legume *Griffonia simplicifolia*
Lanthionine	Antibiotics (subtilin, penicillins)
Lathyrine	Seeds of *Lathyrus tingitanus*
Lisopine	Crown-gall tissues of salsify, tobacco, and normal plant tissues
1-Methylhistidine	Anserine, human urine
β-Methylene-L-norvaline	Found in the mushroom *Lactarius helvus*
β-Methylene-L-norleucine	Found in the mushroom *Amanita vaginata*
S-Methylmethionine	Methylsulfonium derivative of methionine found in cabbage and asparagus
N-Methyltryptophan	Methyl ester found in the legume *Aotus subglauca*
Ornithine	Tyrocidine, urea cycle, as ornithuric acid in excreta of birds, some fishes
Octopine	Octopus muscle
Pipecolic acid	Occurs in plant tissues and in mammalian livers as a product of lysine metabolism
L-Saccharopine	Bakers' and brewers' yeasts
Taurine	Sulfur amino acid essential to infants fed cows' milk
Theanine	Green tea. Causes a specific relaxation effect in humans
Tricholomic acid	Responsible for the good taste of mushrooms. Toxic to flies
L-Willardiin	Seeds of several *Acacia* species, including *Acacia willardiana*



L-Theanine (γ-glutamylethylamide)



Tricholomic acid



Alliine

Figure 11 The structures of L-theanine, tricholomic acid and alliine.

free form, manufactured by the body from cysteine or methionine and essential for the production of conjugated bile salts (taurocholic acid). Since cows' milk has low concentrations (1–3 μmol 100 ml^{-1}) of taurine in relation to human milk (27–35 μmol 100 ml^{-1}), there is concern that infants fed formulas based on cows' milk may develop a deficiency of taurine.

Amino Acids, Neurotransmitters, and Hormones

The amino acids glutamate, glutamine, asparate, glycine, and γ-aminobutyric acid (GABA) will act as neurotransmitters for specific types of neurones or regions of the brain. Glutamate is one important transmitter in the central nervous system of invertebrates and possibly in humans. GABA is found in relatively high concentrations (around 0.8 mmol l^{-1}), almost exclusively in brain tissue. It acts as an inhibitory transmitter by making it more difficult for a nerve to fire impulses. The structure of GABA is shown in Figure 12.

Thyroxine and triiodothyronine (Figure 13) are hormones derived from the amino acid tyrosine. Both these hormones stimulate metabolism in tissues. (*See* **Hormones**: Thyroid Hormones.)

Chemical and Physicochemical Properties Relevant to Foods

The participation of amino acids in the many changes that occur during ripening, storage, or processing of raw materials and foodstuffs is a direct consequence of their capacity to react chemically or interact physicochemically with other food components. Amino acids, *per se*, for example have little direct relevance on flavor, while proteins have even less. Proteins and peptides however have an important role as emulsifiers, fat and odor binders and thus

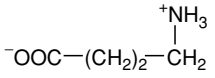


Figure 12 The structure of γ-aminobutyric acid (GABA).

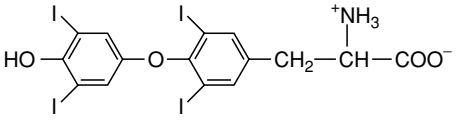
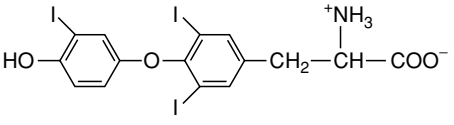


Thyroxine



Triiodothyronine

Figure 13 The structures of thyroxine and triiodothyronine.

can affect the flavor and texture characteristics significantly, while some amino acids or their derivatives have direct bearings on food flavor and aroma. Examples are the sweet taste of naturally grown shrimp because of the high concentrations of glycine and the characteristic flavor of mushrooms imparted by tricholomic acid (Table 4, Figure 11).

The shifting of the pK_as of a free amino acid towards lower pH values makes the amine groups more reactive against carbonyl compounds. Side chain reactivity is also enhanced through the effect of the α-amino/α-carboxylic system. Amino acids with aromatic or alifatic side chains are also not as hydrophobic as they would be without the α-amino/α-carboxylic system. The following are reactions responsible for the development of some food attributes.

Deamination

Amino acids undergo deamination during fermentation. This is important in the production of flavor compounds in bread, some cheeses, and beers. If deamination is allowed to proceed extensively, diamines and biogenic amines may form, giving the food a fishy or spoiled odor.

During the ripening of bananas L-leucine can give rise to 13 volatile alcohols, aldehydes and esters, while L-phenylalanine will generate seven and L-valine produce four, some of which contribute to the characteristic banana aroma. Sulfur amino acids can be precursors of such volatile compounds as H_2S, CH_3SH, CH_3CH_2SH, propanethiol, dimethylsulfoxide, methylisothiocyanate, allylthiocyanate,

allylisothiocyanate, thiophene, acetylthiophene, benzothiophene. Garlic, onions chives, leeks, and shallots are rich in alliins (*trans-S*(+)-1-propenyl-L-cysteine-sulfoxide is a major alliin), important sulfur compounds that are released when the bulbs are crushed (Figure 11). (*See* **Flavor (Flavour) Compounds:** Structures and Characteristics.)

Maillard Browning

Under a wide range of moisture and temperature conditions, amino acids and carbonyl compounds can undergo a complex series of condensation, deamination, decarboxylation, and polymerization reactions called 'Maillard browning.' The products of the reaction of amino acids or proteins with aldehydes, ketones, and reducing sugars are numerous. They can be volatile, low-molecular-weight or complex brown-colored, high-molecular-weight, fluorescent compounds referred to collectively as 'melanoidins.' The correct amount of Maillard products is very important in determining the acceptability of baked and roasted foods. Even though an extensive part of the classical nutritive value of the reacted amino acids will be lost and some biogenic amines may form, these products add to the desired aroma, flavor, and color of cakes, pies, powder and condensed milk, roasted groundnuts, chocolate, and coffee.

Processing Aids

L-Cysteine, L-glutamyl-L-cysteine, L-cysteinylglycine and glutathione (γ-L-glutamyl-L-cysteinyl-glycine) are naturally present in wheat flour. In certain dough processes the flour can be enriched with these molecules or with mixtures of these compounds with oxidizers to produce desired properties in the dough or to reduce mixing times. MSG, naturally present in cabbage and other products of either vegetable or animal origin, has a 'meaty' taste and can be added in the crystalline form as a flavor enhancer. (*See* **Flour:** Dietary Importance.)

Amino Acids in Artificial Sweeteners

Aspartame is the dipeptide L-aspartyl-L-phenylalanine methylester. This molecule is about 200 times sweeter than sucrose with almost no aftertaste. It degrades slowly under acid conditions at room temperature and rapidly at higher temperatures, making it unsuitable for baked foods. Phenylketonurics cannot tolerate this sweetener because of the phenylalanine content. (*See* **Sweeteners:** Intensive.)

Determination

A P Williams, Leatherhead Food Research Association, Leatherhead, UK

Background

Analysis of foods to determine their amino acid composition has long been of importance nutritionally, but there are an increasing number of other applications, including detection of adulteration and potentially toxic amino acids produced by new food-processing technologies. This article will review current methods of the determination of amino acids.

Isolation of Free and Protein Amino Acids

Although determination of the total amino acid composition of foods, after protein hydrolysis, is the prime requirement, it is sometimes necessary to determine free amino acids in foods, beverages,

physiological fluids, and tissues. To do this, it is necessary to remove any protein before analysis. Methods of deproteinizing include precipitation with acids or alcohols, high-speed centrifugation, ultrafiltration, ion exchange, and equilibrium dialysis. None is perfect, but precipitation with sulfosalicylic acid is the most popular method although not always suitable for all derivatization procedures.

It may be necessary to remove nonprotein substances from samples before hydrolysis, since they can affect the accuracy of the analysis or damage stationary phases by irreversible adsorption. Since the extraction procedures are lengthy and can result in losses of protein, they are normally only used when these substances are present in high concentrations, e.g., lipids in mechanically separated meat. Such samples are homogenized with 15 ml g^{-1} of an acetone/chloroform (3:1) mixture and filtered on a Buchner funnel until air dry. In addition to lipids, it is claimed that this procedure removes nucleic acids and most of the carbohydrates. Nucleic acids may also be removed by heating the lipid-free sample with 10% NaCl at 85 °C, removing the NaCl with water and drying with acetone. After hydrolysis or deproteinization, nonprotein substances can interfere with precolumn derivatization procedures used for reversed-phase chromatography (RPC) and gas–liquid chromatography (GLC). Lipids can be extracted with chloroform, and salts, carbohydrates, and acids can be extracted by cation exchange followed by recovery of the amino acids with 2 M NH_4OH. The strength of the NH_4OH is critical since concentrations > 2 M can lead to degradation of amino acids. (*See* **Chromatography**: High-performance Liquid Chromatography; Gas Chromatography.)

Hydrolysis Procedures

Acids, alkalis, or enzymes may be used for protein hydrolysis. Alkaline hydrolysis is generally only used in the determination of tryptophan, since other amino acids are degraded.

Enzymatic hydrolysis Enzymatic hydrolysis is rarely used except for the determination of glutamine and asparagine, which are converted to aspartic and glutamic acids together with ammonia by acid hydrolysis. Since no single protease will hydrolyze all the peptide bonds in proteins, the procedure is lengthy, and there is evidence of contamination by amino acids derived from the enzymes. A better method is to analyze the sample before and after treatment with bis(1,1-trifluoroacetoxy)iodobenzene, which converts the carboxamide residues to their corresponding amines. (*See* **Enzymes**: Uses in Analysis.)

Acid hydrolysis The most favored procedure involves heating the protein with excess 6 M HCl under reflux or in a sealed tube *in vacuo* or under nitrogen at 110 °C for 24 h. After filtration, the HCl must be removed, usually by rotary evaporation or neutralization with NaOH, before analysis. However, this procedure is a compromise, since no one method can provide satisfactory values for all amino acids. The problem of tryptophan has already been mentioned, but cystine, cysteine, and methionine undergo variable degradation through oxidation during acid hydrolysis, and an alternative procedure must be used. Tyrosine losses can also occur due to oxidation, but this may be reduced by the addition of phenol to the HCl.

There are smaller, but progressive, losses of threonine and serine, which may be compensated for by corrections of 5 and 10%, respectively, or more precisely by hydrolyzing for 24, 48, and 72 h and calculating to zero time. Since isoleucine and valine are difficult to liberate completely in 24 h, for the most accurate values, it is again necessary to hydrolyze for 24, 48, and 72 h and then to calculate to infinite time. This is rarely carried out for foods.

To obtain the ideal amino acid analysis, much time and care must be spent on the hydrolysis stage. Since the analysis time has been reduced from 24 h to around 30 min, there have been many efforts to automate and reduce the time of the hydrolysis. Commercial systems are available for 42 samples to be hydrolyzed in 24 h at 110 °C using standard liquid-phase HCl. The same number can be hydrolyzed in 1 h at 150 °C using vapor-phase hydrolysis. In liquid-phase hydrolysis, HCl is added directly to the sample. In vapor-phase hydrolysis, tubes containing the sample are sealed into a larger vessel containing HCl. As the vessel is heated, the HCl vaporizes so that only the vapor comes into contact with the sample. This has the advantage of preventing contamination from amino acids present in all but the highest-purity HCl. A recent development is microwave irradiation in which samples can be hydrolyzed in liquid phase HCl at 180 ± 5 °C in 5 min in a microwave oven. Special tubes that can resist high temperatures and pressures must be used. In common with most new innovations developed for use with pure proteins, care should be taken in applying them to foods where the presence of carbohydrates often results in losses of amino acids during hydrolysis.

Chromatographic Methods

After hydrolysis or deproteinization, it is necessary to separate the amino acids from each other, and for this, chromatography is the method of choice.

Chromatographic separations may be of three types: column chromatography in which the stationary phase is packed into glass or metal columns; thin-layer chromatography (TLC) in which the stationary phase is coated on to inert plates; and paper chromatography in which the stationary phase is supported by the cellulose fibers of a paper sheet. Neither of the latter two methods is particularly quantitative, and neither is used to any great extent, although TLC is used to monitor inborn errors of metabolism. Column chromatography consists of GLC and high-performance liquid chromatography (HPLC). (*See* **Chromatography**: Principles; Thin-layer Chromatography.)

High-performance Liquid Chromatography

HPLC can be subdivided into methods involving postor precolumn derivatization.

Postcolumn derivatization Postcolumn derivatization involves separating underivatized amino acids on a chromatographic column, mixing a derivatization reagent with the eluent from the column, and passing the mixture through a reaction coil and then through a detection system (spectrophotometer or fluorometer). This type of HPLC is usually carried out using ion-exchange chromatography (IEC) with sulfonated polystyrene cation exchange resins as the stationary phase and aqueous sodium citrate (for hydrolysates) or lithium citrate (for physiological fluids) mobile phases. This, when coupled with derivatization with ninhydrin, is the traditional method and is still considered to be the best. Other derivatizing reagents, *o*-phthalaldehyde (OPA), fluorescamine, dabsyl chloride (DABS-Cl), and 4-fluoro-7-nitro-2,1,3-benzoxadiazole, have been used to increase sensitivity, as the derivatives formed can be detected by fluorescence.

Precolumn derivatization In precolumn derivatization, the mixture of amino acids is treated with a reagent to form derivatives, which are highly fluorescent or ultraviolet-absorbing and can be separated by RPC. RPC, a fairly recent innovation to amino acid analysis, is a partition system in which the mobile phase is more polar than the stationary phase. The most popular stationary phases are octadecyl-bonded silicas with acetate buffer as the mobile phase and a gradient of acetonitrile or methanol.

Many derivatizing reagents have been used, e.g., OPA, DABS-Cl, 1-fluoro-2,4-dinitrobenzene (FDNB), dansyl chloride (DNS-Cl), phenylisothiocyanate (PITC), 9-fluorenylmethyl chloroformate (FMOC), 4-*N,N*-dimethylaminoazobenzene-4′-isothiocyanate, 1-fluoro-2,4-dinitrophenyl-5-L-alanine amide, and 4-chloro-7-nitro-2,1,3-benzoxadiazole (NBD-Cl). Although they give a high sensitivity, there are several problems with all of these reagents (Table 1). Cleanup and derivatization are laborious but can be automated in commercial instruments, where DABS-Cl, PITC, and FMOC are most commonly used.

Gas–Liquid Chromatography

In GLC, the stationary phase is a liquid such as silicone grease supported on an inert granular solid, and the mobile phase is an inert gas (N, He, Ar). Since

Table 1 Comparison of IEC, RPC, and GLC methods of amino acid analysis

	IEC	*RPC*	*GLC*[a]
Analysis time (min)			
Hydrolysates	30	30	10
Physiological fluids	90	50	35
Sensitivity (pmol)	50[b]	10	0.01
Disadvantages	Expensive instruments Complex mobile phases Low sensitivity	Some multiple or unstable derivatives Complex purification and derivatization Interference from salts, lipids, and reagent contaminants Shorter column life Resolution poor for some amino acids	Complex purification and derivatization Interference from carbohydrates and lipids
Recommended applications	Protein hydrolysates Complex mixtures	Individual amino acids Peptide hydrolysates Screening metabolic disorders Enantiomeric analysis	Enantiomeric analysis Identification of amino acids

[a] *N*-HFB isobutyl esters, capillary column, and electron capture detector.
[b] 5 pmol with OPA replacing ninhydrin.

amino acids are not volatile, they must be converted to volatile derivatives before analysis. This is not difficult, but there are even more derivatives than for RPC. However, the *N*-trifluoroacetyl (*N*-TFA) *n*-butyl and *N*-heptafluorobutyl (*N*-HFB) isobutyl esters appear to be the best. Derivatization is laborious, although it has recently been automated. The major difference between these derivatives is their chromatographic separation. All the *N*-HFB isobutyl esters of protein hydrolysates can be readily separated on a single methylsilicone-packed column (e.g., OV 101, or 3% SE30 coated on 100–200 mesh Gaschrom Q) in 35 min or in less than 10 min with a capillary column (DB-1). Capillary columns are recommended for physiological fluids, with analysis taking 1 h. With the popular *N*-TFA *n*-butyl esters, it is impossible to separate all the amino acids on a single column. A column of 1% OV 7 + 0.75% SP2401 on 100–200 mesh Gaschrom Q is used for histidine, arginine, and cystine, and one of 0.65% EGA on 80–100 mesh Chromasorb W for the remainder. A major advantage of GLC is its sensitivity and specificity; since the mobile phase is gaseous, flame ionization, electron capture, and nitrogen-specific detectors can be used. It is possible to detect femtomole levels of amino acids as their *N*-HFB isobutyl esters using capillary columns and electron capture detectors or mass spectrometry. Another advantage of GLC is that it can be linked with a mass spectrometer to provide confirmation of the identity and purity of peaks.

Comparison of IEC, RPC, and GLC

A good agreement between these methods has often been claimed but usually in comparative studies with pure proteins. The choice of method is difficult and often depends on the applications, sensitivity, and urgency required. Table 1 summarizes their main features. It is often suggested that a major advantage of RPC and GLC is that the instruments can be used for other analyses. If the requirement for amino acid analysis is small, and RPC and GLC instruments and expertise are already available, these would be the methods of choice. The traditional, well-tried method is IEC followed by derivatization with ninhydrin. This is ideal for protein hydrolysates and complex mixtures where maximum accuracy and reproducibility are required, and there is no shortage of sample. The sensitivity, analysis times, and cost of the instruments have improved considerably. Sample purification is rarely necessary, since it is almost completely insensitive to sample matrix. The time taken for sample purification and derivatization for RPC and GLC should not be ignored, and recent automation of these stages adds to the overall cost. The higher sensitivities of RPC and GLC are ideal where the amount of sample is limited, but care should be taken to avoid contamination by amino acids from reagents and glassware.

A major problem with RPC is the choice of derivative, with little agreement on which is the best, since none is ideal. Ideally, it would be better if pre- and postcolumn derivatization could be avoided altogether. The separation of underivatized amino acids, at picomole levels, using anion-exchange chromatography followed by pulsed amperometric detection has recently been proposed for protein hydrolysates. This uses complex aqueous mobile phases and would be difficult to apply to more complex mixtures. Whichever method is selected, it should be stressed that the hydrolysis of proteins and the deproteinization of physiological fluids are still major problems.

Methods for Specific Amino Acids

Methionine and Cystine

These amino acids are difficult to estimate because they are present in low concentrations and undergo oxidation to multiple derivatives during acid hydrolysis. To overcome this problem, controlled oxidation of methionine to methionine sulfone and cystine to cysteic acid must be carried out with performic acid prior to acid hydrolysis. This involves oxidizing the sample with performic acid–hydrogen peroxide for 16 h at 0 °C. After removal of excess oxidizing reagents, acid hydrolysis is carried out as normal.

Tryptophan

Tryptophan is also present in low concentrations and extensively degraded during acid hydrolysis. However, there is no measurable end product, and so it is normal to use alkaline hydrolysis specifically for tryptophan analysis. Sodium, barium, or lithium hydroxides may be used at concentrations ranging from 4 to 6 M, with additives such as maltodextrin, starch, or thiodigycol often recommended to reduce tryptophan losses. Hydrolysis may be for 8 h at 145 °C or 20 h at 110 °C using polypropylene vessels. Ideally, the tryptophan should be separated from interfering compounds, e.g., lysinoalanine (LAL) by IEC or RPC. The latter takes only a few minutes, and precolumn derivatization is unnecessary, since tryptophan can be detected by its native fluorescence.

Tryptophan has also been estimated by acid hydrolysis of intact proteins in the presence of ninhydrin with which it reacts before it can be degraded. Corrections must be made for tyrosine.

Lysine and Available Lysine

There has been considerable interest in a specific method for lysine. However, even RPC methods take 15 min and would appear to have little advantage over complete analysis. However, available lysine is usually determined separately. If foods are subjected to heat during processing, lysine can become nutritionally unavailable if its free ε-amino group reacts with, for example, carbohydrates, forming bonds, which are resistant to digestive enzymes. Available lysine can be measured by treating proteins with FDNB or 2,4,6-trinitrobenzene sulfonic acid, which reacts with the free ε-amino groups of lysine to form either ε-dinitrophenyllysine (DNP-lysine) or ε-trinitrophenyllysine (TNP-lysine). The lysine derivatives can be separated by RPC from other DNP or TNP amino acids in 15–20 min.

Lysinoalanine

Alkaline treatment of proteins is used extensively in food processing, e.g., in the preparation of textured proteins. This results in the formation of amino acids such as LAL, ornithinoalanine, lanthionine, and β-aminoalanine. LAL is formed by reaction of the ε-amino group of lysine with the double bond of dehydroalanine, which can result in the loss of available lysine and toxicity problems. LAL can be measured in 16 min by RPC after derivatization with DNS-Cl. Alternatively, LAL and all the common amino acids can be determined by IEC, followed by ninhydrin derivatization in 110 min.

3-Methylhistidine

3-Methylhistidine is an analog of histidine found mainly in skeletal muscle. Methylation of histidine occurs after its incorporation into the peptide chains of actin and myosin. Since, after the catabolism of these proteins, 3-methylhistidine is not recycled but quantitatively excreted in the urine, it has been proposed as an index of muscle protein turnover. It has also been used to determine the meat content of foods, where vegetable or microbial protein has been added for economic or fraudulent reasons. 3-Methylhistidine may be estimated after derivatization with fluorescamine. Histidine and 3-methylhistidine give acid-stable fluorescent derivatives, which can be separated by RPC in 20 min.

Hydroxyproline

If 3-methylhistidine is used as an index for meat protein, hydroxyproline must also be measured to correct for the collagen content. Collagen has a low content of essential amino acids, and excessive amounts in foods reduce their nutritive value. New technologies also make it possible to incorporate collagenous materials into meat products at high levels. There are histochemical, histological, and immunological techniques available, but for routine purposes, there is a British Standards method available. This involves oxidation of the hydroxyproline with chloramine T to pyrrole, followed by photometric determination of the reaction product of the pyrrole with *p*-dimethylaminobenzaldehyde. An RPC method taking 10 min also exists using NBD-Cl derivatization.

D- and L-Amino Acids

During alkali or heat treatment L-amino acids in proteins are racemized to their D-isomers. Since most D-amino acids cannot be utilized by humans, and some are toxic, their determination is of considerable interest. The D- and L-isomers have identical chemical properties and must first be converted to diastereomeric dipeptides by reaction with chiral (optically active) reagents before chromatography or separated by chiral stationary or mobile phases. The leucyl-DL-aspartic acid dipeptides are prepared by coupling aspartic acid with L-leucine *N*-carboxy anhydride (NCA). Basic amino acids are coupled with L-glutamine NCA. *N-t*-Butoxycarbonyl-L-cysteine and OPA are other chiral agents that have been used. Separation of 21 enantiomers in 40 min can be achieved by RPC and fluorescence detection. Precolumn derivatization can be avoided by using a chiral mobile phase, a copper–proline (Cu–Pro) complex, with IEC. Diastereomeric Cu–amino acid complexes are formed on the column and detected by postcolumn derivatization with OPA. Alternatively, an RPC method using a chiral stationary phase, in which the Cu–Pro or Cu–hydroxyproline complex is bound to a silica stationary phase, can be used.

D- and L-amino acids can also be determined by GLC with the introduction of a second, optically pure, asymmetric center into the molecule to make diastereoisomers, which can be separated on conventional packed columns. The use of (+)-butan-2-ol to form (+)-2-butyl esters appears to be the best method. Alternatively, the enantiomers, converted to normal derivatives, e.g., *trans*-fatty acid isopropyl esters, can be separated on capillary columns coated with chiral stationary phases, e.g., *N-trans*-fatty acid-L-valyl-L-valine cyclohexyl ester.

Introduction

Naturally occurring amino acids may be conveniently grouped into three categories: protein amino acids (sometimes known as 'standard,' 'primary,' and 'normal'), uncommon amino acids, and nonprotein amino acids. Protein amino acids are those that are coded for in the genes and incorporated directly into proteins. For some time it seemed well established that all proteins, whatever their origin, were constructed from the same set of 20 amino acids. Recent studies, however, have shaken the foundation of this classical dogma. It now seems that the genetic code may dictate the incorporation of more than 20 amino acids. Thus, for example, selenocysteine and phosphoserine, previously considered to be uncommon amino acids, can be directly incorporated into the polypeptide chain. All protein amino acids are α,L-amino acids. It is not clear why amino acids incorporated by organisms into proteins are of the L form, since L-amino acids have no obvious inherent superiority over their D isomers for biological function. Thus, in this article, unless otherwise stated, an L configuration is assumed.

The 20 classical protein amino acids may be grouped into several classes reflecting important characteristics of their side chains: straight aliphatic amino acids (glycine, alanine), branched-chain amino acids (valine, leucine, isoleucine), hydroxy amino acids (serine, threonine), sulfur-containing amino acids (cysteine, methionine), aromatic amino acids (phenylalanine, tyrosine), heterocyclic amino acids (tryptophan, histidine), basic amino acids (lysine, arginine), acidic amino acids and their amides (aspartate, glutamate, asparagine, glutamine), and imino acid (proline). Amino acids can also be classified on the basis of the polarity of their side chains. (*See* **Protein: Chemistry.**)

Analyses of proteins have revealed that they contain well over 100 different amino acids. The occurrence of uncommon amino acids in proteins is the result of posttranslational, covalent modification of protein amino acids. Cystine, for example, is formed by the posttranslational cross-linking of two cysteine residues. Citrulline, *N*-formylmethionine, *O*-galactosylserine, and *N*-acetylthreonine constitute other examples of amino acids found in proteins.

The amino acids found in proteins are by no means the only ones to occur in living organisms. Thus the term 'nonprotein amino acids' is used to include those naturally occurring amino acids which are present in free or combined forms but not in proteins. Over 200 nonprotein amino acids are known, most of them occurring in plants and frequently limited, in each case, to certain taxonomic groups. Some, such as cystathionine and saccharopine, fulfill important roles in the primary metabolic pathways. However, the great majority of these compounds have obscure functions and are generally regarded as secondary products. Many of the nonprotein amino acids from plants are known to be toxic to animals, plants, and microorganisms. Some accumulate to exceptionally high levels, as in the case of 5-hydroxytryptophan, canavanine, or 3,4-dihydroxy-phenylalanine, which may constitute up to 14% of the seed weight in some Leguminosae species. Storage and protection against predation are probably two of the many possible roles that these amino acids play in plants.

Essential and Nonessential Amino Acids

Organisms differ greatly in their abilities to synthesize the amino acids required for protein synthesis. Many microorganisms and plants are entirely self-sufficient in that they can synthesize the entire basic set

of protein amino acids. However, the bacterium *Leuconostoc mesenteroides* can synthesize only four of the protein amino acids, whereas *Lactobacillus*, which flourishes in milk, must be provided with all amino acids required for protein synthesis. Mammals are intermediate, being able to synthesize about half of the protein amino acids. Amino acids which cannot be synthesized by an organism in adequate amounts are called essential or indispensable because they must be supplied by the diet. Those which can be synthesized by an organism from readily available precursors in sufficient amounts to meet its needs are not required in the diet and are referred to as nonessential or dispensable amino acids. A consensus of current nutritional opinion indicates that the L isomers of 10 amino acids – arginine, histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine – are considered to be essential for mammals, including humans.

The designations of essential and nonessential amino acids refer to the needs of an organism under a particular set of conditions. Thus essential amino acids are often species-specific, i.e., the set of amino acids that are essential for a particular organism is not necessarily the same for other organisms. The essential amino acid requirements depend on a variety of factors, including age, sex, physiological conditions, and diet. Arginine (see *Urea Cycle*, below) and histidine are synthesized by humans in quantities sufficient to meet the needs of an adult but not those of a growing child. These amino acids have been termed semi- or half-essential. Adults have proportionally lower demands for essential amino acids than infants and children because adults are able to recycle such amino acids efficiently, whereas infants need them for tissue growth. When the ratio of total essential amino acids required to total protein required is considered, it is 0.37 for infants and 0.15 for adults. Tyrosine and cysteine are considered nonessential amino acids for mammals only as long as the diet contains adequate amounts of, respectively, phenylalanine and methionine; this is because, in mammals, tyrosine is formed in one step directly from phenylalanine, and cysteine derives its sulfur uniquely from dietary methionine (see *Synthesis of Amino Acids*, below). Hence the apparent quantitative phenylalanine requirement is actually a requirement for phenylalanine plus tyrosine, whereas that of methionine is for methionine plus cysteine.

The essential amino acids include those with complex structures, which are formed by complex routes, whereas the nonessential are those whose syntheses are the simplest and whose intermediate precursors are always present in all organisms. Indeed, 59 enzymes are required by prokaryotic cells to synthesize the essential amino acids for humans, but only 15 are required for the nonessential. Essential amino acids other than lysine and threonine (the only amino acids that, in mammals, do not participate in transamination reactions; see *Transamination and Deamination*, below) can be replaced by their α-keto analogs in the diet. This indicates that the carbon skeleton of the essential amino acid is the fundamental part of the amino acid molecule.

A deficiency of even one essential amino acid in the diet of an organism results promptly in a negative nitrogen balance, i.e., total nitrogen excretion exceeding total nitrogen intake, indicating that tissue protein is being degraded and used to supply the missing amino acid for those 'high-priority' proteins that need to be continually synthesized. The remaining amino acids then accumulate and are shunted into catabolic pathways – hence the loss of nitrogen. Under these conditions protein synthesis is severely inhibited because the ribosome–messenger ribonucleic acid (mRNA)–nascent polypeptide complex must suspend its operation at the point where the missing amino acid should be incorporated. Thus the degree of negative nitrogen balance is similar whether only one, several, or all of the essential amino acids are missing. This is logical because nearly all body proteins contain all the essential amino acids.

Regardless of the organism or of the essential amino acids considered, the net result of its deficiency inevitably involves a decreased growth rate, increased susceptibility to disease, and biochemical dysfunctions along with ultimate death. However, deficiencies of a specific essential amino acid may also result in disturbances characteristic of that particular amino acid. This is the case for tryptophan in nicotinic acid formation, and lysine in the formation of hydroxylysine in the biosynthesis of collagen. (*See* **Niacin:** Physiology.)

Amino Acid Biosynthesis

Amino acid metabolism involves the dynamic occurrence of anabolic and catabolic pathways. It is sometimes difficult to distinguish between catabolic and anabolic reactions because the catabolism of one amino acid may be involved in the biosynthesis of another. Because of the complexity and multiplicity of these pathways only a simplified version of the major routes will be considered.

Nitrogen Assimilation

Inorganic nitrogen is incorporated into organic nitrogen compounds as ammonium. This process, called

ammonium assimilation, leads to the formation of glutamate, glutamine, and carbamoyl phosphate. Utilization of the nitrogen of carbamoyl phosphate is limited to the biosynthesis of arginine (see *Urea Cycle*, below) and pyrimidine nucleotides. Essentially, all other nitrogen atoms of amino acids and other nitrogenous compounds are derived directly or indirectly from glutamate or glutamine.

The reductive amination of 2-oxoglutarate by ammonium ions (NH_4^+), catalyzed by glutamate dehydrogenase, is the simplest route to the formation of α-amino groups:

$$\text{2-Oxoglutarate} + NH_4^+ + \text{NADPH} + H^+ \longrightarrow \text{glutamate} + H_2O + \text{NADP}^+$$

(NADPH, $NADP^+$ represent the reduced and oxidized forms of the nicotinamide adenine dinucleotides.) This reaction occurs in plants and bacteria only under situations of high NH_4^+ concentration, which is toxic to cells and does not happen frequently under natural conditions, implying that this enzyme does not play a significant role in primary ammonium assimilation. Under natural conditions, the glutamate synthase cycle constitutes the major pathway by which plants and microorganisms assimilate NH_4^+. This cycle involves the sequential action of two enzymes: glutamine synthetase, which catalyzes the adenosine triphosphate (ATP)-dependent amidation of glutamate to produce glutamine, and glutamate synthase, which catalyzes the reductive transfer of the δ-amino group of glutamine to 2-oxoglutarate, to produce two molecules of glutamate. The sum of these reactions is as follows:

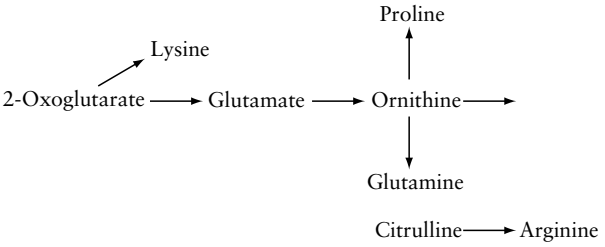
$$\text{2-Oxoglutarate} + NH_4^+ + \text{NADPH} + \text{ATP} \longrightarrow \text{Glutamate} + \text{NADP}^+ + \text{ADP} + P_i$$

(NADPH or reduced ferredoxin; $NADP^+$ or oxidized ferredoxin; P_i inorganic phosphate)

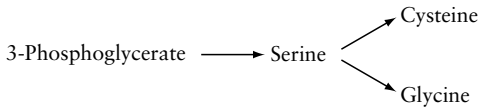
Synthesis of Amino Acids

The biosyntheses of protein amino acids arise as branching pathways from a few key intermediates in the central metabolic routes that are common to all cells, namely glycolysis, the pentose phosphate pathway, and the tricarboxylic acid (TCA) cycle. It is convenient to divide the 20 classical protein amino acids into six biosynthetic families according to the central metabolites that serve as starting points for their syntheses. (*See* **Glucose:** Function and Metabolism.)

The glutamate family 2-Oxoglutarate, a TCA cycle intermediate, serves as the starting point in the formation of glutamate and the other members of the glutamate family, glutamine, proline, arginine and, in the fungi and *Euglena*, lysine:



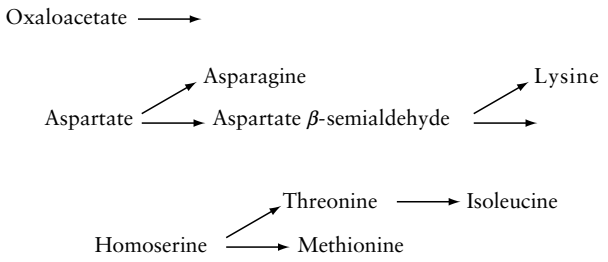
The serine family 3-Phosphoglycerate, an intermediate of the glycolytic pathway, serves as a precursor for the serine family of amino acids, comprising serine and its derivative amino acids, glycine and cysteine:



In common with carbon and nitrogen, environmental sulfur is available to organisms in the form of inorganic compounds. Sulfur assimilation is largely confined to plants and microorganisms since higher animals, unable to assimilate inorganic sulfur, must rely on ingested methionine and cysteine. Thus, whilst some microorganisms can reduce sulfate, thiosulfate or elemental sulfur, higher plants use sulfate for amino acid synthesis. Reductive assimilation of sulfate, i.e., incorporation of sulfate sulfur into thiol groups of amino acids and other organic compounds, requires the reduction of sulfate to sulfite and, subsequently, of sulfite to sulfide.

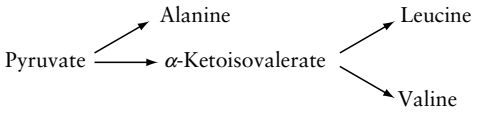
Two major pathways exist for the biosynthesis of cysteine in living organisms. Plants and microorganisms, which utilize H_2S as the source of sulfur, synthesize cysteine by the direct sulfhydrylation pathway. However, in mammals, which synthesize cysteine by the transsulfuration pathway, cysteine derives its carbon skeleton from serine but its sulfur atom is obtained uniquely from methionine.

The aspartate family Oxaloacetate, an intermediate of the TCA cycle, provides the carbon skeleton for the synthesis of six different amino acids: aspartate, asparagine, lysine (in bacteria and plants but not in fungi), methionine, threonine, and isoleucine, which constitute the aspartate family of amino acids:



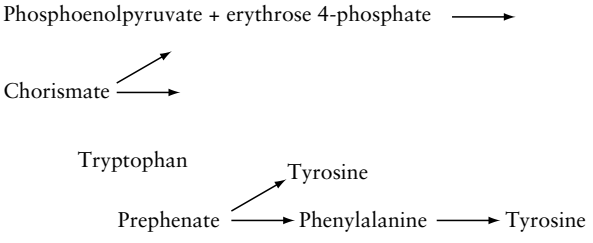
However, isoleucine is frequently included in the pyruvate family since four of its five biosynthetic enzymes are common to the valine pathway. Methionine derives its sulfur atom from cysteine.

The pyruvate family The pyruvate family of amino acids includes alanine, valine, and leucine:



Pyruvate, a glycolytic intermediate, gives rise to the carbon skeletons of alanine and valine, and to four of the six carbons of leucine. In addition, pyruvate also donates two carbon atoms to the synthesis of isoleucine and, on average, 2.5 carbons to the synthesis of lysine in bacteria and plants. As mentioned earlier, isoleucine, a member of the aspartate family, is most conveniently considered along with valine, since the biosynthesis of both involves a common set of enzymes.

The aromatic family Phenylalanine, tyrosine, and tryptophan, which comprise the aromatic family of amino acids, are synthesized from phosphoenolpyruvate and erythrose 4-phosphate, intermediates of glycolysis and the pentose phosphate pathway, respectively:



These amino acids are synthesized by a branched pathway in which chorismate is the major branch-point metabolite. Chorismate is synthesized by a seven-step pathway, often referred to as the shikimate or common aromatic pathway, to build the benzene ring.

In some organisms, including humans, tyrosine can be synthesized by hydroxylation of phenylalanine in a reaction catalyzed by phenylalanine hydroxylase. This reaction, the only known reaction of aromatic amino acid biosynthesis in animals, accounts for the nonessentiality of tyrosine in mammals, and is not reversible, which explains why tyrosine cannot replace the nutritional requirement for phenylalanine.

The histidine family Histidine is synthesized from ribose 5-phosphate, a pentose phosphate pathway intermediate, by a pathway unrelated to those of the other amino acids.

Uncommon amino acids are synthesized by post-translational, covalent modification of protein amino acids. These modifications, which may either be enzyme-catalyzed or occur spontaneously, involve a variety of chemical processes including glycosylation, phosphorylation, hydroxylation, methylation, acetylation, and amidation. Hydroxyproline and hydroxylysine, for example, are two uncommon amino acids almost exclusively associated with collagen. The preformed amino acids, as they may occur in ingested food protein, are not incorporated into collagen since there are no transfer RNAs (tRNAs) capable of recognizing and inserting them into a nascent polypeptide chain. Rather, these amino acids are synthesized by hydroxylation of prolyl and lysyl residues, in reactions catalyzed by prolyl hydroxylase and lysyl hydroxylase, respectively. 3-*N*-Methylhistidine constitutes another example of an uncommon amino acid. This amino acid, found in actin and myosin, is synthesized by methylation of a histidyl residue in an enzymatic reaction that utilizes *S*-adenosylmethionine as the methyl group donor. This process is clearly highly specific because only one histidine out of the 35 found in the heavy chain of myosin is methylated. Furthermore, the extent of methylation varies with a number of factors, including age and diet, and is generally not complete in that specific residues are found to be methylated in only a fraction of the myosin molecules.

Relatively little work has been done on the biosynthesis of nonprotein amino acids. There are four different ways by which these amino acids may be formed: (1) as intermediates in protein amino acid synthesis; (2) modification of protein amino acids; (3) modification of pathways to protein amino acids; (4) novel pathways.

Regulation of Amino Acid Biosynthesis

Living cells contain a small pool of free protein amino acids resulting from a precise and coordinated control of the rates at which each amino acid is synthesized and degraded. The mechanisms that control amino acid synthesis vary widely in the various pathways and, for the same pathway, in different organisms. Most studies have been performed with

microorganisms, in particular with *Escherichia coli, Bacillus subtilis*, and *Salmonella typhimurium*. The regulation of amino acid biosynthesis occurs at two levels: regulation of enzyme activity or metabolite flow over a pathway and regulation of enzyme amount. (*See* **Enzymes:** Functions and Characteristics.)

Control of enzyme activity The control over the flow of metabolites into an amino acid biosynthetic pathway can be efficiently achieved by blocking the first, usually irreversible step which is specific for that amino acid. The inhibition of the committed step by the end product, i.e., the amino acid itself, constitutes the simplest kind of feedback inhibition. Some examples include the regulation of the biosynthesis of proline, arginine, histidine, and of the branched-chain amino acids. Alanine, aspartate, glutamate, and glycine are four amino acids for which no form of feedback inhibition is known. However, these amino acids are usually in equilibrium, by means of reversible reactions, with compounds that are key intermediates in the central metabolic routes. Metabolite flow into the biosynthetic pathways of the remaining 16 protein amino acids is controlled by several types of feedback inhibition.

Sequential feedback inhibition regulates the synthesis of aromatic amino acids in *B. subtilis*. The first divergent steps in the synthesis of these amino acids are inhibited by their final products. If all three are present in excess, the branch-point intermediates chorismate and prephenate will accumulate, inhibiting the first common enzyme in the overall pathway, i.e., the first reaction of the shikimate pathway.

Enzyme multiplicity regulates the synthesis of aromatic amino acids in *E. coli, S. typhimurium*, and *Neurospora crassa* and the synthesis of the aspartate family of amino acids in *E. coli*. In the former, those organisms possess three isoenzymes which catalyze the first reaction of the shikimate pathway – one inhibited by phenylalanine, one by tyrosine, and one by tryptophan. In the latter, three forms of the enzyme catalyzing the first reaction of the pathway leading from aspartate to aspartate β-semialdehyde exist – one inhibited by methionine, one by threonine, and one by lysine.

B. polymyxa and *Rhodopseudomonas capsulata* possess a single enzyme catalyzing the first reaction of the pathway leading from aspartate to aspartate β-semialdehyde, and its regulation is achieved by concerted feedback inhibition. Lysine and threonine alone are only weak inhibitors, but when both are present, a strong synergistic inhibition occurs.

The regulation of *E. coli* glutamine synthetase, a key enzyme in the flow of inorganic nitrogen to organic compounds, is an example of cumulative feedback inhibition. Eight inhibitors are either metabolic end products of glutamine (tryptophan, histidine, carbamoyl phosphate, glucosamine 6-phosphate, cytidine triphosphate and adenosine monophosphate, or AMP) or in some other way indicators of the general status of amino acid metabolism (alanine and glycine). Each of the eight compounds alone gives only partial inhibition, but in combination, with each acting independently of the others, the degree of inhibition is increased until the activity is almost completely switched off when all eight compounds are simultaneously present.

Other ways of controlling enzyme activity include the following: (1) activation of enzyme activity by metabolites; (2) modification of enzymes (e.g. adenylation of certain enzymes may render them more susceptible to feedback inhibition); (3) protein–protein interactions (e.g. activity of multienzyme complexes may change with the amounts of its components present).

Control of enzyme amount The amount of an enzyme may be controlled by a number of different mechanisms: (1) end product repression of enzyme synthesis (e.g., the coordinate repression of the synthesis of all the enzymes involved in histidine biosynthesis in *E. coli* by histidine); (2) substrate induction of enzyme synthesis (e.g., the induction of the synthesis of the first enzyme involved in cysteine biosynthesis in *E. coli* by the product of its reaction); (3) metabolite depression of enzyme synthesis (e.g., the synthesis of all amino acid biosynthetic enzymes is strongly reduced when *E. coli* is grown in a rich medium); (4) regulation of enzyme degradation. Very little is known on this last topic. Nevertheless, the protection of a given enzyme against proteolysis is probably an important regulatory process.

Amino Acid Catabolism

All living cells undergo intracellular protein degradation, with the resulting amino acids being recycled into proteins or degraded oxidatively to yield energy. In microorganisms and plants amino acids are not generally present in excessive amounts. In higher animals, however, where amino acid intake may largely exceed the metabolic needs, amino acids present in excess are not stored or excreted as such. Instead, they are used for energy production. It is estimated that amino acids supply about 15% of the total energy required by an average human adult. This value may be increased under conditions of energy insufficiency or nutritional pathologies. Amino acids can also constitute an important energy

source in plants, during the germination of protein-storing seeds, and in microorganisms, when carbohydrates or fatty acids are not available. This is the case in many bacteria that can grow in media containing amino acids as the source of energy, carbon, and nitrogen. These organisms utilize amino acid catabolic pathways analogous to those of higher animals.

The catabolic metabolism of amino acids is mainly concerned with the separation of the amino groups from the carbon skeletons and the subsequent fate of both the amino groups and the carbon chains. (*See* **Energy:** Measurement of Food Energy.)

Transamination and Deamination

In general, one of the first steps in the degradation of amino acids involves the removal of the α-amino group to give the corresponding 2-oxo acid. Two distinct types of reactions are known to accomplish this task: transamination and deamination.

Transamination, the most common mechanism for deamination of amino acids, involves the transfer of an amino group from a donor amino acid to an acceptor 2-oxo acid, with the formation of a new amino acid and a new oxo acid. Transamination reactions are catalyzed by pyridoxal phosphate-dependent enzymes termed transaminases or, more properly, aminotransferases. These enzymes have a twofold specificity in that they are specific for the acceptor 2-oxo acid but nonspecific for the donor amino acid. Most aminotransferases are specific for 2-oxoglutarate as the acceptor 2-oxo acid, although some may use either pyruvate or oxaloacetate. Accordingly, there are three classes of aminotransferases, which form glutamate, alanine, and aspartate, respectively. More than 50 aminotransferases have been identified. With the exception of lysine and threonine, the α-amino groups of all the amino acids found in proteins can be removed by transamination. Moreover, transamination is not restricted to α-amino groups since, for example, the δ-amino group of ornithine is readily transaminated. Transaminases fulfill central catabolic as well as anabolic functions in the metabolism of several amino acids because they catalyze freely reversible reactions, having equilibrium constants close to unity.

Transamination does not result in a net removal of nitrogen from amino acids. It does, however, allow for the collection of amino groups in glutamate. Oxidative deamination of glutamate by glutamate dehydrogenase results in the liberation of ammonium. The 2-oxoglutarate thus produced can either be used as the acceptor 2-oxo acid in further transamination reactions or enter the TCA cycle. Glutamate is the only amino acid for which a specific and highly active dehydrogenase exists. This pathway, i.e., the concerted action of the aminotransferases and glutamate dehydrogenase, is responsible for most of the ammonium produced by the catabolism of amino acids.

Additional minor routes for the deamination of amino acids are provided by amino acid oxidases, capable of oxidizing most naturally occurring amino acids, and by dehydratases, capable of removing non-oxidatively the amino groups of some amino acids.

Urea Cycle

Plants and microorganisms commonly excrete very little nitrogen. Growth of these organisms is often restricted by a limited availability of nitrogen so that nitrogen liberated by catabolic pathways is usually reassimilated. However, because high concentrations of NH_4^+ are extremely toxic to cells, animals must get rid of the excess ammonium produced by the catabolism of amino acids, either by direct excretion or, when removal of NH_4^+ by simple diffusion is difficult, by conversion to less toxic excretory products. Most terrestrial vertebrates, including mammals, excrete ammonia in the form of urea. Urea is highly soluble in water but nontoxic to cells.

Urea is synthesized by the urea cycle, which is carried out almost exclusively in liver cells. This cycle, discovered by Hans Krebs and Kurt Henseleit in 1932, consists of five sequential enzymatic reactions:

1. $NH_4^+ + HCO_3^- + 2ATP \longrightarrow$ carbamoyl phosphate + 2ADP + P_i + H^+
2. Carbamoyl phosphate + ornithine $\longrightarrow$ citrulline + P_i
3. Citrulline + aspartate + ATP $\longrightarrow$ argininosuccinate + AMP + PP_i
4. Argininosuccinate $\longrightarrow$ arginine + fumarate
5. Arginine + H_2O $\longrightarrow$ ornithine + urea

The sum of these reactions is as follows:

$$NH_4^+ + HCO_3^- + 3ATP + H_2O + \text{aspartate} \longrightarrow \text{urea} + 2ADP + AMP + 2P_i + PP_i + H^+ + \text{fumarate}$$

Virtually all organisms synthesize arginine from ornithine by reactions 2–4. However, only ureotelic organisms are capable of catalyzing the hydrolysis of arginine (reaction 5), the reaction responsible for the cyclic nature of the urea cycle. The synthesis of urea is energetically expensive, requiring the hydrolysis of 4 molecules of ATP per turn of the cycle (2 molecules of ATP are needed to convert AMP to ATP). The fumarate produced is hydrated to malate and oxidized to

oxaloacetate by TCA cycle enzymes. Aspartate is then regenerated from oxaloacetate by transamination. Thus both amino groups of urea originate from amino acids: one is derived from ammonium produced by deamination (reaction 1) and the other is provided by aspartate (reaction 3). Bicarbonate (reaction 1) furnishes the carbon atom of urea. In this respect it is interesting to note that not all the urea produced in the human liver is excreted in the urine – a considerable fraction is hydrolyzed in the colon by bacterial ureases. The mucosa of the human colon is relatively permeable to urea. However, the great majority of the urea molecules is rapidly hydrolyzed within the lumen of the colon with a large proportion of the resulting ammonia nitrogen being absorbed into the portal system or metabolized by the intestinal flora. The ammonium absorbed from the colon may be available for transamination into amino acids in the liver or resynthesized to urea also in the liver, with some of this urea distributed back to the gastrointestinal tract for degradation to ammonia and consequent recycling.

Catabolic Pathways

Once the amino groups of amino acids have been removed, the remaining carbon skeletons are funneled into seven major metabolic intermediates, namely pyruvate, acetyl coenzyme A (acetyl-CoA), acetoacetate, 2-oxoglutarate, succinyl-CoA, fumarate, and oxaloacetate (Table 1), which may be either directly oxidized into carbon dioxide and water by the TCA cycle or reincorporated into glucose or fatty acids. Glycogenic amino acids are those possessing carbon skeletons which generate pyruvate or TCA cycle intermediates and can, therefore, be converted to glucose via gluconeogenesis. In contrast, amino acids possessing carbon skeletons which are metabolized to acetyl-CoA or acetoacetate, precursors of fatty acids and ketone bodies, are termed ketogenic. Recall that, with the exception of some species of plants and microorganisms which possess the glyoxylate cycle, all other organisms lack a pathway for the net synthesis of glucose from acetyl-CoA or acetoacetate. A few amino acids are both glycogenic and ketogenic since portions of their carbon skeletons are converted into carbohydrate derivatives whereas other portions are converted into ketone bodies. Note that the classification presented in Table 1 is not universally accepted because several amino acids are glycogenic under some conditions but ketogenic under others.

Regulation of Amino Acid Catabolism

Microorganisms regulate the level of their amino acid degradative enzymes in different ways:

1. The enzymes are subjected to catabolite repression, i.e., repression of the amino acid catabolic pathway by a carbon and energy source, even in the simultaneous presence of that amino acid as the only source of nitrogen. Thus these enzymes are induced only when carbon and energy limit growth (e.g., the induction of tryptophanase – the enzyme which cleaves tryptophan to yield ammonium, pyruvate, and indole – by tryptophan in *E. coli*).

Table 1 Metabolic fates of the carbon skeletons of amino acids

Amino acid	*Product(s) of catabolism*	*Metabolic fate*
Alanine	Pyruvate	Glycogenic
Arginine → glutamate	2-Oxoglutarate	Glycogenic
Asparagine → aspartate	Oxaloacetate	Glycogenic
Aspartate	Oxaloacetate, fumarate[a]	Glycogenic
Cysteine	Pyruvate	Glycogenic
Glutamate	2-Oxoglutarate	Glycogenic
Glutamine → glutamate	2-Oxoglutarate	Glycogenic
Glycine → serine	Pyruvate	Glycogenic
Histidine → glutamate	2-Oxoglutarate	Glycogenic
Methionine	Succinyl-CoA	Glycogenic
Proline → glutamate	2-Oxoglutarate	Glycogenic
Serine	Pyruvate	Glycogenic
Threonine	Pyruvate	Glycogenic
Valine	Succinyl-CoA	Glycogenic
Isoleucine	Succinyl-CoA, acetyl-CoA	Glycogenic and ketogenic
Phenylalanine → tyrosine	Fumarate, acetoacetate	Glycogenic and ketogenic
Tryptophan	Pyruvate, acetyl-CoA, acetoacetate	Glycogenic and ketogenic
Tyrosine	Fumarate, acetoacetate	Glycogenic and ketogenic
Leucine	Acetyl-CoA, acetoacetate	Ketogenic
Lysine	Acetoacetate	Ketogenic

[a]See text (section on urea cycle).

2. The enzymes are induced when nitrogen limits growth (e.g., the induction of proline oxidase – the enzyme which catalyzes the first step of proline degradation – by proline in *E. coli*, even in the presence of ample carbon supply).
3. The enzymes are induced independently of carbon and energy or nitrogen supply (e.g., the induction of threonine dehydrogenase – an enzyme involved in threonine catabolism – in *E. coli* by growth in leucine, even in the presence of other carbon and nitrogen sources). In some microorganisms, catabolite repression can be bypassed by a nitrogen limitation signal that allows the induction of a particular amino acid catabolic pathway. This nitrogen limitation signal is probably related to the complex regulation mechanisms of glutamine synthetase (see *Regulation of Amino Acid Biosynthesis*, above).

In animal cells, amino acid catabolism is also subjected to control mechanisms. Thus, for example, removal of amino groups from amino acids is regulated mainly by control of glutamate dehydrogenase. This enzyme is allosterically inhibited by ATP and guanosine triphosphate (GTP) and stimulated by ADP and guanosine diphosphate (GDP). Hence, when cellular energy charge is low the rate of amino acid oxidation increases. On the other hand, the urea cycle is controlled by *N*-acetylglutamate. This compound is a positive allosteric effector of carbamoyl phosphate synthetase, which catalyzes the first and rate-limiting step in the pathway. *N*-acetylglutamate is also a precursor of arginine and its synthesis is inhibited by arginine. However, the amino acid catabolic enzymes of animal cells are much more often subjected to a hormonal control than are the microbial enzymes. Thus, for example, the synthesis of tryptophan oxygenase, regulated by adrenal activity, is developmentally controlled so that the enzyme is formed only in certain tissues and at certain times during development. A high-protein diet is also a factor that is known to stimulate the formation of a number of amino acid degradative enzymes in liver, namely urea cycle enzymes and tryptophan oxygenase.

Synthesis of Biologically Important Compounds

In addition to their role in protein synthesis, energy production, and gluconeogenesis, many amino acids serve as precursors for the synthesis of other amino acids and other biologically important compounds.

Many oligopeptides containing up to 20 residues, including hormones, antibiotics, and antitumor agents, are synthesized in living organisms by mechanisms different from the usual ribosome-dependent processes of protein synthesis. The dipeptides carnosine (β-alanyl-histidine) and anserine (β-alanyl-1-*N*-methylhistidine) are synthesized enzymatically from β-alanine and histidine, and from carnosine and *S*-adenosylmethionine (SAM), respectively.

Glutathione (γ-glutamylcysteinylglycine) plays a variety of roles in living organisms. This tripeptide is synthesized by a two-step enzymatic pathway:

1. The formation of a peptide linkage between the γ-carboxyl group of glutamate and the amino group of cysteine, to produce γ-glutamylcysteine;
2. The condensation of this dipeptide with glycine, to form glutathione.

Thus the order of the amino acids in glutathione is specifically determined by the enzymes catalyzing the formation of each peptide bond.

At least 90 different peptide antibiotics are produced by strains of *Bacillus subtilis* and *B. brevis*. Gramicidin S, for example, is a cyclic decapeptide composed of two identical pentapeptides (D-phenylalanine-L-proline-L-valine-L-ornithine-L-leucine). Gramicidin S is synthesized by a multienzyme complex, gramicidin synthetase, composed of two enzymes, one of which, serving as a template, specifies the amino acid sequence in the antibiotic.

SAM, the metabolically activated form of methionine, functions as an important source of methyl and propylamino groups for a wide variety of compounds, including alkaloids, choline, creatine, epinephrine (adrenaline), *N*-methylated amino acids, nucleotides, and polyamines, as well as for phospholipids, proteins, polysaccharides, and nucleic acids. It is synthesized from methionine and ATP, in a reaction catalyzed by SAM synthase.

A wide variety of amines occurring in bacteria, plants and animals are derived directly or indirectly from amino acids by decarboxylation; these include ethylamine (from alanine), agmatine (from arginine), γ-aminobutyric acid (from glutamate), methylamine (from glycine), histamine (from histidine), cadaverine (from lysine), putrescine (from ornithine), phenylethylamine (from phenylalanine), ethanolamine (from serine), tryptamine, and 5-hydroxytryptamine (from tryptophan), and tyramine and dopamine (from tyrosine). These amines and their derivatives often play a variety of physiologically important roles. For example, γ-aminobutyric acid, phenylethylamine, tryptamine, 5-hydroxytryptamine, or serotonin, tyramine, dopamine, norepinephrine (noradrenaline), and epinephrine are all neurologically active compounds, whereas histamine, a powerful vasodilator, is involved in allergic reactions. (*See* **Amines**.)

Tyrosine plays several important roles in animal metabolism as a precursor to melanins, thyroid hormones (thyroxine and triiodothyronine), and catecholamines (dopamine, norepinephrine, and epinephrine). In the synthesis of melanins, tyrosinase catalyzes first the hydroxylation of tyrosine to 3, 4-dihydroxyphenylalanine (dopa), followed by the oxidation of dopa to phenylalanine-3,4-quinone (dopaquinone). Dopaquinone undergoes a sequence of reactions, including polymerization, to yield both red and black melanins. Another enzyme forming dopa is tyrosine hydroxylase, which catalyzes the first reaction in the sequential enzymatic pathway leading to the biosynthesis of catecholamines. Dopa is then decarboxylated to yield 3,4-dihydroxyphenylethylamine (dopamine). Dopamine is hydroxylated to norepinephrine, which in turn is methylated by SAM to give epinephrine. (*See* **Hormones**: Adrenal Hormones; Thyroid Hormones.)

Putrescine, or 1,4-diaminebutane, is synthesized by decarboxylation of ornithine, in a reaction catalyzed by ornithine decarboxylase, a highly regulated enzyme. Another route to putrescine formation involves the conversion of arginine to agmatine by arginine decarboxylase, followed by cleavage of agmatine to putrescine and urea by agmatine ureohydrolase. Putrescine is an intermediate in the biosynthesis of two important polyamines, spermidine and spermine. Spermidine is synthesized enzymatically by the SAM-mediated transfer of a propylamino group to putrescine. The enzymatic transfer of an additional propylamino group from SAM to spermidine produces spermine. These polycations play multiple roles in stabilizing negatively charged intracellular components such as nucleic acids and membranes.

Creatine phosphate, which serves as a source of high-energy phosphate in mammalian muscle and brain, is synthesized in three steps from arginine, glycine, and methionine.

There are four classes of tetrapyrrole compounds – hemes, chlorophylls, phicobilins and cobalamins – all of which are synthesized from a common precursor, δ-aminolevulinic acid (ALA). In bacteria and animals, ALA is synthesized by the condensation of glycine and succinyl-CoA, with loss of carbon dioxide, in a reaction catalyzed by ALA synthase. In plants, however, ALA is formed from glutamate by a three-step pathway.

An enormous amount of carbon in the biosphere passes through the pathway leading to lignin biosynthesis, the major constituent of woody tissue. In the first reaction, phenylalanine ammonia lyase catalyses the cleavage of phenylalanine to *trans*-cinnamic acid and NH_4^+. Cinnamic acid is a precursor for the synthesis of a huge number of plant substances, including lignin, tannins, flavonoids, pigments, many of the flavor components of spices, and various alkaloids, such as morphine and colchicine. (*See* **Lignin**.)

In addition, the synthesis of a variety of other important molecules utilizes various amino acids as precursors. Thus β-alanine is a component of CoA, asparagine is a major form of transport of organic nitrogenous compounds in plants, and aspartate is involved in purine and pyrimidine biosynthesis. Glutamate is a precursor of folic acid; glutamine contributes to the synthesis of a variety of substances, including purines, pyrimidines, ATP, cytidine triphosphate, NAD, amino sugars, and glycoproteins; cysteine is a precursor of taurine, isethionic acid, CoA, vasopressin, various types of pigments, including phaeomalins and trichochromes, and other sulfur-containing compounds. Glycine also plays multiple roles, including contributions to the one-carbon pool and as a precursor of purines, glyoxylate, and various conjugates such as hippurate and glycocholate. Histidine is involved in ergothionine and homocarnosine biosynthesis, and methionine, via SAM, is the precursor of the plant hormone ethylene, which influences plant growth and development and induces the ripening of fruits. Serine is involved in the biosynthesis of phospholipids, and tryptophan is the precursor of several important physiological substances, including NAD, NADP, and the plant hormone indole 3-acetic acid. (*See* **Niacin**: Physiology; **Ripening of Fruit**.)

ANALYSIS OF FOOD

K Gupta , V Jain, S Jain, K Dhawan and G Talwar, CCS Haryana Agricultural University, Haryana, India

Background

The science of food analysis has developed rapidly in recent years. Analysis of food not only provides information about composition, appearance, texture, flavor, shelf-life, safety, processibility, and microstructure, but also guarantees product quality. Knowledge of the chemical and biochemical composition of foods is important to the health, well-being, and safety of the consumers. Also, it is important for compliance with legal standards, quality assurance, nutritional value determination, and adulteration detection.

Analysis of food involves sample preparation, analysis, and detection of major food components (amino acids, peptides, proteins, enzymes, lipids, phospholipids, carbohydrates, alcohols, fat-soluble vitamins, water-soluble vitamins, organic acids, organic bases, phenolic compounds, bittering substances, pigments, aroma compounds, and dietary fiber) and miscellaneous components (preservatives, antioxidants, colorants, and nonenzymic browning substances). A large number of different analytical techniques have been developed to analyze the properties of food because of the complexity and diversity of food components. These techniques can be divided in to three general segments focusing on physical techniques including spectroscopy, chromatography and electrophoresis, biochemical analysis, and sensory analysis.

Sources of Information

The food analyst has to identify and choose the best analytical method available for analyzing a food sample depending upon its complexity. For this, the food analyst must be familiar with all the recent advances in food analysis methods and must know where to look for the needed information/literature. The main sources of information and general approach to a literature search are detailed below.

Books

The best way to obtain general information about food analysis is to consult textbooks. A number of textbooks are available on food analysis, and these textbooks generally provide information on the background and basic principles of food-analysis methods, sophisticated instruments, and classical procedures that have been in use for many years. The textbooks usually concentrate on the fundamental principles rather than detailed methodology.

For a wide range of information, several encyclopedias exclusively for food chemistry or food technology are good sources of literature, such as *The Encyclopedia of Science and Technology*. Monographs are basically comprehensive surveys of current knowledge on a specific subject. Recently, a number of books (monographs) have become available for specialized areas like the use of spectroscopy and/or HPLC for food analysis. Handbooks are another source of comprehensive information. For example, the *Handbook of Food Analysis*, in its two volumes, deals with the methods for physical characterization as well as for biochemicals, nutrients,

and sensory analysis for a diverse number of food components.

Reviews

Once general information has been obtained, the next step is to consult a critical review of the current knowledge on the particular field. A review may be written about the determination of a specific component, about the specific technique that can be used for different food sample analyses or about the current aspects of a new technique/instrument. Critical reviews pertinent to food analysis are usually published in scientific journals like *Advances in Food Research*, *Annual Review of Nutrition*, *Methods of Biochemical Analysis*, *Recent Advances in Food Science*, etc.

Periodicals

Scientific journals are one of the best sources of information as they deal with the articles/information about current and new analytical methods. Periodicals provide information about the research work or analytical methods developed by other scientists. They cover all scientific aspects of the chemical composition of foods, e.g., *Journal of Food Composition and Analysis, Analytical Chemistry, Food Testing and Analysis*, etc. Related journal articles can now be searched for on the internet on specific sites, such as *www.academicpress.com/jfca* for *Journal of Food Composition and Analysis*.

Official Methods

Several standard analytical methods have been approved by the respective governments/scientific agencies (e.g. Association of Official Analytical Chemists (AOAC), American Association of Cereal Chemists, American Oil Chemists' Society (AOCS), etc.) for use in the food industry. These standard methods are generally compiled in volumes, and they are being improved and updated from time to time.

Symposia

Programs of conferences and symposia are published in several journals and are included on websites. In symposia, prominent scientists present invited review papers in the area of their competence. Abstracts of papers presented at scientific meetings are generally published in the form of a book by the sponsoring scientific society. The Asia Pacific Food Analysis Network and American Chemical Society hold regular meeting/symposia on topics related to food chemistry/analysis, and programs and abstract books are available from the organizing society office bearers.

Trade Publications

The purpose of the companies that trade in chemicals and instruments is to sell products, but advertisements are also sources of valuable information. These publications are the best source on the properties and application of specialized equipment and chemicals. Several manufacturers periodically issue bibliographies and abstracts of technical-scientific articles in a specific area, and some publish periodicals that reproduce specialized articles from regular scientific journals. Even detailed handbooks giving specification, properties, and details of analytical procedures in selected areas are provided by these companies. The advertisements or lists of major commercial companies for chemicals and instrumentation appear in several scientific and trade journals (*Science, Nature, Prepared Foods*, etc.). The instruction manuals supplied with instruments are very useful for installing, using, and servicing equipments.

Modern Information Retrieval Systems

Nowadays, computerized systems have a great capacity for storing and retrieving scientific information. A number of websites are available, on which one can search information on a particular subject. These sites can be accessed from any computer terminal linked to the internet. The proper use of these systems reduces the time, cost, and effort involved in searching the literature. Some of these sites/search engines include http://agrifor.ac.uk, www.altavista.com, www.biacore.com, www.bmn.com, www.cabi.org, www.google.com, www.ncbi.nlm.nih.gov, www.national academics.org, http://highwire.stanford.edu, and www.yahoo.com.

Several more such sites/databases are available for information on food analysis, such as Agricola (USDA, National Agricultural Library, Beltsville, MD), Dissertation abstracts online (University Microfilms International, Ann Arbor, MI), Science Citation Index (Institute for Scientific information, Philadelphia, PA), and Food Science and Technology Abstracts (International Food Information Service, Reading, UK).

Preparation of Samples

Food is a complex inhomogeneous mixture of chemical substances and microorganisms (active or not). Therefore, improper sampling may result in variable analysis results. Ideally, the sample analyzed in a laboratory should have exactly the same properties as the total population it is supposed to represent. There are three steps involved in sample preparation for chemical analysis of foods.

Sampling

An analyst has to decide on the number of samples of a given population to test, the location from which the sample should be selected, and the method used to collect them. The choice of a particular sampling plan depends on the purpose of the analysis, the physical property to be measured, the nature of the total population and of the individual samples, and the type of analytical techniques used to characterize the samples.

Homogenization

The complex structure and composition of food substances necessitate homogenization prior to most chromatographic analysis. Each sample should be homogenized using methods proven to be effective with a particular matrix from experience, from the literature, or by experiment to a degree that meets all the requirements of the assay procedure. This must be confirmed by replicate assays, blanks, and recoveries.

Sample Preparation

Physical and chemical manipulation of the test portion prior to analytical measurements is carried out. This includes storage, weighing, dilution, clean-up, extraction, digestion, purification, separation, derivatization, etc. It is also important to report the results of any analysis in a clear fashion, stating the procedures used, the number of replications performed, and the estimated reliability of the measured value. The analytical method selected must be specific, accurate, precise, and sensitive for the substance to be analyzed.

Selection of a Method for Food Analysis

Once proper sampling and sample preparation have been completed, the food product is ready for analysis. There are numerous analytical procedures available to analyze a particular food product. Selection of the most suitable procedure is often the key to the success of an analysis. Some of the important factors that should be considered are as follows.

Specificity Specificity relates to the absence of interfering substances that give a measurement of the same kind as the substance being determined or the ability to detect and quantify specific components within the food material, even in the presence of similar food components.

Accuracy This is a measure of how close one can approach the true value of parameter being determined.

Precision This is the ability to reproduce a result between the determinations of a substance by the same scientist (or group of scientists) using the same equipment and experimental approach.

Reproducibility This is the ability to reproduce a result by scientists using the same experimental approach in different laboratories using different equipment.

Economy This is the total cost of analysis including reagents, time, and instrumentation.

Simplicity of operation This is the ease with which the analysis may be carried out by other workers.

Sensitivity This is the smallest detectable amount of the substance/sample that can be quantified/detected by the given technique.

Safety This concerns the potential hazards associated with reagents and procedures used in analysis.

Speed This relates to the time required to complete the analysis.

Destructive/nondestructive This indicates whether the sample is destroyed during analysis or remains intact.

Techniques and Methods

The analytical techniques involved in food analysis can be categorized as physical, biochemical, and sensory evaluation techniques.

Physical Techniques

A variety of physical techniques have been developed to analyze the properties of food materials. These have been categorized according to the principles on which they are based.

Spectroscopy Spectroscopic methods involve the quantitative evaluation of the phenomenon resulting from the interaction between a certain form of radiation (electromagnetic, acoustic, electron or neutron beam) and matter (atoms, molecules, ions) to provide information about the properties of a food. Radiation energy interacts with the matter in a variety of ways, including absorption, emission, reflection, refraction, dispersion, and polarization. Spectroscopic methods based on each of these interactions are used in food analysis, and those methods based on absorption and emission are the most common (Table 1).

Table 1 Spectroscopic methods for food analysis

Type of spectroscopy	*Information obtained*	*Material required*	
		Nature	*Quantity*
Atomic absorption and emission spectroscopy	Analysis of elements	Solution	Small
Atomic fluorimetry	Analysis of elements	Solution	Small
UV-visible absorption spectroscopy	Chemical and quantitative analysis	Liquid extracts	Small
Electron paramagnetic	Physical state	Native material	Moderate
X-ray spectroscopy	Structure and composition	Native material	Very small
Nuclear magnetic resonance	Physical state and chemical analysis	Native material or solid or liquid extract	Large
Infra-red spectroscopy	Physical state and chemical structure	Native material depending on the type of IR	Small to large
Mass spectroscopy	Analysis of elements and structure determination	Usually solid extracts	Very small

The quantity very small, sub-microgram level; small, sub-milligram level; moderate, tens of milligrams; large, hundreds of milligrams.

Atomic spectroscopy is based on the transition of outer shell electrons between the different energy levels upon interaction of atoms with electromagnetic radiation in the ultraviolet, visible, and infrared regions. When the electron returns to its normal state, it releases its acquired energy in the form of radiation that is specific to that element, and emitted radiation can then be measured using suitable detectors. Each element has a specific set of energy levels, and so the wavelength of the absorbed or emitted radiation can be used to identify the element, and the extent of absorption or emission can be used to quantify this element. Atomic spectroscopy is used to determine the concentration of mineral elements in food. In atomic absorption spectroscopy, the interaction between the source of energy in the correct frequency region and a sample is measured. An atomic absorption instrument contains a source of radiation with a wavelength that matches those required to excite atoms in the flame, thereby providing a more efficient means of atomic excitation. In atomic emission spectroscopy, a sample is heated to atomize it and to excite electrons to a higher energy state. The emission of radiation by the excited atoms is measured using suitable detectors. The disadvantage of atomic absorption spectroscopy is that it can measure only one element at a time. In comparison, atomic emission spectroscopy (also called flame photometry) can determine several elements simultaneously.

Atomic fluorimetry is based on the absorption of a photon by an atom that causes the passage of a valence electron of one orbital to another orbital with a higher energy. The atom, being unstable, returns to its ground state, emits a photon with a different frequency (usually lower than the absorbed photon) causing fluorescence. This can be used to detect a few mineral elements (Ca, Cd, Fe, Pb, Ni, Cr, Cu, etc.)

UV-visible absorption spectroscopy is one of the most common spectroscopic techniques used to resolve problems of compound identification, quantification, and qualitative analysis of food. Like atomic spectroscopy, it is also based on the transition of outer-shell electrons. A beam of monochromatic radiation is transversed through the sample, and reduction resulting from absorption is measured. A spectrum is obtained by carrying out measurements over a wide range of wavelengths that contain peaks corresponding to the absorbing groups. A compound can be characterized by its spectrum, provided that the absorption coefficients of bands are known, or by comparing it with reference spectra. The quantitative aspects of this technique are based on the Lambert–Beer law, which states that the absorbance of a solution (the log of the ratio of light entering a sample to light leaving the sample) is proportional to its concentration at a particular wavelength under a set of standard conditions. The quantity of a substance can also be determined by measuring the height of one of these absorption peaks (if there is no interference from other molecules). Derivative spectroscopy can be used to eliminate any interference caused by the reaction environment. Photodiode array spectroscopy represents a great advance on absorption spectroscopy allowing simultaneous detection at a wide range of wavelengths in a liquid flow. It provides immediate information of spectra for each eluted compound.

Electron paramagnetic resonance spectroscopy arises from the fact that electrons have a quantum mechanical property, called spin, that results in the generation of a magnetic moment. Only atoms or molecules with unpaired electrons possess a magnetic moment. The transition at this moment when a sample is placed in magnetic field can be detected

and characterized. This technique is employed to detect lipid peroxidation, molecular damage to proteins, and nucleic acids.

Nuclear magnetic resonance (NMR) techniques are concerned with the transition of nuclei between different energy levels when these are placed in a magnetic field. The frequency at which the moment of spin 'wobbles' allows the elementary segments of a molecule to be identified. The nuclei having a net spin angular momentum can be detected by NMR, the most common being ^{1}H and ^{13}C. NMR can be used to determine the moisture, concentration, molecular structures, phase transitions, diffusion, and image, and can be used to check the authenticity of food and drink ingredients whose commercial value is related to their natural origin.

Infrared (IR) spectroscopy techniques are based on the absorption/emission of electromagnetic radiation by a sample resulting from vibration or rotation of molecules. The interaction of IR radiation with matter leads to an IR spectrum containing detailed information on different types of chemical groups of the substance in the form of peaks. The location and magnitude of a peak provide information about the type and concentration of the groups present. IR spectroscopic techniques are available to determine the proteins, lipids, carbohydrates, moisture contents, flavor, and toxic constituents in food.

Mass spectroscopy techniques rely on the production of ions by bombarding organic compounds (in their vapor state) with high-energy electrons. The ions formed are accelerated and separated as a function of their mass and charge under the effect of variable electric and/or magnetic fields, and their relative abundance can be detected. These techniques can be used to identify and determine components in mixtures of organic materials, e.g., flavor components, lipids, amino acids, carbohydrates, vitamins, minerals, toxicants, antinutritional factors, and additives in food, and to identify food microorganisms.

X-ray spectroscopy/spectrometry techniques are based on the emission of X-rays when accelerated electrons/X-rays collide with matter and eject an electron from atom's internal layer. The vacancy is filled by another electron from a higher orbital, and this equilibration leads to the emission of X-rays. The excitation can be produced by accelerated electrons/X-rays, leading to emission spectroscopy or X-ray fluorescence spectroscopy. These techniques provide information about the structure, composition, and purity of the food material.

Optical techniques Analytical techniques utilize the interaction of monochromatic beam of light with matter to provide information about the composition and quality of a food. These techniques include photometry and turbimetry, which concern the dispersion of incident light by suspended particles in liquid and even in gases to measure colloidal particles in water, and clarity of juices, syrups, and wines. Polarimetry relies on the rotation of the plane of polarized light by an optically active solution and is used to determine lactose in condensed milk and sugars in juices. Refractrometry is based on the change in refractive index caused by the displacement of a molecule/substance in solution or by refraction caused by that substance in solution. These techniques can be used in the analysis of lipids, carbohydrates, and protein concentration in liquid and dry matter. In combination with density determination, these techniques can be used to determine unknown substances or structures of known substances. For very precise measurements, differential refractrometry and interferometry can be used.

Chromatography Chromatography designates a variety of techniques that can separate mixture of molecules into individual components on the basis of their differences in size, shape, mass, charge, solubility, and adsorption properties. It is used for purification and constituent preparation in the food industry. A solution of a mixture of molecules (usually in a liquid or gas carrier) is passed through a porous medium. The carrier is called the mobile phase, because it moves through the porous medium, whereas the porous medium is called the stationary phase. In this process, different solute components are separated as a result of the different affinities of the components for a stationary (solid or liquid) phase; the stronger the interaction, the slower they move. The affinity or strength of an interaction depends on the physico-chemical properties of the substance and the stationary phase. Molecules can be separated according to their size, shape, mass, polarity, electric charge, solubility, and molecular interactions. The chromatographic techniques can be divided into different categories depending on their physico-chemical basis of separation (Table 2).

Chromatographic separation can be carried out in one of the three modes, depending on the nature of the support that holds the stationary phase. In paper chromatography, the stationary phase (liquid) is supported by cellulose fibers of a paper sheet. The sample is spotted on to the bottom of a sheet of paper, and the paper is kept in an atmosphere saturated with water vapors to form a thin film of a stationary phase. An appropriate solvent system acting as a mobile phase is then allowed to flow over the sample spot. The various components of the sample are then partitioned between the stationary and mobile phases.

Table 2 Classification of separation techniques of chromatography on physico-chemical basis

Molecular characteristics	*Physical principles*	*Example*
Polarity	Differences in partitioning coefficient between polar and nonpolar solvent	Partition, i.e., liquid–liquid; liquid–solid gas–liquid chromatography and HPLC
Ionic	Differences in electrostatic interaction between charged groups on molecules in the mobile phase and stationary phase	Ion-exchange chromatography
Size	Differences in the size and shape of molecules	Gel-permeation chromatography
Affinity/shape	Specific interactions between molecules in the mobile phase and stationary phase	Affinity chromatography

Components with a higher affinity for the stationary phase move less rapidly than those with a higher affinity for the mobile phase. A more sophisticated separation can be achieved using two-dimensional paper chromatography.

Thin-layer chromatography (TLC) has largely replaced paper chromatography, because it is more convenient, quicker, and more sensitive, and it has a better resolution and reproducibility. This technique is similar to that of paper chromatography, except that paper is replaced by a plastic or glass sheet coated with a thin film of porous material that acts as the stationary phase. In column chromatography, separation is achieved by passing the sample through a vertically fixed tubular glass or polypropylene column using either gravity or a slight vacuum to move the mobile phase through. Steel columns and high pressures are now used to speed up the process. In gas chromatography, the sample is volatilized and then carried along by a gaseous mobile phase through a column coated with the stationary phase. The efficiency of separation can be controlled by selecting the appropriate combination of stationary and mobile phase. In high-performance liquid chromatography (HPLC), the sample dissolved in the liquid mobile phase is passed through a column containing the stationary phase (which may be either solid or liquid). This gives a faster and superior resolution, as high pressure is applied to move the mobile phase.

Electrochemical techniques Analytical techniques involve measuring the electrical properties of food, e.g., potential, current intensity or resistance, to provide information on composition. Potentiometric methods rely on measurements of the potential difference between a specific (an indicator) electrode and a reference electrode, and this is directly proportional to the concentration of the species being measured.

Polarographic methods are based on the potential difference between a mercury electrode and a reference electrode immersed in a solution containing electroactive species. These are used to determine heavy metals polluting water or foods, pesticides, and preservatives. Coulometric methods involve measuring the quantity of electric current required to electrolyze the substance being analyzed; the greater the electric charge, the higher the concentration of the substance. The electrical conductivity is based on the displacement of different components of a substance in the solution, which is equivalent to the current passing between a pair of electrodes. The amount of current is measured and then extrapolated to the composition of a specific component within the food.

Electrophoresis relies on differences in the movement of charged macromolecules in an electrical field applied across a substance. It is used to separate molecules on the basis of a net charge, size, and/or shape. The sample to be analyzed is added to a buffered porous matrix (usually a strip of paper or gel), and a current is applied. Charged molecules move through the matrix in a direction that depends on the sign of their electric charge. The rate of movement depends on the magnitude of the charge and resistance to movement through the matrix. The resistance is determined by the relationship between the effective size of the substance and the size of the pores in the matrix. The larger the size of the pores or the smaller the size of molecules to be separated, the lower the resistance, and therefore, the molecules will move faster through the matrix. Isotachoelectrophoresis (separation of sample components based on differences in net mobility) has a high resolving power, because of its concentrating effect. Components with different isoelectric points are separated better by isoelectric focusing (IEF). Two-dimensional electrophoresis can be carried out to improve the resolution. Substances are separated in one direction, according to their charge by IEF, and in a second dimension (perpendicular to the first), on the basis of their size.

Rheological techniques These techniques are based on the relationship between the stress and strain in a material, with a behavior between that of solids and

liquids. Measurements of these properties of foods can be based on either an analytical or integral approach. In the analytical approach, the properties of a material are related to a simple system such as Newtonian fluids or Hookian solids. In the integral approach, a simple empirical relation between stress, strain, and time is established. The relationship measures the way in which rheological properties vary under a specific system of applied forces. The instruments used provide a measure of baking quality of flours, thickening properties of biopolymers, texture, hardness, flakiness, consistency of food, tenderness of meat, and texture of fruits and vegetables. Rheological techniques are now essential tools, especially as a quality-control tool in food science and technology.

Biochemical techniques There are a number of biochemical techniques available that can be used to determine the identity and/or concentration of specific components of food. Enzymatic analysis means analysis with the aid of enzymes utilizing specific enzyme reactions. The major advantage of enzymatic techniques lie in their ability to react specifically with individual components of a mixture. This avoids lengthy separation of the components and reduces the time required for analysis. These techniques require small amounts of sample and do not require components to be extracted from their native medium.

Immunochemical techniques These rely on specific interactions between an antigen and an antibody. Since macromolecules found in microorganisms, food, and agricultural products are good antigens, antibodies against these molecules can be obtained. The potential applications for immunological techniques are numerous, as much for raw material and final product quality control as for tracking production and conservation effectiveness.

Analytical microbiology involves the use of microorganisms as reagents for the quantitative determination of certain chemical compounds present in food. Since some of the nutritional requirements of microorganisms and experimental animals are similar, it is possible to use analytical microbiological techniques to determine some substances that are essential constituents of living cells. These are used for vitamins, nucleic acids, amino acids, heavy metals, growth factors, and nutritional values of proteins and antibodies. The basic principle is that in the presence of limiting amounts of certain compounds, the amount of microbial growth is a function of the concentration of those compounds. The microorganisms used for assay are primarily bacteria, but yeast, fungi, algae, and protozoa have also been used. These can be assayed after diffusion of the substance through solid inoculated culture media by turbidimetric, dilution, gravimetric, and metabolic response methods.

Sensory evaluation The sensory attributes of the quality of a food are measured to determine consumer preference in order to help in the manufacture of an acceptable product at maximum production economy. Sensory attributes include appearance (color, size, shape, and consistency of liquid and semisolid products), kinesthetic (texture, consistency, and viscosity) and flavor (taste and odor). The evaluation is also done in order to determine the conformity of a food with established government or trade standards and food grades. The technique of sensory evaluation involves using individuals as the data generator, and so, it is influenced by factors such as social, cultural, religious, psychological, and climatic factors, physical status of the individual, availability, and nutritional education. Large, highly trained groups of experts are employed for evaluation to minimize the effects of such factors. Laboratory tests may be conducted to study the human perception of food attributes, to correlate sensory attributes with chemical and physical measurements using principal component analysis, to evaluate raw material selection; to study the processing effects and means of maintaining uniform quality, to establish shelf-life stability, and to reduce costs.

Food Components

Structural changes occur during the processing and storage of foods. Therefore, knowledge of the composition of a food is necessary in order to determine the extent of any change in the concentration of the nutrients. The use of agrochemicals and additives also may affect the quality of the food product. In order to obtain quality assurance, in accordance with legal requirements, nutrition, and food safety, the concentration of major and minor food components must be known. The methods used for the analysis of food components are discussed below, and these methods form part of the techniques already described.

Major Components

Moisture Water is the major component of most foods and is an index of the economic value, stability, and quality of food products. It is important to note that the removal of water either by conventional dehydration or by separation locally in the form of fine ice crystals (freezing) greatly alters the native properties of foods. Therefore, it is very important to use

simple, rapid, and accurate methods for moisture determination in food products. The food sample should be homogenized using a number of electrical/mechanical devices like blenders, mincers, graters, homogenizers, and grinders. Analytical methods of moisture determination can be classified as direct and indirect procedures. Direct procedures include the determination of moisture by drying (oven, vacuum, freezing, chemical desiccation), distillation, chemicals (Karl Fischer titration), and extraction (gas chromatography and refractrometry). The drying method relies on the evaporation of water from the sample and is one of the most commonly used procedures for determining moisture content (conventional ovens, forced air ovens, vacuum oven, microwave oven, and IR oven). The weight of the sample is taken before and after it is dried, and the moisture content is then calculated. In the distillation method, the food sample is mixed with an organic solvent, and water is evaporated and collected in a graduated collection arm, in which its volume can be determined. The most commonly used chemical methods for moisture determination are Karl Fischer titration and the gas-production method. These methods rely on specific chemical reactions between water and other substances that lead to some quantifiable parameters. Indirect methods include rapid and nondestructive methods, and these involve calibration against standard moisture values that have been precisely determined by using one or more of the direct methods. These methods are based on differences in the physical properties of water compared with other components and are widely used to determine moisture content including IR gas chromatography, NMR, and several electrical methods. These instruments are simple to use, provide rapid and reliable measurements, and are, therefore, particularly suitable for routine quality-control applications.

Mineral components Ash is a measure of total mineral components in a food and is regarded as a general measure of quality in certain foods such as tea, flour, and edible gelatin, etc. There are two major procedures of ashing that are used to determine the mineral content of the sample. These are dry ashing and wet ashing. The nature of the ashing procedure is governed by the purpose for which ash is prepared, the particular constituents to be determined, and the method of analysis to be used. In dry ashing, the sample is ignited at 550–600 °C to oxidize all organic material without a flame, whereas in wet ashing, the sample is digested in acid to determine mineral elements. The individual elements within ash can be determined by titrimetric methods, colorimetric methods, or atomic spectroscopy techniques. Atomic spectroscopy techniques can provide a complete profile of different types of elements in a food material, whereas the titrimetric and colorimetric methods are usually designed to determine a particular element. In addition, atomic spectroscopy techniques have a much higher sensitivity and specificity.

Carbohydrates Carbohydrates are present in all grains, vegetables, fruits, and other plant parts and vary in form from simple monosaccharides to oligosaccharides and more complex polysaccharides. These are a major source of energy for the human body, and their varied functional properties are utilized by the food industry to enhance the palatability, acceptability, and shelf-life of foodstuffs. There is thus a continuous need to monitor levels of carbohydrates in foods. The complete analysis of foodstuffs may require the determination of several groups of compounds, e.g., simple sugars, reducing sugars, polysaccharides, and fibers, all of which may play an important role in the quality of the product. For this purpose, a number of physical and chemical methods have become well established and commonly used in many laboratories. Physical methods include refractrometry, polarimetry, and hydrometry, whereas chemical methods include titrimetric and colorimetric, which determine the quantity of a particular sugar present in food. Chromatographic techniques such as paper chromatography, TLC, gas liquid chromatography (GLC), and HPLC provide more rapid analyses with a greater precision and specificity. Nowadays biochemical methods of analysis are often used because these are specific, sensitive, rapid, and reproducible. Flow injection analysis (FIA) gives an excellent performance and has been the basis of a large number of methods for the separation, processing, and analysis of carbohydrates. The future of carbohydrate analysis undoubtedly belongs to three analytical techniques – HPLC, enzymatic assays, and FIA – all having a close relationship to one another.

Proteins The determination of proteins in foods and food products has an important nutritional, functional, and technological significance. The methods for protein estimation depend on the measurement of a specific element or chemical group in the proteins. The elements or groups most commonly used are nitrogen, aromatic amino acids, or peptide linkage. Based on nitrogen content (approx. 16% of protein weight), either protein can be estimated by Kjeldahl's method (AOAC) or ammonia can be directly determined in the digest by color-inducing compounds such as ninhydrin, indophenol, or Nessler's reagent.

A variety of spectrophotometric methods are also available to determine protein content. These include the biuret method (based on the binding of copper (II) to a peptide bond in protein molecules at alkaline pH values), the Lowry method (based on the reduction of Folin–Ciocalteau reagent by oxidation of tyrosine and tryptophan on the polypeptide side chain), and the dye binding method (based on the measurement of excess dye remaining in solution after removal of the precipitated protein–dye complex). Most proteins exhibit an absorption maximum at 280 nm, because of the presence of a side chain of aromatic amino acids, and so UV-spectrophotometry is also used for protein identification and quantification. IR spectrophotometry has become a popular method for the determination of protein in cereal products, because of its speed, simplicity of operation, safety, and low running costs. Specific protein components in food and food products can be quantified by chromatography, electrophoresis, immunology, or a combination of these. Among the methods of chromatography, HPLC is becoming increasing important in the analysis of specific protein components in foods and food products. The separation of proteins in an electric field on the basis of their charge density is a powerful and frequently used technique for the analysis of specific protein components in food. Methods such as immunoelectrodiffusion and enzyme-linked immunosorbent assay are immunological methods (based on the interaction between an antigen and its corresponding antibody) that are highly specific and sensitive means to identify and quantify minor protein components in complex matrices. To improve and optimize the accuracy of the protein quantification in food and food products, further research for new and alternative absolute protein quantification methods is necessary. Amino acids are the building blocks of proteins, and these can be determined after hydrolysis of proteins by colorimetric, enzymatic, and chromatographic (ion-exchange and gas-chromatography (GC)) methods.

Lipids Most of the methods used in food lipid analysis cannot be directly applied to foods themselves because of their complexity. Lipids should first be extracted either for total lipid estimation or for further analysis. Neutral lipids (triacylglycerols) can be easily extracted by nonpolar solvents such as petroleum ether, hexane, or supercritical carbon dioxide. If a sample contains phospho- or glycolipids, polar solvents such as methanol must be used for quantitative determination. Standard methods are used to determine the oil content (AOAC or AOCS) by refluxing the sample in petroleum ether using Soxhlet apparatus. There are a number of procedures for oil estimation in which a sample is not destroyed, such as low-resolution NMR or high-resolution NMR. Methods have been developed to separate different classes of lipids such as neutral lipids, glycolipids and phospholipids. The techniques commonly used are TLC, column chromatography, and HPLC, especially with mass detection.

General information on the constituent fatty acids of fats can be obtained from different chemical analyses giving specific values such as the saponification value, iodine value, hydroxyl value, etc. The presence of free fatty acids in oil, which is an index of rancidity, can be determined by titrating against a standard alkali. Specific fatty acids in fat can be determined by gas–liquid chromatography (GLC), which is still the most informative technique in fatty acid analysis. Mass spectrometry coupled to GC is the most powerful tool for identifying fatty acids separated by GLC. IR spectroscopy and Raman spectroscopy are most often used to detect *trans*-fatty acids and isomers of *cis*-unsaturated fatty acids. UV-spectroscopy at 200–400 nm is generally used to detect the presence of conjugated double bonds. The processing and quality of food oils are often determined by physical characteristics such as their melting point, smoke point, flash point, fire point, solid-fat content, and degree of oxidation. These characteristics can be determined by different analytical techniques.

Other Food Components

A large number of different analytical techniques have been developed to analyze food components such as bitter compounds like terpenoids, flavonoids, phenols; pigments like carotenoids, chlorophyl, anthocyanins; vitamins (water- and fat-soluble); aroma compounds; dietary fibers; residues; alcohols; organic acids; antioxidants; preservatives, etc. The standard methods of the AOAC are generally adopted for the analysis of these components. Apart from this, often techniques that are commonly used for the detection and quantification include colorimetric, enzymatic, chromatography (paper chromatography and TLC), UV-visible absorption spectroscopy, gas chromatography, HPLC (reverse phase, normal phase), capillary electrophoresis, etc. HPLC is the most popular alternative to the standard methods and is commonly used nowadays for the analysis of almost all types of different food components.

ANEMIA (ANAEMIA)

Contents

Iron-deficiency Anemia

S R Lynch, Eastern Virginia Medical School, Norfolk, VA, USA

Introduction

A lack of iron is the commonest nutritional deficiency disorder in human beings. Anemia occurs when body iron stores have been exhausted and the rate of delivery of iron to developing red blood cells in the bone marrow is insufficient to support the level of heme synthesis required to maintain a normal circulating red cell mass and hemoglobin concentration. It is estimated that more than 500 million people throughout the world suffer from iron-deficiency anemia. This article will review the causes, methods of detection, physiological consequences, as well as treatment and prevention of iron-deficiency anemia. (*See* **Iron:** Physiology.)

Iron Balance

Iron balance in human beings is uniquely dependent on the body's ability to match the rate of iron absorption from the proximal small intestine to iron requirements. During childhood, iron absorption normally exceeds immediate requirements, ensuring a positive balance and the gradual establishment of an iron store. In the adult, the level of absorption is approximately equal to a relatively fixed rate of loss that is

governed by factors unrelated to iron balance. When requirements are increased, e.g., during periods of rapid growth and in pregnancy, absorption increases to replace the storage iron that is used up. (*See* **Children**: Nutritional Requirements; **Lactation**: Human Milk: Composition and Nutritional Value.)

Once iron stores are exhausted by increased demand, anemia supervenes if adaptive changes in the rate of absorption are insufficient to restore iron balance. Dietary iron intake almost always exceeds the body's requirements by a large margin, but the ability of absorptive mechanisms to extract the iron from food may be limited. Iron-deficiency anemia is therefore most commonly encountered when the relationship between requirement and dietary intake of bioavailable iron is least favorable. Periods of increased vulnerability include infancy, adolescence (particularly among girls after the onset of menstruation), and the child-bearing years for women.

After the first 4–6 months of age, stores are no longer the primary source of iron for growth. By the age of 12 months total body iron should have increased by about 70%. Iron-deficiency anemia is therefore commonly encountered in infancy. The risk tends to decrease after about 18 months of age because the rate of growth slows and the diet becomes richer in bioavailable sources of iron. The adolescent growth spurt and the onset of menstruation in girls constitute the second high-risk period. In adulthood, increased menstrual bleeding or blood loss from the gastrointestinal tract may contribute to an unfavorable balance. For example, the monthly menstrual loss in 10% of healthy women is more than 80 ml (average for most women is 30 ml). This increases the daily iron requirement by about 0.8 mg or 6% of the dietary intake. It would be necessary for such an individual to increase her absorption of dietary iron from about 10% to 16%. Hookworm infestation, which is prevalent in many developing countries, may induce sufficient blood loss to increase iron requirements by 3–4 mg day^{-1}. Iron balance would only be maintained if percentage absorption from the diet were increased by 20–30%. Many of these individuals will become anemic because maximal total absorption from a normal diet is usually only 4–5 mg day^{-1}. Pregnancy presents the greatest physiological challenge to the body's adaptive mechanisms. The daily iron requirement during the last trimester is between 4 and 6 mg. (*See* **Premenstrual Syndrome: Nutritional Aspects**.)

The diets of most western adults contain large quantities of meat, which is rich in highly available heme iron, as well as fresh fruit and other sources of vitamin C, that increase the absorption of inorganic iron. This diet provides sufficient bioavailable iron to prevent anemia even in the presence of higher requirements. For example, a recent study in which dietary iron absorption was measured over a 2-week period indicated that a menstruating woman eating a mixed diet containing meat would absorb about 10% of the iron and maintain an iron store of approximately 350 mg. The composite 10% absorption value is achieved by assimilation of about 30% of the heme iron and 6% of the nonheme iron. A woman with relatively high menstrual losses would also be expected to maintain iron balance by increasing her nonheme iron absorption to 12%, although her iron store would be estimated at only 200 mg.

The iron requirements during the second and third trimesters of pregnancy usually exceed the body's capacity to extract sufficient iron from the diet even if the bioavailability is high. Most women require a small iron supplement to prevent iron imbalance.

As indicated above, relative iron requirements are also high in infants between the ages of 6 and 18 months. Foods given to young children during and immediately after the weaning period usually have low iron bioavailability. However some countries have been very successful in preventing iron deficiency during this vulnerable period by fortifying infant foods with iron.

Iron balance is much less satisfactory in many people living in developing countries. Heme iron is often absent from the diet since meat is not eaten in significant quantities. The bioavailability of the nonheme iron is usually low because the staple foods tend to have high levels of phytate and polyphenols. Iron-deficient individuals may be able to absorb only 5–10% of the nonheme dietary iron. Under these circumstances even modestly increased requirements may not be met. Poor dietary iron availability is often accompanied by high requirements due to factors such as multiple pregnancies and hookworm infestation. As a result, iron-deficiency anemia is widespread.

Prevalence

On the basis of data obtained during the third National Health and Nutrition Examination Survey (NHANES III, 1988–1994) the highest prevalence rates for iron-deficiency anemia in the USA occur in toddlers (3%), and adolescent girls and menstruating women (2–5%). Iron-deficiency anemia is rare in men and postmenopausal women. Among the elderly, inflammatory disease, not iron deficiency, is the commonest cause of anemia. Iron deficiency is much more frequently encountered in developing countries. At least 500 million people are affected globally.

Laboratory Diagnosis

Iron-deficiency anemia may be suspected on the basis of the clinical symptoms and the setting in which it occurs, but precise identification depends on the results of laboratory tests designed to confirm the presence of anemia and to evaluate iron status (Table 1).

Identification of Anemia

Anemia is identified by the finding of a hemoglobin concentration or hematocrit that is below the normal range. This usually presents little difficulty in the clinical situation since symptoms only occur in individuals with moderate or severe anemia. On the other hand, prevalence studies of nutritional anemia depend on the identification of mild anemia in an otherwise healthy population. The World Health Organization (WHO) criteria established in 1975 are the most widely accepted. Hemoglobin concentrations below 13 g dl^{-1} for adult males, 12 g dl^{-1} for menstruating women, and 11 g dl^{-1} in pregnancy are considered indicative of anemia.

In mild iron deficiency, the diagnostic value of a low hemoglobin concentration or hematocrit is limited by the significant overlap in the frequency distribution curves for anemic and normal populations. In one study using a single value criterion, 17% of women responded to oral iron despite the fact that they were classified as normal, while 35% of 'anemic' women failed to show any change in hemoglobin after being treated. The problem is even more complex in children, where developmental changes affect the normal hemoglobin concentration. The accuracy of diagnosis can be improved by using a criterion that employs an abnormal hemoglobin or hematocrit value in combination with one or more laboratory markers of iron deficiency.

Evaluation of Iron Status

Laboratory tests of iron status are used both to distinguish iron deficiency from other causes of anemia and to facilitate the recognition of mild iron-deficiency anemia in nutritional surveys. They supply specific information about the adequacy of iron stores and the supply of iron to the bone marrow and other organs.

Table 1 Laboratory evaluation of iron-deficiency anemia

Purpose of test	*Laboratory test*
Confirm presence of anemia	Hemoglobin
	Hematocrit
Evaluate iron status	
Iron stores	Bone marrow iron
	Serum ferritin
Iron supply	Serum transferrin receptor concentration
	Transferrin saturation
	Free erythrocyte protoporphyrin
	Red blood cell indices

Iron Stores

Bone marrow iron Histological evaluation of storage iron by using the Prussian-blue method to stain macrophage hemosiderin in needle aspirate or biopsy specimens of bone marrow provides a semiquantitative estimate of storage iron. Iron-deficiency anemia is characterized by an absence of stainable bone marrow iron. This procedure remains the gold standard in patients suffering from complicated illnesses, but is rarely necessary under most other circumstances and impractical in nutritional surveys.

Serum ferritin Body iron not immediately required for hemoglobin synthesis or other metabolic processes is stored in cells as ferritin and hemosiderin. Ferritin is also present in very small amounts in the plasma. The development of sensitive immunological methods has made it possible to measure serum ferritin (SF) accurately. This has become the most useful indirect estimate of body iron stores. SF concentration is directly proportional to the size of the storage pool in health and in uncomplicated iron deficiency: 1 μg l^{-1} is equivalent to 8–10 mg storage iron in adults (SF 1 μg l^{-1} is equivalent to 140 μg kg^{-1} storage iron). A serum ferritin below 12 μg l^{-1} is diagnostic of iron deficiency. Unfortunately, higher SF levels do not exclude iron deficiency when disorders such as infection, chronic inflammatory diseases, malignant disorders, and liver disease are present because they elevate SF values independently.

Internal Iron Supply

Serum transferrin receptor concentration Transferrin receptors are expressed on the surfaces of all cells in concert with their need for iron. A truncated form of the extracellular domain of the receptor is produced by proteolytic cleavage and is present in the plasma in direct proportion to the total number of receptors expressed in all body tissues. When functional iron depletion occurs more transferrin receptors appear on cell surfaces and the concentration of the proteolytically cleaved extracellular domain (serum transferrin receptor or STfR) in the plasma increases concomitantly. The magnitude of the increase is proportional to the size of the functional iron deficit. This assay has only recently become available, but may prove to be a very important measure of functional iron deficiency. The transferrin saturation and free erythrocyte protoporphyrin levels

are both abnormal in the anemia of chronic disease even if iron stores are adequate because the iron supply is reduced by impaired release from stores. The serum transferrin receptor concentration may help to distinguish these two common causes of anemia, since serum transferrin receptor levels are normal in the anemia of chronic disease.

Transferrin saturation As body iron stores become depleted, the concentration of the iron transport protein, transferrin, in the plasma increases, leading to a rise in the total iron-binding capacity (TIBC). Once iron stores are exhausted and the tissue demands exceed the rate of supply, the serum iron (SI) concentration falls. Since an impaired iron supply in an iron-deficient individual is characterized by a rise in TIBC and a fall in SI, a reduction in the transferrin saturation ($TS = SI \times 100/TIBC$) from the normal value of approximately 35% to less than 15% is the best single criterion of a suboptimal supply.

Free erythrocyte protoporphyrin An impaired iron supply can also be recognized by measuring the protoporphyrin IX (free erythrocyte protoporphyrin or FEP) in peripheral red blood cells. Insufficient iron limits the final step in heme synthesis, leading to the accumulation of FEP in red cell precursors. The cellular content remains unchanged throughout the life span of the erythrocyte. Peripheral blood FEP values therefore reflect iron supply during red cell production. FEP levels are also raised in lead poisoning. If exposure to lead can be excluded, a raised FEP provides the same information as a reduced TS, but it is more stable. FEP is raised only after several weeks of iron-deficient erythropoiesis and requires a similar period for normalization once an adequate supply of iron is reestablished.

Red blood cell indices As the severity of iron deficiency progresses, morphological abnormalities (microcytosis and hypochromia), resulting from reduced hemoglobin synthesis, appear in the peripheral blood. The sensitivity with which these changes can be recognized has improved dramatically with the introduction of electronic counting and sizing equipment. Both the mean corpuscular volume (MCV) and the mean corpuscular hemoglobin (MCH) are reliable measures of impaired hemoglobin synthesis, although not specific for iron deficiency. The MCV is the more widely used.

The best approach to diagnosing iron-deficiency anemia depends on the setting in which it is being evaluated. The accuracy of prevalence studies of nutritional anemia is improved by the concurrent measurement of hemoglobin or hematocrit and one or more specific tests for iron status, such as SF, STfR, FEP, or TS. The SF concentration is currently the most widely used measure of iron status. A similar approach or a therapeutic trial of oral iron may be satisfactory for clinic or office patients in whom iron deficiency is considered likely. In hospitalized patients, anemia complicated by other illnesses may occasionally require the direct histological evaluation of bone marrow iron stores. (*See* **Nutritional Assessment**: Anthropometry and Clinical Examination; Biochemical Tests for Vitamins and Minerals; Functional Tests.)

Physiological Consequences of Iron-deficiency Anemia

Mild anemia usually causes few symptoms in individuals with sedentary occupations because of compensatory physiological adjustments, including increased cardiac output and a shift in the oxygen dissociation curve with improved oxygen delivery to tissues. Aerobic work capacity in human beings is however reduced when the hemoglobin concentration falls below $12\,g\,dl^{-1}$.

Patients with moderate or severe anemia are pale and have symptoms such as reduced exercise capacity, shortness of breath, and palpitations that are indicative of a decreased cardiopulmonary reserve.

Iron deficiency usually develops gradually. Compensatory adjustments to oxygen transport insure adequate oxygen delivery at rest. However the ability to carry out sustained physical activity is significantly impaired, even in relatively mild iron-deficiency anemia, because of a reduction in available oxygen and the associated tissue iron deficiency that directly affects skeletal muscle function. Manual laborers who suffer from iron-deficiency anemia are less productive and may have a reduced earning capacity.

A study carried out among Indonesian rubber plantation latex tappers, who were paid a daily wage based on the weight of latex they collected, demonstrated a direct correlation between hemoglobin concentration and income. Anemic men were 18.7% less productive than their nonanemic fellow workers; when they were given 100 mg elemental iron per day for 60 days their income increased by 37%. It has been estimated that for every 1% increase in hemoglobin, work output will increase by 1–2%.

Iron-deficiency anemia also has insidious effects in children. Mental and motor development is impaired in infants. Cognitive function and school performance are affected in older children. The observed abnormalities are thought to be due primarily to direct effects of iron deficiency on cellular and neurotransmitter function. They are discussed in the chapter on physiology.

During pregnancy iron-deficiency anemia has significant consequences for the mother and the infant. Maternal anemia is associated with low infant birth weight, premature delivery, and increased perinatal mortality. Furthermore, although fetal requirements tend to be met at the expense of the mother's needs, several studies indicate that infants born to iron-deficient women have lower iron stores at birth and lower SF levels at 3–6 months of age. The risk of maternal death is also increased in women with severe anemia.

Finally iron-deficiency anemia may be associated with several abnormalities that are considered to be specific consequences of a tissue iron lack. They include impaired immunity, mucosal and epithelial changes, the eating of nonfood material (pica), and impaired temperature regulation.

Treatment and Prevention

Treatment

The recognition of iron-deficiency anemia is never a complete diagnosis. Iron administration may produce a rapid and gratifying correction of the anemia, but a satisfactory long-term solution to the problem depends on a clear understanding of the reasons for increased requirements and/or reduced absorption. For example, iron-deficiency anemia in western men is usually a symptom of unsuspected blood loss from the gastrointestinal tract. Identification of the underlying disorder is essential (Table 2).

Oral iron therapy using a soluble ferrous salt, such as sulfate, gluconate, or fumarate, that provides a daily dose of 60–120 mg elemental iron in adults, or 2–3 mg kg^{-1} in children, is usually the most appropriate method both to repair the anemia and restore a normal body iron store in patients with moderate or severe anemia. Once this has been accomplished, continued iron balance can only be assured if the cause of excessive requirements is eliminated or if more available dietary iron is supplied (in situations in which iron-deficiency anemia is the result of an inadequate intake of bioavailable iron).

Prevention

The prevalence of nutritional iron-deficiency anemia in western societies has fallen markedly in recent years. The many factors that have been suggested to contribute to this improvement in adults include dietary fortification, a general improvement in income level and diet, a large increase in the sale of medicinal iron preparations, routine iron supplementation in pregnancy, and reduced menstrual blood loss as a result of the use of oral contraceptives.

Table 2 Causes of iron-deficiency anemia

Underlying disorder	*Site of action*	*Causal factors*
Nutritional deficiency		Low dietary bioavailability
		Unrefined cereal diet
Malabsorption		Gastric surgery
		Clay eating
		Gluten-induced enteropathy
Blood loss	Uterine	Menorrhagia
	Gastrointestinal	Hookworm, schistosomiasis
		Peptic ulcer disease, esophagitis
		Stomach and colorectal cancer
		Angiodysplasia, hereditary telangiectasia
		Aspirin, NSAIDs
		Inflammatory bowel disease
		Diverticulosis, hemorrhoids
	Renal tract	Hemoglobinuria
		Severe hematuria
	Lung	Idiopathic pulmonary hemosiderosis

NSAIDs, nonsteroidal antiinflammatory drugs.

Similarly, increasing awareness of the importance of adequate iron nutrition in early infancy has led to a reduction in the prevalence of iron deficiency in young children. As with adults, improved iron nutrition reflects the effect of several different factors, including the use of iron-fortified infant foods and the provision of supplemental iron when appropriate.

The situation in developing countries is far less satisfactory. Attempts to reduce iron losses or improve the intake of bioavailable iron have had only limited success. Iron supplementation (usually the provision of iron tablets) has been effective in pilot studies, but the inadequacy and cost of distribution systems, as well as poor compliance, have limited the value of this approach as a long-term solution. Nevertheless, supplementation is the preferred method of intervention in severely anemic individuals and during pregnancy.

Increasing the population's intake of bioavailable dietary iron is the only feasible means of improving iron nutrition at the national level. Despite years of research and numerous field trials, this has proved to be extremely difficult to achieve. The traditional diet of people in most developing countries tends to inhibit iron absorption. Dietary customs are not easily modified. In addition, foods that promote iron bioavailability tend to be expensive. Iron

fortification of the diet has also encountered several obstacles. The introduction of iron into the food chain in developing countries is complicated by the difficulty of identifying a suitable vehicle. Most foods are produced at the local level and not processed or distributed through a limited number of centers where the fortificant can be introduced into the food. In addition, the inhibitory effect of vegetable diets on bioavailability tends to reduce the effectiveness of fortification iron. Finally it is often difficult to add iron to dietary items without affecting consumer acceptability. Iron salts that do not alter the appearance or organoleptic and storage properties of foods tend to be poorly absorbed. Despite these formidable obstacles, field trials and targeted national programs have been successful in Chile, South Africa and, more recently, Venezuela. (*See* **Food Fortification.**)

Megaloblastic Anemias

N M F Trugo, Universidade Federal do Rio de Janeiro, Instituto de Quimica, Rio de Janeiro, Brazil

Background

Megaloblastic anemia is characterized by morphological abnormalities of hemopoietic cells that include the formation of abnormally large erythrocyte precursors (megaloblasts) and giant metamyelocytes in the bone marrow, and abnormally large (macrocytic) erythrocytes and hypersegmented neutrophils in the blood. Megaloblastic anemia is caused by a reduction in the rate of DNA biosynthesis, resulting in abnormal nuclear maturation and ineffective erythropoiesis. Folate and cobalamin deficiencies are the most common causes of the impaired DNA synthesis that leads to megaloblastic hemopoiesis; other less common factors are the use of drugs that interrupt DNA biosynthesis and inherited conditions presenting defective enzymes of DNA biosynthesis. Megaloblastic anemia caused by folate and/or cobalamin deficiencies present indistinguishable morphological abnormalities, and will be the main focus in this chapter.

Etiology

Consequences of Folate and Cobalamin Deficiencies

Folate and cobalamin deficiencies are primary causes of megaloblastic anemia. Folate is an essential cofactor involved in many single-carbon transfer reactions in intermediary metabolism, including the synthesis of purine bases, thymidylate and methionine. Folate deficiency thus causes impairment in the DNA synthesis and in the methylation reactions that are dependent on *S*-adenosylmethionine.

Both folate and cobalamin are required for the methyl transfer reaction catalyzed by methionine synthase. In this reaction methionine is recycled by remethylation of homocysteine and simultaneous demethylation of 5-methyltetrahydrofolate to tetrahydrofolate, a source of other folate coenzymes. Methionine synthase requires methylcobalamin as a cofactor. Impairment of this reaction by cobalamin deficiency thus causes a decrease in the availability of 10-formyl-tetrahydrofolate for purine synthesis and of 5,10-methylene-tetrahydrofolate for conversion of deoxyuridylate into deoxythymidylate, which might be explained by 'trapping' of methyltetrahydrofolate that cannot be converted back to the other folate forms, resulting in a decrease of folate coenzymes. An alternative hypothesis is that the impairment of the methionine synthase reaction decreases the supply of formate that would be required for generation of 10-formyl-, 5,10-methenyl- and 5,10-methylene tetrahydrofolate, due to the failure of methionine synthesis and resulting low levels of *S*-adenosylmethionine.

Therefore, deficiencies of both or either of these vitamins affect DNA replication and consequently cell division, especially in rapidly proliferating

tissues. In the bone marrow, the impaired DNA replication causes asynchronous maturation of the nucleus and cytoplasm of cells in the erythroid and myeloid series, with cytoplasmic components being synthesized in excessive amounts during the delay between cell divisions. This results in the enlargement of the precursor cells and the presence of larger than normal circulating erythrocytes and leukocytes, which are characteristic features of megaloblastic anemia.

Besides megaloblastic anemia, cobalamin deficiency also causes a neuropathy characterized by an early demyelination of peripheral nerves, as a result of the impaired methylation of the myelin basic protein, a major constituent of myelin. This is currently explained by the inadequate activity of methionine synthase in cobalamin deficiency, which leads to a reduction in the methylation cycle due to the impaired recycling of *S*-adenosylmethionine. Several evidences indicate that the other enzymatic reaction requiring cobalamin as a coenzyme (5′-deoxyadenosylcobalamin), which is the conversion of methylmalonyl-coenzyme A (CoA) to succinyl-CoA by methylmalonyl-CoA mutase, seems not to be implicated in the neuropathy of cobalamin deficiency. Folate deficiency usually does not lead to this neuropathy, unless the deficiency is prolonged and severe, possibly because the neural tissue concentrates more folate than other tissues and may also have alternative pathways to preserve the supply of *S*-adenosylmethionine when there is folate deprivation. (*See* **Cobalamins**: Physiology; **Folic Acid**: Physiology.)

Causes of Cobalamin and Folate Deficiencies

Deficiencies of cobalamin and folate may result from inadequate intake, increased requirements and impaired utilization, due to several underlying factors that are presented in Tables 1 and 2.

Cobalamin deficiency due to insufficient dietary intake is rare, but may occur in strict vegetarians, since cobalamin is supplied primarily by foods of animal origin. Recommended daily intakes of dietary cobalamin are in the range of 1–2 μg for adults. A normal western diet usually provides an excess of the body requirements for cobalamin, and cobalamin body stores represent a further protection, with an efficient conservation through the enterohepatic circulation.

Among the causes of cobalamin deficiency described in Table 1, the most common is intestinal malabsorption, which can be the result of a decreased production or lack of gastric intrinsic factor, a protein required for cobalamin absorption, as occurs in atrophic gastritis, gastrectomy, and pernicious anemia, an autoimmune disease in which there is production of autoantibodies against intrinsic factor and of autoantibodies that cause destruction of gastric parietal cells. Moreover, hypochlorydria or achlorydria and low pepsin secretion in the stomach affect release of cobalamin from its bound state in food. When this happens, but secretion of intrinsic factor is normal, there is protein-bound cobalamin

Table 1 Causes of cobalamin deficiency

Reduced intake
Strict vegetarianism
Breast-feeding by severely cobalamin-deficient mothers
Malabsorption
Pernicious anemia
Gastric dysfunction caused by gastritis due to *Helicobacter pylori* infection or alcohol consumption
Gastrectomy or gastric bypass
Protein-bound cobalamin malabsorption
Enteropathy: Crohn's disease, celiac disease
Ileal resection
Pancreatic insufficiency
Microbial overgrowth in intestinal stasis and parasitic (fish tapeworm) infestation
Use of drugs such as colchicine, neomycine, omeprazole, or *p*-aminosalicylic acid
Congenital absence or dysfunction of intrinsic factor
Lack of ileal receptor for intrinsic factor
Impaired utilization
Congenital transcobalamin II deficiency
Inactivation of cobalamin by prolonged exposure to nitrous oxide
Decreased conversion to active coenzyme forms of cobalamin due to enzyme defect

Table 2 Causes of folate deficiency

Reduced intake
Malnutrition
Alcoholism
Intake of foods poor in folate (raw; processed)
Increased demands
Pregnancy
Rapid growth rate (prematurity; early infancy; adolescence)
Diseases associated with increased cell turnover (hemolytic anemias; leukemia; chronic diseases; exfoliative dermatitis; severe infection)
Excessive losses (hemodialysis; liver disease)
Malabsorption
Enteropathy: Crohn's disease, celiac disease, tropical sprue
Intestinal resection
Chronic giardiasis
Bacterial overgrowth
Use of sulfasalazine and of anticonvulsive drugs (phenytoin, phenobarbital)
Impaired utilization
Congenital abnormalities in enzymes of folate metabolism (5,10-methylene tetrahydrofolate reductase; methionine synthase; di-hydrofolate reductase)
Use of drugs such as methotrexate and oral contraceptives
Alcoholism

malabsorption, because cobalamin from food is poorly absorbed whereas absorption of ingested synthetic cobalamin is not affected.

Differently from cobalamin, dietary inadequacy is a common cause of folate deficiency (Table 2), since folate intake is not usually in great excess of nutritional requirements and the body reserves are meager. Recommended daily intakes of folate are in the range of 0.15–0.20 mg for adults, 0.4 mg for women of reproductive age, and 0.6 mg for pregnant women. Diets poor in folate are characterized by a predominance of starches and grains (white bread, white maize meal, polished rice, etc.) and overcooked vegetables, and insufficient amount or lack of foods of animal origin, dark green vegetables, fresh or lightly cooked, and fruits, as occurs in some parts of Africa and India. In developed countries, nutritional folate deficiency has been found in elderly persons living on a marginal subsistence diet, and in people on very low incomes. Alcoholism may cause folate deficiency, not only because of the reduced folate intake, but also due to altered folate metabolism and interference with the folate enterohepatic cycle.

Intestinal malabsorption can also be a cause of folate deficiency and may be associated with ineffective food folate deconjugation prior to absorption as occurs in subtotal gastrectomy and with the use of sulfasalazine, as well as with ineffective absorption due to extensive intestinal resection, tropical sprue, gluten-sensitive enteropathy, chronic giardiasis, and the use of drugs such as anticonvulsants (phenytoin and phenobarbital).

Due to the high folate requirements, periods of intense cell proliferation such as pregnancy, early infancy, and adolescence predispose to folate deficiency. Increased requirements of folate may also occur in diseases such as hemolytic anemia, malignant metastatic tumors, and leukemias. Folate deficiency may also occur with the use of drugs that are folate antagonists and impair folate utilization, such as those used for cancer chemotherapy (methotrexate) and immunosuppression, as well as antiprotozoal (pyrimethamine) and antibacterial (trimethroprim, pentamidine) drugs.

A genetically carried impairment in the folate utilization, due to one variant of 5,10-methylenetetrahydrofolate reductase that has a lower affinity for folate, and which is apparently common in many populations, increases folate requirements. Another genetic problem related to 5,10-methylenetetrahydrofolate reductase is its deficient production in some patients, leading to hyperhomocysteinemia, homocystinuria, and neurological disturbances, but without any hematological abnormality. (*See* **Cobalamins**: Physiology; **Folic Acid**: Physiology.)

Morphological and Clinical Aspects

The reduction in DNA biosynthesis in the bone marrow delays the development of the erythrocytes, leading to megaloblastosis of erythocyte precursors and macrocytosis of erythrocytes, and reduces their number, leading to anemia. The megaloblastic anemia is morphologically indistinguishable in the deficiency of either vitamin. The changes in the erythroid and myeloid cells result in pallor and weakness.

In the bone marrow, there is an overt megaloblastosis and a reduction in the ratio of myeloid to erythroid cells. Megaloblasts present a characteristic chromatin pattern with a lacy appearance. There are more immature erythroblasts than mature ones, due to selective death of the latter. In the myeloid series, giant and abnormally shaped metamyelocytes (granulocyte precursors) are found. Megakaryocytes (platelet precursors) may also be enlarged, with increased numbers of nuclear lobes.

In blood, erythrocytes are large (macrocytic) and often oval in shape, and some may be fragmented and irregularly shaped. Neutrophilic leukocytes often have abnormal nuclei, with an increase in the number of nuclear segments (hypersegmentation). There is an increased mean corpuscular volume of red cells, and decreased erythrocyte, reticulocyte, leukocyte, and platelet counts in peripheral blood, due to ineffective erythropoiesis that results in cell destruction before maturity. The decrease in erythrocyte counts leads to low hemoglobin values, as the deficiency becomes more severe.

Besides the hemopoietic system, the epithelial cells of gastrointestinal, respiratory, urinary, and female genital tracts, and the gonads are also affected. The decreased replication of enterocytes in the small intestine leads to villus atrophy that, if severe enough, can cause malabsorption. Other symptoms, such as glossitis (sore tongue), cheilitis (sore lips), diarrhea, and weight loss may thus result from impaired proliferation of epithelial cells. Infertility and impotence may also be present.

Cobalamin deficiency may also result in a complex neurologic syndrome, manifested with or without megaloblastic anemia, including peripheral neuropathy, subacute combined degeneration of the spinal cord, and optic atrophy. Common neurological symptoms are paresthesias, ataxia, numbness, impairment of memory, depression, dementia, and psychosis. Folate deficiency can occasionally cause mental changes, such as mental slowing, depression, dementia, and other neurologic syndromes.

There are, however, variations in the hematologic and neurologic expressions of cobalamin and folate deficiencies among patients. In children, for instance,

hereditary and acquired deficiencies result more often in developmental delay and neurological dysfunctions than in megaloblastic anemia. Also, genetic and acquired characteristics of ethnic and racial groups seem to impose variations related to cobalamin deficiency, which could have implications in diagnosis and issues of public health.

During pregnancy, risks from folate deficiency include poor pregnancy outcome, such as prematurity and low birth weight. In addition, there is considerable evidence that folate is a key factor for prevention of neural tube defects (NTD; congenital birth defects such as spina bifida and anencephalus). Although NTD have multiple etiologies, maternal folate supplementation during the periconceptional period can reduce both their occurrence and recurrence. The first 3 weeks after conception represent a crucial period because closure of the neural tube occurs about the 23rd day. Although the underlying mechanism for the folate role in the prevention of NTD is not known, there are indications that in the vast majority of cases the problem is not of maternal dietary deficiency, and may be due to a maternal and/or fetal defect in folate metabolism or transport into the cells, that can be overcome by maternal supplementation. An impairment in homocysteine metabolism seems to be involved in NTD manifestation. Although NTD may affect pregnancies in women who present a wide range of folate erythrocyte levels, from low to normal, the risk is strongly reduced when status is improved, even in those women who do not present low erythrocyte folate levels. Cobalamin status, not necessarily in the deficient range, is also an independent risk factor for NTD. (*See* **Cobalamins**: Physiology; **Folic Acid**: Physiology; **Pregnancy**: Maternal Diet, Vitamins, and Neural Tube Defects.)

Laboratory Diagnosis

Hematology

An elevated blood mean corpuscular volume (MCV) due to macrocytosis is suggestive of megaloblastosis. In cobalamin and folate deficiencies the MCV tends to increase before the decrease in the hemoglobin levels. The increase in MCV may not be present when there is concurrent microcytosis due to iron deficiency and thalassemia. Examination of a bone marrow aspirate may be useful for the diagnosis of megaloblastic anemia, since macrocytosis can be due to other conditions (chronic alcoholism, liver disease, etc.) that do not cause changes in the bone marrow. However, megaloblastosis can also be due to the use of anticancer drugs, mainly methotrexate, which impair folate metabolism. The presence of hypersegmented neutrophils, with five or more nuclear lobes, in the peripheral blood smear is a sensitive indicator of megaloblastic anemia, and is useful for the diagnosis of folate and cobalamin deficiencies when erythrocyte changes are masked by coexistent iron deficiency and when folate and cobalamin deficiencies are still subclinical, because hypersegmentation occurs earlier than the anemia and macrocytosis.

Biochemical Tests

A range of biochemical tests are used to investigate whether megaloblastic anemia is due to folate or cobalamin deficiency. Biochemical indicators of either vitamin status corresponding to different degrees of depletion are used for this purpose, despite the problems in establishing 'cut-off' levels.

Serum (or plasma) cobalamin may be a poor indicator of tissue levels, but levels lower than 200 pg ml^{-1} probably indicate a deficiency state of cobalamin. About one-third of patients with folate deficiency present low serum cobalamin levels, which return to normal with folate therapy. Low serum folate (less than 3 ng ml^{-1}) is an indicator of negative balance that, if persistent, can result in tissue depletion, which is assessed by determination of erythrocyte folate. Values of erythrocyte folate of less than 150 ng ml^{-1} are indicative of an initial folate deficiency (marginal status) and those less than 120 ng ml^{-1} indicate established deficiency. These three indicators are the most widely used to assess cobalamin and folate status. They can be measured by microbiological assays or by competitive protein-binding radioassays, but since values vary between assay procedures, the range of normal values should be established for each procedure.

Once established whether megaloblastic anemia is due to folate or cobalamin deficiency, or to other causes, the underlying causes of these deficiencies should also be investigated. For instance, dietary assessment is useful to detect whether dietary insufficiency of either vitamin is an underlying factor.

Other biochemical and functional tests provide valuable information regarding the nutritional status of folate and cobalamin and the underlying causes of deficiency. Serum homocysteine is a sensitive indicator of intracellular folate and cobalamin, and it is increased when depletion of either vitamin occurs because they are required for conversion of homocysteine to methionine.

The deoxyuridine suppression test in bone marrow cells or in lymphocytes assesses the thymidylate synthesis from deoxyuridylate, which requires 5,10-methylene tetrahydrofolate as a coenzyme and is impaired in folate and cobalamin deficiencies. Exogenous deoxyuridine added to normal cells

suppresses the incorporation of subsequently added radiolabeled thymidine to DNA due to conversion of the added deoxyuridine to thymidylate within the cell. In cells from deficient patients, suppression by deoxyuridine is less efficient due to blockage of this conversion. Folate and cobalamin deficiencies can be distinguished by this test through its correction with the respective vitamins.

Determination of serum holohaptocorrin (cobalamin-carrying haptocorrin), the cobalamin storage glycoprotein, can be used to assess cobalamin body stores. Measurement of holotranscobalamin II, the cobalamin transport protein to tissues, may also be used, because it falls below the normal range before serum cobalamin does. The increase of urinary and serum methylmalonic acid concentrations indicates cobalamin deficiency, because of the impairment in the methylmalonyl-CoA mutase reaction, which requires adenosylcobalamin as a cofactor.

The Schilling test is used to detect cobalamin malabsorption. This test is performed usually in two stages: (1) an oral dose of radiolabeled cobalamin is given and its percentage of excretion in urine during a 24-h collection is determined, after flushing it into urine with a large parenteral dose of unlabeled cobalamin; (2) another test is performed 3–7 days later, with an oral dosing of radiolabeled cobalamin and intrinsic factor. There are several interpretations of the Schilling test regarding the causes of malabsorption in cobalamin-deficient patients, depending on the results in each of the two stages. For instance, when the result is abnormal in the first stage, but normal in the second, pernicious anemia, or any other cause of absence, abnormal or insufficient amount of intrinsic factor, is present. A normal Schilling test in these patients may indicate dietary deficiency or protein-bound cobalamin malabsorption. Pernicious anemia can also be diagnosed by the presence of parietal cell autoantibodies and of antiintrinsic factor autoantibodies in serum.

The biochemical tests described above can all be useful to detect folate and cobalamin deficiencies at earlier stages, the so-called subclinical or marginal deficiencies, well before the manifestation of the clinical and overt signs of deficiency. The recognition of the atypical and subclinical deficiency states is an important step towards preventing not only the progression of deficiency to the clinical manifestations, but also to avoid the consequences that even marginal deficiencies of both vitamins can cause.

Folate subclinical deficiency has been associated with increased risk for dysplasia and various cancers, such as in the uterine cervix, bronchus, and colon, due to uracil misincorporation into DNA, impaired chromosome repair, and DNA strand breaks. Other adverse associations are immunological changes; birth defects, such as the NTD; and abnormalities of the homocysteine metabolism, leading to hyperhomocysteinemia. This last condition is an independent risk factor for cerebral, coronary, and peripheral vascular diseases, and occurs in both folate and cobalamin subclinical deficiencies. (*See* **Cobalamins**: Physiology; **Folic Acid**: Physiology.)

Prevalence

Recent and comprehensive worldwide epidemiological data on megaloblastic anemia and on subclinical folate and cobalamin deficiencies, especially in tropical and developing countries, the ones most likely to be affected by these problems, are scarcely available. Most data concerning the prevalence and distribution of these deficiencies were obtained more than two decades ago.

Those earlier studies showed that nutritional folate deficiency had a worldwide distribution, differing greatly in severity, with the subclinical, nonanemic forms being predominant, and was, in general, a primary cause of megaloblastic anemia. It affected mainly pregnant women in the third trimester of pregnancy, since their increased folate requirements may be difficult to achieve through the habitual diet, especially in low socioeconomic groups. Megaloblastic anemia due to dietary folate deficiency was reported to be highly prevalent in Asian countries such as India, Burma, Singapore, and Malaysia, and in African countries, affecting up to 25% of nonsupplemented pregnancies in certain parts of Asia, Africa, and Latin America, and 2.5–5.0% in developed countries. These values were higher (up to 60% in developing countries) when bone marrow aspirates were used for the diagnosis. Subclinical folate deficiency was estimated to affect up to one-third of the pregnant women on a global scale. The widespread use of iron and folate supplements substantially reduced the prevalence of folate deficiencies during pregnancy. Presently, the patterns of folate deficiency may still be the same, but scattered data indicate a possible decline in the incidence and prevalence of megaloblastic anemia, with a relative increase of subclinical deficiencies. In developing countries subclinical deficiency is high in nonsupplemented pregnancies. Folate deficiency, especially subclinical, is highly prevalent in the elderly.

Cobalamin deficiency due to inadequate intake has been mostly reported in strict Hindus from the Indian subcontinent. Recent studies show that cobalamin deficiency is more prevalent in other countries than formerly believed, but it is mostly due to malabsorption. In developed countries, malabsorption of

cobalamin affects mainly elderly populations. In northern Europe, cobalamin malabsorption is mainly due to pernicious anemia, affecting 1–2.5% of the population over the age of 60. Its frequency in caucasians is higher in women than in men (about 1.5:1), and increases with increasing age, being rare before 30 years of age. There is recent indication that cobalamin malabsorption due to pernicious anemia, and not folate deficiency, may be the main underlying factor of megaloblastic anemia in sub-Saharan Africa, as shown in Zimbabwe, where 86% of patients with megaloblastic anemia had cobalamin deficiency mainly due to pernicious anemia. In rural Mexico, a high prevalence of low levels of cobalamin in plasma of preschool children and in plasma and milk of lactating anemic women has been reported and seems to be caused by malabsorption.

Prevention and Treatment

The prevention and treatment, not only of clinical manifestations of cobalamin and folate deficiencies, but also of the subclinical deficiencies are important to avoid their consequences. The association of subclinical deficiencies of these vitamins with adverse conditions, as mentioned in a previous section, provides support for the case of improving the nutritional status of both vitamins in individuals in the earlier stages of deficiency progression.

The consumption of foods rich in folate and cobalamin is the best prophylaxis for deficiencies of nutritional origin of both vitamins. However, in conditions of increased requirements, such as pregnancy, the adequate intake of food folate may be difficult to attain. Therefore, due to the overall high incidence of folate deficiency in pregnant women, folate supplements ($0.4\,mg\,day^{-1}$) are usually recommended in the latter half of pregnancy during prenatal care. Since folate supplementation in the periconceptional period results in a decreased risk of NTD-affected pregnancies, in developed countries such as the USA, Canada, UK, and Australia it is recommended that all women of child-bearing age consume $0.4\,mg\,day^{-1}$ of folic acid. For women with a prior confirmed or suspected NTD-affected pregnancy, a supplement of 4 mg of folic acid is recommended if they might possibly become pregnant.

Possible public health strategies for supplying women with folate in the periconceptional period are the use of supplements by all women of child-bearing age, changes in food habits, and food fortification with folate. This last alternative, however, has raised concern since a higher folate intake through fortified foods by the general population could be detrimental to individuals with cobalamin deficiency. Although the elderly should benefit from increased folic acid intake added to foods, in those with cobalamin deficiency high intakes of folic acid could contribute to the development of neurologic abnormalities.

In the case of strict vegetarians, supplements or fortified foods providing cobalamin should be used. Folate supplements may also be recommended for people with sickle-cell anemia.

Megaloblastic anemia due to folate deficiency is usually treated with oral syntethic folic acid ($5\,mg\,day^{-1}$) for 2 months, or more depending on the etiology. In the case of malabsorption, parenteral folinic acid (5–10 mg) administered daily may also be used.

Treatment of megaloblastic anemia due to cobalamin deficiency resulting from low intake may be carried out with oral administration of cyanocobalamin or intramuscular injections of $1\,mg\,day^{-1}$ for 1 week, followed by the use of oral supplements or fortified foods containing 2 μg cyanocobalamin if the diet cannot be improved. When megaloblastic anemia is due to malabsorption, intramuscular injections of 1 mg hydroxocobalamin are given daily for 1 month, followed by monthly or bimonthly injections for life in the case of pernicious anemia. In the cases where the causes of cobalamin deficiencies are abnormal transport and utilization, daily doses of 1 or 5 mg are administered indefinitely. For patients with neurological manifestations due to cobalamin deficiency, 1 mg of cyanocobalamin every 2 weeks for 6 months is recommended. In the case of cobalamin deficiency, folic acid supplementation may correct megaloblastic hematologic changes, but allows the development of neurologic abnormalities, because synthetic folic acid, unlike dietary folate, is reduced directly to tetrahydrofolate and not through the methionine synthase reaction.

In any case, treatment of the primary causes of folate and/or cobalamin deficiencies should concomitantly be pursued.

Background

Anemia is a condition where there is a reduction in the hemoglobin content, size, and/or number of erythrocytes. Nutritional anemias may result from various vitamin and mineral, as well as some macronutrient deficiencies, but the most common are megaloblastic anemia, resulting from folic acid or vitamin B_{12} deficiency, and microcytic, hypochromic anemia, resulting from iron (Fe) deficiency. The fat-soluble vitamins A and E, and water-soluble vitamins B_2 (riboflavin), B_6 (pyridoxine), and C (ascorbic acid) have also been implicated as causes of anemia in humans. In addition, deficiencies of the microminerals copper (Cu) and zinc (Zn), essential to erythropoiesis, can cause anemia. Protein–energy malnutrition (PEM), a multifaceted nutritional condition, is also associated with anemia, but this is often not classified as a true nutritional anemia, since the role of PEM is physiologic rather than pathologic. Essential fatty acid deficiency may also play a role in the development of anemia. These nutritional associations with anemia are summarized in **Table 1**.

The two criteria for defining a nutritional anemia are that: (1) deficiency or lack of a specific nutrient must cause the anemia, and (2) replacement of that specific nutrient must correct the anemia. Anemias resulting from the aforementioned deficiencies of vitamins and minerals may not directly conform to these two criteria, because isolated deficiencies are rare, and an anemia may not be directly related to a single nutrient deficiency, but most often is complicated by other nutrient deficiencies.

Fat-soluble Vitamins

Vitamin A

Vitamin A deficiency, or hypovitaminosis A, is a prevalent nutritional problem in both developing and developed countries, especially among children. The biological interactions between vitamin A deficiency, iron metabolism, hematopoiesis, and the development of anemia are clearly established. However, polycythemia, as well as altered water balance leading to dehydration may mask anemia resulting from vitamin A deficiency.

Morphological changes, such as poikilocytosis and anisocytosis in erythrocytes in peripheral blood, may result from vitamin A deficiency. Subjects with vitamin A deficiency often develop microcytic, hypochromic anemia with elevated storage of Fe in the liver and other reticuloendothelial systems. The later finding suggests that the role of vitamin A in erythropoiesis of mobilizing or releasing Fe form the liver and adequate Fe in diet are not sufficient to correct or prevent anemia. Vitamin A deficiency may also decrease transferrin with subsequent reduction in Fe transport. Experimental studies have demonstrated this in subjects with vitamin A deficiency who respond well to vitamin A supplementation, but are refractory to Fe administered to correct anemia. Results from randomized clinical trials document that vitamin A supplementation alone or in combination with Fe supplementation improves anemia. Vitamin A supplementation alone yields a significant increase in serum retinal and Fe, blood hemoglobin (Hb), hematocrit (Hct), and erythrocyte, and transferrin saturation without affecting the total iron-binding capacity and serum ferritin. However, in contrast to Fe-deficiency anemia, serum ferritin levels remain normal, and vitamin A supplementation does not alter the absorption of Fe in the intestines. This implies that vitamin A does not inhibit the absorption of Fe, and that a high liver

Table 1 Selective nutrients and characteristic features of anemias resulting from deficiencies

Nutrient deficiency	*Peripheral blood*	*Bone marrow*
Vitamin A	Microcytic	Not known
Vitamin E	'Distorted and fragmented' RBCs, anisocytosis, poikilocytosis, polychromatophilia, spherocytosis, Heinz bodies	Erythroid hyperplasia
Vitamin B_2	Normocytic, normochromic, sideroblastic	Erythrocytic hopoplasia, increased myeloid erythroid ratio, pronormoblast
Vitamin B_6	Hypochromic, microcytic, sideroblastic	Erythroid hyperplasia, basophilic normoblast
Vitamin C	Normocytic normochromic	Not known
Copper	Normocytic, microcytic or macrocytic	Cytoplasmic vacuoles in myeloid and erythroid precursors, ringed sideroblast
Zinc	Microcytic, normochromic or macrocytic	Ringed sideroblast, cytoplasmic vacuolization in both myeloid and erythroid precursors
Protein	Normochromic, normocytic, variations in size and shape	Normo- or hypocellular, reduced erythroid/myeloid ratio
Essential fatty acid	Aplastic	Not known

concentration of Fe is not the result of hemolysis secondary to the increased erythrocyte fragility associated with vitamin A deficiency. Rather, experts in this field of research speculate that vitamin A may improve the metabolic utilization of Fe.

Several mechanisms of vitamin A action have been proposed in erythropoiesis, including mobilization of Fe from the tissue stores (reticuloendothelial system) through increased receptor synthesis; an influence on the proliferation or differentiation of red blood cells; and facilitation of Fe absorption by forming a complex with nonheme Fe. It has also been noted that vitamin A deficiency increases one's susceptibility to infection, leading to diminished erythropoiesis.

Vitamin A deficiency may also impair the utilization of other nutrients crucial for erythropoiesis. The relationship between vitamin A and Zn has been documented in view of the role of vitamin A in the synthesis of Zn-dependent retinal-binding protein (RBP), and absorption and transport of Zn. In some instances, the association between RBP and hemoglobin synthesis is explained in children and pregnant women.

Vitamin E

Vitamin E, primarily α-tocopherol, acts as a free-radical scavenger and natural antioxidant to protect cell membranes against free-radical reactions or lipid peroxidation. Normal healthy individuals who consume a nutritionally adequate diet rarely develop vitamin E deficiency, and no overt deficiency symptoms have been described. Table 2 describes some circumstances that may result in a low vitamin E level in humans.

In animals, vitamin E deficiency-associated anemia was induced experimentally, with Dinning and Day in 1957 first describing vitamin E deficiency anemia in rhesus monkeys. The monkeys developed a very low reticulocyte count that was reversed by vitamin E supplementation, with subsequent correction of the anemia. Subsequent prolonged vitamin E deficiency studies in similar animals revealed normochromic and normocytic (occasional macrocytic) anemia in peripheral blood, but bone marrow examination showed hyperplasia of erythroid cells and the presence of nuclear chromatin abnormalities with multinucleated forms. A high rate of red blood cell hemolysis has also been reported. It was presumed that all these changes were the result of an abnormal erythropoiesis, but ineffective erythropoiesis was eliminated as the primary cause of anemia, since the stability of reduced glutathione, osmotic fragility, and serum iron were normal.

Table 2 Causes of vitamin E deficiency

Congenital	i. Cystic fibrosis ii. Inherited hemolytic anemia iii. Biliary cirrhosis iv. Abetalipoproteinemia
Acquired	i. Liver disease ii. Gallbladder disease iii. Pancreatitis iv. Sprue v. Inflammatory bowel disease vi. Extensive small bowel resection vii. Malabsorption viii. Steatorrhea
Premature infants	Poor absorption and metabolism of nutrients resulting from underdeveloped systems
Infants and children with protein–energy malnutrition	Poor intake, transport, metabolism, and storage of nutrients.

The relationship between vitamin E deficiency and anemia in humans is less conclusive, since no clinically and hematologically well-defined anemia has been reported in humans. It has been theorized that vitamin E deficiency may cause hemolytic anemia in humans by affecting the hematopoietic system. It is widely accepted that erythrocytes are susceptible to membrane damage in premature infants with vitamin E deficiency because of high lipid peroxidation. Increased erythrocyte fragility, when exposed to hydrogen peroxide (H_2O_2), is considered to be an index of tissue vitamin E deficiency, as the consistent inverse relationship between serum tocopherol concentration and degree of H_2O_2 hemolysis has been established. For example, it has been shown that a serum tocopherol level $< 0.2\,mg\,dl^{-1}$ correlated with a mean H_2O_2 fragility of about 90%. In 1952, increased hemolysis of red blood cells in vitamin E-deficient premature infants was observed when the cells were exposed to H_2O_2. However, *in-vivo* experiments have not documented any significant damage to red blood cells.

In 1967, Oski and Barness first described vitamin E deficiency anemia in a group of premature infants 6–10 weeks of age. Peripheral blood smears showed 'distorted and fragmented' erythrocyte morphology characterized by anisocytosis, poikilocytosis, polychromatophilia, fragmented red cells, and a few mild spherocytosis and Heinz bodies. Examination of the bone marrow of these premature infants revealed erythroid hyperplasia. A low serum concentration of vitamin E ($< 0.5\,mg\,dl^{-1}$), low hemoglobin level ($7.6 \pm 1\,g\,dl^{-1}$), and increased sensitivity of the erythrocytes to hemolysis when exposed to dilute H_2O_2 solution have also been reported. All these hematological abnormalities were corrected by vitamin E supplementation. Other researchers have also reported vitamin E deficiency anemia among premature infants (body weight $< 1500\,g$) with moderately high reticulocyte counts that responded to vitamin E therapy, suggesting an anemia that is hemolytic in nature.

It has been reported that plasma levels of vitamin E are similar in both premature and mature infants, and a linear relationship has been described between body tocopherol content and body weight during gestation. Some studies have found shortened red blood cell survival in vitamin E deficient premature infants and adults, suggesting the presence of hemolytic anemia. Several other studies have observed that, although premature infants and adults with vitamin E-deficient diets did not develop anemia, they experienced decreased plasma tocopherol levels and increased erythrocyte susceptibility to H_2O_2.

Convincing results from studies involving patients with sickle-cell anemia (SCA) also support the association between vitamin E deficiency and anemia. One of the clinical manifestations of SCA is chronic hemolytic anemia. Among sickle-cell patients who usually experience impaired vitamin E absorption, increased susceptibility of sickle erythrocytes to peroxidation has been demonstrated, partly due to abnormal membrane phospholipid organization and low serum and erythrocyte vitamin E deficiencies. It has been documented that preincubation of sickle erythrocytes with vitamin E may significantly reduce susceptibility to oxidation.

It is also plausible that vitamin E plays a role in erythropoiesis. The potential role of vitamin E in erythropoiesis has been highlighted in studies conducted in Uganda, Jordan, and Thailand on protein–energy-malnourished subjects who developed anemia and responded to vitamin E supplementation. In contrast, subjects in India and West Africa with similar deficiencies did not respond to vitamin E supplementation. Chronic vitamin E deficiency is found among patients with cystic fibrosis, biliary atresia, biliary cirrhosis, sprue, pancreatitis, extensive small bowel resection, inflammatory bowel disease, and other malabsorption syndromes without any evidence of related anemia or ineffective erythropoiesis.

In summary, based on currently available information, there are several plausible mechanisms for hemolytic anemia resulting from vitamin E deficiency, such as increased oxidation of erythrocyte cell membranes with increased erythrocyte susceptibility to fragility. There is also the promotion of free radical generation by iron and hemoglobin in vitamin E deficiency, with free radicals acting as potent catalysts for erythrocyte lipid peroxidation.

Water-soluble Vitamins

Vitamin B_2

The two biologically active coenzyme forms of vitamin B_2 (riboflavin) are flavin mononucleotide and flavin adenine dinucleotide. The latter is required for red blood cell glutathione reductase activity, and so a deficiency of riboflavin may lead to anemia. Anemia secondary to riboflavin deficiency was initially observed among animals as hypoplastic anemia with fatty infiltration of the bone marrow and normocytic hypochromic anemia in riboflavin-deficient dogs and calves, respectively. In humans, anemia resulting from riboflavin deficiency has only been reported among patients receiving medications such as galactoflavin, ouabain, theophylline, penicillin, probenecid, and chlorpromazine, which decrease the absorption or metabolism of riboflavin. This anemia

is characterized in peripheral blood smears by red blood cell morphology described as normocytic and normochromic. However, in the bone marrow, there is marked erythrocytic hypoplasia with increased myeloid erythroid ratio, pronormoblasts with cytoplasmic and nuclear vacuoles, and a marked decrease in normoblasts. Reticulocytopenia is also noted. Riboflavin supplementation results in a prompt decrease in the myeloid erythroid ratio and the disappearance of anemia.

New research has identified two paths by which flavoproteins may be linked to sideroblastic anemia. Flavin monooxygenase is an intracellular ferrireductase involved in the reduction of iron (ferric to ferrous) so that it can be incorporated into heme by ferrochetalase. Decreased flavin monooxygenase can result in accumulation of ferric iron in the mitochondria of erythroid cells, the production of ringed sideroblasts, and impaired hemoglobin synthesis. This may lead to sideroblastic anemia and erythropoietic hemochromatosis. Another flavoprotein, pyridoxine phosphate oxidase, is essential in the formation of pyridoxal 5′-phosphate (PLP) from pyridoxine and pyridoxamine phosphate. The riboflavin link to sideroblastic anemia in this case is therefore indirectly through its role in the activation of vitamin B_6.

Vitamin B_6

PLP, the most active coenzyme form of vitamin B_6 is essential for numerous metabolic reactions, including the initial regulatory step of heme biosynthesis involving δ-aminolevulinic acid, the precursor of porphobilinogen (Figure 1).

The typical features of anemia resulting from pyridoxine deficiency have been described as hypochromic, microcytic, and hyperferremic, with bone marrow showing erythroid hyperplasia and maturation arrest with predominantly basophilic normoblasts. Malnourished patients with hypochromic anemia respond to vitamin B_6 supplementation but are unresponsive to iron therapy. Complete recovery from anemia with normal hemoglobin levels can be achieved by adequate pyridoxine therapy, but not by Fe or other vitamins or minerals.

Some researchers have tried to illustrate that the association between pyridoxine and the development of sideroblastic anemia involves the defective conversion of pyridoxine to PLP. However, there was no evidence of low erythrocyte pyridoxine kinase among patients with sideroblastic anemia or there was no deficiency of vitamin B_6. The relationship between pyridoxine deficiency and sideroblastic anemia therefore warrants further investigation.

Vitamin B_6 deficiency has also been reported among patients with sickle cell anemia, who responded well to PLP supplementation. PLP binds specifically to the amino terminus of the β chain of deoxyhemoglobin, and high levels of PLP may be an active inhibitor of erythrocyte 'sickling' *in vitro*. In addition, PLP may increase the affinity of hemoglobin-S to oxygen and, at high concentrations, inhibits the gelation of deoxyhemoglobin-S and reduces the number of sickled erythrocytes. However, *in-vivo* studies have not proven that vitamin B_6 supplementation increases red blood cell counts or improves hemoglobin status.

Although isolated vitamin B_6 deficiency is rare, some populations such as users of some oral contraceptives, amphetamines, isoniazid, chlorpromazine, and reserpine, as well as alcoholics have developed an anemia that can be easily corrected by therapeutic doses of vitamin B_6.

Vitamin C

Although anemia is commonly observed among patients with the vitamin C deficiency disease scurvy, the direct role of vitamin C or ascorbic acid in hemopoiesis is not well documented. Usual hematological findings in this case are normocytic, normochromic anemia with reticulocytosis, which can be corrected, with an accompanying rise in hemoglobin concentration, by vitamin C supplementation.

Vitamin C deficiency may be involved indirectly in the development of anemia through its relation to folic acid and Fe metabolism. It is well established that vitamin C increases the bioavailability of Fe in foods and facilitates intestinal Fe absorption, particularly nonheme Fe. Vitamin C also enhances the utilization of heme Fe and facilitates ferritin synthesis. It has been documented that vitamin C augments the translation of ferritin mRNA by maintaining the Fe-responsive element-binding protein in its active form. In addition, *in-vitro* experiments have shown that vitamin C prevents degradation and enhances the stability of ferritin. A proposed, but indirect, role of vitamin C in erythropoiesis is that vitamin C facilitates the turnover of Fe in the body.

Vitamin C is also required for the maintenance of folic acid reductase, which converts folic acid to its active tetrahydrofolate form. Failure to synthesize tetrahydrofolate leads to megaloblastic anemia. Occasional megaloblastic cells have been observed among scurvy patients.

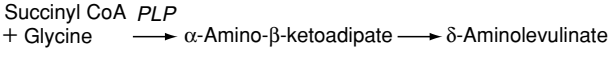

Figure 1 Role of pyridoxal phosphate in the biosynthesis of δ-aminolevulinate.

Minerals Implicated in Anemias

Copper

The essential trace element copper (Cu), is widely distributed in commonly eaten foods, and deficiency of this mineral is extremely rare in people who maintain adequate and recommended caloric intakes. The indispensable role of Cu in humans was first documented during the 1960s among anemic children in Peru, who were refractory to iron (Fe) but responsive to Cu supplementation. Subsequent studies have established that Cu is essential for red and white blood cell maturation and Fe transport.

Cu is a component of several metalloenzymes called the cuproenzymes, with ceruloplasmin (Cp) being the most studied. More than 90% of the body's Cu is found as Cp, and about 60% of the Cp in red blood cells, is bound to superoxide dismutase. Cu-deficiency anemia is thought to result from reduced Cp activity, resulting in impaired iron mobilization. The other Cp-associated enzymes whose impaired function may result in anemia include ferroxidase (which converts Fe^{2+} to Fe^{3+}), ferrochelatase and cytochrome aa_3. Ferroxidase is vital in the incorporation of Fe into circulating transferrin, so that decreased Cp results in poor ferroxidase activity, and Fe, being trapped in the reticuloendothelial system, is unavailable for erythropoiesis. Decreased ferrochelatase and cytochrome aa_3 activity are associated with poor heme synthesis owing to decreased reduction of Fe^{2+} in the mitochondria and poor incorporation of iron into protoporphyrin IX.

Cu deficiency may be acquired easily as a result of an imbalance between body requirements and dietary Cu supply as well as a high zinc intake. In 1956, Sturgeon and Brubaker first described Cu-deficiency anemia in infants. Under normal conditions, liver stores provide adequate amounts of Cu to comply with the infant's need during the first 5 months of life. Acquired Cu deficiency in premature infants is well documented because of a small liver size, low Cu deposits in the liver, and increased need due to the high growth rate. Healthy infants who are fed exclusively cow's milk are prone to Cu deficiency because of the low Cu content and poor bioavailability of Cu from cow's milk. Individuals who receive total parenteral nutrition may also develop Cu deficiency. Table 3 presents several causes of acquired Cu deficiency in humans.

The most common clinical manifestations of acquired Cu deficiency are anemia and pancytopenia observed in both animals and humans. A wide range of morphologic changes in peripheral blood smears and bone marrow biopsies have been reported.

Table 3 Etiology of acquired copper deficiency in humans

Decreased storage in liver	Premature infants
Decreased supply	i. Total parenteral nutrition
	ii. Infants fed cow's milk only
Increased requirements	High growth rate
	i. Celiac disease
	ii. Tropical and nontropical sprue
	iii. Cystic fibrosis
	iv. Short bowel syndrome
	v. Intestinal resection
Decreased absorption	vi. Diarrhea
	vii. Abnormal bile loss
	viii. Intestinal fistula
	ix. High zinc intakes
	x. High iron intakes
	xi. High vitamin C intakes
	xii. Fructose and other refined sugars
Interactions with drugs	i. Penicillamin
	ii. High alkali therapy

The red blood cells can be normo- or macrocytic, dimorphic, and hypochromic. A low reticulocyte count and bone marrow iron content, as well as hypoferremia may exist. Morphological findings in bone marrow cytology include megaloblastic changes with two consistent findings – cytoplasmic vacuoles in the myeloid and erythroid precursors, and the maturation arrest of the myeloid precursors with the appearance of ringed sideroblasts. However, patients with Cu deficiency may not develop megaloblastic changes or there may be the absence of sideroblasts in bone marrow. These changes are easily reversed by Cu supplementation, but refractory to Fe therapy.

Three mechanisms have been proposed for these clinical/morphological manifestations, including reduced Cp activity leading to defective Fe mobilization/transporation. First, even in the presence of normal Fe stores, Fe transfer from macrophages and hepatocytes to plasma is impaired, resulting in hypoferremia. Second, Fe cannot be incorporated into heme and accumulates in the cytoplasm, producing sideroblasts. Third, there is shortened erythrocyte survival as a result of membrane defects secondary to decreased superoxide dismutase activity.

Zinc

The trace element zinc (Zn) functions in several biochemical reactions by way of Zn metalloenzymes. Although several pathological conditions have been related to Zn deficiency in humans, at present, there is no evidence that isolated Zn deficiency causes anemia. In iron depletion, Zn protoporphyrin (ZPP) is formed, and although it is able to bind to heme sites

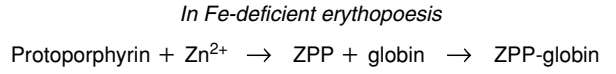

Figure 2 Zinc complexing with protoporphyrin and globin in iron deficiency.

on globin, the resulting molecule is nonfunctional. However, there is evidence that the ZPP–globin complex (Figure 2) accumulates in developing erythrocytes where it inhibits the action of heme oxygenase (involved in heme catabolism), thereby conserving heme.

The involvement of Zn in anemia may be indirectly through its role in Cu metabolism. Several studies have documented that, in the absence of evidence of hemolysis or other nutritional deficiencies, excessive Zn intakes (> 660 mg) may induce Cu deficiency by sequestering Cu in the enterocytes, thus limiting its absorption and increasing fecal losses. Since Cu is essential for mitochondrial Fe transport and heme synthesis, Zn-induced Cu deficiency produces the same anemia as isolated Cu deficiency.

Protein Deficiency and Protein–Energy Malnutrition

Protein is essential for optimal production of hemoglobin and red blood cells. Animal studies have provided evidence of a causal relationship between protein deficiency and the development of anemia. Rats fed a protein-deficient diet show a marked reduction in erythropoiesis and subsequently develop severe anemia, which can be reversed by restoring protein to the diet. In humans, this condition is associated with kwashiorkor. It is thought that protein deficiency causes reduced body mass and a decreased oxygen consumption or requirement, which then leads to reduced erythropoeisis and a fall in red cell mass. Protein deficiency also interferes with the maturation of erythroblasts and decreases the erythropoietin-sensitive pool. The resulting anemia manifests as normocytic, macrocytic, megaloblastic, hypoplastic, normochromic or hypochromic anemia, accompanied by higher-than-normal reticulocyte counts, and a normal to low mean corpuscular hemoglobin concentration. Low serum total protein, albumin fraction, serum iron, and total iron-binding capacity are also observed.

Anemia, as a result of PEM, is poorly understood, and the underlying mechanisms remain obscure. It is thought that this anemia is an adaptation to a lowered oxygen requirement in PEM. Assessing anemia in PEM or kwashiorkor is extremely difficult because of ethical concerns and multiple associations such as infections and deficiencies of iron, folic acid, vitamins B_2, B_{12}, and E, and selenium. In PEM, there is decreased red cell survival, whereas erythropoetin levels are adequate or elevated, and bone marrow iron supplies are normal. Selenium deficiency is thought to significantly influence red cell survival through its relationship with impaired glutathione peroxidase activity. In addition, PEM-related anemia presents with normocytic, normochromic RBCs, low serum Fe, serum iron-binding capacity, serum total protein, albumin, and Fe absorption, but increased γ-globulin. There is evidence that protein supplementation alone in PEM does not correct the related anemia but may exacerbate it. Even when serum vitamin E levels are normal, concurrent protein and vitamin E supplementation appears to significantly increase hemoglobin levels.

Essential Fatty Acid Deficiency

Anemia has also been associated with essential fatty acid (EFA) deficiency. An EFA intake of < 2–4% of total calories is reflected in red blood cells by decreased linoleic acid levels with corresponding increases in eicosatrienoic acid levels. This results in altered triene/tetraene ratios (> 0.4 being considered EFA deficiency). In the plasma fatty acid profile, linoleic acid is generally elongated to arachidonic acid, but in a deficiency, linoleic (tetraene) is replaced by oleic (triene) acid. The RBC fatty acid profile reflects that of the plasma because RBC fatty acids are continually diacylated and reacylated with those in the plasma. Aplastic anemia and thrombocytopenia are the result of altered fatty acid profiles seen in EFA deficiency.

ANIMAL MODELS OF HUMAN NUTRITION

J R Hunt and Z K Roughead, United States Department of Agriculture, Grand Forks, ND, USA

Background

Experimentation with animals has been fundamental to human nutrition knowledge. By using small animals, researchers can economically control experimental diets to determine the biological effects of dietary constituents. Studies with small animals fed controlled diets led to the discovery of most of the vitamins and essential trace minerals. Because of animal research, nutrient-deficiency diseases of humans have been eradicated in many countries. Animal research in the future should help us understand how diet affects disease, reproduction, brain function, and longevity.

Advantages of using animals in nutrition research include: (1) large groups can be studied economically; (2) dietary consumption and living conditions can be carefully controlled; (3) short life-spans improve the feasibility and efficiency of developmental, longevity, or multiple generation studies; and (4) controlled breeding reduces biological variability and can allow the testing of specific peculiarities in metabolism. If dietary deficiencies or imbalances are suspected of causing disease in humans, these hypotheses should be tested in controlled studies with animals. Likewise, new dietary additives should be tested in animals for human-safety purposes. Although animal research is indispensable for our expanding knowledge about diet and health, investigators must weigh the benefits of such knowledge against the discomfort of animals in research. New knowledge for the health of our own and possibly other species should be obtained with an ethical responsibility for the humane treatment of experimental animals.

History

Since the earliest times, humans have recognized that they share with animals a basic need for food and water. Accordingly, the history of nutrition is replete with examples of animal experimentation. Erasistratus (310–250 BC), tested his ideas that *pneuma* in the atmosphere became spirit in the body. He placed fowls in a jar and weighed them and their excreta before and after food. Galen (AD 130–200) studied digestion in hogs and concluded that, in the stomach, foods were reduced to smaller particles that could later be absorbed.

In 1774, Joseph Priestley (1733–1804) exposed mercuric oxide to focused sunlight to produce 'pure dephlogisticated air' (oxygen). He demonstrated that this air caused a candle flame to burn brighter and that mice could live in it.

Guinea-pigs were employed by Crawford, Lavoisier and Laplace, and Despretz in the late eighteenth and early nineteenth centuries to study respiration and body-heat production. Lavoisier and Laplace invented an ice calorimeter and compared the amount of ice melted by a guinea-pig with the amount of carbon dioxide produced. In addition to using guinea-pigs, Lavoisier measured his own respiratory exchanges and those of his friends and assistants. These studies led to the conclusion that respiration was a combustion of carbon and hydrogen which transformed oxygen into carbon dioxide, similar to the burning of a candle or an oil lamp.

Spallanzani (1729–1799) first obtained gastric juice from the stomach of a hawk by using a sponge and string. He demonstrated that it dissolved flesh, bones, and bread without putrefaction.

Boussingault performed the first balance study in 1839 on a cow, by measuring carbon, hydrogen, oxygen, nitrogen, and salts in the feed, urine, feces, and milk. Later, he performed similar experiments with a horse and a turtle dove.

In 1849, Regnault and Reiset used rabbits, dogs, and fowl to determine the effect of various foods on the ratio of carbon dioxide produced to oxygen inspired, later called the 'respiratory quotient.' Dogs were used extensively in the last half of the nineteenth century by German investigators studying protein and energy metabolism. Voit (1831–1908) demonstrated 'nitrogen equilibrium,' and an increase from negative to positive nitrogen balance as dogs were fed greater amounts of meat. He also discovered that muscular work by the dog did not increase protein metabolism. Rubner (1854–1932), a student of Voit, employed dogs to compare energy utilization by direct and indirect calorimetry, and to measure the 'specific dynamic action' (increased heat production) associated with protein consumption. From his measurements of metabolic rates of various species, including humans, Rubner demonstrated that the basal metabolism is proportional to the surface area of the animal.

Animals played an indispensable role in the discovery of the vitamins. In 1897, Eijkman, a Dutch physician in Java, reported that chickens fed polished rice developed a paralysis. This paralysis was similar to that of the disease beriberi in humans. Unmilled rice or a water extract of rice polishings cured the chickens. Hšlst, a Norwegian, repeated Eijkman's experiments, and obtained similar results with pigeons. However, he and Frölich reported in 1907 that guinea-pigs fed a cereal diet developed scurvy, rather than the paralysis of beriberi. This fortunate discovery – of one of the few species in addition to humans that require ascorbic acid – soon led to a biological assay for the antiscorbutic potency of foodstuffs.

In 1906, Hopkins reported from the University of Cambridge, that mice required the amino acid, tryptophan. This initiated the concept of essential amino acids and differences in the biological value of proteins. Hopkins studied both mice and rats and reported in 1912 that animals could not live on purified protein, fat, carbohydrates, and minerals alone; other unknown nutrients were essential.

In 1907, at the University of Wisconsin, McCollum set out to identify what was lacking in purified diets that did not nourish small animals. Frustrated by tedious studies with cows fed various grains, he recognized the advantages of studying animals that have a short lifespan and eat little. McCollum decided to use rats because of their convenient size, omnivorous feeding habits, and lack of economic value. Within 5 years, McCollum and Davis reported a fat-soluble factor (later named vitamin A) in butterfat that was not present in lard or olive oil. Vitamin A deficiency was later found to be a major cause of human blindness.

In the UK, Mellanby used dogs, known to be susceptible to rickets, to show that the disease resulted from a dietary deficiency. Incidental to this research, Mellanby discovered that nitrogen trichloride bleaching of wheat flour caused canine hysteria, a nervous disorder that also occurred in ferrets, cats, and rabbits. Rats that had been used in safety testing were less sensitive to the compound. Commercial use of nitrogen trichloride in flour for human consumption was discontinued after Mellanby's discovery.

McCollum used rats to differentiate between the effects of vitamins A and D. He developed the 'line test,' a measure of the width of a line of new calcification in the bone of a deficient rat given vitamin D.

This became a widespread biological assay for vitamin D in foods.

Rats were the principal animal used to discover most of the vitamins, the essential trace elements, and the essential amino acids. As a result, more is known about the nutritional requirements of the rat than about any other species. Dogs, chickens, pigeons, mice, and guinea-pigs have also made valuable contributions to our knowledge of nutrition.

Animals as Models of Human Nutrition in Research

Factors considered when selecting an animal model include anatomical, physiological, and biochemical similarities to humans, similarities of disease processes, susceptibility to etiological agents, availability, cost, breeding lines available, behavior, size, genetic characteristics, lifespan, resistance to infections, suitability for experimental manipulation, and accumulated pathobiological information. Considerations particularly pertinent to nutrition research are as follows.

Natural Diet in Habitat

The omnivorous feeding patterns of the rat usually make it a better model for human-nutrition questions than a strict herbivore such as the rabbit. Although nonhuman primates may be most genetically related to humans, primates include insectivores, herbivores, and omnivores. Researchers must evaluate each primate species separately. Strict carnivores such as cats have associated differences in nutrient metabolism and requirements. For instance, the cat requires arachidonic acid and preformed vitamin A from animal foods, as it cannot synthesize these from the respective plant food precursors, linoleic acid and β-carotene.

Nutrient Requirements

The requirement for vitamin C is a striking example of qualitative differences between species; few species require it in the diet. Humans share this uncommon requirement with other primates, the guinea-pig, the red-vented bulbul, and some Indian fruit-eating bats.

Dietary fiber may provide a more subtle example of species differences in nutrient requirements. Two herbivores, the guinea-pig and the rabbit, require dietary fiber, according to the US National Research Council. Other laboratory animals are apparently not as vulnerable to a fiber deficit. However, fiber is routinely added to research diets for rodents, and continued research may reveal reduced gastrointestinal diseases associated with fiber in the diets of primates.

Quantitative comparisons of nutrient requirements across species are difficult: limited research on some species has yielded knowledge of adequate intakes without determination of minimum requirements. Vitamin requirements between species are influenced by differences in production by intestinal flora. The mineral requirements of most species are quite similar.

Digestion and Absorption

The relative influence of gastrointestinal microorganisms on metabolism of digesta varies widely between species. Extensive fermentation in the pregastric chambers of ruminants and the hindgut of the horse makes these animals poor models for human nutrition. Dogs and pigs are similar to humans in many aspects of gastrointestinal morphology and physiology, including the relative length of small and large bowels, ingesta transit times, influence of dietary factors on gastric emptying, glucose or xylose absorption, fecal fat excretion, activities of intestinal brush border and pancreatic enzymes at maturity, and colonic volatile fatty acid concentration. However, humans, dogs and pigs differ in the developmental patterns and primary structure of some digestive enzymes. The composition of bile and the structure of bile acids differs substantially between humans and pigs. Colonic volatile fatty acids may be an important energy source for the pig, but not for the dog; the importance of colonic fermentation for humans probably falls between these two species. Numerous strains of miniature pigs have been developed and used in experiments related to digestion and absorption.

Body Composition, Nutrient Metabolism, and Excretion

Species differences in chemical composition may influence the suitability of animals as models for human-nutrition problems. As an example, differences in relative skeletal mass may reduce the usefulness of animal models for bone health and related nutrients. The skeleton constitutes about 16% of the adult human body, as compared to 11% of the rat, 10% of the rabbit, and 7.7% of a 28-week-old pig. This probably accounts for considerably higher amounts of calcium and phosphorus per kilogram of fat-free body tissue in humans than in pigs, cats, rabbits, rats, or mice. Human cortical bones have greater nitrogen and lower calcium:nitrogen ratios than those of pigs, cats, rabbits, rats, and fowl. Differences in nutrient excretion may complicate animal modeling further. For example, the rat excretes less than 1% of dietary calcium in the urine, which is an important route for calcium excretion (and its

hormonal control) in humans. These examples may help explain why there has not been a satisfactory animal model for human osteoporosis.

Coprophagy (the ingestion of feces) by rabbits and rodents can confound dietary intake measurements in nutrition studies. By increasing the total nutrient intake, coprophagy can lower apparent requirements and reduce signs of deficiency for many nutrients. Particularly affected are those nutrients synthesized or made more bioavailable through colonic microbial flora, including the B-complex vitamins and essential fatty acids. To study signs of deficiency for such nutrients, steps must be taken to prevent coprophagy.

Reproduction

Animal studies have demonstrated vital roles for nutrition from estrus to parturition and lactation. For example, animal studies have shown the essentiality of zinc for normal estrus cycling and fertility, development of preimplantation eggs, normal development of organ systems (especially the skeletal and central nervous systems), fetal growth, and normal labor and delivery. Zinc deficiency during specific stages of gestation causes postnatal abnormalities in behavior and immune function.

Special considerations when evaluating animals as models of human reproduction include the number of fetuses, the type of placentation, the tendency to abort or resorb fetuses under teratological conditions, the rate of development, and the maturity of the fetus at delivery. Because members of a litter have a similar genetic inheritance and intrauterine environment, these similarities must be considered to plan experiments with an appropriate number of animals and distribution of experimental treatments. Maturity at birth can determine the suitability of an animal model for studies of late gestational development. For example, epiphyseal calcification of the femur is much greater in newborn piglets than in newborn humans, and pigs walk soon after birth. This would limit the usefulness of the pig in some studies of prenatal bone development. Maturation at birth is also a concern when selecting animals to study early infant development. Another difficulty is that newborn mammals often require maternal lactation, limiting the investigator's control of dietary variables in early life.

Animal Models of Nutrient Evaluation

Historically, animals were useful for food evaluation, such as vitamin assays, because chemical techniques were inadequate for direct analysis of foods. While chemical-analysis difficulties have largely been overcome, difficulties predicting nutrient bioavailability have not.

Bioavailability is the fraction of a nutrient in food that is absorbed and utilized. It is affected by chemical form, interactions with other food components, and, probably, physiological responses to food. For example, the zinc bioavailability of foods fed to rats depends on the amount of food fed, even though the foods are compared in amounts providing similar quantities of zinc. Important *in vivo* variables may be pancreatic secretions in response to different foods, competition between endogenous (pancreatic carboxypeptidase) and dietary sources of zinc for absorption, and coabsorption with ligands such as histidine that have separate facilitated pathways of absorption. *In vitro* estimates of zinc absorption are limited by our incomplete understanding of the dynamic gastrointestinal response to foods.

For investigating the bioavailability of some nutrients, even animal models may not be sufficient. For example, the heme form of iron present in foods of animal origin is much better absorbed by humans than ferrous iron; this is not true for rats.

The nutritional quality of dietary proteins has been evaluated since as early as 1917 by measuring animal growth or nitrogen retention. Despite attempts since the mid-1940s to replace the biological assays with a 'chemical score' of amino acid composition, the biological assays continue to be used extensively. Although chemical scoring accounts for essential amino acid composition and requirements, scoring does not account for differences in amino acid bioavailability, which can be reduced by chemical changes during heating, or by inhibitors of proteolytic digestion.

In vitro testing has progressed substantially and is often preferred by scientists for efficient use of resources. However, the complexity of living organisms remains incompletely understood, and frequently, the nutritional value of foods or diets is more accurately evaluated by direct *in vivo* testing.

Genetically Altered Animal Models

Inheritance affects individual responses to nutritional stress. Genetic factors may determine the absorption and/or utilization of a given nutrient. Also, the amount of the nutrient in the diet may influence gene expression. Genetic engineering technology has been used to study the effects of overexpression of a specific gene on nutrient metabolism. More recently, gene-ablation technology, commonly known as gene knockout, has been used (primarily in mice) to study the effects of inactivating a specific gene. Mice with alterations to specific genes are produced by targeting the specific gene in the embryonic stem cells. Knockout mice provide an opportunity to

analyze the function and physiological effects of specific mammalian genes, to model a range of human inherited disorders (e.g., low-density-lipoprotein receptor knockout mice for the study of familial hypercholesterolemia and vitamin D-receptor knockout mice for the study of dietary calcium and bone health) and to explore potential intervention strategies for disease treatment. Cross-breeding of knockout mice to strains with other mutations can be useful in understanding biochemical controls and interactions. For instance, a mutation in the HFE protein is associated with hemochromatosis, a disorder of excessive iron absorption and accumulation. Similar iron accumulation occurs in HFE knockout mice, and this effect can be exacerbated or reduced by cross-breeding these mice with other knockout mice missing genes for other proteins involved with iron absorption and metabolism. Such mice can be further studied to assess the interaction of the genetic mutation with different forms and concentrations of dietary iron. Newer methods can introduce more subtle gene alterations, including specific point mutations. Animal research is making an important contribution to improved protocols for gene therapy, which should help in the alleviation of many inherited human diseases.

Animal Models of Disease States

With the help of animal models, a major cause of human disease – overt nutrient deficiency – was largely solved as a scientific problem (it unfortunately remains as a political and economic problem). Scientific emphasis has turned to diet and chronic disease. Perhaps because they are as yet unresolved, the problems of chronic disease seem more complex. Dietary variables are likely to be slight deficiencies, excesses, or imbalances in a lifelong interaction with other genetic and environmental factors. Animal models can provide the advantage of controlled environmental and dietary factors over a short lifetime. While genetic differences can limit application to humans, animal models of disease are improving through genetic technology. The use of animals to study nutrition and major chronic diseases is considered briefly below.

Atherosclerotic Cardiovascular Disease

The responsiveness of serum cholesterol and atherosclerosis to dietary cholesterol and saturated fatty acids varies among animal species. Rabbits, guinea-pigs, swine, and rhesus and cynomolgus monkeys are more susceptible than humans. Rats and dogs are more resistant. Baboons and vervet monkeys are in the same moderate range of susceptibility as humans. Genetic differences in lipid metabolism are confirmed by the variation observed within and between species.

Hypertension

Hypertension in response to dietary salt is not observed in all animal models but occurs in specific animal strains without sufficient renal capacity to excrete salt rapidly. The Dahl S and the Kyoto spontaneously hypertensive rat are susceptible to dietary salt, and the addition of potassium to high-salt diets reduces the incidence of stroke in these animals, and in the Sprague–Dawley rat. Research on animal models verifies an interaction between diet and genetic susceptibility to hypertension, and susceptible animals may be useful in identifying dietary variables that affect susceptible humans.

Obesity

Genetically obese strains of rodents – obese (*ob/ob*) and diabetic (*db/db*) mice and obese (*fa/fa*) rats (Figure 1) – confirm that inheritance can contribute to obesity. The obese strains are either resistant to leptin (db/db mice and fa/fa Zucker rats) or deficient in leptin (ob/ob mice), a hormone produced by adipocytes. This in turn results in overfeeding and increased concentrations of Neuropeptide Y in plasma and in the hypothalamus. Obesity in such models has been associated with hyperinsulinemia, abnormal glucose tolerance, and high body-fat composition even with normal diets. Rats without genetic obesity increase their food intake and thermogenesis in response to a 'cafeteria' diet of mixed human food. The relationship between energy intake, physical activity, thermogenesis, and body weight has been extensively studied in rodents. Results of these studies generally support the biological maintenance of a 'set-point' for body weight; that varies only slightly and controls energy balance.

Cancer

Approximately one-third of human cancer mortality may be related to diet. Animal studies, mostly using rats, have indicated that tumor development is enhanced in a variety of tissues by high-fat diets, especially diets rich in ω-6 (but not ω-3) polyunsaturated fatty acids. This effect of high-fat diets has not been completely differentiated from the effect of high energy consumption. Animal models have shown that selenium inhibits both the initiation and proliferative phases of tumorigenesis. The effect of some dietary components may depend on the specific site, type, and stage of carcinogenesis as well as the relative nutrient requirements of host and tumor. For instance, zinc deficiency in animals increases

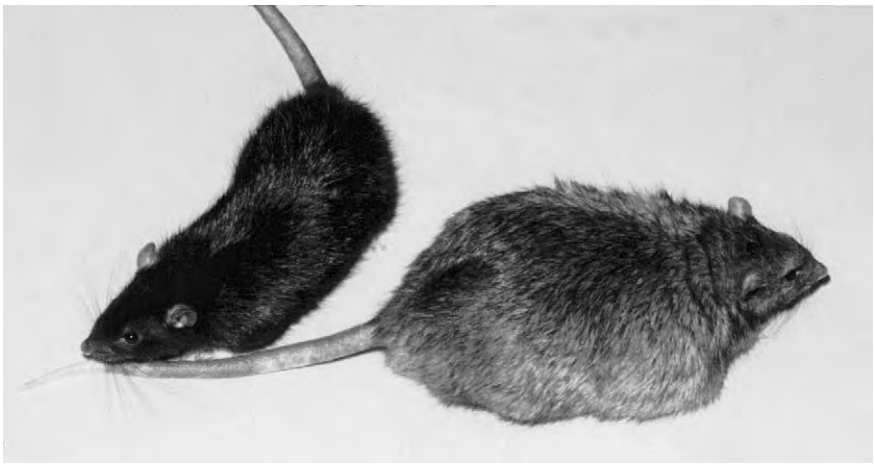

Figure 1 Control and *fa/fa* Zucker rat, a genetic strain used to investigate obesity. From Judith S. Stern, Sc.D., Professor, University of California at Davis, USA with permission.

the incidence of esophageal carcinoma induced by methylbenzylnitrosamine but decreases the incidence of tumors induced by 3-methylcholanthrene and 4-nitroquinoline-*N*-oxide.

Animal models are commonly used to test food additives for carcinogenicity. Careful studies generally involve more than one species and exposure over an extended portion of the lifespan. A US food additive law, known as the Delaney Clause, which prohibits the use of a food additive in any amount if it has been shown to produce cancer in animal studies, has been controversial because it prohibits any amount of a substance that may have been tested only in high amounts. The evaluation of research results must consider the average and peak human exposures to the substance, and the potency of the substance to determine whether dietary characteristics have been experimentally exaggerated, and whether extrapolation to humans is realistic.

Osteoporosis

Diets low in calcium or high in phosphorus increase bone reabsorption and decrease bone mass in rats, mice, cats, dogs, and nonhuman primates. In contrast with experimental animals, calcium balance in humans is relatively insensitive to high dietary phosphorus. There are few animals that experience the spontaneous ovarian failure in middle age that occurs in humans. Researchers have not identified any appropriate animal model of postmenopausal or age-related osteoporosis (see the above section Body Composition, Nutrient Metabolism, and Excretion).

Diabetes Mellitus

Experimental diabetes can be induced in animals by pancreatectomy or injection of β-cell toxins such as streptozotocin or alloxan. There is a genetically obese strain of diabetic (*db/db*) mice. The *Psammomys obesus* (sand rat) strain of rat remains lean and nondiabetic in the wild but becomes obese and diabetic under laboratory feeding conditions. In normal strains of animals, a greatly increased food intake for an extended time leads to adiposity and an increased incidence of insulin resistance, which is reversible with weight reduction. It has not been possible with animal research to show that a high energy consumption causes diabetes.

Interpretation and Extrapolation of Data

Animal studies are most appropriately applied to humans when they complement, and are consistent with, human studies. Relevance of animal research to humans is more likely if the results are confirmed in several animal species.

The highly uniform experimental conditions characteristic of animal models can provide disadvantages as well as advantages. For example, energy restriction reproducibly increases longevity in rodents. However, such studies are usually conducted under laboratory conditions in which the rodents spend their entire lives in a small space, have no social relationships, do not reproduce, have low exposure to hazardous biological or chemical substances, and have little need for physical activity or development of self-preservation skills. Scientists must evaluate whether the food-restricted animals would have an improved *quality*, or even *quantity*, of life if tested under more realistic living conditions.

The control of experimental diets in animal nutrition studies can present similar problems in extrapolation to humans. To enhance experimental control

and comparability between studies, animal diets for nutrition research are often standardized, purified, and fed *ad libitum*. Purified diets composed of a small number of refined ingredients, such as refined proteins, carbohydrates, and fat, with added vitamin and mineral mixtures, reproducibly control specific nutritional variables but also limit the context of the experiment. Unlike many animal research diets, human diets contain thousands of compounds and are usually scheduled in meals. As nutrition research moves from single nutrient deficiencies to more complex dietary interactions that affect health, laboratory diets and other conditions may need to become more like human conditions to facilitate comparability to humans. An example is the 'cafeteria' diet of mixed human food used to attain overeating in rodents.

Limitations of Animal Models in Nutrition Research

Nutritional knowledge has rapidly expanded in the nineteenth and twentieth centuries. During this time, an increasing share of biomedical advances depended on animal research. Two-thirds to three-quarters of major biomedical advances in the 1900s required the use of animals. This trend was accompanied by an antivivisectionist movement in Victorian England in the late 1800s, which may be a predecessor of the current 'animal rights/liberation' movement. High-quality animal care improves experimental reliability and engenders public trust. Scientists have an ethical obligation to ensure animal well-being and minimize pain and suffering. Scientists must be involved in public policy influencing legal regulations that benefit humans through science while treating animals humanely and without inefficient bureaucracy.

Scientists should consider alternative methods, including the use of more socially acceptable species, such as the experimental use of rodents rather than dogs, cats, or monkeys, and the possible use of non-mammalian vertebrates, invertebrates, and micro-organisms. However, depending on the research problem, such alternatives may be unacceptable in answering questions applicable to humans. Nutrition knowledge may also be gained by using cell and tissue cultures, human tissues removed at surgery or at autopsy, and *in vitro* systems and mathematical models. Such methods can be more efficient, controlled, and economical than research with living animals. But again, researchers must be cautious not to extrapolate to human nutrition without adequate validation of the simpler model.

A straightforward alternative to using animals is to study humans directly. Although the technology to study humans safely continues to improve, many nutrition research topics require animal models. Such topics include the effects of nutrition on reproduction, growth and development, longevity, and behavior. Animal experiments can verify observations in humans that often cannot be controlled sufficiently to be conclusive. The use of animals for initial experiments in nutrition research improves efficiency and progress. Animal studies facilitate the investigation of physiological and molecular mechanisms. Animal research has been instrumental in identifying required nutrients and developing the science of nutrition. Animal research continues to answer questions about nutrition and health that can be learned only from living organisms.

ANNONACEOUS FRUITS

A P George and R J Nissen, Maroochy Horticultural Research Station, Nambour, Queensland, Australia

Introduction

The main commercial species of *Annona* grown throughout the world are the cherimoya (*A. cherimola*), the atemoya (*A. hybrids*), and the sugar apple (*A. squamosa*). Expansion of production of these three species in many subtropical countries is limited by several factors, including low yields of better-quality cultivars, unattractive external appearance of the fruit, a high susceptibility of the fruit to blemishing, poor and unreliable internal fruit quality, and a very short postharvest shelf- and storage life. In the short term, fruit quality can be improved by field management practices. In the longer term, selection and breeding of new varieties will be necessary.

Classification

The family, Annonaceae, comprises 50 genera. Three genera (*Annona, Rollinia*, and *Asimina*) produce edible fruit, but only two genera are of commercial importance – *Annona*, comprising approximately 100 species, and *Rollinia*, comprising approximately 50 species. The four most commercially important species are the cherimoya, the sugar apple, the atemoya, and the soursop (*A. muricata*). The cherimoya is native to the subtropical highlands of Peru and Ecuador, and is grown commercially in Chile, Spain, California, and New Zealand. The atemoyas, most of which are hybrids between *A. cherimola* and *A. squamosa*, are grown commercially in Florida and Australia. Both the sugar apple and the soursop are widely distributed throughout the tropical regions of South-east Asia and Central America, where they are found growing wild. The rollinia (*Rollinia mucosa*) and biriba (*R. deliciosa*) are native to the jungles of South America. A list of the edible species of *Annona* and *Rollinia* grown throughout the world is presented in Table 1. It should be noted that common names, such as custard apple, have been used with reference to many different species.

Climate

Most *Annona* species are tropical or subtropical in their growth requirements. Both the atemoya and the cherimoya are best grown in frost-free locations as the young trees are killed at −1 °C and mature trees at −3 °C. The cherimoya is more cold-tolerant than the atemoya and is able to stand a longer duration of cold at −3 °C. The sugar apple and the soursop, on the other hand, are very frost-sensitive. Most cherimoya and atemoya cultivars are semideciduous and enter either a true rest or environmentally induced dormancy in the late winter or spring. This dormancy or rest period allows the plant to avoid the effects of late-winter frost and drought.

Different species exhibit varying climatic requirements for fruit development and maturation. Excessively low temperature during the fruit maturation period may retard the process, while excessively high temperatures during this period may cause premature ripening and fermentation of the fruit whilst still on the tree. For example, atemoya cultivars grown in cool subtropical regions of California or New Zealand may fail to mature properly. In these regions the main commercial species grown is the cherimoya. In contrast, cherimoya fruit grown in tropical climates often fails to develop full flavor, and postharvest shelf-life is short.

Besides the influence of temperature on fruit maturation, physiological disorders such as skin russetting are more prevalent under cool night temperatures, particularly when ambient temperatures fall below about 13 °C.

Fruit Morphology

The cherimoya, atemoya, and sugar apple fruits are syncarpiums, made up of many individual carpels which are fused together with the receptacle to form a fleshy mass. Each carpel, if pollinated, contains an oval seed. Depending on species and cultivar the number of seeds per 100 g of flesh can vary from five to 15. The fruit ranges in shape from conical, through globular to ovoid, and the skin type may be smooth, finger-imprinted, or bumpy. The skin is relatively thick and contains numerous stomata. The mesocarp consists mainly of parenchyma, cholenchyma, and sclerenchyma cells, the latter often being highly lignified, similar to those found in pears.

Varietal Selection and Breeding

The atemoya and the cherimoya produce fruit superior in quality to other *Annona* species. The fruit of some species, such as the bullock's hearts (*A.*

reticulata) and ilama (*A. diversifolia*), are barely edible. The fruit of the sugar apple are highly seeded and are not grown commercially in regions where cherimoya or atemoya can be grown. The fruits of rollinia and biriba, although edible, deteriorate rapidly within a few days after harvesting, thus limiting their commercial acceptability for local markets only.

The University of Puerto Rico's Agricultural Experiment Station at one time cataloged 14 different types of soursop. In El Salvador, two types of soursop are grown: guanaba azucarón (sweet), eaten raw and used for drinks, and guanaba acida (very sour), used only for drinks. A yellow, fiberless form of soursop has been selected in Cuba.

The most important commercially grown cultivars are as follows: of cherimoya, Bronceada (Chile), Fino de Jete (Spain), and Bays (California); of atemoya, African pride (Australia) and Gefner (Israel, Florida and Hawaii); of soursop, Cuban fiberless. Wide genetic variability exists between different species of cherimoya and atemoya. Selection of varieties with round, symmetrical shape, smooth skin, high ratios of flesh to seed, and long postharvest storage life is highly desirable. Intensive varietal selection programs for cherimoya are currently being undertaken in Spain, New Zealand, and Chile. A small breeding program, currently in progress in Queensland, Australia, has produced promising new interspecific and intraspecific hybrids.

Maturity and Quality

No reliable quantitative maturity indices for when to harvest *Annona* fruit have been developed. Individual trees are normally harvested up to 10 times, and fruits are judged to be mature when the skin changes from a darker to a lighter green and becomes smoother. In some regions, fruits which develop during the colder winter months may fail to mature properly. Total soluble solids contents at full maturity can vary from 18% to 28%.

Physiological Disorders

Fruit Splitting

Fruit splitting may occur while fruits are still on the tree or after harvest. Splitting appears to be related to sudden changes in fruit moisture content or temperature. Some cultivars appear to be less susceptible than others.

Russetting

Superficial russetting of skin seems to be caused by low night temperatures (less than 13 °C), accompanied by low humidity. Near-mature fruit appear to be particularly susceptible. Cherimoya cultivars are apparently less susceptible than atemoya cultivars.

Crocodile Skin

The extremely wavy and pointed carpels that are symptomatic of this disorder are particularly severe on highly vigorous trees, which may indicate some harmful effect of tree vigor on pollination processes. Based on fruit and leaf analyses, nutrition does not appear to be implicated.

Hard Seed Casing and Brown Lumps

Possible causes are boron deficiency or sudden changes in fruit water content.

Postharvest Handling and Physiology

The skin of most *Annona* fruits, in particular those cultivars which produce fruit with protruding carpels, is easily damaged by rough handling. Fruits are usually size-graded by hand because of their irregular shape, and are packed into single-layer trays before shipment. The cherimoya and atemoya are classified as climacteric fruits which show two peaks in carbon dioxide production. The fruit softens, develops pleasant aroma and flavor, and is considered ripe at the beginning of the second respiratory rise. Compared with other fruits, the cherimoya and atemoya have high rates of ethylene production and respiration. With the exception of a few cultivars, postharvest shelf-life is short (between 7 and 10 days). (*See* **Ripening of Fruit**.)

Storage

The optimum storage temperatures for atemoya and cherimoya fruit are between 13 °C and 16 °C. At these temperatures most atemoya and cherimoya cultivars can be stored for up to a maximum of 2 weeks with minimum loss of quality. One cultivar of cherimoya, Bronceada, has a reported cool storage life of 3 weeks. Storage at temperatures below 13 °C for more than 1 week can cause severe chilling injury. Chilled fruit develops blackened skin, discoloration of the core, and watery patches in the fruit flesh; after removal from storage the fruit fails to ripen properly. However, fruit used for processing can be stored for 1 week at between 5 °C and 10 °C without loss of internal fruit quality. For short-distance transport precooling of fruit at 10 °C for up to 18 h prior to shipment at ambient temperatures has been shown to be beneficial in extending shelf-life by 3–4 days. Because of the presence of numerous stomata on the surface of the fruit, one of the main problems during storage is rapid water loss. Maintenance of relatively high humidity during storage should improve the appearance of fruit after the removal from storage. The main postharvest disease is anthracnose, caused by a range of disease organisms (*Colletotrichum* spp., *Phomopsis* spp., *Rhizopus* spp.). Postharvest fungicidal dips have successfully controlled fruit rots, provided that recommended dipping temperatures and concentrations are adhered to. Only limited studies have been conducted on controlled-atmosphere storage of *Annona* species. Further studies are needed to evaluate the benefits of packaging fruit in polyethylene bags, which may help to prevent water loss and blackening of fruit during storage. (*See* **Controlled-atmosphere Storage: Applications for Bulk Storage of Foodstuffs; Fungicides; Storage Stability: Mechanisms of Degradation.**)

Fresh Food Uses

The flesh of most *Annona* species is most commonly eaten out of hand. Because seeds of the fruit are interspersed throughout the flesh, cultivars containing few seeds are the most desirable. Eating quality of atemoya and sugar apple fruit, which are particularly sweet, may be enhanced by adding a few drops of lime juice to the flesh. Soursops of least acid flavor and least fiber are the only ones suitable for eating fresh. The best eating quality is obtained from fruit that has been ripened at 17–20 °C and then placed in the refrigerator to cool just before eating. In terms of

appearance, color, flavor, and texture, the most acceptable pulp for both eating and processing is to be found 1 day after the first detectable softening. Softened fruit can be stored in the refrigerator (4 °C) for about a week with a minimal loss in flavor, but some skin blackening will result. Segments of the pulp can be added to fruit salads, or used for making sherbets or icecream.

Processed Products

Atemoya, cherimoya, and soursop pulp has potential for mixing with dairy products such as icecream and yogurt, and sweetened soursop juice can be made into a canned beverage. Because of its higher acidity, soursop pulp is the most suitable of all the *Annona* species for processing. Cultivars with a low level of grit or fiber in the flesh have been found to be more suitable for processing than others. Passing the flesh through fine screens (20 000–10 000 μm), and homogenization, as used for guava pulp, should eliminate this problem. The pulp can also be used to make semi-dried fruit 'leathers,' and jams and jellies of fair flavor and quality. In Central America, sweet soursop pulp is sieved and squeezed, diluted with either milk or water, and sweetened, before canning to make a refreshing drink. When mixed with a little cream or icecream, the frozen soursop concentrate makes a delicious dessert.

Some species of *Annona* have been used in the production of soaps, domestic cooking oils, essential oils, herbal medicines, alcohol, fertility drugs, and insecticides. However, the commercial potential of these products at the present time appears limited.

Pulp Extraction

The production of pulp on a commercial scale does not appear to be easy because the skin of *Annona* fruits, at full ripeness, is soft and disintegrates easily if conventional processing techniques are used for skin removal. Other processed fruits, such as mango, passion fruit, and guavas, have leathery skins which are brushed clean of pulp before being discarded. *Annona* fruit disintegrates and is brushed through the screens and mixed in with the pulp. The skins of most *Annona* fruits are high in polyphenols. This causes two problems when the skin is mixed with the flesh – a rapid browning of the pulp and a strong off-flavor. The Food Industry Development Centre of the University of New South Wales, Australia, has evaluated two methods for removing custard apple pulp – a screen pressing process and a reaming process. Although the reaming process offers yield advantages, it requires the use of skilled labor, and this would reduce its potential economic advantages. A prototype screen press extractor has been

developed but this unit has yet to be tested commercially. (*See* **Phenolic Compounds**.)

Pulp Storage

Heating or pasteurization impairs pulp flavor considerably, and often results in the development of a bitter character. However, unblanched frozen pulps treated with either ascorbic acid (1500–2000 mg kg^{-1}) or potassium metabisulfite (500 mg kg^{-1}) can be stored for up to 120 days with minimal loss of flavor. Upon thawing, pulp treated with ascorbic acid may develop a pinkish discoloration, whereas pulp treated with potassium metabisulfite retains a bright, fresh color. (*See* **Ascorbic Acid**: Properties and Determination.)

Nutritional Value

The fruit is rich in starch when firm but increases markedly in sugar as it softens. The main sugars are glucose and fructose (80–90%). There is some phenolic content associated with an increase in the activity of peroxidase, which causes oxidation of the pulp. The volatile fraction consists of alcohol, esters, carbonyls, and hydrocarbons. The nutritional properties of the more important *Annona* species are presented in Table 2. Compared with other fruits, the *Annona* fruits contain significant quantities of vitamin C, thiamin, potassium, magnesium, and dietary fiber content. The calorific value of the flesh is high (300 kJ per 100 g) and is almost double that of peach, orange, and apple. Refer to individual nutrients.

Marketing Characteristics

Both the cherimoya and the atemoya are best eaten as fresh fruits. Both fruits are currently virtually unknown on world markets, and Chile is the only country which exports significant quantities. The major problem facing expansion of cherimoya and atemoya production throughout the world is the high perishability of the product. The transportation of atemoya and cherimoya to distant export markets, given current cultivars and postharvest technology, is difficult. The processing potential of soursop and other *Annona* fruits is yet to be fully exploited. (*See* **Fruits of Tropical Climates:** Commercial and Dietary Importance.)

ANOREXIA NERVOSA

D S Goldbloom and P E Garfinkel, Centre for Addiction and Mental Health, Toronto, Ontario, Canada

Definition

Anorexia nervosa (AN) is an eating disorder that is characterized by self-imposed starvation accompanied by an idealization of thinness and a morbid fear of becoming fat. The resultant emaciation leads to significant medical and psychiatric complications. Contrary to the literal meaning of its name – a nervous loss of appetite – AN does not reflect a true loss of appetite except in the later stages of starvation; rather, it is a determined battle waged against sensations of hunger in order to achieve an illusory sense of control. Since its original modern description by Sir William Gull in 1874, the diagnostic criteria for AN have evolved to reflect the biological, behavioral, and psychological disturbances characteristic of the

disorder. The formal criteria as defined by the American Psychiatric Association in 1994 are listed below:

1. Refusal to maintain body weight at or above a minimally normal weight for age and height (e.g., weight loss leading to maintenance of body weight less than 85% of that expected; or failure to make expected weight gain during period of growth, leading to body weight less than 85% of expected).
2. Intense fear of gaining weight or becoming fat, even though underweight.
3. Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight.
4. In postmenarcheal females, amenorrhea, i.e., the absence of at least three consecutive menstrual cycles. (A woman is considered to have amenorrhea if her periods occur only following hormone, e.g., estrogen, administration.)

Subtypes

1. Restricting type: during the current episode of AN, the person has not regularly engaged in binge-eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas).
2. Binge-eating/purging type: during the current episode of AN, the person has regularly engaged in binge-eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas).

Prevalence

AN is, in about 90% of cases, a disorder of females, typically between the ages of 12 and 40. Studies of the age of onset of this disorder reveal bimodal peaks at 14 and 18 years of age; at these ages, the demands of secondary sexual development and autonomy in the context of leaving home may be related to the increased incidence. The current accepted prevalence rate for AN among western adolescent and young adult women is approximately 0.5–1.0%. AN is, relatively speaking, a culture-bound disorder limited to industrialized societies with western values.

Etiology and Groups at Risk

The etiology of this disorder is unknown; most clinicians and researchers endorse a multidimensional model of AN which acknowledges psychological, biological, and social risk factors that exist at the level of the individual, the family, and society. While dieting is almost ubiquitous behavior among women in western society, the significant medical and psychiatric manifestations of AN and its characteristic psychological features argue for the definition of AN as a distinct disorder, and not a simple exaggeration of current western values; indeed, AN was recognized long before our cultural preoccupation with being thin.

At the level of the individual, women who by career choice experience pressures both to be thin and to achieve may be particularly vulnerable. This includes ballerinas, fashion models, and gymnasts, in whom thinness and perfectionism are not only demanded but also equated. Conflicting pressures on women to nurture and to perform professionally may intensify concerns about control that are shifted on to weight regulation as a focus. Further, chronic physical illness, physical or sexual abuse, or other traumas which heighten preoccupation with the body as a reflection of control or self-esteem may increase vulnerability to AN.

At the familial level, there may be a magnification of social idealization of thinness and denigration of obesity. Genetic influences through vulnerability to a variety of psychiatric disorders such as depression, alcoholism, and eating disorders themselves in other family members may also play a role. First-degree relatives of AN subjects also display an elevated prevalence of eating disorders over controls. Twin studies indicate an increased concordance rate for monozygotic (identical) versus dizygotic (nonidentical) twins.

At the societal level, the last 75 years have witnessed shifting models of the ideal female form toward thinness, in contrast to the increasing biologically ideal weights for women in the context of good nutrition. However, it must be remembered that the decription of AN in 1874 long predates our cultural preoccupation with thinness and a broader understanding of this disorder must be sought.

Psychopathology

The focal behavioral point of AN is the individual's relentless pursuit of thinness and the associated conviction that her body is too large. This latter belief may emanate from a variety of sources, from a past history of obesity (with its attendant social humiliation and a sense of failure) to physical or sexual abuse which has led to body loathing. Alternatively, AN may reflect a symbolic focus on the body in a search for personal mastery that in turn reflects a sense of personal ineffectiveness. It may also allow retreat from the maturational demands of adolescence, as expressed by the development of secondary

sexual characteristics. Associated psychopathological features often include a fear of losing control in many spheres, self-esteem that is highly contingent on the opinions of others, an all-or-nothing thinking style that allows no middle ground between being thin and being fat, and a pervasive sense of helplessness.

Clinical Features

The initial manifestations of AN are deceptively benign; the disorder frequently commences with dieting behavior which is itself common in the western female population. However, this particular form of dieting leads to increased criticism of one's appearance and greater social isolation than typical adolescent dieting behavior; further, weight goals continue to drift downward as they are approached. Food aversion becomes more general than specific and, as emaciation progresses, the individual exhibits a marked denial of her illness. A typical but not universal characteristic of AN is a distortion of body image in which the individual overestimates her body size substantially, believing herself to be fat even when thin. This perceptual disturbance is usually accompanied by feelings of loathing of one's appearance.

At the level of behavior, routine dieting evolves into more elaborate food avoidance and other activities to counteract the effect of ingested calories. Individuals restrict their intake dramatically, skip meals, or secretly dispose of food. Elaborate rituals related to eating develop, and decreased consumption of food is paralleled by increasing cognitive preoccupation with it. This translates into thinking, reading, and dreaming about food or working in food-related industries. Weighing oneself becomes not only a frequent ritual but also a regulator of subsequent eating, socialization, and self-esteem. In addition to calorie restriction, individuals may exercise intensively for the express purpose of weight loss, or use purgative techniques such as diuretics, diet pills, laxatives, or self-induced vomiting.

Initially, because the consequences of the disorder are consistent with the individual's desire to be thin and in control, there is seldom the motivation to seek help or to acknowledge the evolving AN as a problem. Rather, the individual with AN may contact a nutritionist, physician, or other health professional, seeking advice on dieting in the absence of obesity or help in dealing with the secondary medical and psychiatric effects of starvation.

Physiological Effects

Virtually no body system is spared the effects of nutritional deprivation in AN. The changes are too extensive to enumerate here; they reflect not only loss but also homeostatic compensatory mechanisms to minimize energy expenditure in the context of decreased energy intake. Loss of menstrual function is the most classically recognized of these sequelae, to the point that it is a diagnostic criterion thought to reflect disturbances in gonadotropin function in the hypothalamus. Other common starvation effects include lowered body temperature and heart rate, dry skin and the development of a fine body hair, abdominal bloating and constipation, and edema.

Psychological Effects

Starvation due to AN also produces distinct psychological effects such as depressed, irritable, or anxious mood, cognitive preoccupation with food, and decreased concentration. Individuals with AN may appear to suffer from a coexistent depressive illness and are vulnerable to the long-term development of such disorders. However, many of the psychological sequelae of the disorder – which are more troubling to the affected individual than the dieting itself – are reversible with adequate nutrition.

Nutritional Status

The food restriction of AN may be severe. Individuals may abstain from all solid foods for days at a time or subsist on as little as 200–500 calories per day. Typically, there is an avoidance of perceived high-calorie, high-fat foods – and foods become imbued with moral as well as nutritional value. Individuals may develop frank cachexia, with vigorous dieting and exercise behaviors persisting at weights as low as 30 kg. Fasting hypoglycemia, abnormal glucose tolerance tests, and increased insulin sensitivity are among the metabolic responses to this form of starvation. Elevations of cholesterol and carotene may occur and plasma zinc levels have variably been reported as low. Low platelet, red blood cell and white blood cell counts, accompanied by a relative paucity of precursors in bone marrow, have been described as a consequence of the disorder.

The nutritional status of AN patients may have implications for the chronicity of the disorder. Brain neurotransmitters such as serotonin and norepinephrine (noradrenaline) are integral in the hypothalamic regulation of appetitive behavior. Serotonin synthesis itself is dependent on the dietary availability of its precursor, the essential amino acid tryptophan. Tryptophan availability may be decreased in AN, and both neuroendocrine provocation tests and cerebrospinal fluid metabolite assays indicate altered serotonin activity in AN. This may be associated with

disturbances in satiety, thought (with increased obsessionality and perfectionism), mood, and sleep found in AN. Delayed gastric emptying may occur in response to the decreased volume of food consumed. This further contributes to altered senses of satiety; an augmented sense of fullness may perpetuate food restriction.

Diagnosis

The diagnostic criteria of the American Psychiatric Association listed above reflect the confluence of biological, behavioral, and psychological factors characteristic of AN. However, clinicians may perceive them as arbitrary, particularly with regard to the degree of weight loss required and the presence of amenorrhea as essential for diagnosis. Epidemiological research requires dichotomous criteria, while clinical practice demands the recognition from a dimensional perspective of disorders in evolution. The diagnosis of AN in a young woman with weight loss requires consideration of other medical and psychiatric illnesses with a superficially similar presentation. These include endocrine disorders, bowel disease, malignancy, depression, schizophrenia, and conversion disorder. All of these differential diagnoses typically lack the central psychological preoccupation of AN – the relentless pursuit of thinness.

Treatment

The goal of treatment of AN includes but is not limited to nutritional rehabilitation. Clearly, if weight gain is the only purpose of therapy for an individual dedicated to the attainment of weight loss, her commitment to the treatment will be poor. At the same time, however, treating personnel cannot ignore the nutritional status of the individual while focusing on psychological issues; when this occurs, it results in collusion with the denial by the individual of her illness and obscures the connection between food deprivation and its sequelae.

The initial phase of treatment is a careful diagnostic assessment, with emphasis on both the evolution of the disorder and its various sequelae. A family assessment is often relevant, particularly in younger patients, both to understand familial influences and to substitute education for guilt. A target weight range is established, allowing the minor fluctuations that are normal (1–2 kg). This range should be able to be maintained without dieting, should allow the return of normal menstrual function, and should reflect consideration of the individual's longitudinal weight history. Generally, a target weight range is above 90% of the average for an individual's weight and height or a body mass index (kg m^{-2}) greater than 20. Despite a seemingly encyclopedic knowledge of nutrition, these individuals usually require directive counseling regarding meal frequency, portion size, and macronutrient selection. A daily diary of eating and associated thoughts, feelings, and behaviors may be helpful. An initial intake of 1500 calories per day is usually sufficient to promote weight gain without inducing the gastric dilatation that can complicate refeeding. A rate gain of 0.5–1.0 kg per week is desirable; more rapid weight gain may induce its own complications, including hypophosphatemia and edema, as well as mistrust in an individual who is reluctantly relinquishing weight control. Caloric intake is usually increased by 200–300 calories per week toward a goal of 2400–3000 calories per day. To date, controlled clinical trials indicate no role for drugs in the promotion of eating or weight gain in AN; food remains the drug of choice; there is modest evidence that the antidepressant fluoxetine may assist weight-recovered AN patients to maintain weight gain, possibly through an antiobsessional effect.

Psychotherapy is usually offered in conjunction with nutritional rehabilitation, and builds on the establishment of a therapeutic relationship. Issues include the recognition of feelings, self-trust, and disconnecting one's sense of self-worth from body weight. A variety of approaches, from psychodynamic to cognitive-behavioral, may be employed. Family therapy may be particularly helpful for the younger AN patient.

Hospitalization is not necessary for the majority of individuals with AN; rather, it is reserved for cases where the weight loss has been either precipitously acute or impinging on basic function, where medical sequelae such as hypokalemia pose an imminent risk, where suicidal tendencies accompany the AN, where AN coexists in a threatening fashion with another illness such as diabetes mellitus, or where other forms of treatment have been ineffective.

Prognosis

AN is a usually gradual, initially covert, and sometimes chronic disorder. Long-term follow-up studies indicate that while two-thirds of patients show eventual improvement or recovery, less than one-third recover within 3 years. More disturbing, some long-term follow-up studies have indicated a mortality rate of 10–20% as a consequence of AN. In addition, these women are vulnerable over the long term to the development of mood disorders, anxiety disorders, and substance abuse, regardless of whether the AN is active or quiescent. They are also susceptible to such diverse medical complications as

osteoporosis with pathological bone fractures and a form of brain tissue atrophy. Beyond reversal of the nutritional deprivation and weight loss, there is no established method of tertiary prevention.

ANTIBIOTIC-RESISTANT BACTERIA

J J Klawe and M Tafil-Klawe, The Ludwik-Rydygier Medical University, Bydgoszcz, Poland

Bacterial Resistance to Antimicrobial Agents

The antimicrobial resistance may be intrinsic or acquired. Intrinsic–innate resistance may be considered a fundamental property of the organism: it was present in bacterial strains isolated before the antibiotic era. Some organisms can produce enzymes that chemically modify a specific drug. Bacteria may also use the system to transport detrimental compounds out of a cell, using efflux pumps.

Acquired resistance is not found in species strains, unless they have been exposed to antimicrobial drugs. Acquired resistance may occur as a result of spontaneous chromosomal mutation or by acquisition of extrachromosomal elements, such as plasmids and transposons.

Chromosomal mutation can occur during treatment or in the absence of the agent, against which resistance develops. Extrachromosomal pieces of DNA, called plasmids (R plasmids), contribute to bacterial virulence or to antimicrobial resistance. Genes of resistance to antimicrobial agents may be transferred from chromosomes to plasmids or from plasmids to chromosomes, as a result of classic recombination. The plasmid and chromosome recombine pieces of DNA in areas of genetic homology. The presence of a *rec* A gene is needed. Many plasmids are composed of two parts: the resistance genes, or R genes, which code for the resistance traits, and the resistance transfer factor, which codes

for the transfer of the plasmid to other bacteria by conjugation.

Transposons, however, can insert into chromosomes in areas where no homology exists, independent of a *rec* A gene. Thus, transposons are less restrictive and play a major role in the transfer of resistance among many different species.

Biochemical Mechanisms of Bacterial Resistance

The biological mechanisms of bacterial resistance may be classified into four groups:

1. modification of the target site of the antimicrobial agent – for example, resistance to rifampin caused by alteration of the targeted RNA polymerase;
2. enzymatic inactivation of the agent – production of β-lactamases, enzymes that hydrolyze the β-lactam ring of the β-lactam antibiotics;
3. decreased membrane permeability and entry of the agent – resistance to tetracycline is due to decreased accumulation of the antimicrobial agent;
4. a combination of two or more mechanisms – for example, resistance of *Neisseria gonorrhoeae*.

Examples of Emerging Antimicrobial Resistance

Enterococci

The Enterococci are a group of bacteria that are a part of the normal intestinal flora. Many enterococci have plasmid-encoded resistance genes. This group of bacteria is intrinsically less susceptible to many common antimicrobials. Enterococci cause nosocomial infections, an old problem that has occurred ever since the first hospitals were established. Nowadays, nosocomial infections make up at least half of all cases of infectious disease treated in the hospitals and may range from very mild to fatal. Enterococci are a common cause of nosocomial urinary-tract infections as well as wound and blood infections.

Staphylococcus aureus

Many people, including healthcare personnel, are carriers of this organism. It is a common cause of nosocomial pneumonia and surgical infections. Hospital strains are resistant to a variety of antibiotics. Over the past 50 years, most strains have acquired resistance to penicillin, due to the acquisition of a gene encoding the enzyme penicillinase. New strains, methicillin-resistant *Staphylococcus aureus*, are resistant to methicillin and to other β-lactam drugs. *Staphylococcus aureus* has also been reported to have become vancomycin-resistant.

Staphylococcus Species other than *S. aureus*

These normal skin flora can colonize the tips of intravenous catheters. The resulting biofilms continuously seed organisms into the bloodstream, thus increasing the risk of systemic infection.

Streptococcus pneumoniae

Some strains, now isolated, are resistant to penicillin. This acquired resistance is due to the modifications in the chromosomal genes coding for different penicillin-binding proteins, which decrease their affinities for the drug. The nucleotide changes are due to the acquisition of chromosomal DNA from other species of *Streptococcus*.

Mycobacterium tuberculosis

Treatment of infections of *Mycobacterium tuberculosis* has always been a complicated process, often requiring a combination of two or three different drugs taken for 6 months or more. *Mycobacterium tuberculosis* is developing resistance to first-line drugs. Strains that are resistant to isoniazid and rifampin are called multiple drug-resistant *Mycobacterium tuberculosis*.

Pseudomonas species

These bacteria grow in a large number of moist, nutrient-poor environments, such as the water in the humidifier of a mechanical ventilator. *Pseudomonas* species are resistant to many antimicrobial drugs. They are a common cause of hospital-acquired pneumonia and infections of the urinary tract and burn wounds.

Slowing down the Emergence and Spread of Antimicrobial Resistance

More effort from healthcare workers to identify the causative agent of infectious diseases and to prescribe suitable antimicrobials is necessary to slow down the spread of antimicrobial resistance. Also, patients need to be vigilant, and a great effort must be made to educate the public about the appropriateness and limitations of antibiotics.

ANTIBIOTICS AND DRUGS

Contents

Uses in Food Production

K N Woodward, Veterinary Medicines Directorate, Weybridge, UK

Background

Veterinary medicines are used to improve or maintain the health of animal species regardless of whether these are intended for food production. They are designed and manufactured to cover a wide variety of prophylactic and therapeutic purposes, and they are administered to household pets, exotic species, and wild animals in addition to food-producing animals.

Most countries possess a governmental regulatory authority charged with assessing veterinary medicines and granting some form of marketing authorization before a product may be sold, and the UK's system is used here to exemplify this in practice. Veterinary medicines, like their human counterparts, are assessed against three basic criteria – efficacy, quality, and safety – although the terms of these criteria differ from country to country. The efficacy is the ability of the drug to accomplish the task claimed for it by its producer. Quality refers to pharmaceutical quality; the levels of contaminants must meet acceptable criteria, the shelf-life must be as claimed by the manufacturer, and the product must be produced to appropriate standards. Safety means that the product must not harm the animal patient, the environment, the users of veterinary medicines, or the consumer of food of animal origin. This latter aspect is of paramount importance when assessing the safety of veterinary medicines. When a veterinary drug is given to an animal, most of the dose will be excreted in urine, feces, and expired air, but small amounts will remain in body tissues. These are known as residues, and it is the responsibility of regulatory authorities to ensure that these do not pose a threat to the consumer when veterinary medicines are used in food-producing animals.

Uses of Veterinary Medicines

In general, veterinary medicines are available to treat most of the types of animal disease state that are encountered in humans. In practice, diseases such as cancer are not usually treated in food-producing species, largely for economic reasons, although they are frequently dealt with in companion animal medicine. The majority (but not by any means all) of the medicines used in food-producing animals are for the prevention or treatment of diseases caused by infectious agents. These fall into a number of categories, and they are described briefly below.

Antibiotic and Antimicrobial Agents

Antibiotics are antibacterial agents derived from living organisms, but the term includes closely related synthetic analogs. The archetypal compound is penicillin, the structure of which has now formed the basis for a wide range of naturally occurring and semisynthetic analogs. Other major categories of antibiotics

used in veterinary medicine are the tetracyclines, the aminoglycosides, the macrolides, and the polymixins. Sulfonamides constitute the major class of antimicrobial agent, drugs that are unrelated to naturally occurring compounds. A number of sulfonamides have been prepared for fast, medium, or long-acting functions. Sulfadimidine is one of the most widely used sulfonamide drugs in veterinary medicines, particularly in pig production, where it is employed to combat respiratory disease.

Ectoparasiticides

Cattle and sheep are often subject to attack by ectoparasites. For example, in the UK and other parts of Europe (and indeed elsewhere) cattle are susceptible to attack by the warble fly (*Hypoderma* spp.), which, in addition to causing animal suffering, results in considerable economic loss. Sheep scab is another disease that poses serious animal welfare and economic problems, and in several countries, including the USA and the UK, it is a notifiable disease. Both diseases are treated and prevented by the application of organophosphorus compounds. For warble fly, treatment is usually in the form of a relatively viscous formulation that is spread on to the back of the animal (a pour-on formulation); in the case of sheep scab, dipping and showering are the most therapeutically and economically effective methods currently available.

Fish too are susceptible to external parasites, and as fish farming (aquaculture) becomes more important, so the effects of disease become more significant. Salmon farming is a fast-growing industry in many parts of the world, particularly in North America, Chile, Norway, and Scotland. Salmon are vulnerable to infestation by the sea louse, an arthropod that attacks the external surface of the fish and in severe cases causes death.

Anthelmintics

'Anthelmintics' is a term almost universally abused to describe agents used to treat internal parasite infestations and not merely those caused by helminth worms. Many of the diseases caused by internal parasites can be extremely distressing to affected animals, and all can result in substantial economic losses. A number of drugs have been developed to combat these diseases, including the benzimidazoles, levamisole and invermectin.

The first benzimidazole to achieve widespread use in veterinary medicine was thiabendazole, but newer compounds include albendazole, oxfendazole, fenbendazole, and mebendazole. Levamisole is extremely efficacious in the treatment of gastrointestinal nematodes in cattle, sheep, and pigs. Ivermectin is a mixture of two closely related compounds derived from abamectin, a metabolite of *Streptomyces avermitilis*, and it has found wide use as an antiparasitic agent in veterinary medicine (and in some areas of human medicine).

Antifungal Agents

In veterinary medicine, several drugs have found uses as antifungal agents for application to the external surfaces of the body. These include ketoconazole, thiabendazole, aliphatic acids, and benzoic acid. Nystatin and griseofulvin are extensively used as systemic treatments for fungal infections in both food-producing and other species.

Steroid Hormones

It has long been known that testosterone exerts anabolic effects in both humans and animals, and testosterone and chemically related steroid hormones have been widely used for this purpose in beef production. However, the EC has prohibited the growth-promoting uses of steroid hormones in animal production, although certain so-called zootechnical (e.g., synchronization of estrous for mating) and therapeutic (e.g., treatment of recurrent abortion) uses are still permitted using naturally occurring compounds or closely related derivatives. In other countries, notably in the North and South Americas, the growth-promoting uses of steroid hormones are legally permitted.

Regulatory Control of Veterinary Medicines

Regulatory control of the uses of veterinary medicines is almost universal, and, as described earlier, drugs must meet exacting standards of efficacy, quality, and safety. In the UK, for example, human and veterinary medicines are controlled by the Medicines Act 1968 and by integrated EC legislation. Product licences and other forms of marketing authorization are granted by a licensing authority established under the act. The Licensing Authority is defined in the act as the Health and Agriculture Ministers acting together, and in practice, responsibility is given over to civil servants working in the Department of Health for human medicines, and in the Veterinary Medicines Directorate (VMD) of the Ministry of Agriculture, Fisheries and Food (MAFF) for veterinary medicines. Applications for product licences are submitted to the VMD by companies together with the quality, efficacy, and safety data. Staff of the VMD then vigorously assess these data and submit them with their appraisals to

the independent Veterinary Products Committee appointed under the Medicines Act. This committee may then recommend licensing, require further information, or refuse the application. When a product is not recommended for licensing, companies have recourse to an appeals procedure, whereby they can submit their arguments. (*See* **Legislation**: Contaminants and Adulterants.)

Essentially similar systems exist in other countries, including other member states of the EC. For this latter group, national laws are amended from time to time to incorporate EC legislation. Three European directives are worthy of note for the impact that these have had on national legislation within the EEC.

The two Veterinary Medicines Directives (81/851/EEC and 81/852/EEC) provide a legislative framework for the European 'licensing' of conventional veterinary medicines. They establish an expert committee, the Committee for Veterinary Medicines Products, and offer a system of control, including a multistate authorization procedure within the EC. Moreover, they provide comprehensive guidelines on safety, quality and efficacy. The so-called Feed Additives Directive (70/524/EEC) covers both medicinal and nonmedicinal ingredients intended to be added to the animal feeds. Although conventional veterinary medicines and medicinal feed additives are therefore dealt with separately at community level, in the UK, they are subject to the same treatment under the Medicines Act, once they have been accepted by the EC.

On a worldwide basis, the marketing authorization of veterinary medicines and the steps preceding this can be summarized briefly as follows: development of a drug and its formulations; testing to fulfill the requirements of safety, quality and efficacy; submission of an application for marketing authorization with the data from safety, quality, and efficacy tests to the appropriate national authorities; appraisal, assessment, and consideration by those authorities; granting or refusal (or requirement for further studies) of marketing authorization.

Safety Data Requirements

Safety data with respect to consumer safety can be divided into two main categories: toxicity data and residues data. In recent years, there has been an increasing demand for data on microbiological safety with respect to possible effects on the gastrointestinal flora of consumers.

Toxicology Studies

Toxicology data usually take the form of the results from a package of studies using laboratory species and *in-vitro* tests. Pharmacokinetic and pharmacodynamic data are also used where relevant in the interpretation of the results of these endeavors. The precise requirements for toxicology testing differ from country to country, but in general terms, they are exemplified by those of the EC, which include the following:

- single-dose (acute) toxicity;
- repeated-dose toxicity;
- reproductive toxicity: effects on reproduction; effects on the embryo or fetus and teratogenicity (birth defects);
- mutagenicity studies;
- carcinogenicity (induction of tumors) studies;
- pharmacodynamics.
- pharmacokinetics;
- observations in humans.

There are three basic aims in conducting toxicology studies: to identify a no-observed effect level (NOEL), to calculate an acceptable daily intake (ADI), and to determine a maximum residues limit (MRL).

The NOEL is the lowest dose level, usually quoted in milligrams per kilogram bodyweight, below which an effect or range of effects do not occur in the species being investigated (usually mice or rats). It is usually necessary to eliminate those effects thought to be irrelevant – usually because they are known to occur only in rodents or because they represent a phenomenon induced by excessive doses – and then select the study thought to be of most relevance, although in practice, the lowest NOEL from the battery of tests is often used.

The ADI is calculated by dividing the NOEL by an arbitrary safety factor. This is usually 100 for minor toxic effects, but factors of up to 2000 may be used with severe effects or when the battery of tests is considered to be deficient in some relatively minor aspect; if deficient in some major area, e.g., if a carcinogenicity study has not been conducted, an ADI may not be set. The ADI is often expressed in terms of human weight by use of the additional factor of 65 kg, this being widely accepted as representing human adult weight. Hence, the ADI can be expressed (in milligrams per day) as follows:

$$\text{ADI} = (\text{NOEL} \times 65)/\text{safety factor}.$$

The MRL is the maximum permitted level of the drug residue, which regulatory authorities perceive as being acceptable in food of animal origin on the basis of the results of the safety studies described earlier. As such, it is often difficult to describe in purely arithmetical terms, for, although it is based primarily on the ADI, it must take into account other factors, not least of which is the intake of the

food commodity in question. Every consumer has a varied intake of most of the products of food of animal origin, such as muscle, fat, kidney, and liver; some, for example, eat more liver or kidney than others. To try to cover the majority of possibilities, the Food and Agriculture Organization, World Health Organization (FAO/WHO) Joint Expert Committee on Food Additives (JECFA) has recommended standard daily intake values of 300 g of muscle, 100 g of liver, 50 g of fat, 50 g of kidney, 100 g of egg, and 1.5 l of milk to be used in the elaboration of MRLs. The types of food-producing animals are shown in Figure 1. In general terms, the ADI is 'spread' across the different types of food commodity, bearing in mind their relative standard intakes, so that MRLs, which will not result in the ADI being exceeded, can be elaborated.

When considering values for MRLs, a major factor that must be taken into account is the chemical nature of the residues and their resultant biological activity. This is an extremely complex area and one that is not without controversy. Most chemicals, including veterinary medicines, when given to animals are converted to a range of metabolites, usually but not exclusively by the liver. Consequently, the residues present in tissue may be the parent compound or a mixture of metabolites or both. Moreover, either the parent drug or its metabolites may be highly reactive and may therefore combine with cellular constituents to give rise to so-called bound residues. In these circumstances, it is desirable and sometimes essential to know to what extent these may be released to yield potentially harmful substances following consumption of products of animal origin. The most likely place for such a release to occur is in the gastrointestinal tract of the consumer, and a number of animal as well as several chemical models have been developed in an attempt to provide information on this area of hazard assessment. One of these makes use of a technique known as relay toxicology, although in this context, relay pharmacology might be more appropriate. The radiolabeled drug is administered to the food-producing animal, which is later slaughtered, and its tissues, known to contain bound residues, are fed to laboratory animals such as rats. Detection of radioactivity in the plasma (for example) of these animals would indicate that the bound residues are bioavailable and, as a result of digestive processes, have been released for subsequent absorption. Chemical methods using solvent extraction and acid–base treatments investigate the ease with which bound residues can be released. These methods then determine whether or not the contribution from bound residues needs to be taken into account in the MRL setting procedure.

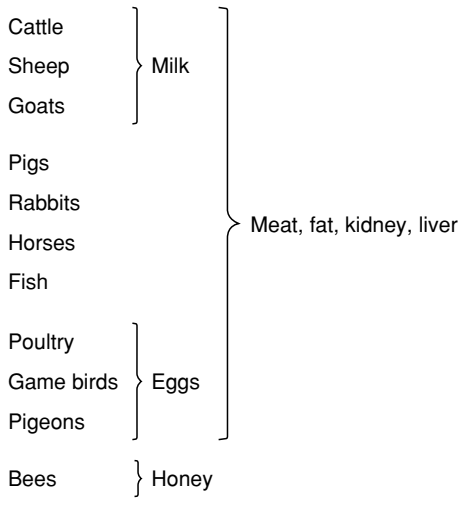

Figure 1 Major food-producing species and their products important in considering maximum residues limits (MRLs) and residues studies. Reproduced from Antibiotics and Drugs: Uses in Food Production, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

As indicated earlier, microbiological safety testing has been proposed for use in the hazard assessment process and indeed has been incorporated into some testing guidelines, including those of the EC. The requirement for such testing is based on the premise that residues of some antibiotic and antimicrobial compounds may have the potential to affect adversely the gastrointestinal flora of the consumer, either by favoring the growth of resistant bacteria or by allowing the growth of organisms not normally found in any numbers in the gastrointestinal tract, by reducing the numbers of other organisms that normally suppress them. This is an extremely controversial area of safety assessments for two main reasons. First, despite the use of antibiotic and antimicrobial drugs in veterinary medicine for many years, there is no evidence to suggest that harmful effects have arisen in the human population as a result of biological changes in the gut flora. Second, the tests proposed to identify these effects have not been validated, so that even if the effects do exist, it is not known whether or not the proposed tests would actually detect them.

There are three tests currently available. Human volunteer studies involve the administration of the drug and subsequent examination of feces and the oral cavity for changes in floral composition. The major alternative involves the use of germ-free rodents in which human gut flora have been seeded into the gastrointestinal tract. These are then given the drug under investigation and changes in the gut

flora monitored. The third approach makes use of *in-vitro* studies of the susceptibilities of various types of bacteria to antibacterial drugs, before and after exposure to low, sublethal levels of the drug. The numerical results in terms of dose can then be employed in the calculation of the ADI.

Residue Studies

Having determined an MRL value (or values) for a drug, it is then essential to ensure that residues in the tissues or other products of food-producing animals do not exceed these. This is achieved by determining the withdrawal (or withholding) period for the drug in question. Small groups of animals are treated with the medicine, usually at the maximum dose recommended for its use in practice. The animals are then slaughtered in a serial manner after various intervals to determine when residue levels fall below the MRL. This time period for depletion of residues to below the MRL is then usually chosen as the withdrawal period; animals must be retained unmedicated during this time as the minimum interval between drug administration and slaughter. Where appropriate, milk, eggs, and honey must be discarded until this minimum time has elapsed.

Enforcement

There is little point in progressing through the various procedures detailed above if the withdrawal period is ignored, and unacceptable levels of residues result. There is often pressure to ensure that animals are sent to slaughter at particular times, and this can lead to abuse.

To ensure that withdrawal periods are observed, most countries operate some form of residues surveillance scheme. In the UK, for example, over 40 000 samples are taken annually from slaughterhouses, and these are tested for residues of various veterinary drugs in compliance with the requirements of the EC Residues Directive (86/469/EEC). Other EC member states carry out similar surveillance in order to comply with the requirements of this directive. The system allows enforcement officers to trace carcases back to farms to determine why the problem arose and, where necessary, to take legal proceedings against offenders.

The Codex Alimentarius Commission

The Codex Alimenatarius Commission is a joint WHO and FAO body, and one of its objectives is to ensure that food of plant and animal origin worldwide is safe for human consumption. It has recently commenced work on establishing MRLs for veterinary drugs, having been involved for many years in setting these for pesticide residues. The Codex is advised on toxicological and residues issues by JECFA, the published scientific reports of which summarize the major conclusions and the proposed MRLs.

Given the international standing of the Codex system and of the JECFA, it seems likely that the MRL values that it promulgates will find their way eventually into various national regulations. In particular, it offers a basis for scientific assessment not currently available in some poorer and less developed nations.

Concluding Considerations

In most countries of the world, veterinary medicines are assessed for their ability to induce toxic effects, and these effects and the doses that produce them are taken into account when calculating the ADI, which is in turn used to determine an MRL value or values. Residues studies are then used to determine when levels of the drug and its metabolites are depleted to below the MRL in food-producing animals. Residues surveillance is essential to ensure that withdrawal periods are observed and, moreover, to ensure that the consumer is not exposed to unacceptable residue levels.

Residue Determination

A A Bergwerff and J Schloesser, Utrecht University, Utrecht, The Netherlands

Residue Determination

Farming of husbandry animals, as well as aquatic animals, is associated with veterinary application of pharmaceuticals, with the aim of influencing growth, weight gain, fat/protein distribution, milk production, stress, microbial infections, inflammation reactions etc. (*See* **Antibiotics and Drugs: Uses in Food Production**). This administration of pharmaceuticals results in so-called residues in the treated animal, including its edible parts, and products such as muscle (meat), organs, eggs, honey, and milk.

In some cases, residues are persistent, and concentrations may be high enough to affect the health or well-being of the consumer. In the case of direct carcinogenic substances, in theory, a single molecule may cause malignancies in the consumer. The veterinary use of such substances, when xenobiotic, is of course unacceptable. Veterinary medicinal products that have the ability to accumulate in the animal are banned world-wide as well. As well as the risk to public health, the production or quality of food may be affected by residues, for example by inhibition of fermentation processes during cheese production.

This phenomenon of negative effects of lagging drugs is known as the 'residue problem.' Controlling this problem through residue determination in the food chain from 'stable to table' is necessary to guarantee food quality and safety and to secure the consumer's trust.

Test at Maximum Residue Limit

In the case of registered substances, and thus substances allowed for veterinary use, international, national, and supranational legal bodies have agreed on so-called 'maximum residue limits' (MRL) for each edible product, and for each husbandry species. The consumer may be exposed to a nonacceptable health risk when this MRL is offended, i.e., the concentration of the indicator molecule is in excess of this concentration. This makes statutory and nonstatutory control of residues in food of major importance. MRL values may differ from one (inter)national authority to another, as consensus is not always reached on quantitative public health risks.

Authorities have also introduced a definition for residues of veterinary medicinal drugs, which, according to EU council regulation 2377/90, is:

> All pharmacologically active substances whether active principles, excipients or degradation products, and their metabolites which remain in food stuffs obtained from animals to which the veterinary medicinal product in question has been administered.

This description clearly does not include contamination arising from environmental substances, phyto-, phyco-, or mycotoxins, or as a result of food handling, processing, and preparation. The description highlights the environmental influences on the original molecules administered to the animal. The chemical appearance of a residue in muscle (*ante mortem*) or in meat (*post mortem*) is not static. In addition to biochemical processes in the animal, storage, food processing, and food preparation, which may include fermentation and heating, frequently initiate reactions converting the original pharmacon into derivatives. The residue analyst has to account for these processes, since they may mask the presence of residues.

Relatively soon after administration, furazolidone, for example, is metabolized completely and occurs as a so-called bound residue, which is a covalent linkage of the residue molecule with predominantly proteins. Bound residues are, by definition, not extractable. The remaining and nonreacting 3-amino-2-oxazolidone fragment is extractable and is used for furazolidone residue determination. The cephalosporin ceftiofur is converted into a reactive desfuroyl ceftiofur species, which reacts with itself, proteins, and other biomolecules. The residue is released chemically and stabilized prior to residue analysis. Another example is that of the antibiotic sulfadimidine, which may occur in the presence of relatively high concentrations of glucose, as in sausages, as an extractable sulfadiminyl glucose residue. In the living animal, many veterinary drugs are sulfated or conjugated to glucuronic acid in order to detoxify and excrete these substances. Incubation with sulfatases and glucuronidases prior to residue determination may be necessary to obtain reliable results.

Authorities have to decide on the indicator residue molecule for analysis. The MRL value of this indicator molecule should correspond with the total concentration of residue components, including derivatives of *ante-* and *post-mortem* reactions.

Analysis Strategies

Before going into a detailed description of residue analysis techniques, it should be noted that two different situations occur, which dramatically influence the desired degree of reliability of an analytical method.

In the situation of registration of pharmaceuticals, methods are designed and validated in well-defined experiments. A defined number of healthy animals are treated, allowing statistical analysis and averaging of errors. Target tissues may be sampled, and these usually contain easily detectable amounts of residues. In contrast, in an inspection or a monitoring situation, a juridically useful judgment should be made on the basis of a single sample for which the history is generally unknown and the concentrations are usually relatively low. In most cases, meat is sampled, which is mostly not the ideal matrix to trace the (illegal) use of pharmaceuticals. Furthermore, in contrast to the 'registration methods', time pressure is relatively high in the field of 'forensics' especially in the case of inspection of carcasses in the slaughter line. Swine are slaughtered at a rate of up to 12 carcasses per minute, whereas chickens are slaughtered at a rate of up to 270 exemplars each minute. The storage capacity becomes critical when a decision on condemnation of a carcass has to be made. The quality criteria for analytical methods in these different situations may therefore vary considerably.

The situation and analysis strategy therefore determine the characteristics of the assay of choice. The ideal method, which is inexpensive, fast, specific, selective, sensitive and allows a high throughput, does not exist. Compromises have to be made. A low-cost screening method with a high throughput may be followed by a usually more expensive, more selective, more sensitive, and specific confirmatory method. In arbitrage situations, a reconfirmation may be needed through so-called reference methods involving expensive instrumental techniques requiring highly skilled personnel.

Inventory Expected Residue Levels

Of the enormous collection of veterinary drugs, antibiotics are used most frequently and in the largest amounts compared with the other groups listed in Table 1. In the EU, a considerable part of antibiotic use is still for growth promotion. From the point of view of residue analysis strategies, it is important to consider the use of a drug before developing or introducing a new method in the residue laboratory. The different levels at which veterinary drugs are applied will result usually in proportional concentrations in edible tissues. For that reason, legal antibiotic growth promoters do not result in high levels of residues. Tracing the use of illegal antibiotic growth promoters in animal products may be more worthwhile, but will require sensitive tests amenable for detecting relatively low concentrations. Therapeutic use of antibiotics, however, may yield residues at concentrations of milligrams per kilogram, when withdrawal times are not obeyed, or as high as grams per kilogram at the injection site. The withdrawal time is the prescribed interval between administration and allowance to bring products of a treated animal to the market.

Besides antibiotics, the occurrence of substances with hormonal activity is attracting much attention, at least in the EU. Since steroid hormones are effective at very low levels, tracing residues in meat needs ultrasensitive assays for detecting concentrations as low as the subnanogram per kilogram level. These methods also may need to be able to differentiate between endogenous and administered, exogenous hormones, as in the case of nortestosterone of 17β-estradiol, for example. In these situations, it is difficult to answer the questions 'when is a residue a residue, and when is a residue not a residue?'

Monitoring and inspection programs should be aware of the use of 'cocktails' of illegal hormonal compounds. The mixture will exert its biological effect, but the individual components may not be detected as a result of low concentrations per component. The illegal use of β-agonists may co-occur, for example, with corticoids and thyreostats. Residue analysis strategies may therefore focus on the most easily extractable and detectable residue in first screening.

Sampling

In setting up a method, a few steps can be recognized (Figure 1). Each step from sampling, extraction, and concentration to (instrumental) analysis is essential and should be carried out appropriately for successful analysis. The statement: 'collect the wrong sample, or collect the right sample incorrectly, and you will trivialize all that follows, rendering your data worthless' emphasizes the importance of the first step, namely sampling. The selection of the laboratory sample for analysis, its transport, and storage should always be carefully evaluated (cf. Table 2). The storage of a

Table 1 Classes and examples of veterinary drugs[a]

Activity/class	*Subclass*	*Examples*[b]
Antibiotics, including growth-promoters and chemotherapeutics	Nitrofurans	Furazolidine, nitrofurazone, furaltadone
	(Fluoro)quinolones	Enrofloxacin, oxolinic acid, flumequine
	Tetracyclines	Oxytetracycline, doxycycline, chlortetracycline
	Penicillins and cephalosporins	Amoxiciline, cloxacillin, penicillin G, ampicillin, ceftiofur
	Aminoglycosides	Gentamicin, lincomycin, streptomycin
	Sulfonamides	Sulfadimidine, sulphaquinoxaline
	Macrolides	Erythromycin A, spiramycin, tylosine
	Peptides	Virginiamycin, bacitracin
	Miscellaneous	Chloramphenicol, carbadox, salinomycin
Anti-ectoparasitica	Phosphoesters, carbamates, pyrethroids a.o.	Dichlorvos, carbaryl, deltamethrine, lufenurone, cyromazin, lindane
Anthelmintics	Imidazothiazoles	Levamisole, dexamisol
	Benzimidazoles	Mebendazole, fenbendazole, lobendazole
	Tetrahydropyrimides	Pyrantel
	Avermectins	Ivermectin, abamectin, moxidectine
	Salicylanilides	Closantel, rafoxanide, niclosamide
Coccidiostats[c]		amprolium, dimitridazole, monensin,
Antimycotica		nystatine, griseofulvine, enilconazole
Hormones	Glucocorticosteroids	Dexamethasone, cortisone (hydrocortisone)
	Androgenic and estrogenic sex steroids	17β-Estradiol, methyltestosteron, trenbolone
	Progastegens	Megestrol, medroxyprogesteronacetate
	Resorcylic acid lactones	Zeranol, taleranol
	Stilbenes	Diethylstilboestrol, hexoestrol, dienoestrol
	β-agonists	Clenbuterol, salbutamol, bromobuterol
	Thyreostats	Tapazole, thiouracil
	Proteins	Somatropins
Tranquilizers		Azaperone, carazolol, xylazine

[a]This table is a summary and not a complete list of compounds and classes of compounds used in veterinary medicine.
[b]Some of these compounds are registered veterinary drugs. The EU-accepted MRL values in food from bees, cattle, deer, horses, pigs, poultry, salmonidae, sheep, etc. are published on the internet at http://eudrams1.is.eudra.org
[c]Many antibiotics are used as coccidiostats as well.

laboratory sample of homogenated or intact tissue may influence the final determined residue content dramatically. Furthermore, the test sample should reflect the laboratory sample, which usually means thorough homogenization of the latter. The laboratory sample should reflect the tissue, body fluid, or total animal that is sampled. At the same time, the result of an individual sample should not be overvalued. Unfortunately, many mistakes have been made at this level, sometimes with huge political impact.

When tracking the illegal use of prohibited substances, the choice for the most suitable matrix for analysis is obvious, since the MRL in an edible product does not have to be tested. In such cases, urine (anabolics), feces (steroid hormones), bile (antibiotics), retina (β-agonists), or hair (β-agonists), instead of meat, may be most suitable.

Extraction and Clean-up

Milk and diluted honey, but also urine, serum used to trace contamination of the animal, may be analyzed in some cases without extensive sample processing (Figure 1). Solid matrices, including fat, hair, meat, kidney, retina, and skin, however necessitate extraction of residues prior to analysis. Specific solvents are mixed with the homogenized matrix to facilitate solubilization of the residues. As an exception, the collection of meat drip through heating or compressing, or of pre-urine from the kidney cortex may be sufficient for microbiological growth-inhibition assays (see below).

Matrices are complex, and it should be noted that the residue analyst looks for a single particle in a heap of a million to billion other potentially interfering particles. These particles are also for a part solubilized and extracted from the matrix. Clean-up of samples is therefore necessary in most cases to overcome any interference of the analysis method.

A good knowledge of the chemical nature of the analyte in terms of stability, pK_a value(s), polarity, and functional groups will support the design of a selective, effective, and appropriate clean-up procedure. Before the availability of sorbent materials in the mid-1980s, sample clean-up was carried out by

liquid/liquid partition and/or atmospheric pressure chromatography. Sample concentration was obtained through rotary evaporation. A major improvement in this laborious work was obtained by the launch of commercially available, and thus standardized, solid-phase extraction (SPE) cartridges. The cartridges enabled selectivity and concentration in a single step with minimal sample and solvent consumption. The choice of stationary phases and supportive material in SPE is comparable with that used in high-performance liquid chromatography (HPLC), including normal- and reversed-phase, partition and ion-exchange chromatography. Combinations of phases within a single cartridge are available as well. For example, so-called 'restricted access materials', such as alkyl-diol-silica particles, combine the ability of gel filtration and solid-phase extraction within one material. These special SPE materials allow the extraction of aqueous extracts or liquid samples like milk or urine without prior deproteination. With the advent of chelating agents and the availability of antibodies and receptors, it is now possible to develop cartridges facilitating affinity extraction with a high selectivity.

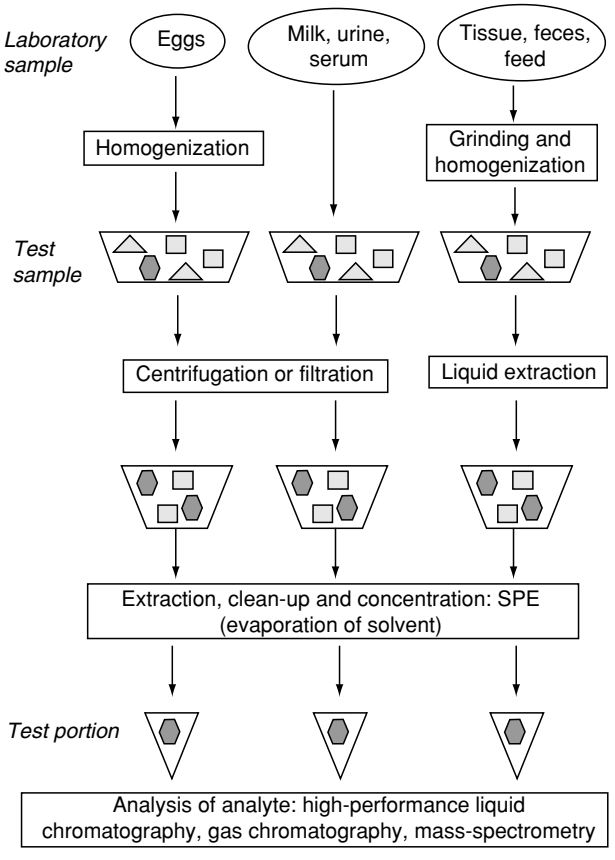

Figure 1 Typical scheme for sample processing involving SPE and determination of residues of veterinary drugs in different matrices.

More recently, disks consisting of membranes of polymers with high, reversed and ion-exchange phase capacity have been introduced. These disks are used as filters, allow fast-flow processing, purify and concentrate analytes like SPE cartridges with small to large sample volumes. Interfaces are available, enabling the coupling of such disks to HPLC columns.

Another sorbent extraction approach is matrix solid-phase dispersion, which allows homogenization and extraction by mixing of sorbent material in a single run omitting liquid extraction of the homogenate as a separate step. Columns prepared with the mixture are eluted in a similar way to SPE cartridges. Alternatives for these extraction procedures are supercritical fluid extraction and accelerated solvent extraction. The approaches are slowly gaining popularity but are still used in niche applications.

After extraction, the analyte-containing solution often has to be concentrated by removing excess solvent through evaporation or sublimation by applying a vaccum or a flow of an inert gas (nitrogen) sometimes in combination with heat. Loss of a part of the amount of the analyte can occur if unsuitable glass- or plastic ware is used. Many analytes, like penicillins and avermectins, tend to become adsorbed by free silanol groups of glass surfaces. Deactivation of free silanol groups through silanization of glassware

Table 2 Stability of veterinary drug residues in different matrices upon cold storage and heating

Pharmaceutical	*Storage at −18 °C*	*Storage at + 4 °C*	*Heated (Percentage activity recovered)*
Penicillin	Stable in muscle for 14 days	Stable in muscle for 14 days	10% in pork at 80 °C for 10 min
	Degraded in kidney	Degraded in kidney	0% in sterilized sausages at 125 °C for 65 min
Furazolidone	Unstable	Unstable	
Oxytetracycline	Stable for 6 months	Stable for 6 months	No recoverable activity in pork at 100 °C for 10 min
Sulfadimidine[a]	Degraded in liver	Degraded in liver	100% in well-done steak at 80 °C for 30 min
Chloramphenicol	Degraded in liver	Degraded in liver and kidney	37% in pork at 80 °C for 10 min
Spectinomycin	Degraded in liver and kidney	Degraded in liver and kidney	

[a]Sulfadimidine reacts with nitrite and glucose in sausages.

using chlorsilane often enhances the recovery in such situations.

Analysis of Analyte

Overviewing all available methods for separation and detection of residues in the nonprocessed test sample or in the obtained extract, an enormous gamma of (immuno)chemical and physicochemical approaches can be disentangled (Table 3). Thin-layer chromatography (TLC) was applied frequently in the early days of residue analyses and was closely followed in time by gas chromatography (GC). Analytes on TLC plates were visualized by generating chromophores or fluorescents by applying (through spraying or dipping) derivatizing molecules. Thermal conductivity, flame ionization, and, in certain applications, electron-capture and nitrogen phosphorus (NPD), detectors were popular in GC analysis. In current residue GC methods, the universality, selectivity and specificity of the mass spectrometer (MS) in combination with electron-impact ionization (EI) is by far preferred.

HPLC, in combination with a range of different detectors, became popular in the 1980s and 1990s. The stationary phases used predominantly are reversed-phase materials, especially phenyl-hexyl, octyl- or dodecyl-modified silica gels, but also, partition and ion-exchange chromatography is found in residue-determination protocols. Highly end-capped silica gels or polymeric stationary phases may be necessary to prevent tailing of amphoteric residues, such as tetracyclines. Polymeric phases also allow elution under alkaline conditions without solving the supporting silica material.

In addition to adequate extraction, clean-up and chromatography, the choice of detection system is an important parameter to achieve selectivity and specificity. Analytes, which are not detected by light absorption, refractive index, or fluorescence at the level they are expected to occur in animal-derived matrices, may require chemical modifications rendering them as fluorescents, chromophores, or UV-light absorbing compounds. For example, spectinomycin is converted postcolumn into a fluorescent derivative following oxidation and reaction of two *o*-phthaldialdehyde molecules with the two primary amines into conjugated *iso*-indoles. In such cases, chemical modification may also introduce a tremendous improvement in the selectivity of the method.

Alternative detection systems compatible with LC that have been used in residue analyses comprise evaporative laser-scattering and electrochemical detection, including (pulsed) amperometric detection.

In electrochromatography, electroosmotic flow is used for mobile phase delivery. Packed and open tubular columns are used in these systems, giving very small band widths, since extremely small particles can be used as the stationary phase. The development of heat is, however, a major drawback of this separation technique. Instead of chromatography, capillary electrophoresis with a high resolving power may be considered as well. However, the maximum sample size, which is very small, limits its use in residue analysis. To obtain namely dissolved extracts, relatively large solvent volumes are required, which reduce residue concentrations.

The identification of analytes in TLC, GC, and LC separation systems is carried out by comparison of the migration or elution positions with those of standard substances under identical chromatographic and detection conditions. However, comigration or coelution is usually not considered as a proof of identity of the analyte, especially if juridical consequences are involved. For this reason, combination of chromatography with spectrometric (MS) or spectroscopic detection techniques (NMR, IR) may provide data with

Table 3 Examples of residue analysis approaches

Analyte	*Matrix type*	*Analytical method*	*Sample pretreatment*
Penicillins (group-specific method)	Meat	GC-NPD or GC-EI-MS	Acetonitrile/buffer extraction, multiple liquid–liquid partition ion-exchange-SPE, elution with sodium chloride, liquid/liquid partition, derivatization
Penicillins	Milk	HPLC, photochemical postcolumn derivatization, UV detection at 300 nm or electrochemical detection	Centrifugation and ultrafiltration, on-line SPE (restricted-access material)
Avermectins	Liver	HPLC, fluorescence detection (λ^{ex}: 365 nm λ^{ex} 470 nm)	Acetone/water extraction, liquid–liquid partition, SPE, concentration, precolumn derivatization
Quinolones	Poultry meat	HPLC-APCI-MS/MS	Phosphate-buffer extraction, SPE
Tetracyclines	Kidney	HPLC-ESI-MS/MS	McIlvain-buffer extraction, on-line SPE
Sulfamethazine, Sulfdaizine	Meat, milk	Biosensor (surface plasmon resonance)	Homogenization with buffer, centrifugation

sufficient evidence. Of the spectroscopic approaches, nuclear magnetic resonance (NMR) and Fourier-transform infrared (FTIR) spectroscopy are most suitable, although certainly not in routine settings. The so-called hyphenated techniques, like in TLC-MS, GC-MS, LC-MS, LC-NMR, and GC-FTIR, have proved very powerful techniques for separation and molecular identification of the residue.

The evolution, and sometimes revolution, of mass selectors, ionization techniques, and their interfacing, has made the mass spectrometer standard equipment in a residue analysis laboratory. Mass selectors comprise sector, quadropole, ion-trap, time-of-flight instruments, and combinations thereof. In particular, mild-ionization techniques, such as atmospheric pressure chemical ionization (APCI) and electrospray ionization (ESI), facilitate MS analysis of small to relatively large and hydrophobic to hydrophilic molecules. APCI and ESI are therefore very suitable for residue determination. Using mass spectrometer-induced molecular fragmentation, it is possible to elucidate the chemical structure of the residue. A major pitfall is matrix-caused interference, which may reduce the response of the analyte to nil.

Besides physicochemical methods, the use of microbiological growth-inhibition assays to test meat and milk for the presence of antibiotics is popular over a long period of time. In terms of the number of analyses performed each year, this type of residue determination is most important. In addition to the low cost, this may be a result of an early implementation of such tests in national legislation. Examples of such methods are the EU Four Plate Test, the New Dutch Kidney Test, and the Delvotest SP, which use very antibiotic-sensitive bacterial reporter strains, such as *Bacillus subtilis* and *Bacillus stearothermophilus* var. *calidolactis*. These bacteria are inoculated under optimal conditions with and without sample. After culturing, results are read from visible inhibition zones or from the color change of the bacterial suspension in agar gels.

The availability of relatively large amounts of immunoglobulins in the 1980s, of which the production could be assured, enabled the development of immunoassays, like radio-immunoassays, enzyme-immunoassays, enzyme-linked immunosorbent assays, and later strip- and dip stick-based immunoassays. Specific enzymes and receptors have been used in a similar way in such analysis approaches, which are referred to as receptor assays, such as the commercially available CHARM Test II and Penzyme III. The major advantage of immunoglobulins and receptors is their high specificity, which reduces the sample clean-up to a minimum. However, their high specificity is a disadvantage in multiresidue methods.

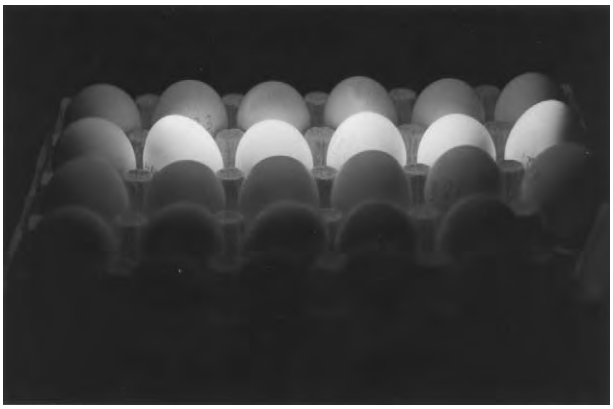

Figure 2 Eggs examined under UV light. The white/yellow fluorescence of the eggs in the middle is a result of tetracycline residues complexed with calcium in the eggshell. Positive eggs were collected from tetracycline treated laying hens. Courtesy of Dr. Michael Petz and Dr. Georg Zurhelle, University of Wuppertal, Germany.

In immuno- and receptor assays, the binding of small-molecular-weight compounds to their corresponding receptors or immunoglobulins is not directly detectable. These assays are therefore mostly competitive assays in which the analyte competes with a radio-isotope- or enzyme-labeled reporter compound for a limited number of binding sites. In contrast to conventional immuno- and receptor assays, advanced biosensor techniques do not require this labeling in most cases. From the point of view of signal transduction, biosensors fall into four categories, namely mass, optical, electrical, and thermal. Of the few applications so far, the 'surface plasmon resonance' optical biosensor has shown benefits in screening residues, including ciprofloxacin, clenbuterol, enrofloxacin, gentamycin, streptamycin, sulfadiazine, and sulfamethazine.

The ability of tetracyclines to fluoresce and to form complexes with alkali metals has revealed its presence in many cases (Figure 2). The article entitled 'The dog with the luminous bone' in the *Daily Telegraph* several years ago is certainly an example of a tetracycline contamination of bone tissue.

Quality Assurance

The validation of a developed method, but also that of an existing method newly introduced in a lab, is of absolute importance to assure reliable outcomes. In fact, international trading requiring certification of foodstuffs dictates that the performance of analytical methods be supported by validation data. The topics that have to be assessed are limit of detection and quantification, specificity, selectivity, accuracy,

precision, reproducibility, repeatability, etc. The robustness of the method should also attract attention. Critical points that may influence the measurement like minor changes in pH, temperature, SPE flow rate, the use of different SPE batches or of different producers, etc. therefore have to be evaluated as well.

In analysis strategies, the predictive value of the method should be considered. The false-negative rate of validated screening methods should be less than 5% (β-error) at the level of interest, whereas up to 20% false positive outcomes are not appreciated but are generally accepted. In contrast, false-positive results are not accepted in confirmatory methods, which usually carry a higher risk with systemic errors and interference. Criteria for the positive identification and quantification of residues are increasingly gaining attention. The suitability of confirmatory and/or reference methods for registered veterinary drugs, as proposed, is given in Table 4. In the case of banned substances, methods have to be based on molecular spectrometry, and the number of so-called 'identification points' (Table 5) should be at least four for positive identification.

Besides validation of methods, quality-assurance systems, such as good laboratory practice (GLP) are also essential for residue laboratories. Such systems not only ensure clarity on the performance of the method, but also increase the traceability of the results. Furthermore, GLP or similar systems assure appropriate laboratory management and properly trained analysts.

Table 4 Suitability of methods for confirmatory analysis of nonbanned veterinary medicinal products

Technique	*Criterion*
LC or GC in combination with MS	Suitable (at least three identification points)[a]
LC-diode array detector	Suitable
Two-dimensional TLC-spectrophotometry	Suitable
GC-electron capture detector	Suitable, only if combined with other methods
LC-immunogram	Suitable, in combination with other techniques
LC-UV/VIS (single wavelength)	Suitable, in combination with other techniques

[a]See **Table 5** for clarification of identification points. Adapted from the pending revised EU commission Decision 93/256/EC.

Table 5 Awarding mass-spectrometric approaches for confirmatory analysis of banned veterinary products with so-called identification points[a]

MS technique	*Identification points awarded per ion*
Low-resolution (LR) MS	1.0
LR-MS^n precursor ion[b]	1.0
LR-MS^n transition products	1.5
High resolution (HR) MS	2.0
HR-MS^n precursor ion	2.0
HR-MS^n transition products	2.5

[a]At least four identification points are necessary for confirmation of banned veterinary drugs. Adapted from the pending revised EU Commission Decision 93/256/EC.
[b]MS^n spectra are generated with tandem MS machines (MS^2) or with ion-trap mass selectors.

Outlook in Residue Analysis

'Multianalyte', i.e., testing various residues in a single run with a single instrument, is a magical word in the field of residue analysis. It requires generic extraction methods and highly resolving and robust analytical techniques. The fulfillment of this ideal still seems to be far away. Computerization and miniaturization and the introduction of SPE cartridges already have revolutionized residue analysis in the past. Advances in computerization and miniaturization will certainly increase sensitivity and selectivity further. This and further technical improvements in instrumental techniques will make multianalyte analyses possible to an increasing degree. Automation and analysis within minutes and even seconds, but also the type of matrices (body fluids and excreta), will transform future residue analysis labs into clinical chemistry labs.

Recent scandals have shown that residue determination at the slaughter-line stage is not effectual in protecting public health. The need for high analysis frequencies to guarantee consumers' trust is obvious. However, it is impossible to test every product for all possible contaminations. Analysis should be performed in the food chain, starting in the stable and at the feed mill. Laboratory samples should be collected not only from animals, but also from the feed and drinking water in order to trace cross- or other accidental contamination. Furthermore, inspection systems will not focus on the individual animal anymore, but on the complete herd or flock. Analysis of a number easily collectable samples will need to reflect the complete herd and predict the level of contamination of the animals, so that its products can be processed and placed on the market accordingly. At the same time, future veterinary control systems are being developed that will monitor residue levels to be in compliance with withdrawal times and MRL values. The residue lab may therefore be (at least in part) situated in the slaughterhouse or located in a vehicle visiting farms, e.g., for certification purposes. In particular, biosensor systems are attracting considerable attention for such targets. (*See* **Antibiotics and Drugs**: Uses in Food Production.)

ANTIOXIDANTS

Contents

Natural Antioxidants

M H Gordon, The University of Reading, Reading, UK

Background

Natural antioxidants have been of interest for many years because of their ability to retard the development of off-flavors in foods. However, an upsurge in interest in these components has occurred in recent years because of their importance for the prevention of diseases mediated by free radical reactions *in vivo*. The onset of a variety of major health problems, including cancer, atherosclerosis, rheumatoid arthritis, inflammatory bowel disease, immune system decline, brain dysfunction, cataracts, and malaria may be delayed by natural antioxidants.

Natural antioxidants are primarily plant phenolic compounds which may occur in all parts of the plant. Nonphenolics including carotenoids and phospholipids may also show antioxidant activity under some conditions. Plant phenolics are multifunctional. They can act as radical scavengers, metal chelators, singlet oxygen quenchers, or reducing agents. Though they are considered to be safe at normal levels of consumption they have not been toxicologically tested in many cases and therefore the possibility of mutagenic or carcinogenic activity cannot be discounted for some natural phenolics at unnaturally high levels of consumption. Some antioxidants add color, aftertaste, or off-flavor to a product and this may restrict their use in some types of foods.

Natural antioxidants can be found in a wide range of food raw materials. Tocopherols and related compounds occur at levels of about 50–1000 mg kg^{-1} in vegetable oils. Animal fats contain very low levels (e.g., butter oil 20–50 mg kg^{-1}), but cereal germ oils are very rich sources (1500–5000 mg kg^{-1}).

Tocopherols are added to some foods as antioxidants. They occur with various degrees of methylation of the dihydrochromanol ring as α, β, γ and δ-tocopherol. They have the chemical structure shown in Figure 1.

The activity of the tocopherols depends on their concentration, the food system, and the presence of heavy metals since they can act as prooxidants with iron or copper. Tocopherols are strongly effective as antioxidants in emulsions, but they are less effective in oils. Their antioxidant activity under common test conditions in oils decreases from δ-tocopherol> γ-tocopherol > β-tocopherol > α-tocopherol. They are most effective in the presence of a synergist like ascorbic or citric acid. In biological systems, however, α-tocopherol or vitamin E is the most active antioxidant with a strong antioxidant effect in biological membranes. Tocopherols are commercially produced and they are used as food additives. (*See* **Tocopherols**: Properties and Determination.)

About 50 carotenoids can be found in the human diet as minor components of fruit and vegetables. Carotenoids, including β-carotene (Figure 2), demonstrate antioxidant properties under certain conditions. Due to their multiple conjugated double-bond system, the carotenoids act as singlet oxygen quenchers during photosynthesis. They are also able to scavenge free radicals and act as antioxidants at low partial pressure of oxygen.

There is considerable interest in the nutritional properties of carotenoids. Besides the provitamin A property of some of the carotenoids, the antioxidant properties may also be of nutritional significance.

8-Methyltocol (δ-tocopherol)	$R_1,R_2=H$, $R_3=CH_3$

Figure 1 Tocopherol structure.

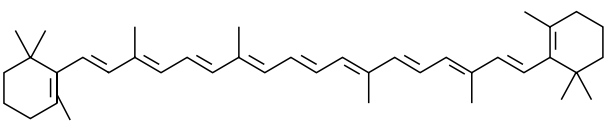

Figure 2 Structure of β-carotene.

Epidemiological studies have found that consumption of fruit and vegetables, which contain carotenoids, is associated with a reduced risk for several chronic diseases, including cardiovascular and photosensitivity diseases, cataracts, and some cancers. However, the results from large controlled trials involving β-carotene supplementation do not always support these beneficial associations, providing in some cases evidence for adverse effects, including an increase in the incidence of lung cancer and overall mortality in smokers.

It has been suggested that other carotenoids, including α-carotene, lycopene, lutein, and zeaxanthin, may show a higher potency than β-carotene in the suppression of the development of various types of cancer, including lung, breast, and stomach cancer. Dietary consumption of tomato products containing lycopene is associated with reduced risk of cancer and coronary heart disease. Although the antioxidant properties of lycopene may be responsible for its beneficial properties, other mechanisms, including effects on intercellular gap junction communication, or on the hormonal or immune system, may be partly responsible. (*See* **Carotenoids**: Occurrence, Properties, and Determination.)

Flavonoids are an important class of natural antioxidants that occur in a wide variety of fruit, vegetables, leaves, and flowers. They are found mainly as glycosides and methylated derivatives. The most important subgroups are the colorless catechins, the red-purple-colored anthocyanidins, the yellow flavonols and flavones, as well as the colorless proanthocyanidins.

The flavonoids share a common C_6-C_3-C_6 skeleton. The flavonoid aglycone normally consists of an aromatic ring (A) condensed with a six-membered oxygen-containing ring (C) which carries a phenyl substituent in the 2-position (B). The six-membered ring condensed with the benzene ring is either a γ-pyrone ring (flavonols and flavones) or its dihydro derivatives (flavanols and flavanones).

Flavonoid Structure (Figure 3)

The position of the attachment of the B-ring to the central C-ring divides the flavonoid class into

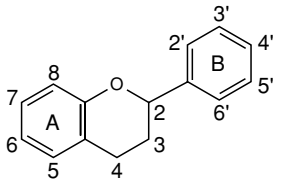

Figure 3 Flavonoid structure.

flavonoids (2-position) and isoflavonoids (3-position). Flavonols including quercetin and myricetin are important natural antioxidants. Quercetin occurs as the glycoside quercetrin in onions, apple skins, and black tea. Anthocyanidins differ from the other flavonoids in having a charged oxygen in the C-ring. The C-ring is open in the chalcones. Flavonoids are often hydroxylated in position C-3,5,7,3′,4′ or 5′.

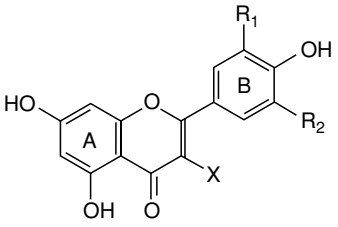
Flavonol and Flavone Structure (Figure 4)

Attention was focused on the nutritional significance of dietary flavonols and flavones by the Zutphen Elderly Study in The Netherlands. The study started in 1960 with 878 men aged 40–59 years and continued until 1985 with 555 of the original subjects and 250 replacements aged 65–84 years. Nutritional intake was studied by cross-checked dietary history for 5 years. The mean baseline of flavonoid intake was 25.9 mg day^{-1} (as aglycones). The major flavonoids in the food were quercetin, myricetin, kaempferol, apigenin, and luteolin. Their sources of intake were mainly tea (61%), onions (13%), and apples (10%).

After adjustment for age, body mass index, smoking, serum total and high-density lipoprotein cholesterol, blood pressure, physical activity, coffee consumption, and intake of other antioxidants and fiber, the flavonoid intake was significantly inversely associated with mortality from coronary heart disease and showed an inverse relationship with the incidence of myocardial infarction.

In Mediterranean countries, wine is an important source of flavonoids (10–20 mg l^{-1} combined flavonoids). This may partly contribute to the low risk of coronary heart disease of wine drinkers who consume a high level of saturated fats in France, the so-called French paradox.

Tea catechins are very strong antioxidants. For the tea catechins, stronger activity than BHA or α-tocopherol in lard autooxidation systems was shown with activity increasing in the order: (−)-epicatechin < (−)-epicatechin gallate < (−)-epigallocatechin < (−)-epigallocatechin gallate (Figures 5–8).



Flavonol aglycone:	X=OH	quercetin R_1=OH, R_2=H myricetin R_1,R_2=OH
Flavonol:	X=glucose	quercitrin R_1=OH, R_2=H
Flavone aglycone:	X=H	luteolin R_1=OH, R_2=H

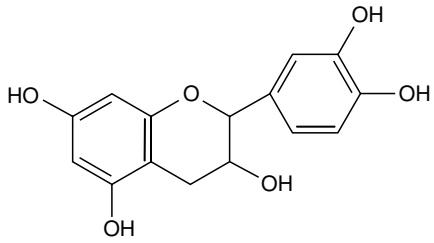

Figure 5 Epicatechin.

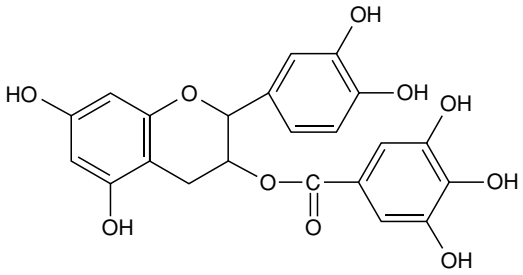

Figure 6 Epicatechin gallate.

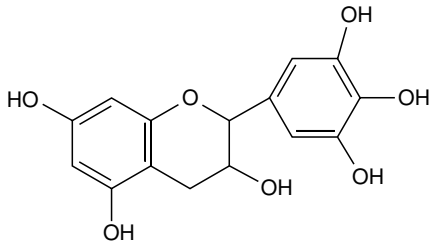

Figure 7 Epigallocatechin.

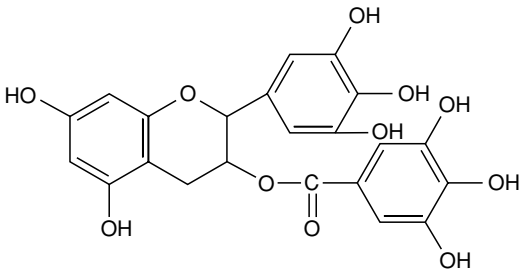

Figure 8 Epigallocatechin gallate.

Isoflavonoids are a subclass of flavonoids which are of interest for their estrogenic activity. The main isoflavones are daidzain and genistein, which occur in soya beans, chickpeas, and lentils. The normal western diet contains much smaller amounts of isoflavones than the Chinese or Japanese diet, due to the low level of consumption of soy products in the west. Epidemiological studies suggest that foods containing phytoestrogens may have a beneficial effect in protecting against several chronic and degenerative diseases, including cancer. Although antioxidant effects may be important, the estrogenic and antiestrogenic effects, induction of cancer cell differentiation, inhibition of tyrosine kinase and DNA topoisomerase activity, and suppression of angiogenesis may be more important.

The unsaponifiable fraction of sesame oil shows good antioxidant activity, and this is mainly attributed to sesamolin which can be hydrolyzed on heating to sesamol which is an active antioxidant (Figure 9).

Olive oil contains a mixture of antioxidants derived from hydroxytyrosol and other polyphenols. From comparisons with a limited number of phenolic constituents, it has been claimed that hydroxytyrosol is the most active antioxidant compound in virgin olive oil, although the concentration of free hydroxytyrosol is low. In the last few years, the antioxidant activity of this compound and its derivatives has been investigated *in vitro*. Oleuropein is an important derivative of hydroxytyrosol, which occurs in large amounts in olive leaves and olive fruits (up to 14% of the dry weight in unripe olives), but it appears to have a weaker antioxidant activity than free hydroxytyrosol in olive oil.

Phospholipids (e.g., commercial lecithin) can also exhibit antioxidant activity in heated oils, where they may act as hydroperoxide decomposers and/or metal chelators. However, they appear to be less active in oils stored at ambient temperature. Phospholipids are present in crude vegetable oils but are removed during oil refining. (*See* **Phospholipids**: Properties and Occurrence.)

Phenolic acids may also play important roles as natural antioxidants.

Hydroxyderivatives of cinnamic and benzoic acids can be found in many plant foods. In oats, esters of caffeic acid (Figure 10, e.g., chlorogenic acid) and ferulic acid seem to be the most important antioxidants. (*See* **Phenolic Compounds**.)

Many spices contain antioxidants, especially oregano, sage, thyme, clove, ginger, and rosemary. The main active compound of rosemary is carnesol (Figure 11).

Organic acids, such as citric and ascorbic acid and its esters, are often used as stabilizers for fats and oils. Citric acid (Figure 12) is a very important antioxidant because it is very effective at chelating traces of metals such as iron and copper that have a strongly detrimental effect on the shelf-life of edible oils. Citric acid is commonly added to oils at the end of the refining process. Ascorbic acid (Figure 13) has a weaker metal-chelating action, but it also removes oxygen and can contribute to the oxidative stability of foods when a limited amount of oxygen is available, e.g., in canned foods.

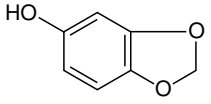

Figure 9 Sesamol.

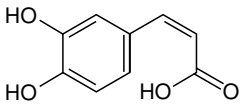

Figure 10 Caffeic acid.

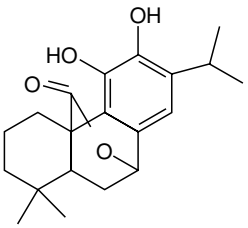

Figure 11 Carnosol.

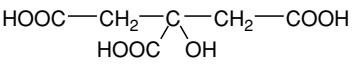

Figure 12 Citric acid.

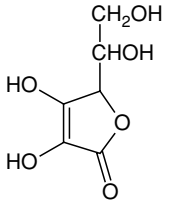

Figure 13 Vitamin C (ascorbic acid).

Amino acids are powerful synergists in combination with phenolic antioxidants, acting as scavengers of heavy metals and promoters of hydroperoxide decomposition. Protein hydrolysates have similar activity. Maillard reaction products (formed by the nonenzymic reaction of amino acids and reducing sugars) have been shown to have some activity, particularly by chelation of heavy metals. Because of their low solubility and color, they can only be added to certain foods. Low-molecular-weight products of carbonyls and amino acids produced by the Maillard reaction, such as dihydropyridines, have strong antioxidant activity. (*See* **Browning**: Toxicology of Nonenzymatic Browning.)

A wide range of other natural plant components have also been shown to have antioxidant activity, e.g., tannins and leaf waxes.

Synthetic Antioxidants

G Ramis-Ramos, Universidad de Valencia, Burjassot, Spain

Background

Lipid Oxidation

Lipid oxidation is a process that results in rancidity and deterioration of fats and progresses via free-radical propagated chain reactions. Free radicals are produced by the reaction of unsaturated fatty acids with molecular oxygen and traces of other oxidants, as metal ions (Fe^{3+} and Cu^{2+} are particularly effective) and H_2O_2, and by UV light. Primary lipid oxidation yields hydroperoxides that cause a variety of secondary reactions with evolution of aldehydes, ketones, acids, and other low-molecular-weight volatile substances. The ensuing decrease in the flavor and color quality, which renders a food unappetizing in

appearance, and the accumulation of toxic reaction products pose a major problem to the food industry. Natural and synthetic antioxidants and antioxidant synergists are substances of low toxicity that slow down lipid oxidation, and therefore, they are used to increase the stability of fat components of food under a variety of storage and cooking conditions.

Further, there is ample evidence showing that free radical oxidation plays an important role in many pathological situations, including many types of cancer, atherosclerosis, coronary heart disease, rheumatoid arthritis, and other degenerative diseases. Antioxidants are also employed in order to prevent and treat these pathologies. Prevention arises as a consequence of the inhibition of the formation of toxic and mutagenic substances during storing, cooking and in the stomach, and the modification of the basal levels of some enzymes, which results in increased detoxification and reduced rates of carcinogenic activation. Other benefits derived from the intake of antioxidants include the increased resistance to radiation effects, assistance in the treatment of gastroduodenal ulcer and craniocerebral injury (including meningitis effects), and help in slowing down the aging process.

Mode of Action and Functions of Antioxidants and Antioxidant Synergists

Some antioxidants are reducing substances that remove oxygen and other oxidants, thus hindering the initiation of free-radical reactions. Examples are sulfur dioxide, sulfites, and sodium nitrite. The antioxidant activity of tocopherols, alkyl gallates, and other phenol derivatives is mainly due to resonance stabilization of their free radicals. Stabilized radicals are not sufficiently reactive, and the chain reaction is terminated. The antioxidant activity of thiodipropionic acid and its esters relies on a rather different mechanism: these decompose hydroperoxides.

Antioxidant synergists are substances that prevent free-radical initiation and catalysis by complexing metal ions. When bound to a ligand with oxygen as the donor atom, the redox potential of metal ions as Fe^{3+} and Cu^{2+} is largely reduced, and their catalytic activity is seriously limited. Typical examples are the polycarboxylic substances, including citric and tartaric acids, and ethylenediaminetetraacetate salts. Some antioxidants, e.g., ascorbic acid and sodium thiosulfate, exhibit both reducing and metal ion complexing capabilities. Phenol derivatives are free-radical scavengers, but they are also effective in complexing iron, copper, and other metal ions.

When two antioxidants of a different type are jointly used, synergistic antioxidant activity is frequently achieved, although sometimes, antagonistic inhibition can also occur. For instance, polycarboxylic acids are often used in combination with oxygen-reactive antioxidants, such as ascorbates and erythorbates, and with free radical scavengers, as butylated hydroxyanisole (BHA) and butylated hydroxytoluene (BHT), to achieve synergistic food protection.

The substances classified by the Codex Alimentarius Commission (CAC) within the class 'antioxidant' or the subclass 'antioxidant synergist' are listed in Table 1. The order of the INS code (international numbering system for food additives) has been followed. As shown in the table, many antioxidants and antioxidant synergists also belong to other CAC classes and subclasses, whose meaning is indicated in Table 2. The subclasses are not subclassifications but descriptions of technological functions of the additive. The equivalent or similar definitions stated by the FDA regulation 170.3 (reg. of title 21, as all other FDA references within the text) are also given in this table.

It should be remembered that the use of antioxidants is not the only way to protect food against lipid oxidation. For instance, protection from light and packaging under an inert atmosphere, e.g., nitrogen gas (INS 941), using a gas-impermeable packing material, also constitutes a nontoxic and excellent solution.

Natural Versus Synthetic Antioxidants

It is customarily understood that a 'natural' food additive is extracted from a vegetal source (e.g., tartaric acid, which is a byproduct of the wine industry) or produced by microorganisms using substrates of vegetal origin (e.g., this is the case for more than 99% of the citric acid used in food), whereas a 'synthetic' food additive derives from the mineral oil industry or from other mineral resources.

However, this division is at least excessively simple, as can be shown with several examples. Thus, lactic acid is a natural product that is also produced in large amounts by a strongly competitive chemical process. Ascorbic acid, another natural substance, is almost exclusively produced by a process comprising several chemical steps assisted by a single microbiological transformation. The microbiological production of citric acid uses glucose as the substrate, but hydrocarbons can also be used. Finally, bleaching, neutralization, or esterification of the additives using reagents that may be of natural or synthetic origin is frequently performed to improve their technological properties.

The properties of food antioxidants obtained largely or exclusively from mineral resources, or with important concurrence of chemical procedures, are discussed here. Where applicable, emphasis is placed on the similarities and differences between the natural

Table 1 Substances classified by the CAC as food antioxidants or antioxidant synergists, with the exclusion of those of exclusive 'natural' origin

INS substance name (common acronym) (formula); selected synonyms	*CAC functional classes and subclasses*
220 Sulfur dioxide (SO_2); sulfurous oxide; sulfurous anhydride	Preservative, antioxidant
221 Sodium sulfite (Na_2SO_3)	Preservative, antioxidant

223 Sodium metabisulfite ($Na_2S_2O_5$); sodium disulfite; sodium pyrosulfite	Preservative, bleaching agent, antioxidant
224 Potassium metabisulfite ($K_2S_2O_5$); potassium disulfite; potassium pyrosulfite	Preservative, antioxidant
225 Potassium sulfite (K_2SO_3)	Preservative, antioxidant
226 Calcium sulfite ($CaSO_3$)	Preservative, antioxidant
227 Calcium hydrogen sulfite [$Ca(HSO_3)_2$]; calcium bisulfite	Preservative, antioxidant
228 Potassium hydrogen sulfite ($KHSO_3$); potassium bisulfite	Preservative, antioxidant
250 Sodium nitrite ($NaNO_2$)	Preservative, antioxidant
300 Ascorbic acid ($C_6H_8O_6$); L-(+)-ascorbic acid; vitamin C; antiscorbutic factor	Antioxidant
301 Sodium ascorbate ($NaC_6H_7O_6$); L-(+)-ascorbic acid sodium salt; vitamin C sodium salt	Antioxidant
302 Calcium ascorbate ($Ca\ C_{12}H_{14}O_{12}.2H_2O$); L-(+)-ascorbic acid calcium salt dihydrate	Antioxidant
303 Potassium ascorbate ($KC_6H_7O_6$); L-(+)-ascorbic acid potassium salt	Antioxidant
304 Ascorbyl palmitate ($C_{22}H_{38}O_7$); L-(+)-ascorbic acid 6-palmitate	Antioxidant
305 Ascorbyl stearate ($C_{24}H_{42}O_7$); L-(+)-ascorbic acid 6-stearate	Antioxidant
306 Tocopherol-rich extract (mixed tocopherol concentrate); vitamin E	Antioxidant
307 Synthetic α-tocopherol ($C_{29}H_{50}O_2$); 5,7,8-trimethyltocol	Antioxidant
308 Synthetic γ-tocopherol ($C_{28}H_{48}O_2$); 7,8-dimethyltocol	Antioxidant
309 Synthetic δ-tocopherol ($C_{27}H_{46}O_2$); 8-methyltocol	Antioxidant
310 Propyl gallate (PG) ($C_{10}H_{12}O_5$); *n*-propyl 3,4,5-trihydroxybenzoate; gallic acid propyl ester	Antioxidant
311 Octyl gallate ($C_{15}H_{22}O_5$); *n*-octyl 3,4,5-trihydroxybenzoate; gallic acid octyl ester	Antioxidant
312 Dodecyl gallate ($C_{19}H_{30}O_5$); *n*-dodecyl 3,4,5-trihydroxybenzoate; gallic acid dodecyl ester	Antioxidant
313 Ethyl gallate ($C_9H_{10}O_5$); ethyl 3,4,5-trihydroxybenzoate; gallic acid ethyl ester	Antioxidant
314 Guaiac resin; guaiacum; guaiac gum; gum guaiac	Antioxidant
315 Erythorbic acid ($C_6H_8O_6$); isoascorbic acid; D-araboascorbic acid	Antioxidant
316 Sodium erythorbate ($NaC_6H_7O_6$); sodium isoascorbate	Antioxidant
317 Potassium erythorbate ($KC_6H_7O_6$); potassium isoascorbate	Antioxidant
318 Calcium erythorbate ($CaC_{12}H_{14}O_{12}$); calcium isoascorbate	Antioxidant
319 *tert*-Butylhydroquinone (TBHQ) ($C_{10}H_{14}O_2$); 2-(1,1-dimethylethyl)-1,4-benzenediol	Antioxidant
320 Butylated hydroxyanisole (BHA) ($C_{11}H_{16}O_2$); 3- and 2-*tert*-butyl-4-methoxyphenol	Antioxidant
321 Butylated hydroxytoluene (BHT) ($C_{15}H_{24}O$); butylated hydroxytoluol; 2,6-di-*tert*-butyl-1-hydroxy-4-methylbenzene; 2,[6]-di-*tert*-butyl-*p*-cresol; 2,6-di-*tert*-butyl-4-methylphenol; 3,5-di-*tert*-butyl-4-hydroxytoluene; dibunol	Antioxidant
322 Lecithins; phosphatides; phospholipids	Emulsifier, antioxidant synergist
323 Anoxomer (polymerized mixture of phenolic antioxidants)	Antioxidant
324 Ethoxyquin (EQ, EMQ) ($C_{14}H_{19}NO$); 6-ethoxy-1,2-dihydro-2,2,4-trimethylquinoline	Antioxidant
325 Sodium lactate ($Na[CH_3CH(OH)COO]$); sodium 2-hydroxy-propanoate	Antioxidant synergist, humectant, bulking agent
326 Potassium lactate ($K[CH_3CH(OH)COO]$); potassium 2-hydroxy-propanoate	Antioxidant synergist, acidity regulator
334 Tartaric acid [HOOC-CH(OH)CH(OH)-COOH]; L(+)-2,3-dihydroxybutanedioic acid	Acidity regulator, sequestrant, antioxidant synergist
338 Orthophosphoric acid (H_3PO_4)	Acidity regulator, antioxidant synergist
339 Sodium orthophosphates (NaH_2PO_4, Na_2HPO_4, Na_3PO_4)	Acidity regulator, antioxidant synergist
340 Potassium orthophosphates (KH_2PO_4, K_2HPO_4, K_3PO_4)	Acidity regulator, antioxidant synergist
341 Calcium orthophosphates [$Ca(H_2PO_4)_2$, $CaHPO_4$, $Ca_3(PO_4)_2$]	Acidity regulator, antioxidant synergist
384 Isopropyl citrates; mixture of the citric acid esters of 2-propanol	Antioxidant, preservative, sequestrant
385 Calcium disodium ethylenediaminetetraacetate ($CaNa_2[(OOCCH_2)_2NCH_2CH_2N(CH_2COO)_2]$)	Antioxidant, preservative, sequestrant
386 Disodium ethylenediaminetetraacetate ($Na_2H_2\ [(OOCCH_2)_2NCH_2CH_2N(CH_2COO)_2]$)	Antioxidant, preservative synergist, sequestrant
387 Oxystearin; mixture of glycerides of partially oxidized stearic and other fatty acids	Antioxidant, sequestrant
388 Thiodipropionic acid ($S[(CH_2)_2COOH]_2$)	Antioxidant
389 Dilauryl thiodipropionate ($S[(CH_2)_2COO(CH_2)_{11}CH_3]_2$); didodecyl 3,3′-thiodipropionate; 3,3′-thiodipropionic acid di-*n*-dodecyl ester	Antioxidant
390 Distearyl thiodipropionate ($S[(CH_2)_2COO(CH_2)_{17}CH_3]_2$); dioctadecyl 3,3′-thiodipropionate; 3,3′-thiodipropionic acid di-*n*-octadecyl ester	Antioxidant

INS substance name (common acronym) (formula); selected synonyms	*CAC functional classes and subclasses*
391 Phytic acid [$(H_2PO_4)_6C_6H_6$]; myo-inositol hexakis(dihydrogen phosphate)	Antioxidant
512 Stannous chloride ($SnCl_2$); tin(II) chloride	Antioxidant, colour-retention agent
539 Sodium thiosulfate ($Na_2S_2O_3$); sodium hyposulfite	Antioxidant, sequestrant
586 4-Hexylresorcinol ($C_6H_3(OH)_2(CH_2)_5CH_3$); 4-hexyl-1, 3-benzenediol; 4-hexyl-1,3-dihydroxybenzene; 4-hexylresorcine; 4-*n*-hexylresorcinol; ascaryl	Antioxidant, colour-retention agent
1102 Glucose oxidase	Antioxidant

Table 2 Meaning of the classes of **Table 1** according to the CAC and equivalent definitions of FDA (170.3)

Additive class	*CAC*	*FDA*
Acidity regulators (CAC) and pH control agents (FDA)	Alter or control the acidity or alkalinity of a food	Change or maintain active acidity or basicity, including buffers, acids, alkalies, and neutralizing agents
Antioxidants	Prolong the shelf-life of foods by protecting against deterioration caused by oxidants, such as fat rancidity and color changes	Preserve food by retarding deterioration, rancidity, or discoloration due to oxidation
Color-retention agents (CAC) and colors and coloring adjuncts (FDA)	Stabilize, retain or intensify the color of a food	Impart, preserve, or enhance the color or shading of a food, including color stabilizers, color fixatives, color-retention agents, etc.
Humectants	Prevent food from drying out by counteracting the effect of a wetting agent atmosphere having a low degree of humidity	Promote retention of moisture. Include moisture-retention agents and antidusting agents
Preservatives (CAC) and antimicrobial agents (FDA)	Prolong the shelf-life of foods by protecting against deterioration caused by microorganisms	Preserve food by preventing growth of microorganisms and subsequent spoilage, including fungistats, mold and rope inhibitors, and the effects listed by the National Academy of Sciences/ National Research Council under 'preservatives'
Sequestrants		Combine with polyvalent metal ions to form a soluble metal complex, to improve the quality and stability of products
Synergists		Act or react with another food ingredient to produce a total effect different or greater than the sum of the effects produced by the individual ingredients

and synthetic products. The reader should resort to section (a) 'Natural Antioxidants' to become familiar with antioxidants of exclusive vegetal or microbiological origin, or with complementary aspects of some of the substances discussed here.

Properties of Synthetic Antioxidants and Antioxidant Synergists

Sulfur Dioxide, Sulfites, Bisulfites and Metabisulfites

Sulfur dioxide is a colorless gas (a liquid below $-10\,^{\circ}C$ or under pressure) with a characteristic, pungent odor, more soluble in cold than in hot water. In moist environments, sulfurous acid, which reacts slowly with oxygen, is formed. This reaction is accelerated at increasing pH values. Sulfur dioxide gas is a corrosive and severe irritant. Some individuals are extremely sensitive to the effects of sulfur dioxide, whereas experienced workers may become adapted to its irritating properties, e.g., cases of acclimatization at 20–30 $\mu g\,g^{-1}$ have been observed. Exposure to high concentrations (e.g., 1000 $\mu g\,g^{-1}$) for several minutes produces respiratory paralysis and pulmonary edema with a risk of death. Liquid sulfur dioxide produces skin burns from the freezing effect of rapid evaporation.

Sodium, potassium and calcium sulfites, hydrogen sulfites (bisulfites), and metabisulfites exhibit almost identical preserving and antioxidant properties to sulfur dioxide. Thus, anhydrous sodium sulfite is relatively stable but reacts rapidly with oxygen in the presence of moisture; all dissolved oxygen is removed in a few seconds. Commercial sodium bisulfite consists mainly of sodium metabisulfite. Sodium and potassium metabisulfites are irritants and possible sensitizers.

At the levels used in food, sulfur dioxide, sulfites, bisulfites, and metabisulfites are generally recognized as safe (GRAS); however, a small segment of the population has been found to develop hives, nausea, diarrhea, shortness of breath, or even fatal shock after consuming these substances. For this reason, its use on fresh fruits and vegetables to be sold or served raw to consumers, or to be presented to consumers as fresh, was banned by the Food and Drug Administration (FDA) (182.3862, 3766, 3637, 3616). Further, these substances decompose vitamin B_1, and so they cannot be used in food recognized as a source of vitamin B_1.

Sulfur dioxide has been used in the manufacture of wine for thousands of years to destroy bacteria, molds, and wild yeasts without harming the yeasts used in fermentation. Sulfur dioxide, sulfites, bisulfites, and metabisulfites are used as antiseptics and bleaching agents in breweries and other fermentation industries, and are used to retard spoilage of meat, egg yolks, grains, dried and fresh fruits, and other products. Sodium sulfite is allowed as a bleaching agent for gelatin, beet sugars, and food starch (FDA 73.85), and sodium and potassium sulfites can be used to assist caramelization (FDA 73.85).

Sodium Nitrite

Sodium nitrite is an odorless, white or slightly yellow, hygroscopic and air-sensitive solid (it slowly oxidizes to nitrate), having both reducing and oxidizing properties. It presents a fire risk when in contact with reducing materials; for example, it is liable to render any organic matter (wood, paper and textiles) dangerously combustible when dry. It is decomposed by acids (even weak acids) with evolution of a brown mixture of nitrogen oxides (NO_x). It is very toxic and dangerous to the environment, and it is an irritant and harmful substance that may damage the cardiovascular and central nervous systems. (*See* **Nitrates and Nitrites.**)

Nitrates and nitrites are used in cured meat products, to control the growth of microorganisms, particularly to avoid the development of *Clostridium botulinum*, and also to serve as color and flavor fixatives. When added to meat, nitrate and nitrite react with the myoglobin and hemoglobin present in the trapped red blood cells, eventually producing nitric oxide myoglobin. After curing, almost all the nitrate and nitrite have reacted with the meat components, and only a very small residual amount of nitrite remains. The FDA allows the use of sodium nitrite in smoked cured fish products (from 10 to 200 $\mu g\,g^{-1}$) and in meat-curing preparations ($< 200\,\mu g\,g^{-1}$, mixed with sodium nitrate, FDA 172.175).

In the stomach, nitrite can produce dangerous carcinogenic nitrosamines; however, these reactions are inhibited in the presence of phenolic antioxidants, ascorbic acid, or other substances that are also added to food or are present in fruit and fresh vegetable juices that may be consumed with the cured meat. Furthermore, nitrite is naturally present in saliva, in concentrations higher than those found in cured meat products, and lettuce, spinach, beets, and many other vegetables contain nitrate, which is reduced in the mouth to nitrite by the action of bacteria. Therefore, the risks associated with the use of nitrate and nitrite in cured fish and meat products seem to be very small, whereas the benefits are large.

Ascorbic and Erythorbic Acids, and their Salts and Esters

Ascorbic acid is a colorless or white crystalline powder with a pleasant, sharp, acidic taste. When pure and dry, it is very stable, but in solution or when moisture is present, the acid and their salts react readily with oxygen. Oxidation is accelerated at both low and high pH values, and is catalyzed by metal ions, particularly for traces of copper ions. The optimum pH for stability in aqueous solution is 5.4.

Ascorbic acid occurs widely in animals and plants, where it constitutes the primary defensive barrier against oxidative stress. It is also required in many metabolic functions. Today, almost all the commercially available ascorbic acid is produced by synthesis. A process in common use (Reichstein–Grüssner second synthesis, 1934) starts with D-glucose and combines chemical and microbiological steps. Natural and synthetic ascorbic acid are exactly the same product, with identical biological activity; however, synthetic ascorbic acid is more economical, and frequently purer (and, therefore, more stable) than the product that can be extracted from lemons and other vegetables.

Ascorbic acid and its salts are added to food as preservatives and antioxidants, to prevent the oxidation of dyes, thus preserving color during storage and cooking. They are used in the preparation of beer, fruit juices, and canned and frozen vegetables and fruits, to prevent browning of cut apples and other

fruits, and in the flour industry to enhance baking quality and appearance of bread. Ascorbic acid is also added together with nitrite to bacon and other cured meat products to avoid the formation of carcinogenic nitrosamines. Ascorbic acid does not protect oils and fats as it is not fat-soluble. For this purpose, the fat-soluble hydrophobic esters ascorbyl 6-palmitate and ascorbyl 6-stearate are used.

Ascorbic acid is also used in nutrition as a dietary supplement in the treatment of vitamin C deficiency. It cures scurvy and acts as an oxidation–reduction catalyst in the cell, thus increasing resistance to infection. It also helps in the prevention of prostate cancer. It may aid in lowering the blood cholesterol level and slows down the aging process. When serum levels of ascorbic acid are high, synovial fluid becomes thinner, allowing freer movements and reducing arthritic pain.

Pure ascorbic acid is moderately toxic and irritating; there have been cases of allergic reaction with eczema, urticaria, and asthma. Ingestion of large amounts (10 g or more) may cause gastrointestinal distress and diarrhea, and increases the excretion of oxalic acid. Urinary and blood uric acid also rise as a result of a high intake of ascorbic acid, and these factors may increase the risk of kidney or bladder calculi. Finally, the mucolytic effect of ascorbic acid might render the cervical mucus less permeable to spermatozoa.

Erythorbic or isoascorbic acid, the epimer of L-ascorbic acid, has the same redox potential but only one-twentieth of the vitamin C activity of L-ascorbic acid. It is prepared by treating methyl 2-keto-D-gluconate with sodium methoxide, although it can also be produced by microorganisms. Sodium erythorbate has the same antioxidant, preservative, and color stabilizer properties as sodium ascorbate. It is used in soft drinks, and poultry and meat curing. When sodium nitrite is added to cure meat, erythorbic acid is also used to inhibit undesirable nitrite reactions. A brief dip in a bath containing 0.25% citric and 0.25% erythorbic acid improves quality retention in frozen fish. This treatment is also applicable to shellfish to sequester iron and copper ions that catalyze bluing and darkening reactions. (*See* **Ascorbic Acid**: Properties and Determination.)

Tocopherols

Vacuum steam distillation of cereal grain, soybean, and other vegetal oils yields a red, almost odorless, viscous oil, unstable on exposure to heat, light, and oxygen, that is a mixture of the four more abundant forms of vitamin E, i.e., the α-, β-, γ- and δ-tocopherols. The proportion of the four forms varies widely from one vegetal source to another. The most biologically active of the four is α-tocopherol, which plays several important roles in metabolism, including cellular respiration, effective use and storage of vitamin A, protection of B-complex and vitamin C from oxidation reactions, and protection of cellular membranes and body tissues from damaging reactions caused by free radicals. The other members of the vitamin E family also have important functions, some of them similar to those of α-tocopherol, whereas others are different and unique. (*See* **Tocopherols**: Properties and Determination.)

As shown in Figure 1, the differences between the natural tocopherols are due to the number and position of the methyl groups on the aromatic ring. Tocopherols other than α-tocopherol can be converted to this form of vitamin E by methylation of the aromatic ring. Tocopherols also have three asymmetric carbon atoms (one on the chromane heterocyclic ring and the other two on the alkyl chain), whose configuration is of prime importance for their biological activity. The three carbon atoms of natural tocopherols have the *R* configuration, e.g., natural α-tocopherol is the 2*R*,4′*R*,8′*R*-α-tocopherol or (*RRR*)-α-tocopherol isomer.

Synthetic α-, β-, γ-, and δ-tocopherols can be produced by condensation of the appropriate tri-, di-, or monomethylhydroquinone with synthetic isophytol (see Figure 2). In each case, a racemic mixture of the $2^3 = 8$ possible diastereoisomers or *all-rac-* mixture is obtained; for instance, 2,3,5-trimethylhydroquinone yields *all-rac*-α-tocopherol. All the isomers have

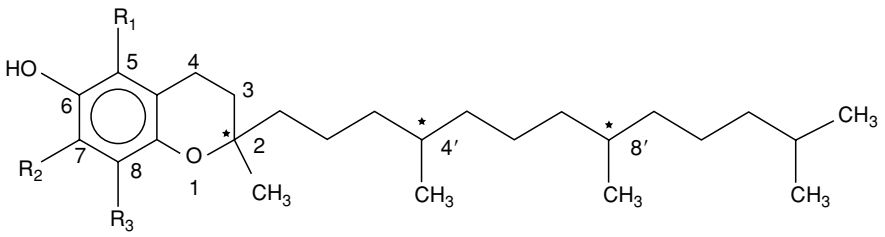

Figure 1 Molecular structure of tocopherols, where R_1═R_2═R_3═CH_3 is α-tocopherol; R_1═R_3═CH_3 and R_2═H is β-tocopherol; R_2═R_3═CH_3 and R_1═H is γ-tocopherol; R_1═R_2═H and R_3═CH_3 is δ-tocopherol.

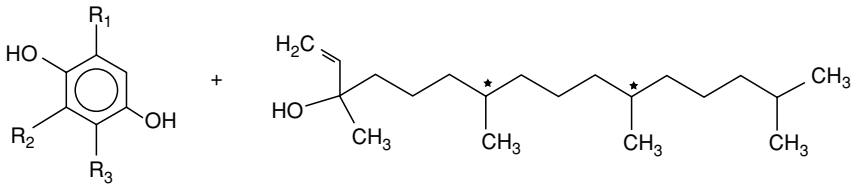

Figure 2 Condensation of 2,3,5-trimethylhydroquinone with synthetic isophytol yields *all-rac*-α-tocopherol, a racemic mixture of eight diastereoisomers.

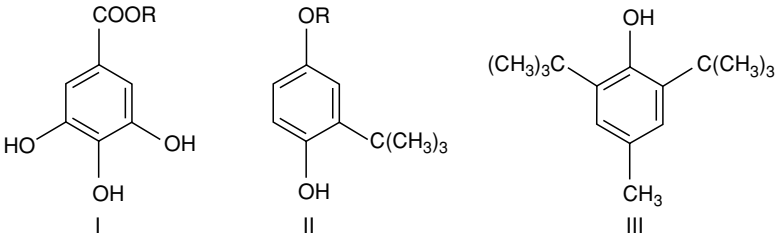

Figure 3 Molecular structures of alkyl gallates (I), *tert*-butylhydroquinone (II with $R = H$), butylated hydroxyanisol (II with $R = CH_3$ is the 2-*tert*-butyl isomer) and butylated hydroxytoluene (III).

similar antioxidant activities, but their biological values differ widely, e.g., (*SRR*)-α-tocopherol (the 2S epimer) has only 21% of the biological activity of the natural (*RRR*)-α-tocopherol. In the body, the 'incorrect' configurations are rapidly excreted, thus, on a weight basis, the synthetic *all-rac*-α-tocopherol is a much less potent vitamin E than the corresponding (*RRR*)-α-tocopherol.

The use of 2,3,5-trimethylhydroquinone and natural phytol (which is a pure *RR* isomer) results in a racemic mixture of only the two (SRR)-α- and (RRR)-α-tocopherol isomers (this latter identical to the natural product) which is called 2-*ambo*-α-tocopherol; 2-*ambo*-mixtures of the β-, γ- and δ-tocopherols can be synthesized in a similar way. Procedures to synthesize the pure (*RRR*)-isomers have also been described.

Both natural and synthetic α-tocopherols are considered as GRAS and can be used as food additives (FDA 184.1890). The recommended dietary intake (RDI) of vitamin E is 30 IU (FDA 101.9) and should be present in infant formulas (FDA 107.100). Tocopherols are used as a dietary supplement, as inhibitors of nitrosamine formation in bacon and other cured meat products, and to prevent rancidity in both chicken and turkey meats during refrigeration or frozen storage. Tocopherols are largely destroyed by cooking and canning. Large amounts of tocopherols are consumed to protect animal feeds, primarily in the poultry industry, and also as supplements and concentrates for cattle and other meat production industries. Finally, vitamin E is used to protect other substances, e.g., vitamin A and unsaturated lipids, during the shelf-life and in the gastrointestinal tract, and to improve the *in vivo* biostability and biocompatibility of medical devices made of polyetherurethane elastomers.

Tocopheryl acetates and succinates are used in pharmaceutical preparations. The esters are less reactive than the corresponding free tocopherols, and thus the shelf-life is much longer. The tocopherols are liberated in the stomach where the ester bonds are readily cleaved off. The international units of vitamin E were standardized on the basis of the *all-rac*-α-tocopheryl acetate (1 IU = 1 mg), because this mixture is the principal commercial form of vitamin E; 1 mg of (*RRR*)-α-tocopheryl acetate equals 1.36 IU.

Alkyl Gallates, BHA, BHT, and Related Compounds

The molecular structures of these phenolic antioxidants are shown in Figure 3. As occurs with other phenols, the antioxidant action of alkyl gallates, *tert*-butylhydroquinone (TBHQ), BHA, and BHT mainly relies on their ability as free radical scavengers. In contrast to tocopherols, ascorbic acid, and other antioxidants, the antioxidant properties of these phenol derivatives are not lost during cooking. According to the FDA, these antioxidants can be added to food products whether singly or in combination of two or more, up to 0.02%, based on the weight of the fat or oil content in the food product.

Propyl gallate (PG) is a white to nearly white odorless crystalline powder that has slightly bitter taste and darkens in the presence of iron salts. It is an

irritant that can cause skin dryness, dermatitis, and sensitization. Inhalation may cause chemical pneumonia. PG is used to stabilize cosmetics, food packaging materials, and foods including edible fats, oils, mayonnaise and other emulsions, shortening, baked goods, candy, dried meat, fresh pork, sausage, and dried milk. The antioxidant activity of PG is synergic with acids, BHA and BHT. It also shows antimicrobial activity, has been reported to be an effective antioxidant-based hepatoprotector, and has been shown to prevent neuronal apoptosis.

PG is markedly hydrophillic, and so its solubility in fats is limited. Substitution of the propyl chain by a shorter (ethyl) or longer (octyl or dodecyl) chain, respectively, decreases or increases fat solubility. Propyl, octyl, and dodecyl gallates (< 0.02%) individually or in combination with BHT, BHA, and ascorbyl palmitate and stearate can be added to margarine (FDA 166.110). Alkyl gallates, although quite effective, can cause discoloration of food substrates, and may also impart off-flavors. Propyl gallate is also used for other industrial purposes, e.g., added to ethers and aldehydes to prevent peroxidation.

TBHQ is sometimes added to food as an antioxidant, and it is also produced in the body as the common metabolite of the two BHA isomers. It is a tan-colored powder with acute irritating properties. It is most effective against oxidation in polyunsaturated vegetal oils, and is often added to soybean oil.

Commercially available food-grade BHA is generally a mixture containing two positional isomers, 3-*tert*-butyl-4-methoxyphenol (> 85%) and 2-*tert*-butyl-4-methoxyphenol (< 15%). It is a white or slightly yellow waxy solid, has an aromatic odor and a slightly bitter burning taste, and degrades following prolonged exposure to sunlight. It is toxic by ingestion, and there is sufficient evidence that it is carcinogenic in animals. It dissolves readily in molten fats, and its antioxidant properties are synergic with acids, BHT, alkyl gallates, hydroquinone, methionine, lecithin, and thiodipropionic acid. At low concentrations, it is used as an antioxidant in fat-containing foods, in edible fats and oils, and as a preservative and antioxidant in cosmetic formulations.

BHT is a white crystalline powder. Contact causes irritation, and inhalation produces lung injury. Depending on the intensity and duration of exposure, effects may vary from mild irritation to severe destruction of tissue. It is more hydrophobic and therefore more soluble in oils and fats than BHA and TBHQ. It is normally used in combination with citric acid in fats and oils, and with phosphate for meat systems. It is also used to protect rubber, plastics, and other industrial products.

BHT combines low costs with heat stability, good antioxidant activity, and high fat solubility, and thus not surprisingly has been the most widely used antioxidant in food in the last quarter of the twentieth century; however, continuing concern over its safety has resulted in decreased usage. Both carcinogenic and anticarcinogenic properties have been reported for BHA and BHT. Thus, metabolites of BHT can promote tumors and produce DNA damage in mice. However, BHT has been found to inhibit the initiation of hepatocarcinogenesis by aflatoxin B1. A study performed in The Netherlands among 120 852 men and women over 6.3 years showed no significant association with stomach cancer risk for an intake of low levels of BHA and BHT. However, when excessively concentrated, phenolic compounds can promote undesired oxidative or degenerative reactions, e.g., natural flavonoids show a marked prooxidant effect that is due to the chain-initiating activity of the radicals formed during inhibition; however, BHA and BHT have no prooxidant activity.

Anoxomer is a complex polymeric substance with a molecular weight of 4500–5000. For its use in food, no more than 5% of the polymer should be greater than 50 000 Da, and no more than 1% of the polymer should be less than 500 Da. It is prepared by condensation polymerization of *m*- and *p*-divinylbenzene with TBHQ, *tert*-butylphenol, hydroxyanisole, *p*-cresol, and 4,4′-isopropylidenediphenol. Anoxomer should be used as an antioxidant at a level no greater than 0.5% of the fat and oil content of foods (FDA 172.105). Gallic acid esters, BHT, BHA, and TBHQ have high vapor pressures at temperatures above 150 °C, and so they are readily lost from thermal processes generating steam. This does not occur with anoxomer. In addition, in contrast to the monomeric phenolic antioxidants, pure anoxomer is not an irritant, thus possibly indicating a greater biological tolerance.

Although not collected in the INS list, there are other phenols with antioxidant properties similar to those exhibited by BHA and BHT, and which have also been used as food additives. Thus, 2,4,5-trihydroxybutyrophenone (THBP) ($C_{10}H_{12}O_4$) or 2,4,5-trihydroxy phenyl propyl ketone has been used as antioxidant for polyolefins, paraffin waxes and food. Nordihydroguaiaretic acid (NDGA) or 4,4′-(2,3-dimethyl-tetramethylene)dipyrocatechol is a natural antioxidant. It can be extracted from an evergreen desert shrub, the creosote bush, *Larrea divaricata*, and can also be prepared by hydrogenation and subsequent demethylation of the guaiaretic acid dimethyl ether, a constituent of gum guaiac. It is added to fats and oils. The molecular structures of THBP and NDGA are shown in Figure 4.

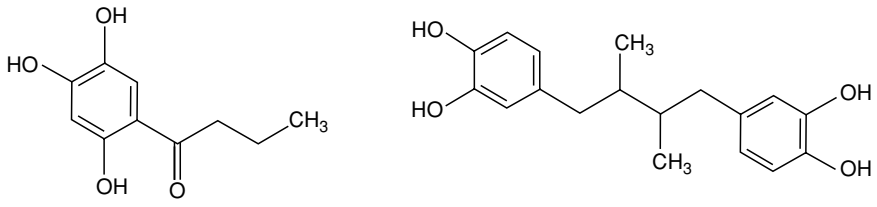

Figure 4 Molecular structures of 2,4,5-trihydroxybutyrophenone and nordihydroguaiaretic acid.

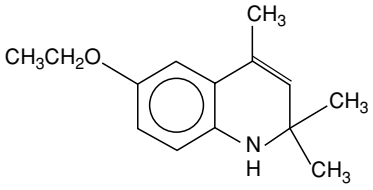

Figure 5 Molecular structure of ethoxyquin.

Ethoxyquin

Ethoxyquin (EQ) (see Figure 5) is a clear, viscous, light yellow to dark brown liquid, with an unpleasant, mercaptan-like smell, that causes irritation of the skin and eyes. It is absorbed through the skin, and is moderately toxic by ingestion. It darkens on exposure to light and air and tends to polymerize, particularly at temperatures above 160 °C (hazardous exothermic reaction). EQ is considered a highly effective antioxidant, is cheap and has a very long shelf-life. It has been the antioxidant of choice in pet food for many years, although it has also been added to other animal feeds and human food. Concern about its toxicity (not yet sufficiently investigated) has promoted the alternative use of tocopherols in pet food, in spite of the higher prices and increasing demand of tocopherols for human consumption. EQ is also used as an insecticide, herbicide, fungicide, postharvest dip to prevent scald on apples and pears, plant growth regulator, and antidegradation agent for rubber.

Sodium and Potassium Lactates

Lactic acid is present in many foods both naturally and as a product of *in situ* fermentation, as in sauerkraut, yogurt, and many other fermented foods. Lactic acid is also a principal metabolic intermediate in most living organisms. Sodium and potassium lactates are produced commercially by neutralization of natural or synthetic lactic acid (FDA 184.1768, 1639). Lactic acid to be used as a food additive can be obtained either by fermentation of carbohydrates or by a chemical procedure involving formation of lactonitrile from acetaldehyde and hydrogen cyanide and subsequent hydrolysis (FDA 184.1061).

The microbiological and chemical procedures to obtain lactic acid are very competitive, with similar production costs. One method of biosynthesis in common use starts with glucose and produces pyruvate, which can be converted to both the L(+) and D(−) isomers using a stereospecific lactate dehydrogenase; however, only the L(+) form is produced commercially. The racemic mixture is always obtained by chemical synthesis. Synthetic lactic acid is free of the contaminants normally found in the product obtained by fermentation, and so it is completely colorless and probably more stable. Lactic acid and its salts are highly hygroscopic, and therefore are usually handled in concentrated solutions (60–80% by weight) rather than in solid form. These solutions are colorless and odorless, and have a mild saline taste.

Lactates complex metal ions, thus improving the stability of food against oxidation. Sodium lactate is used as a pH regulator and antimicrobial, humectant, curing, pickling, and flavor enhancing agent in meat, poultry, seafood, and many other products; potassium lactate is used to replace sodium lactate in low-sodium products. The calcium salt of lactic acid is a good dough conditioner, and the sodium salt is both a conditioner and an emulsifier for yeast-leavened bakery products. The addition of aqueous solutions of lactic acid and its salts during processing of carcasses, particularly those of poultry and fish, increases shelf-life and reduces the growth of anaerobic spoilage organisms such as *Clostridium botulinum*. Sodium lactate is also used as a moisturizer in skin-care products, to supplement the skin's own naturally occurring sodium lactate, as well as in a wide variety of industrial applications. (*See* ***Clostridium***: Botulism.)

Orthophosphoric Acid and Orthophosphates

The antioxidant synergism of orthophosphoric acid and its salts is a result of their ability to complex metal ions. The redox potential of the Fe^{3+}/Fe^{2+} pair is particularly lowered in the presence of phosphates,

even in acid medium. Orthophosphoric acid can be used to assist in caramelization (FDA 73.85), as a neutralizing agent in cacao (FDA 163.110), and as an acidifying agent in cheese manufacture (FDA 133.123, 124). Several sodium and potassium orthophosphates and pyrophosphates can also be used as emulsifying agents to process cheese (FDA 133.169, 173). The acid is also added to soft drinks and has miscellaneous industrial applications.

Ethylenediaminetetraacetates

In an alkaline medium, the dibasic anion of the ethylenediaminetetraacetic acid (EDTA) forms very stable complexes with most divalent and trivalent metal ions. Thus, citric acid and EDTA salts are the most common chelating agents used as antioxidant synergists in food. As a consequence of the concurrence with hydrogen ions, the sequestrant capability of EDTA decreases as the pH is lowered; however, the EDTA complexes of iron, copper, zinc, aluminum, and many other metal ions are still very stable in neutral and slightly acid media. EDTA also lowers the redox potential of the Fe^{3+}/Fe^{2+} pair. The use of calcium disodium EDTA, rather than disodium EDTA, prevents the calcium-depleting action of the ligand in the body. Calcium disodium EDTA can be added to margarine (0.0075%, FDA 166.110), and is also permitted whether alone or in combination with disodium EDTA in a variety of canned vegetables, emulsions, and dressings to preserve color and flavor (FDA 172.120, 169.150).

Thiodipropionic Acid and its Fatty Esters

Thiodipropionic acid and the dilauryl and distearyl thiodipropionates are weak reducing substances, but they are very effective in the destruction of hydroperoxides, which are reduced to alcohols. The sulfur atom is eventually oxidized to sulfate, but the reduced sulfur species originated as reaction intermediates catalyze the decomposition of more hydroperoxide molecules. Up to 20 moles of hydroperoxide can be decomposed by a mole of thiodipropionate. Thiodipropionates display strong synergism with BHT and other phenol derivatives, which also terminate free radical chain reactions through a rather different mechanism.

Thiodipropionic acid and its esters are GRAS for use in food when the total content of antioxidants is not over 0.02% of fat or oil content of the food (FDA 182.3109, 3280). They are used to retain color in dried bananas, beans, peas, canned clams and shrimp, and frozen potatoes. They improve flavor retention in canned carbonated beverages, dressings, mayonnaise, margarine, and sauces. They are also used as antioxidants in soap products and lubricants, and in the manufacture of a variety of polymers (including adhesives). When used in packaging materials, they should not migrate to food in amounts exceeding a concentration of 0.005% in the food (FDA 178.2010, 181.24).

Stannous Chloride

Stannous chloride is a very strong reducing agent that absorbs oxygen from the air. The colorless crystalline solid or the white powder is severely irritating and corrosive, and reacts with alcohols, amines, alkalies, and oxidizers, sometimes with violence; the reaction with hydrogen peroxide is strongly exothermic, even in solution. As a food preservative, it can be added to canned asparagus packed in glass containers in a quantity not exceeding $15\,\mu g\,g^{-1}$ calculated as tin (Sn), but up to $20\,\mu g\,g^{-1}$ can be present if the container lid is lined with an inert material (FDA 155.200). It is also used as a stabilizer for colors and perfumes in soaps, and as a reducing agent in many other industrial applications.

Sodium thiosulfate

The addition of sulfur to sodium sulfite produces sodium thiosulfate, a salt that contains an S–S bond. Its antioxidant properties are due to the presence of a reduced sulfur atom, but it also forms strong complexes with iron, copper, and other metal ions. It can be added to alcoholic beverages (< 0.00005%) and table salt (< 0.1%) (FDA 184.1807). It is also used as a reducing (e.g., to remove residual chlorine from solutions), bleaching, and complexing agent in a variety of industrial applications.

4-Hexylresorcinol

4-Hexylresorcinol is a pale yellow, viscous liquid (becoming solid on standing at room temperature) with a pungent faint fatty odor and a sharp astringent taste. It is an irritant, and its concentrated solutions can cause burns on the skin and mucous membranes. The Canadian Food Inspection Agency allows the addition of up to $1\,\mu g\,g^{-1}$ hexylresorcinol to frozen and fresh crustacean (http://inspection.gc.ca). It is used in medicine as a topical and urinary antiseptic, anthelmintic, cleanser for skin wounds, and anesthetic for throat pain.

Phenolic Antioxidants

Reversed-phase High-performance Liquid Chromatography

The determination of phenolic antioxidants and ethoxyquin (EQ) in food is most frequently accomplished by reversed-phase high-performance liquid chromatography (RP-HPLC), while both HPLC and thin-layer chromatography (TLC) are normally used

for the screening of antioxidant residues in food products. Usually, sample preparation for RP-HPLC involves dilution or suspension with hexane, extraction with a polar solvent (most frequently acetonitrile mixed with some water), preconcentration by evaporation under reduced pressure, reconstitution (e.g., with isopropanol), and, if necessary, clean-up with unmixable solvents or solid phases. Extraction with supercritical CO_2 has been used for capillary electroseparations. RP-HPLC separations are normally performed on C18 columns using gradient elution with aqueous phases containing methanol or acetonitrile and acetic acid, followed by spectrophotometric detection at 280–285 nm. Pentachlorophenol and 2,4,6-trimethylphenol have been employed as internal standards in the analysis of fats and oils and bakery products.

A modification of the AOAC official method applied to butter oil has yielded recoveries higher than 95% for alkyl gallates, *t*-butylhydroxyquinone (TBHQ), butylated hydroxyanisole (BHA), nordihydroguaiaretic acid (NDGA), 2,4,5-trihydroxybutyrophenone, and 2,6-di-*t*-butyl-4-hydroxymethylphenol, and lower for butylated hydroxytoluene (BHT) (79%). Other reported data indicate recoveries higher than 90% for BHA and BHT in vegetable oil and propyl gallate (PG) in lard, and for dodecyl gallate (DG), BHA, BHT, TBHQ, and NDGA in liver pâté, but the less hydrophobic PG and octyl gallate (OG) gave recoveries around 80% in this sample. Using methanol, recoveries between 85 and 95% have been reported for PG, OG, DG, 2- and 3-BHA, NDGA and TBHQ, but 3,5-di-*t*-butylcresol gave 72%. The intralab relative standard deviations (RSDs) range typically between 3 and 7%, but values lower than 2% have also been obtained. Reported interlab RSDs range from 7% for DG to 26% for TBHQ. Low or rather disperse recoveries can be due to oxidation during sample storage and preparation, which easily occurs with TBHQ.

In one procedure for dry food, the sample was homogenized with hexane, water, and acetonitrile (25:5:75) and the combined acetonitrile extracts concentrated by evaporation, injected, and detected at 280 nm. Separation was performed on a C18 column with gradient elution using water–acetonitrile mobile phases containing 5% acetic acid. The detection limits (DLs) for PG, BHA, BHT, *t*-butylquinol, 2,4,5-trihydroxybutyrophenone, 3,5-di-*t*-butyl-4-hydroxymethylphenol, and NDGA ranged from 0.4 to 2.7 $\mu g\,ml^{-1}$. For a typical 20-µl injection loop, these data roughly match with other DLs reported as absolute values: 25 (OG, DG), 35 (PG) and 100 ng (NDGA). In the determination of nine phenolic antioxidants in corn oil, butter oil, butter, niboshi (dried sardines), and frozen shrimps, the DLs were 1.0 µg per gram of sample (85–102% recoveries).

Lower DLs can be achieved with fluorometric, chemoluminometric, and amperometric detection. For BHA, BHT, and TBHQ, excitation at 280 nm yields maximum emission at *c.* 310 nm. Procedures based on the chemiluminescence of luminol are mainly used to measure antioxidant activity, and these are discussed in detail later in the corresponding section. *t*-Butylquinol, 2,6-di-*t*-butyl-*p*-cresol, and 2- and 3-*t*-butyl-4-methoxyphenol have been determined in oils by HPLC with amperometric detection on a glassy carbon electrode. With a previous modification of the carbon electrode surface by electropolymerization of nickel phthalocyanine, DLs ranging from 0.1 to 0.6 $\mu g\,ml^{-1}$ have been achieved. When used in a flow-injection nonchromatographic system, the modified electrode provides a DL of 2.7 $ng\,ml^{-1}$ with a 1.8% RSD (at 0.5 $\mu g\,ml^{-1}$) for BHA in biscuits. Using 0.3- and 0.7-mm microbore HPLC with electrochemical detection, DLs as low as 0.1 and 0.6 $fmol\,l^{-1}$ have been obtained for BHA, BHT, and PG.

HPLC with Ion-pairing and Micellar Mobile Phases

The selectivity of the HPLC separations can be modified by ion-pairing agents, such as alkyl sulfates and carboxylates, and alkyl ammonium salts. These reagents form micelles when at least one of the alkyl chains has 12 or more carbon atoms; however, micelles are disrupted in the presence of a large organic solvent concentration, thus leading to an ion-pairing rather than a micellar separation mechanism. PG, OG, DG, BHA, and BHT can be determined in spiked olive oil with a mobile phase containing sodium dodecyl sulfate (SDS) and 30% propanol in 18 min.

An aqueous micellar mobile phase, which may also contain a lower percentage of an organic solvent (usually 5–15% of a short-chain alcohol), is used in micellar liquid chromatography (MLC). In MLC, physiological fluids and tissue extracts can be injected without deproteinization, because proteins are solved in the micellar phase and elute with the solvent front. Moreover, hydrophobic samples can be simply diluted with a compatible solvent and injected. Thus, several oils and fats diluted with *n*-pentanol (5–30% solutions) can be injected on a C18 column and eluted with an SDS/*n*-propanol mobile phase; PG, OG, TBHQ, and BHA have been quantified in *c.* 15 min with absolute DLs ranging from 0.05 to 0.3 ng. Avoiding a previous two-phase partitioning step simplifies the procedure and may help in obtaining high recoveries and in reducing random and systematic errors, particularly when easily oxidizable solutes such as TBHQ are quantified.

Further, since retention time in MLC is linearly proportional to solute hydrophobicity, isocratic elution is always suitable to separate solutes with large hydrophobicity differences, whereas gradient elution is required in most cases with conventional hydroorganic phases, owing to the exponential dependence of the retention time with solute hydrophobicity. Also, in comparison to hydroorganic phases, micellar phases have a lower toxicity and produce a milder environmental impact, and owing to the lower vapor pressure of its components, a small volume of phase can be recirculated and reused many times without any perceivable alteration of the chromatograms. To prevent clogging by precipitation of the surfactant, a simple cleaning protocol with water and methanol should be followed before stopping the pumps or storing a used column.

Another advantage of MLC is the excellent reproducibility of the chromatograms and, frequently, the almost perfect Gaussian shape of the peaks, which facilitates modeling and prediction. Thus, the chromatographic retention of seven antioxidants has been described, with errors below 3%, by the equation

$$1/k = c_0 + c_1\mu + c_2\varphi + c_3\mu\varphi$$

where k is the relative retention (capacity factor), μ and φ are the concentrations of SDS and organic solvent (*n*-propanol in this study), and c_0 to c_3 are regression coefficients, which are calculated for each solute from five chromatograms obtained with different μ and φ values. Modeling of retention speeds up the optimization of chromatographic procedures, i.e., the resolution between all the peak pairs of a group of solutes can be maximized, and the interference of matrix peaks can be avoided, by using the model predictions. This procedure can be used to optimize the MLC separation of a mixture of antioxidants in a short elution time.

Capillary Electroseparations

Capillary electroseparations are rapid, versatile, and very efficient, solutions in solvent mixtures of all types with the sole requirement of supporting some conductivity can be used to fill up the capillary, and most hydrophilic and hydrophobic samples can be injected without pretreatment. Further, only the anions or the cations present in a sample can be selectively introduced in the capillary by using electrokinetic injection. Antioxidants can be separated in at least two modes: (1) capillary zone electrophoresis (CZE), which is based on the different electrophoretic mobilities of the charged solutes, and (2) micellar electrokinetic capillary chromatography (MECC), in which differential migration results from the different strength of the association of uncharged solutes with charged discriminant agents such as ionic surfactants (both as individual ions or as micelles), vesicles and derivatized (e.g., sulfated) cyclodextrines. In mixed MECC, charged solutes are separated by the joint action of their own electrophoretic mobilities and the different strength of the solute–discriminant agent interactions.

Using a CZE method with spectrophotometric detection, flavonoids and phenolic antioxidants have been determined in red wine and olive leaves. In one experiment, the wine samples were directly injected, and the leaf extracts were prepared by digestion with boiling water or aqueous methanol, Soxhlet extraction with acetone/CH_2Cl_2, and supercritical fluid extraction with CO_2. Triphenyl acetic and benzoic acids were used as migration time markers, to assist in the identification of the analytes. The absolute DL was 3 pmol.

In a mixed MECC procedure, a buffer containing SDS was used to separate 11 phenolic antioxidants with DLs of 2.8–8.6 $\mu g\,ml^{-1}$. Vesicles of bis(2-ethylhexyl)sodium sulfosuccinate have been used to separate six food antioxidants in 15 min. Sodium cholate and SDS have been used to separate nine phenolic antioxidants and ascorbic acid with DLs in the range of 1–10 $\mu g\,ml^{-1}$ (spectrophotometric detection at 214 nm), and the procedure has been applied to wine and sesame seed oil.

In a previous study, CZE, MECC, and HPLC were compared, using a sodium borate buffer of pH 9.5 for CZE, adding SDS to this buffer for MECC, and performing RP-HPLC separations on a C18 column with isopropanol/water/acetonitrile (2:17:31). The resolution was poor with CZE and excellent with MECC. The antioxidants were separated in 6 and 25 min by MECC and HPLC, with absolute DLs in the picomole and nanomole ranges, respectively. The reader should not be misled by the reported absolute DLs, which are usually extremely low due to the very small injection volumes (in the picoliter range). Owing to the short optical path length (limited to the capillary inner diameter), the relative DLs are in fact higher than in HPLC with spectrophotometric detection. The DLs of capillary electroseparations can be reduced by a factor of five to 10 by using capillaries with specially extended path lengths, or more effectively by implementing fluorimetric or mass-spectrometric detection.

Gas Chromatography

BHA, BHT, TBHQ, α-tocopherol, and α-tocopherol acetate have been determined using a gas chromatograph coupled to a solid-phase extractor device, extracting powdered soup with *n*-hexane in the presence of 2-*t*-butyl-4-methylphenol and 5-α-cholestane

as internal standards, and washing the extract with 0.2 M NaCl to remove any water-soluble compounds. Similarly, oil and margarine samples were spiked with the internal standards and diluted with *n*-hexane. The antioxidants were retained on Amberlite XAD-7 resin and eluted with isopropanol, and portions of the eluate were injected. Using a coated fused-silica column and a flame ionization detector (FID), the DLs ranged from 2 to 8 mg l^{-1}, and the RSDs for 50 mg l^{-1} were 2.7–3.5%. The recoveries of 125 mg of antioxidants per kilogram from spiked sunflower seed oil were 93.6–101.4%. Synthetic antioxidants have also been determined by GC in soya-bean oil and sesame oil.

Thin-layer Chromatography

To screen PG, OG, DG, BHA, and BHT by TLC, oil samples have been diluted with hexane and extracted with 80% ethanol and acetonitrile. The combined extracts were evaporated under reduced pressure, and the concentrate was spotted on the TLC plates. After development, the solutes were revealed by oxidative coupling with *N*,*N*-dimethyl-*p*-phenylenediamine in the presence of hexacyanoferrate (III). The R_F values and the color of the spots obtained with several mobile phases were then tabulated.

Nonchromatographic Techniques

Rapidity at the cost of a lower selectivity can be gained by using nonchromatographic techniques. Selectivity can be improved by using kinetic approaches and other masking techniques, and, as detailed below, if the signals given by several solutes overlap, the required qualitative and quantitative information can be retrieved by using multivariate data treatment techniques, including principal-component regression (PCR) and partial least-squares regression when all solutes exhibit linear signal–concentration relationships, and artificial neural network (ANN) algorithms in case of nonlinearity. Thus, in a differential kinetic determination, the oxidation of several antioxidants with Fe(III) has been monitored with 2,2′-dipyridyl, and the spectrophotometric-time data treated with an ANN algorithm.

In comparison to ordinary spectrophotometry, selectivity can be improved by using derivative spectrophotometry. This technique has been used to determine BHA and BHT in lard, diluting the sample with hexane, extracting with dimethyl sulfoxide, and measuring the second derivatives of the spectrum at 311.5 and 278.5 nm for BHA and BHT, respectively (with recoveries of 99.5–109.3% and 90.6–108.1%).

Sensitization of the luminescence of Tb(III) in a micellar medium has been used to determine PG by a stopped-flow initial-rate kinetic method. Dilution of the oil samples with hexane, followed by extraction in an ammonium acetate aqueous solution, mixing with the Tb(III) reagent and data collection over 1 s has yielded recoveries of 90.1–108.2%, a RSD of $\sim$ 2%, and a DL of 0.02 μg ml^{-1}. Mixtures of PG and BHA have also been determined with a stopped-flow setup, the former being evaluated by the initial rate method, by monitoring the luminescence of Tb(III) at 0.1 s, and the latter being determined from the equilibrium signal of its reaction product with the oxidized form of Nile Blue, measured at 1 s. Both systems are excited at 310 nm, and the emission wavelengths are 545 nm for PG and 665 nm for BHA. Recoveries from food samples have been found to range between 94 and 103%, with RSDs of approximately 2% and DLs of 0.03 and 0.09 μg ml^{-1} for PG and BHA, respectively.

Phenolic antioxidants present well-defined oxidation waves, with peak potentials of 629, 818, 599, and 501 mV, with linear concentration ranges of 1–15, 0.5–15, 0.5–8, and 1–15 mg l^{-1}, for PG, BHA, BHT, and TBHQ, respectively. Square-wave voltammetry on carbon-fiber disk ultramicroelectrodes has been used to determine BHA and BHT in acetonitrile extracts of vegetable oils and lard, yielding DLs of a few micromoles per liter and RSDs of about 6–7%. To determine BHA in chewing gum, samples are shaken with ethyl acetate and the polymer components precipitated by freezing; the supernatant is then diluted with a 1% solution of the polymeric nonionic surfactant Pluronic F-68 and buffered. Differential pulsed voltammetry at a glassy carbon electrode has yielded DLs below 1 μmol l^{-1}.

Problems arising from overlapping oxidation waves in mixtures can be overcome by improving the electrode kinetics through modification of the electrode surface. Thus, PG, BHA, TBHQ, and BHT can be simultaneously determined in mixtures by differential-pulse voltammetry on a carbon-fiber electrode coated with a poly-(3-methylthiophene) film. In micellar solutions and in an oil-in-water emulsion, a DL for PG of 0.8 μmol l^{-1} and a RSD for 50 μM of 1.3% have been found. The method has been applied to dehydrated soups. Cyclic voltammetry with modified Pt electrodes has been used to determine PG in cornflakes and potato flakes, extraction with 1:1 water/methanol leading to quantitative recoveries and a DL of 1.5 μg ml^{-1}.

As indicated above, overlapped signals can be discerned by using multivariate data treatment techniques, and thus PCR and PLS have been applied to voltammetric data. Differential pulse voltammetry with PLS calibration has been used to determine PG, BHA, and BHT in dehydrated soup, with DLs of 0.15,

0.7, and 7 μmol l^{-1}, respectively, and recoveries ranging from 77 to 101%.

Finally, an amperometric enzyme biosensor (BAS VC-2 tyrosinase electrode) has been used to determine BHA in biscuits, extracting the samples with ethyl acetate, concentrating the extracts, and diluting with a medium of dioctyl sulfosuccinate reversed micelles. Under flow conditions, the DL has been found to be 30 μmol l^{-1}.

Characterization and Determination of Anoxomer

Anoxomer is a nonabsorbable polymeric phenol obtained by condensation polymerization of *m*- and *p*-divinylbenzene with TBHQ, *t*-butylphenol, hydroxyanisole, *p*-cresol and 4,4′-isopropylidenediphenol. Two types of analytical problems should be addressed in relation to anoxomer: (1) to verify regulations concerning its composition and purity and (2) to detect and determine anoxomer in food products and wrapping materials. According to the US Code of Federal Regulations (CFR 21, 172.105), the specifications to be met are: (1) the purity should not be lower than 98.0%, (2) the total amount of monomers, dimers, and trimers below a molecular mass of 500 should not be more than 1%, (3) the phenol content should range from 3.2 to 3.8 meq g^{-1} and (4) traces of Pb, As, and Hg should not exceed 10, 3, and 1 μg g^{-1}, respectively. Assays to check specifications (1), (2), and (3) are available from the Center for Food Safety and Applied Nutrition and other US Administration agencies.

Several qualitative and quantitative procedures for anoxomer have been investigated, but no methods for real samples have been published. A linear calibration graph over the range of 5–50 μg ml^{-1} can be constructed by heating the product with nitric acid in a medium containing acetic acid, adjusting the pH to 8 with ammonia, and measuring the absorbance at 420 nm. A linear calibration graph over the range 1–10 μg ml^{-1} has been obtained by measuring the native fluorescence of anoxomer in diethylene oxide. A lower sensitivity has been obtained by measuring the infrared absorption of anoxomer in tetrachloroethylene solutions at 3525 cm^{-1} (-OH stretching; linearity range: 150–580 μg ml^{-1}).

4-Hexylresorcinol

4-Hexylresorcinol has been determined in shrimps by extraction with methanol and RP-HPLC with fluorimetric detection (excitation at 280 nm, emission at 310 nm), with a recovery of ~ 82%, RSD of 2.1% within the range 1.5–2.5 mg kg^{-1}, and a DL of 1.98 ng ml^{-1} in the extract and 80 μg kg^{-1} in shrimp. In another method for shrimps, the ethyl acetate extracts have been cleaned up by solid-phase extraction, followed by gradient elution on a C18 column with trifluoroacetic acid/acetonitrile/methanol/water, and detection at 214 nm (DL = 6 ng, 94% recovery). In a method for crab meat, extraction with acetonitrile, cleaning up by solid-phase extraction, and HPLC with diode array detection has been used (RSD = 7.1%, 86–104% recovery).

Nonphenolic Synthetic Antioxidants

Ethoxyquin

EQ can be determined by extracting the samples with hexane, followed by HPLC with spectrophotometric (absorption bands at 230 and 365 nm), fluorimetric (emission at 435 nm with excitation at 365 nm), or electrochemical (oxidation wave at + 0.45 V) detection, or by GC with a FID or with thermionic detection, or using TLC on fluorescent plates. In a comparative study, significant differences among the RDSs were not found for EQ in fish meals using different techniques, which was attributed to the large variability in the extraction process.

EQ is decomposed by light, which should be taken into account in storing samples. It has been found that EQ is stable for at least 9 days by keeping the apple extracts in deep freeze, and for at least 20 days by storing the pieces of apple in hexane in the dark. Further, its degradation products are found in significant concentrations in the food samples. EQ and up to 12 of its degradation products have been resolved by HPLC. Also, EQ and its two major oxidation products, 1,8′-di-1,2-dihydro-6-ethoxy-2,2,4-trimethylquinoline (DM) and 2,6-dihydro-2,2,4-trimethyl-6-quinolone (QI), have been determined in fish meals by HPLC (DL = 5 mg kg^{-1} for EQ and DM, and 0.5 mg kg^{-1} for QI) and gas chromatography (GC), and the changes in the EQ, DM, and QI concentrations during storage have been studied.

HPLC procedures for EQ in meat meals and extruded pet foods (with fluorimetric detection), apples, skins of apples, pears, citrus fruit, and bananas, chilli powder, and paprika have been developed. For paprika, and using spectrophotometric detection, the DL has been found to be 2 μg ml^{-1}, and the RSDs for 20 and 40 μg ml^{-1}, 2.4 and 1.9%, respectively; however, with fluorimetric detection, the DL has been found to be 0.2 μg ml^{-1}, and the RSD for 0.5 μg ml^{-1}, 3.2%. EQ in apples has been also determined using electrochemical detection (DL = 0.03 ng) [69]. The levels of EQ residues in apple varieties stored under different conditions have been tabulated (with spectrophotometric detection, DL = 0.25 μg ml^{-1} in the extract

and 0.2 mg kg^{-1} in the fruit). EQ has also been determined in apples by GC (DL = 50 μg kg^{-1}, ~ 74% recovery). The use of guaiacol as an internal standard in the GC determination of phenolic antioxidants and EQ has been described.

Thiodipropionic and Thiodiglycolic Acids and their Fatty Esters

3,3′-Thiodipropionic acid, thiodiglycolic acid (or 2,2′-thiodiacetic acid) and their dialkyl esters have been separated and identified by HPLC on a C18 column with a water–acetonitrile mobile phase of pH 7.95 and spectrophotometric detection at 254 nm. The determination of thiodipropionic acid esters of fatty alcohols in polyethylene for food packaging has been performed by Soxhlet extraction with $CHCl_3$, followed by saponification with methanolic KOH and capillary GC of the liberated fatty alcohols. The distearyl thiodipropionate has also been determined by GC analysis of the compounds evolved by pyrolysis of the polymers used for packaging.

Selection of the Analytical Method for Phenols and EQ

For screening purposes, TLC on high-performance microplates has the advantages of simplicity and rapidity, while HPLC with both hydroorganic or micellar mobile phases should be recommended for screening and evaluation. Generally, gradient elution is required with hydroorganic phases, whereas solutes with large hydrophobicity differences can be separated in a short time, with good resolution and excellent reproducibility, by isocratic MLC. In relation to spectrophotometry, the DLs of phenols and EQ can be reduced by several decades using fluorimetric or voltammetric detection.

Rapid and extremely selective separations can be achieved by capillary electroseparation techniques, as CZE and MECC; however, the DLs are larger than in HPLC. To reduce the DLs, laser-induced fluorescence (LIF) can be used. Both the selectivity and sensitivity in HPLC and capillary electroseparation can be largely expanded using MS detection. Moreover, MS is excellent for structural characterization studies at the molecular level, and can be further powered by inserting an ion trap (ITMS) between the mass filter and the ion sink.

GC separations are rapid and very efficient, and the antioxidants are sensibly detected with a FID; however, before injection the hydroxyl and carboxyl groups should be derivatized. Superior selectivity and sensitivity can be achieved with MS detection. Further, many mass spectra within the elution time of a single peak can be obtained with a time-of-flight mass spectrometric detector (TOFMS). The commercial availability of portable gas chromatographs, also including miniaturized ITMS and TOFMS detectors, have increased the interest of GC.

Nonchromatographic kinetic and cyclic voltammetric approaches, although useful to resolve simple mixtures, have a limited selectivity. High selectivity and rapidity, almost without sample preparation, can be achieved with computer-aided near-infrared-spectroscopy (NIR). The poor chemical selectivity is compensated by powerful multivariant data treatment techniques. This approach is also applied to sensor-array- and MS-based electronic noses (EN), but in this case, only the volatile fraction of the sample can be analyzed. An advantage of NIR and EN is the capability of direct evaluation of 'fundamental' variables or key factors, such as specific flavors or off-flavors (including rancidity), while skipping the tedious and sometimes impracticable evaluation of all the chemical species on which a given flavor could rely.

Evaluation of the Prooxidant/Antioxidant Activity

The evaluation of the primary prooxidant/antioxidant activity in food is important to compare the performance of antioxidants in different food products under diverse conditions. In these studies, alkyl gallates, BHT, BHA and α-tocopherol are frequently used as references, to evaluate the antioxidant activity of other compounds, including vegetal extracts, but most of the procedures mentioned below can also be used to determine the antioxidants.

The prooxidant/antioxidant activity can be measured with a wide variety of methods, including the evaluation of sensory quality (color and smell) by a panel of 'rancidity'-trained experts, the spectrophotometric monitoring of the 2,2-diphenyl-1-picrylhydrazyl (DPPH), 2,2′-azinobis(3-ethylbenzothiazoline)-6-sulfonic acid, and *N*,*N*-dimethyl-*p*-phenylenediamine radicals, the bleaching of β-carotene, the inhibition of the chemiluminescence of luminol, the GC evaluation of the C18:2/C16:0 ratio and free fatty acid (particularly, linoleic acid) contents, the iodine, peroxide, and thiobarbituric acid values, and other methods which are discussed below. In spite of their promising capabilities, little work has been still published concerning the use of electronic noses in detecting and monitoring rancidification processes.

In a fast TLC test for the evaluation of the total free-radical scavenger capacity of foodstuffs, silica-gel plates were stained with a methanolic solution of the DPPH radical; this test is sufficiently sensitive

for water- and methanol-soluble products, but not for lipid-soluble compounds. In a method for the screening of complex mixtures for radical scavenging components, postcolumn mixing of the HPLC eluate with the DPPH radical was implemented, the bleaching induced by the presence of antioxidants in the eluate being detected as negative peaks at 517 nm; this simple, rapid, and quantitative method is suitable for both isocratic and gradient HPLC runs, with mobile-phase compositions ranging from 10 to 90% organic solvent, with DLs within the 0.33–94 $\mu g\,ml^{-1}$ range, depending on the compound tested.

The antioxidant activity has been evaluated in edible plant material by the inhibition capacity on the hemoglobin-catalyzed peroxidation of linoleic acid, which can be monitored spectrophotometrically. For eight synthetic antioxidants, the antioxidant activity has been shown to be linear with respect to the logarithm of their concentrations. Hydrophilic and hydrophobic antioxidants can be assayed with this method within 15 min.

Inhibition of luminol chemiluminescence has been used to measure the antioxidant capacity of lipid-soluble antioxidants in the lipid phase of systems as blood plasma and tissue homogenates (measuring range for α-tocopherol: 0.1–3 nmol). In a postcolumn HPLC procedure, radical scavengers were detected in vegetal extracts by mixing the eluate with luminol and hydrogen peroxide in the presence of peroxidase at pH 10; by monitoring the quenching of the luminiscent signal, the antioxidants were detected at the nanogram level.

The antioxidant activity of olive oils and wines has been measured with a flow-injection system with electrochemical detection. Using the 'Rancimat' instrument (Metrohm, Herisau, Switzerland) the sample is heated (under computer control), the volatile organic acids produced by lipid oxidation are collected in water, and the resulting conductivity increase is monitored. The rancidification induction time and stability index of the product are automatically obtained. Reported applications include cereals, cookies and biscuits, lard, vegetal oils, butter and margarine, walnut oil, and olive oil. The antioxidant activities of red grape marc (skin and seeds), BHA, BHT, and PG when used in protecting olive oil have been compared. Similarly, the antioxidant activity in soybean oil of extracts from grape bagasse has been evaluated.

The formation of volatile peroxides during lipid oxidation can be followed by static headspace GC. Using this technique, the ability of BHT, BHA and the natural polyphenol antioxidants from olive oil to inhibit lipid oxidation in tuna can be compared. GC with mass spectrometric detection can also be used. In addition, lipid oxidation can be monitored by headspace GC of hexanal. Capillary GC has been used to determine the oxidized fatty acids.

Finally, the free radicals generated during lipid oxidation can be monitored directly by electron spin resonance (ESR) spectroscopy. The free radicals also induce a strong ESR signal in the exposed proteins and amino acids, and simultaneously the fluorescence of the proteins increases, which has been attributed to cross-linking. When added to the proteins prior to incubation with oxidized lipids, antioxidants, including BHT, BHA, ascorbic acid and α-tocopherol, inhibit both the ESR signal and the increase in fluorescence. The ESR of free radicals has been used to compare the efficiency of OG, BHA, and plant extracts (tea, coffee, rosemary, and others) in protecting dehydrated chicken meat.

Role of Antioxidant Nutrients in Defense Systems

S B Astley, Norwich Research Park, Norwich, UK

Background

In the body, nutrients such as the carotenoids and vitamins C and E have been suggested to act as antioxidants. Elements, such as selenium, and plant polyphenols, including the flavenoids, have also been shown to be essential in maintaining the body's antioxidant defense systems or act as antioxidants (**Table 1**).

Oxygen Paradox

Aerobic organisms exploit the inherent reactivity of the oxygen molecule to oxidize food constituents efficiently and provide energy for life. Compared with anaerobes, this form of metabolism gives a selective advantage. Reactive oxygen species (ROS), including free radicals, are normal products of an oxidative metabolism. Moderate levels of ROS not only participate in critical physiological pathways, such as signaling cascades and gene expression, but also are responsible for adjusting their rate of reaction. Under normal conditions, the potential toxicity of ROS is kept in check by a highly regulated antioxidant defense system. Aerobes are, however, subject to oxidative stress – when the rate of ROS production outstrips antioxidant defense mechanisms and the oxidant:antioxidant balance is disturbed in favor of the former. Physiological stress, aging, and environmental sources such as polluted air and cigarette smoke can hasten the imbalance.

ROS Damage and Cell Death

The unstable and highly reactive nature of ROS means that severe oxidative activity can wreak havoc within cells and tissues. Such damage may lead to cell death (apoptosis), which is a natural control mechanism that ensures the removal of damaged cells. High levels of oxidative damage that result in cell death are, however, of far less significance to an organism as a whole than oxidative stress, which can cause changes in the structural and functional integrity of a cell. ROS can damage DNA and other cellular components (e.g., lipids, proteins, and carbohydrates). Such damage has been linked to changes that accompany aging (e.g., age-related macular degeneration) and human disease processes (e.g., cancer and cardiovascular disease) (**Table 2**).

Table 1 Compounds with a role in human antioxidant defense systems

Antioxidants	*'Other role' in antioxidant defense*
Water-soluble	*Cell–cell communication, one-carbon metabolism and redox potential*
Vitamin C	Retinoids
Glucosinolates	Folates
Simple and complex phenols including:	B_6
anthocyanins	B_{12}
flavonols, flavones, and flavanones	Riboflavin
chalcones and dihydrochalcones	Thioredoxin
isoflavones and lignans	Coenzyme Q
hydroxybenzoic acids	Tyrosine
proanthocyanidins and tannins	
ellagitannins, oleuropein, and related compounds	
chlorogenic acids and other cinnamates	
Glutathione and its precursors	
Cysteine	
Glucose	
Pyruvate	
Uric acid	
Bilirubin	
Ubiquinol-10	
Quinones	
Lipid-soluble	*Essential metal ions*
Vitamin E (a, b, g, d tocopherol and trienols)	Selenium
Provitamin A carotenoids	Copper
Nonprovitamin A carotenoids	Iron
Lipoic acid	Zinc
Stilbenes	Manganese
Sterols	

Epidemiology

Epidemiological studies have shown that individuals who eat diets rich in fruit and vegetables are at significantly less risk of developing diseases associated with oxidative stress and, in particular, excess free radical production. Fruits and vegetables contain a myriad of putative health-promoting, disease-preventing compounds. For example, folic acid is necessary for accurate DNA replication and decreases plasma homocysteine, which is a risk factor for cardiovascular disease. Fiber increases the bulk of colonic contents, decreases transit time, and alters the type and metabolism of gut bacteria, all of which decrease the risk of colorectal cancers. Other components that demonstrate antioxidant capacity *in vitro* include vitamins C and E, the carotenoids, and plant polyphenolics. While the overwhelming evidence for a protective effect derived from higher amounts of fruits and vegetables in the diet is accepted, the factors responsible for such an effect remain hotly debated. It is likely that all the suggested components elicit a positive, and interactive, dose-related response, although the issue of benefit/risk should not be forgotten, particularly in relation to supplementation and fortification.

If food-derived components are effective in reducing disease risk, they may not act solely via an antioxidant mechanism – scavenging free radicals. However, since oxidative damage to biomolecules is prevalent, it is reasonable to assume that antioxidants or compounds that preserve antioxidant function and prevent or reduce such damage will be beneficial.

Vitamin C

The recommended daily allowance of vitamin C is 40 mg per day according to the UK Dietary Reference Value, or 60 mg per day, according to the US RDA. It is essential for the prevention of scurvy and to aid healing of wounds and fractures. Vitamin C also assists in the absorption of nonheme iron. Deficiency symptoms include bruising, capillary weakness, soft and bleeding gums, slow-healing wounds and fractures, swollen or painful joints, nosebleeds, tooth decay, loss of appetite, muscular weakness, skin hemorrhages, frequent infections, and anemia. Good sources are citrus fruits and juices, strawberries, vegetables.

Figure 1 shows the structure of vitamin C in its different forms. Vitamin C, or ascorbic acid, is a water-soluble crystalline solid that is one of the most labile nutrients in the diet; it is easily destroyed by oxygen, metal ions, increased pH, heat, and light. All

Table 2 Diseases involving reactive oxygen species and/or free radicals[a]

Primary single organ involvement
Cardiovascular system
Atherosclerosis
Alcohol cardiomyopathy
Brain
Stroke/cerebrovascular/traumatic injury
Dementias and amyloid diseases
Demyelinating diseases
Ataxia-telangiectasia syndrome
Aluminum overload
Lung
Effects of cigarette smoking
Inhalation of oxidant pollutants
Emphysema
Hyperoxia
Acute respiratory distress syndrome
Pneumoconiosis
Skin
Solar radiation and photosensitivity
Thermal injury
Porphyria
Contact dermatitis
Eye
Cataractogenesis
Age-related macular degeneration
Degenerative retinal damage
Ocular hemorrhage
Retinopathy
Joint abnormalities
Rheumatoid arthritis
Gastrointestinal tract
Endotoxin liver injury
Carbon tetrachloride liver injury
Free fatty acid-induced pancreatitis
Nonsteroidal antiinflammatory drug-induced lesions, abetalipoproteinemia
Kidney
Nephrotic membrane diseases
Aminoglycoside and heavy metal nephrotoxicity
Renal graft rejection
Erythrocytes
Lead poisoning
Protoporphyrin photooxidation
Malaria
Sickle-cell and other anemias
Multiorgan involvement
Cancer
Aging
Disorders of 'premature aging'
Premature retinopathy
Immune deficiency
Inflammatory-immune injury
Glomerulonephritis (idiopathic, membranous)
Autoimmune diseases
Ischemia-reflow states
Drug and toxin-induced reactions
Iron overload
Idiopathic hemochromatosis
Dietary iron overload
Nutritional deficiencies
Keshan disease (selenium deficiency)
Kwashiorkor
Vitamin E deficiency
Alcohol damage

[a]ROS and free radicals may be the sole cause of only a few but may make some conditions worse or prevent the normal action of the body's healing processes.

animals except humans, other primates, guinea-pigs, fruit bats, and some bird species are able to synthesize ascorbic acid from glucose.

Aqueous solutions of vitamin C are stable unless transition metal ions are present. Copper and iron both catalyze the oxidation of ascorbic acid, utilizing molecular oxygen, to produce hydrogen peroxide and hydroxyl radicals (Fenton chemistry/Haber–Weiss reaction).

Role in the Body

Vitamin C was first isolated in 1928. It is necessary for the synthesis of the body's cementing substances: bone matrix, collagen, dentin, and cartilage, and is needed as a cofactor for several enzymes. These enzymes include proline and lysine hydroylases, which are involved in the biosynthesis of collagen, and the copper-dependent enzyme dopamine-β-hydroylase, which converts dopamine into norepinephrine.

Deficiency of vitamin C results in scurvy, the symptoms of which are largely related to inadequate collagen synthesis and defective formation of intercellular materials due to reduced hydroxylation. Vitamin C was identified as the curative agent for scurvy in 1932. The symptoms of scurvy are usually not seen for 3–6 months in the absence of any dietary vitamin C (< 1 mg per day) because vitamin C is metabolized slowly in humans.

Smokers have an increased turnover of vitamin C, which means that in order to maintain their body pool and circulating levels at a concentration equal to that of a nonsmoker, their intake should be about 80 mg per day, compared with the 40–60 mg required by a healthy nonsmoker.

Vitamin C promotes uptake of nonheme iron by reducing Fe(III) to Fe(II), and inhibits the activity of nitroso compounds by maintaining them in their reduced inactive form. This ability to act as a reducing agent (electron donor) may also be responsible for the antioxidant role of vitamin C.

Antioxidant Role of Vitamin C

Oxygen-based reactive species are reduced by donation of one electron from vitamin C/ascorbic acid. During this process, the semidehydroascorbate

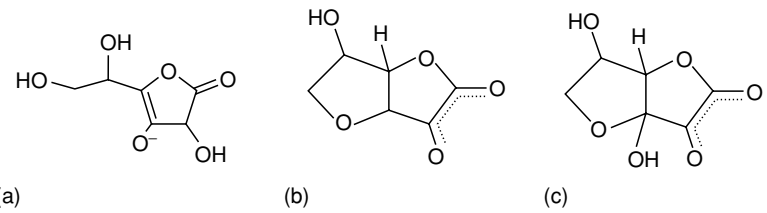

Figure 1 (a) Structure of vitamin C; (b) dehydroascorbate radical; and (c) dehydroascorbic acid.

Table 3 Plasma proteins that bind metals or iron complexes

Protein (plasma concentration)	*Action*
Ceruloplasmin (0.18–0.4 g l^{-1})	Ferroxidase activity
	Inhibits iron and copper-dependent lipid peroxidation
	Reincorporates iron mobilized from the iron storage protein ferritin back to ferritin
	Does not react directly with peroxyl radicals
Transferrin (1.8–3.3 g l^{-1})	Binds iron and stops or slows down its participation in lipid peroxidation and iron-catalyzed Haber–Weiss reactions
	Can take up iron released from ferritin, thereby inhibiting ferritin-dependent lipid peroxidation
Lactoferrin (200×10^{-6} g l^{-1})	Action similar to that of transferrin
Albumin (50 g l^{-1})	Binds copper tightly and iron weakly
Haptoglobin (0.5–3.6 g l^{-1})	Binds free hemoglobin (Hb) and met-Hb, thereby preventing these proteins from catalyzing lipid peroxidation
	Transferrin and hemopexin do not inhibit Hb-mediated lipid peroxidation
Hemopexin (0.6–1.0 g l^{-1})	High affinity for heme ($K_d < 10^{-13}$ mol l^{-1})
	Unlike transferrin and haptoglobin, hemopexin inhibits heme-mediated lipid peroxidation

radical is formed, which, despite being a free radical, is not very reactive (Figure 1). Semidehydroascorbate can undergo disproportionation to reform ascorbic acid and dehydroascorbate. Alternatively, it may be oxidized directly to form dehydroascorbate. Dehydroascorbate is highly unstable and breaks down, via a series of complex reactions, to give oxalic and L-threonic acids. Dehydroascorbate and its breakdown products are, however, toxic and the more usual reaction is the conversion of dehydroascorbate to ascorbic acid. This reaction is catalyzed by the enzyme dehydroascorbate reductase and oxidizes two glutathione molecules in the process. The same enzyme may also recycle the semidehydroascorbate radical. Both vitamin C and dehydroascorbic acid play a pivotal role in protecting lipids against oxidative damage by regenerating vitamin E.

Vitamin C reacts rapidly with superoxide and its derivatives, and even more quickly with hydroxyl radicals. It also scavenges singlet oxygen, and reduces thiyl radicals and hypochlorous acid. The human lens is rich in vitamin C, whereas levels of naturally occurring antioxidant enzymes (e.g., superoxide dismutase) are low. It may, therefore, protect the eye from oxidative damage, in particular the damage caused by UV that is mediated by singlet oxygen.

Prooxidant Potential?

Vitamin C has a potentially duplicitous action. Hydrogen peroxide and hydroxyl radicals produced during oxidation of vitamin C, catalyzed by transition metals, could be responsible for subsequent oxidative damage to the cell and cellular components including DNA.

The sequestration of metal ions *in vivo* by proteins (e.g., transferrin – Table 3) means that the prooxidant role of vitamin C is less likely. It is, however, not impossible because the binding of the metal ions, by the various proteins, does not render them entirely inactive. Furthermore, in the event of physical damage (e.g., bruising) heme iron may be released from erythrocytes, which is available for participation in Fenton chemistry. Oxidative damage caused by the vitamin C in plasma may be a real danger to surrounding tissues.

Risk:Benefit

Megadoses of vitamin C, synthetic or natural, have previously been considered beneficial or, at the very least, harmless. However, there is mounting evidence that doses as small as 500 mg per day may result in increased levels of DNA damage and damage to the lining of major arteries, which subsequently leads to an elevated risk of stroke.

Vitamin E

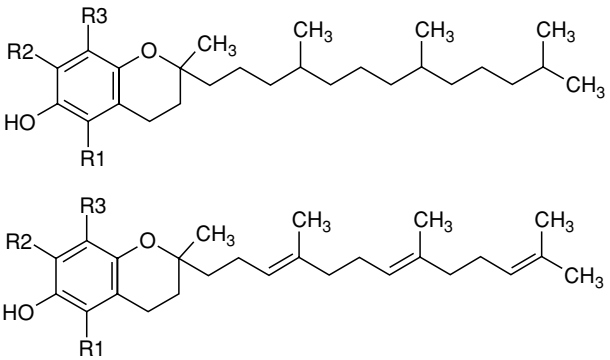
There are no UK dietary reference values available for vitamin E, but the US RDA is 30 IU. Vitamin E is the major lipid-soluble antioxidant nutrient. Deficiency symptoms are very rare, and usually only occur as a result of fat malabsorption syndromes. Good food sources include cereals, nuts and seeds, wheat germ, vegetable oils, and 'spreads,' which contain vitamin E as an antioxidant.

Chemistry

Vitamin E (Figure 2) is an essential nutrient, which happens to function as an antioxidant. The term 'vitamin E' is generic, and includes all entities that exhibit the biological activity of α-tocopherol.

In nature, eight substances have been found to have vitamin E activity: α-, β-, γ- and δ-tocopherol, and α-, β-, γ- and δ-tocotrienol. The acetate and succinate derivatives of the natural tocopherols also have vitamin E activity, as do the synthetic tocopherols and their acetate and succinate derivatives. Of these, D-α-tocopherol (*RRR*-α-tocopherol) has the highest bioavailability and is the standard against which others are compared.

Natural and synthetic vitamin E are not equivalent in composition, structure, or bioavailability. Natural vitamin E (*RRR*-α-tocopherol or D-α-tocopherol) is a single entity, whereas synthetic vitamin E (all-rac-α-tocopherol or DL-α-tocopherol) is a mixture of eight stereoisomers in equal amounts. The other seven stereoisomers have different molecular configurations and lower biological activities.



Compound	R1	R2	R3
Alpha (α)-tocopherol	CH_3	CH_3	CH_3
Beta (β)-tocopherol	CH_3	H	CH_3
Gamma (γ)-tocopherol	H	CH_3	CH_3
Delta (δ)-tocopherol	H	H	CH_3
Alpha (α)-tocotrienol	CH_3	CH_3	CH_3
Beta (β)-tocotrienol	CH_3	H	CH_3
Gamma (γ)-tocotrienol	H	CH_3	CH_3
Delta (δ)-tocotrienol	H	H	CH_3

Figure 2 Tocopherols and tocotrienols.

The richest natural sources of vitamin E are vegetable oils, nuts, and whole grains. Wheatgerm oil is the single richest source, whereas foods of animal origin are generally low in vitamin E. In general, the amount of vitamin E (as D-α-tocopherol) supplied by a normal diet ranges from 6 to 13 mg per day (1 IU = 0.67 mg). In most countries, the estimated average intake is below 10 mg per day. During refining, processing, and storage, all foods containing vitamin E lose some of their activity. Vitamin E in foods is destroyed by oxygen, freezing causes degradation, and, like vitamin C, the oxidative process is accelerated by heat and light.

Role in the Body

Those compounds with vitamin E activity have a number of roles in human metabolism that include (1) acting as an antioxidant to protects cells and other body components from free radical attack; (2) stimulation of the immune response; (3) reducing the severity of prostaglandin-mediated disorders such as inflammation, premenstrual syndrome, and circulatory irregularities (nocturnal leg cramps and blood platelet adhesion); (4) inhibition of the conversion of nitrites in smoked, pickled, and cured foods to nitrosamines in the stomach; and (5) regulation of gene expression in particular the proliferation of smooth muscle cells, which are involved in the development of atherosclerosis.

Most vitamins function as cofactors for enzymatic reactions, but vitamin E has no such role. Requirements for, and utilization of, vitamin E vary according to an individual's oxidative status. Furthermore, unlike other vitamins, deficiency of vitamin E does not produce a disease with rapidly developing symptoms. The absence of vitamin E only produces overt deficiency symptoms in cases involving fat malabsorption syndromes, premature infants, and patients on total parenteral nutrition. However, there are noticeable effects of inadequate vitamin E intake, which develop over a long time, typically decades, and have been linked to the development of degenerative diseases.

Antioxidant Role

Vitamin E is present in all lipids in the body, most significantly in lipids of cell membranes and in circulating low-density lipoproteins (LDL – the so-called 'bad' cholesterol). It is recognized to be the major fat-soluble antioxidant in lipid tissue, and the primary defense against lipid peroxidation – oxidation of fats.

When a free radical reacts with lipid in a cell membrane, the resulting chain reactions oxidizing surrounding lipid (lipid peroxidation) damage both the structure and function of cell membranes. Vitamin E is particularly important in tissues that contain relatively high levels of polyunsaturated fatty acids (e.g., brain and central nervous system), those in direct contact with high concentrations of oxygen (e.g., lung) and cell organelles dealing with oxygen or oxygen-free-radical reactions (e.g., mitochondria).

Epidemiology

Epidemiological studies provide data supporting the benefits of higher intakes of foods containing vitamin E as well as other antioxidants. These studies suggest that individuals with low blood concentrations and/or intakes of foods containing vitamin E have increased risk for development of a number of degenerative diseases including certain types of cancer, heart disease, Alzheimer's disease, and cataract. However, as yet, there is no proof that the vital component in the prevention of these diseases is anymore likely to be vitamin E than any of the other compounds contained in such foods.

A limited number of intervention trials have been completed, with mixed results. However, for the most part, such trials have used isolated natural or synthetic vitamin E, and there is increasing evidence that these compounds do not interact with the body in the same way as food-sourced vitamin E (e.g., reduced bioavailability).

Source and Dose

How much vitamin E an individual needs depends on what is required; enough to prevent deficiency disease, prevent oxidation of lipids, prevent free radical damage and promote optimal health, or to produce a therapeutic effect. Deficiency *per se* can be prevented by intakes in line with government recommended dietary intakes. However, if prevention of oxidative damage and promotion of optimal health is the objective, intakes of up to 10 times the current levels have been proposed. If a therapeutic result is the aim, even higher intakes may be necessary.

Research data suggest that considerably more vitamin E needs to be consumed in the average diet to prevent free radical cell damage. Foods are depleted of vitamin E by processing, refining, and storage, and the current trend to reduce fat intake means that a diet-conscious population tends to eliminate those oil-rich foods likely to provide vitamin E. Not only do most people not get enough vitamin E in their diets for optimal health, but a large number are considered to be marginally deficient of the amount necessary to prevent deficiency disease.

Carotenoids

No dietary reference values are available for the recommended daily allowance. Those with a β-ionone ring are precursors for vitamin A.

No deficiency symptoms are known except those associated with vitamin A deficiency. Good food sources are colorful fruit and vegetables (e.g., peas, tomatoes, and carrots) and commercial products such as 'spreads' and milkshake flavoring, which contain β-carotene as an antioxidant.

Links with Vitamin A

In 1913, it was shown that a fat-soluble factor in butter – later characterized as vitamin A – stimulated the growth of rats fed on an incomplete diet. Vitamin A is a fat-soluble vitamin that helps in the formation and maintenance of healthy teeth, skeletal and soft tissue, mucous membranes, and skin. It is also known as retinal because it generates the pigments that are necessary for the functioning of the retina. However, it is not an antioxidant.

Chemistry

Carotenoids are naturally occurring brightly colored plant pigments. More than 600 different carotenoids have been identified, all derived from the same basic C40 isoprenoid skeleton (**Figure 3**).

Mixed carotenoids can be isolated from algae, β-carotene from palm oil, lutein and lutein esters from marigolds, lycopene from tomatoes, and cryptoxanthin from citrus and tropical fruits, in particular orange fruit. β-Carotene has been synthesized for a number of years, and lycopene more recently.

Natural mixed carotenoid supplements contain a variety of carotenoids, including α- and β-carotene. Commercially available synthetic carotenoid supplements contain only β-carotene. Synthetic β-carotene is composed of the all-*trans* isomers, and β-carotene from algae, and fruits, and vegetables is composed of all-*trans*, 9-*cis*, and other *cis*-isomers.

Role in the Body

Humans regularly consume around 40 different carotenoids, but only a small number of these can be detected in appreciable quantities in human blood and tissues. The major carotenoids are α- and β-carotene, lutein, zeaxanthin, cryptoxanthin, and lycopene.

Provitamin A carotenoids, those carotenoids possessing a β-inone ring, have vitamin A activity, and can be converted into vitamin A by the body. β-Carotene has the highest provitamin A activity, but over 60 carotenoids have some provitamin A activity. Vitamin A is toxic when taken in excess, but these

carotenoids are safe sources because they are only converted to vitamin A as and when the body needs it. The other biological roles of carotenoids, including their antioxidant functions, are completely independent of their provitamin A activity. However, the carotenoids are not recognized as essential nutrients, and there are no recommended dietary intakes. The only exception is a recommended dietary intake for vitamin A of 800–1000 retinol equivalents, where one retinol equivalent is 6 mg of β-carotene or 12 mg of another provitamin A-carotenoid.

Role of Antioxidants

Despite the similarities in their structures, the carotenoids have diverse biological functions and potentially different roles within the body. The carotenoids are effective quenchers of singlet oxygen, with lycopene exhibiting the highest singlet oxygen-quenching activity. They are able to function as chain-breaking antioxidants, much like vitamin E, and may protect cells and cellular components from oxidative damage. The carotenoids will protect lipids from oxidation as well but only in the absence of vitamin E, which is far more abundant. Importantly, the carotenoids exhibit the ability to inhibit oxidative damage at different oxygen tensions. At high oxygen tensions, such as those in the lungs, lycopene is more effective then β-carotene, which in turn is more efficient at low oxygen concentrations.

Carotenoids enhance the immune response and protect the skin from redness and damage following exposure to UV radiation. Certain carotenoids (including lycopene and β-carotene) have the ability to enhance cell–cell communication by increasing the exchange of growth regulatory signals. Increased communication between normal cells and damaged cells encourages the latter to undergo apoptosis (commit suicide) and protects the body from proliferation of initiated potentially precancerous cells. Some carotenoids are more effective in tumor suppression in different cultured cell lines, and it has been suggested that others protect against specific cancer types. For example, increased consumption of tomatoes and tomato products (lycopene) is correlated significantly with a decrease in incidence of prostate cancer and foods containing lutein, zeaxanthin, and α- and β-carotene with a reduced risk of lung cancer. Lutein and zeaxanthin are oxycarotenoids (i.e. they contain an oxygen atom) and are the only carotenoids present in the macular region of the retina. These carotenoids are linked to the normal function of the macula, which is responsible for sharp and detailed vision, and are thought to serve as filters for harmful blue light in the macula and as scavengers of singlet oxygen in retinal tissues.

Epidemiology

The majority of data examining carotenoid intakes show that individuals with low carotenoid intakes or low blood carotenoid levels are at a greater risk of developing degenerative diseases associated with aging. High intakes of carotenoid-rich fruits and

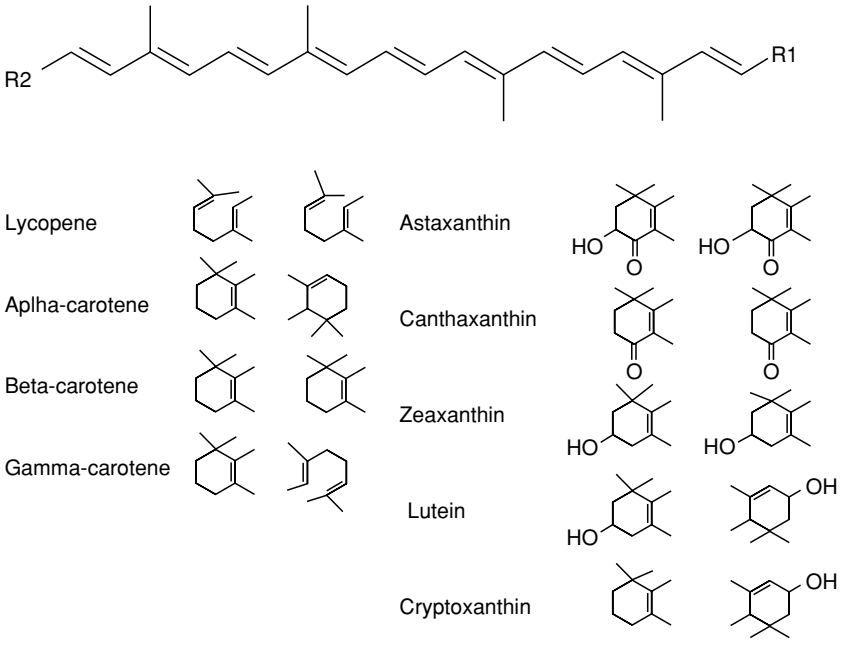


Figure 3 Carotenoids and oxycarotenoids.

vegetables and high carotenoid blood levels are associated with a lower risk of cancer and cardiovascular disease, which may refute the previously held conviction that only vitamin E had the potential to ameliorate risk. In addition, studies have shown an inverse correlation between levels of the oxycarotenoids lutein and zeaxanthin and risk of cataracts and age-related macular degeneration, although there is no evidence that increased intake can reverse existing damage. For the most part, research into the carotenoids has focused on β-carotene, because it is the best known, most abundant, and has provitamin A activity, but recent studies have suggested that lutein, zeaxanthin, lycopene, and cryptoxanthin should also be considered.

Source and Dose

Research suggests that 9-*cis* β-carotene is the most efficient antioxidant and that food sources are better able to increase antioxidant protection than natural isolates. As with vitamin E, the amount of carotenoids required by an individual will depend on the overall aim (i.e., to prevent vitamin A deficiency, prevent oxidation of lipids, prevent free radical damage or promote optimal health). If prevention of vitamin A deficiency is the objective, quantities of provitamin A carotenoids to meet the RDA for vitamin A are adequate for most individuals in developed countries. If prevention of oxidative damage and promotion of optimal health is the objective, higher intakes of carotenoids may be necessary.

The richest dietary sources of carotenoids are brightly colored fruits and vegetables. Currently, the estimated daily intake from a normal diet ranges from 1.5 to 3 mg for β-carotene and from 3.6 to 7.6 mg for total carotenoids. Factors influencing carotenoid intake levels include differences in varieties, variable growth and harvesting conditions, postharvest handling and processing methods, exposure to light and oxygen, and cooking methods. On the whole, mild cooking of food before ingestion improves the bioavailability of carotenoids, because the plant cell wall structure is partially broken down, increasing the ability of the gut to further digest the plant material and release the carotenoids from the cellular structures with which they are intimately associated.

Risk:Benefit

Results from intervention trials using a large dose of synthetic β-carotene supplements over a long period of time, often in combination with vitamin E, have been neutral or negative, suggesting an increase in both cancers and events related to cardiovascular disease. In contrast, studies with other specific carotenoids, mixed carotenoids, or foods with high carotenoid contents have provided neutral or positive results.

The carotenoids are not carcinogenic, mutagenic, teratogenic, or cytotoxic when tested using typical toxicological tests. Doses of 20–180 mg of β-carotene per day, for many years, have been used to treat erythropoietic protoporphyria, with no evidence of toxicity or development of abnormally elevated blood vitamin A levels. Based on current information, therefore, an increased intake of a mixture of natural carotenoids, preferably from food rather than in the form of an isolate or β-carotene alone, may be of greatest benefit in disease prevention.

Introduction

The apple belongs to the genus *Malus*, and is a member of the rose family, Rosaceae. There are about 25 species of *Malus*; however, most horticulturists refer to *Malus domestica* as the cultivated apple. This article discusses the global distribution, varieties, commercial importance, morphology, nutritional composition, handling, storage, and industrial uses of this crop.

Origin and Global Distribution

The domestic apple of the west appears to have arisen on the northern slopes of the Tien Shan range roughly on the border of what is now Kazakhstan and the Xinjiang province of China. This wild apple is called *M. sieversii*. From this species, it seems, have emerged the cultivated apples of our supermarkets, *M. domestica* and *M. pumila*. Several crabapples and other *Malus* species are considered native to China, India, and North America. Although some species are not hardy, the domestic apple (especially *M. pumila*) is one of the hardiest of temperate-zone fruits. Apple seeds require more than 60 days of cold temperature before germination. In addition, its winter chilling requirement for apple trees to break rest dormancy (1000–1600 h) is high enough that it does poorly in latitudes with warm winters. Apples are grown in most temperate climates and many other countries like Argentina, New Zealand, and South Africa. Apples are also grown at the higher altitudes of some countries with less temperate climates such as Mexico. Production statistics for various areas of the world are presented in Table 1.

Varieties

Variability in the wild species has been used by breeders who use parents with desired traits when crosses are made. When seeds from a cross are planted, the resultant plant is a clone. Thus, breeders select individual plants with desired characteristics rather than selecting a population of plants.

The general objectives of apple-breeding programs are as follows: (1) to enhance yields; (2) to improve fruit quality, which includes factors such as flavor, firmness, or other fruit characteristics; (3) to produce plants adapted to specific environmental or cultural conditions; (4) to develop varieties resistant to diseases and insects; and (5) to develop varieties with specific requirements, such as suitability for processing, or extra firmness for long-distance shipping and improved storage and shelf-life.

New apple varieties are continuously being introduced: worldwide, there are more than 7000 varieties, although most are not currently grown commercially. Some of the more important varieties with their uses are listed in Table 2. Apple characteristics vary greatly with variety, and variety selection is a matter

Table 1 Global distribution of apple production by geographical area, including a listing of countries producing 1.0×10^6 metric tonnes (Mt) or more

Global distribution by geographical area and countries within any one area producing 1.0×10^6 Mt or more	*Production (Mt)*

Table 2 Selected apple varieties and their characteristics and uses

Variety	*Flavor*	*Storage life*	*Uses*	*Remarks*
Braeburn	Sweet	Excellent	Cooking, fresh	
Cortland	Slightly tart	Good	Cooking, fresh	White flesh that is slow to darken when cut
Cox's orange	Slightly tart	Good	Cooking, fresh	Orange/red; yellow flesh
Empire	Sweet/slightly tart	Good	Fresh	
Fuji	Sweet	Good	Cooking, fresh	
Gala	Slightly sweet	Short	Cooking, fresh	Orange/red; yellow flesh
Golden delicious	Sweet	Excellent	Cooking, fresh	
Granny Smith	Sweet/tart	Excellent	Cooking, fresh	
Haralson	Tart	Excellent	Cooking, fresh	White, firm flesh
Honeygold	Slightly sweet	Good	Cooking, fresh	
Idared	Slightly sweet	Good	Cooking, fresh	
Jonadel	Slightly sweet	Good	Cooking, fresh	Red fruit
Jonafree	Slightly tart	Good	Cooking, fresh	
Jonagold	Slightly tart	Good	Cooking, fresh	Large yellow fruit with red striping
Jonathan	Slightly tart	Moderate	Cooking, fresh	
Liberty	Slightly tart	Good	Fresh	Greenish yellow with red stripes
McIntosh	Slightly tart	Moderate	Cooking, fresh	Bright red
Mutsu	Slightly tart	Excellent	Cooking, fresh	Yellow-green fruit
Northern spy	Tart	Excellent	Cooking	
Paulared	Slightly tart	Short	Fresh	
Red delicious	Sweet	Excellent	Cooking, fresh	
Rome beauty	Slightly tart	Good	Cooking	
Spartan	Slightly tart	Good	Cooking, fresh

of personal preference and intended use. In general, for fresh eating or dessert apples, North Americans prefer mildly sweet, crisp apples, Europeans favor tarter apples with high flavor and firmness, and Asians and people of the Middle East select very sweet apples. Some Japanese growers will leave apples on the tree until the apples become extremely sweet with an almost syrupy center (known as 'water core'). These apples would be considered overripe and unsaleable in most European and North American markets.

In North America, six varieties account for the majority of the crop. In the USA, Red delicious, Golden delicious and Granny Smith account for 65% of the apples grown. In Canada, McIntosh is the most popular, followed by Red delicious and Spartan. In both countries Gala and Fuji are being increasingly planted in response to higher world prices for new apple varieties.

Golden delicious is the number-one variety in Europe, with many clones being selected from this parent, although plantings are decreasing. Red delicious is popular, but some areas in Europe have difficulty growing it due to susceptibility to frost and physiological storage diseases and it too is experiencing decreased plantings. Granny Smith is very popular and increasing slightly in demand. Rome beauty and Cox's orange were quite popular but plantings are now in decline. In Belgium, Germany, and the Netherlands, Jonagold is the most popular variety. Gala is increasing in demand in Europe, as in North America. In 8 years, production of Gala increased by 1200% in the European Union (EU). Braeburn, which is the most popular variety in New Zealand, its country of origin, is also the favorite variety in the UK and Germany. World demand for Fuji has encouraged increased plantings, although there are difficulties finding suitable growing conditions. In China, approximately 40% of the crop consists of the cultivar Fuji.

Commercial Importance

The Food and Agriculture Organization lists apple production statistics for 88 countries. Thirteen countries – USA, Argentina, Brazil, China, India, Iran, Turkey, France, Germany, Italy, Poland, the Russian Federation, and the Ukraine – each produce in excess of 1 million metric tonnes (Mt) annually. China is by far the world's largest producer of apples, accounting for more than 50% of the world's 6.0×10^7 Mt annual production (Table 1). This worldwide production would have a farm-gate value of over $\$3.0 \times 10^{10}$ (US) based on their value in North America. This return would represent $\$0.50\,kg^{-1}$ average price for fresh-market fruit. Return varies greatly with variety depending upon demand and availability. In North America, per capita consumption averages 10 kg for fresh consumption, with an additional 12 kg for processed products (including juice).

In China, much of the best quality Fuji is destined for East Asian markets. In the last 10 years, apple production in China has quadrupled and is expected to double again in the next few years. Approximately 2.5×10^6 ha of land is devoted to apple production, compared to 3×10^5 ha for all of North and Central America. Ten percent of the crop will be processed. Several other Asian countries also produce large quantities; however, distribution is primarily limited to internal markets. Storage facilities are also limited in some Asian countries.

Central and Eastern Europe contains about 83% of Europe's total land mass but produces less than 50% of its apples. Climate and economic conditions vary greatly throughout this area, resulting in a wide variation of quality, production, and return. Newer varieties are not available in most areas. Returns also vary greatly, ranging from 100 to 150% higher than production costs in countries with extensive cultivation, down to 20–40% in less developed countries. Poland, Slovenia, and Hungary produce sufficient crop to permit export. Storage facilities are limited in most countries with only 20–30% of the fruit stored. Storage is often in natural storages as some lack cold and controlled atmosphere (CA) storages.

Apple production in western Europe has been at a surplus for some time. In 1997, almost 50% of apples in storage were unsold as of 1 December. Changing popularity of varieties and increased imports have partially accounted for this surplus. The EU has been directing orchard removals. Orchard removal has been particularly evident in France, which has accounted for 30% of European orchard removals.

Apples are a major fruit crop in North America, although returns are low for some of the traditional varieties and growers are shifting to the more lucrative varieties. Production in North America is concentrated in three main areas: (1) the eastern section, including the north-eastern and Atlantic states and provinces; (2) the central USA (Ohio to Arkansas); and (3) the western section from Colorado to British Colombia.

Morphology

The apple is a pome fruit which develops from the inferior ovary of the flower. Specifically, it develops from the ovary wall and the floral tube (the base parts of the stamens, sepals, and petals). During maturation, the tube fuses to the ovary wall, expands, becomes fleshy and ripens. The fleshy mesocarp is the edible portion of the fruit. Five cavities are also produced which generally contain two seeds each.

Apples differ greatly in their external characteristics. When ripe, they may be green, yellow, or red depending upon variety. Size, shape, sugar content, acidity, and firmness all vary with variety. Apples may be classified into three categories depending upon the concentration of acid (calculated as malic acid) and phenolic compounds or tannins. Bitter-sweet apples contain greater than 0.2% (w/v) tannins and less than 0.45% (w/v) acidity. Sharp apples have less than 0.2% tannins and more than 0.45% acidity. Sweet apples have less than 0.2% tannins and less than 0.45% acid.

The physiological characteristics of apples, such as the waxy skin and low respiration rate (5–10 mg CO_2/kg h^{-1} at 5 °C), make them very suitable for storage and long-distance shipping, thus apples are harvested once a year but available year-round.

Chemical and Nutritional Composition

A list of some of the nutrients in apples is presented in Table 3, with those for strawberries and oranges included for comparison. Apples contain the highest percentage of carbohydrates and food energy of these three fruits. A serving of one 150-g apple provides 8% of the US Department of Agriculture adult daily requirement for ascorbic acid (vitamin C) and 2% of both the vitamin A and iron requirements. Refer to individual nutrients.

Apples contain virtually no fat, cholesterol, or sodium. Apples are rich in pectins (soluble fiber) which has been found to be effective in lowering cholesterol levels. Apples also contain phenolic antioxidants and flavonoids (especially quercetin) which may also provide health benefits. (*See* **Antioxidants**: Natural Antioxidants; Synthetic Antioxidants; Synthetic Antioxidants, Characterization and Analysis;

Table 3 Nutrient composition (per 100 g fresh weight) of apples compared to that of strawberries and oranges

Handling and Storage

Apples in the northern hemisphere are harvested in the months of August, September, and October. Early varieties usually have a shorter shelf-life than late varieties. Apples are harvested by hand using a lifting and twisting motion to separate the fruit stem from the branch. An apple picker needs to handle the fruit gently to reduce the incidence of bruising on the fruit. Pickers usually carry a harvesting bag to hold the apples while they are walking through the orchard. The bag must be suitable for local conditions and ease of use and not damage the fruit. Often, the bag can be opened at the bottom in order to release apples easily into an orchard bin.

An orchard bin can usually hold approximately 700 l of apples. The size of wood bins is approximately $120 \times 102 \times 74$ cm and that of plastic bins is approximately $122 \times 113 \times 88$ cm. The advantage of using plastic orchard bins is the cleanliness, the faster cooling time, and the ease of fixing damaged bins, which can be simply melted down and reformed. The initial cost of a plastic orchard bin may be higher than the wood orchard bin, but the longer usage life of a plastic bin makes it a more attractive investment for a long-term commercial operation. These orchard bins can be stacked up to eight bins high for the plastic bins and nine bins high for the wood bins when placed inside a cold storage room. Bins need to be stacked closely together in order to force the cold air to pass through the apples.

Most apples can be stored at 0 °C. Some varieties of apples need to be stored at slightly higher temperatures in order to reduce the occurrence of disorders associated with chilling injury. For example, McIntosh apples have to be stored at 2.5–3 °C to avoid brown core disorder. Normally apples can be stored in cold storage for 3–6 months. The length of the storage life of apples depends on apple variety, storage temperature, harvest date, and storage atmosphere. The storage life of apples can be doubled if the apples are stored in CA storage rooms. Oxygen levels in a CA room are maintained at 1–3% and carbon dioxide levels are maintained at 1–5%. A CA room is basically an airtight cold storage room. The pressure in the CA storage room needs to be slightly higher than the atmosphere outside to prevent outside air from seeping into the room. The levels of oxygen can be reduced by burning methane or propane gas or by adding nitrogen gas to the CA room. Combusting oxygen with methane or propane can remove unwanted oxygen and produce the desired carbon dioxide. Nitrogen gas can be provided from a bulk tank of nitrogen gas or by a hollow-fiber membrane separation system. The principle of hollow-fiber membrane air separation is based on varying permeation rates for different gases, such as oxygen, carbon dioxide, and nitrogen, through the membrane.

The hollow-fiber membrane-type gas separator consists of bundles of small hollow polymeric fiber tubes in a vessel. Compressed air is fed into the separator, pressurizing the inside of the individual tubes. As the air flows through the tubes, oxygen and carbon dioxide permeate through the fiber walls faster than the nitrogen. This oxygen-rich stream is vented to the outside. The nonpermeate gas (nitrogen) outflow stream is piped into the storage room. By changing the output flow rate, the purity of the output can be controlled. Nitrogen purity levels of up to 99.9% can be obtained, but for CA applications purity levels of 97–99% are usually used.

The level of carbon dioxide in a CA room can also be achieved by the natural respiration of the fruit. When the level of carbon dioxide reaches 1–5%, excessive amounts of carbon dioxide have to be removed by absorbing carbon dioxide with lime or by adding nitrogen gas to the CA room.

Table 4 shows a summary of recommended storage temperature, levels of oxygen and carbon dioxide, and storage life of apples in CA storage for major apple cultivars in the world. Special care must be exercised when entering a CA storage room because the level of oxygen in a CA room is not enough to support human life. (*See* **Chilled Storage**: Principles; Attainment of Chilled Conditions; Quality and Economic Considerations; Microbiological Considerations; Use of Modified-atmosphere Packaging; **Chill Foods**: Effect of Modified-atmosphere Packaging on Food Quality; **Chilled Storage**: Packaging Under Vacuum; **Controlled-atmosphere Storage**: Applications for Bulk Storage of Foodstuffs; Effects on Fruit and Vegetables; **Ripening of Fruit**.)

Industrial Uses

In most countries, a high percentage of the apple crop is used for processing. In the USA, statistics indicate that, in 1997, 50% of fruit was eaten fresh, 20% was processed into vinegar, cider (fresh or fermented), wine, juice, jelly or apple butter, 17% was canned as apple sauce, baby food, or pie filling, and the remainder was exported to other countries (predominantly for the fresh market). Cider (fermented), wine and brandy production are particularly important uses in Europe. (*See* **Cider (Cyder; Hard Cider)**: The Product

Table 4 Summary of recommended storage temperature, levels of oxygen and carbon dioxide, and storage life of apples in controlled atmosphere storage for major apple cultivars in the world

Cultivar	*Temperature (°C)*	*Oxygen (%)*	*Carbon dioxide (%)*	*Storage life (months)*
Braeburn	0.7	1.8	1.0	6–9
Fuji	0.3	1.4	1.0	7–11

and its Manufacture; Chemistry and Microbiology of Cidermaking.) Other minor uses include dried apples, yogurts, cakes, muffins, candy apples, salads, and fried or baked apples.

Apple juice consumption varies widely with region. In North America, citrus juices are more popular and apple juice accounts for only about 8% of total juice consumption. In contrast, in Germany, apple juice accounts for approximately 45% of total juice consumption. In addition to being a popular single-ingredient juice, apple juice is also very popular as an ingredient in blended juice mixes. The USA and Poland are the largest apple juice-producing countries. These countries each account for about 20% of selected country annual output. In the USA, Michigan, California, and New York account for most of the apple juice production with 40–45, 70, and 40%, respectively, of their crops being processed as juice. Most apple juice (95%) produced in Poland is exported, primarily to Germany and other neighboring countries. The profitability of apple juice production has led many Polish growers to switch to varieties which are more suitable for processing. In South America, Argentina and Chile are the primary producers of apple juice, most of which is exported to the USA. Traditionally, apples not suitable for the fresh market are utilized for juice. In recent years, China has become a major apple juice producer.

APRICOTS

S M Southwick, University of California, Davis, CA, USA

Introduction

Apricots are one of the most ancient crops produced by humans and the fruit is grown on every continent of the globe. Most apricot production in the world is centered in Europe and Asia with lesser production in the Americas, Africa, and Oceania. In the former USSR, after years of collection and evaluation, there are as many as 1800 cultivars and forms of *Prunus armeniaca* and in China there are more than 2000 cultivars, many of which are purported to be widely adapted, large-fruited, and of excellent quality. The apricot is generally adapted to narrow climatic areas. The chilling requirements required for rest limit adaptability. As a result of narrow adaptation, favorable local varieties are not always produced economically in other regions. Apricots are soft fruits with a hard stone (stone fruits) and are generally sensitive to disease and to high or low temperatures. Apricots can have outstanding organoleptic qualities and the fruit is high in fiber and vitamins, making it ideal in the human diet. Consequently, this versatile fruit is consumed in fresh, canned, dried, and other processed forms. The varied germplasm which exists in the world is being utilized to improve existing apricot cultivars, helping to insure a continued supply of high-quality, healthy apricots for the world population.

Global Distribution and Relative Commercial Importance

Apricot production in the former USSR is located primarily in Ukraine, Russian Federation, Armenia, and in the Central Asian Republics (Uzbekistan, Tajikistan, Turkmenistan), and the Northern Caucasus (Krasnodar region, Daghestan and Karbardino-Balkarsk ASSR). Smaller growing regions exist in Azerbaijan, Georgia, Kirghizia, and Kazakhstan.

A relatively small production of apricots is located in Switzerland and Poland, with increased amounts in Bulgaria, Romania, and Hungary. To a larger extent, apricots are grown in the Mediterranean region, Spain, Portugal, France, Italy, Yugoslavia, Slovakia, Croatia, Macedonia, Albania, Greece, and Israel. In North Africa, Algeria, Tunisia, and Morocco are the leading producers. The central and western Mediterranean countries produce more than one-third of the world's production of apricots. Apricot cultivars of the Near East include cultivars found in Iran, Iraq, Syria, Afghanistan, Pakistan, and Turkey. Existing local varieties and ecotypes were developed by growers and horticulturists, and many small orchards today consist of wild seedlings mixed with cultivated forms. Turkey produces many of the world's apricots and there are an estimated 10×10^6 trees, of which about 50% are budded. Most of the fruit is consumed fresh; the remainder is dried and some of that is exported. In Iran there are an estimated 8996 ha (22 230 acres) of apricots. Most of the apricots are consumed fresh or dried both in Iran and in the previously mentioned countries. The apricots grown in Iraq and Pakistan are mostly generated by seed and consequently there is a wide variation in productivity from year to year.

In Australia and New Zealand, apricots are planted to a limited extent. In 1990, it was reported that approximately 27 300 and 7800 t of apricots were produced in Australia and New Zealand, respectively. Approximately 90% of Australia's apricots are produced in the River Murray irrigation areas in South Australia and Victoria and along the tributaries of the Murray in New South Wales and Victoria. Most of the apricots are dried. In New Zealand the main area of production (85%) is located in the South Island in the Central Otago region. Hawke's Bay is another apricot-producing area in New Zealand. In contrast to Australia, 60% of New Zealand's apricot production is sold fresh and 35% processed. South Africa produced approximately 46 000 t of apricots in 1990 (Table 1). The South African production has increased and by 1993–94 there were reported to be about 5400 hectares.

China appears to possess the most extensive repository of apricot and related germplasm in the world. There are eight species in the *Armeniaca* genus located in China, four of which include the common apricot (*Armeniaca vulgaris* Lam. or *Prunus armeniaca* L.), the Sibirian apricot (*P. sibirica* L.), the Manchurian apricot (*P. mandshurica* Koehne.), and the Tibet apricot (*P. armeniaca* var. *holoserice* Batal.). *P. mume* (mume), a related species, also originated in China. The diversity of apricot germplasm in China, if utilized effectively in genetic improvement research, could substantially broaden the existing commerce of apricots in North America and the world. Japan is a minor producer of apricot and produces more *Prunus mume*. Historically, the apricot and mume were utilized for medicinal purposes, but now the fruit is

consumed in processed forms such as syrups, jams, pickles, and liquor. In 1986, mume production approximated 89 100 t and apricot about 1460 t.

Argentina and Chile are the two leading producers of apricots in the southern hemisphere, with production of 15 500 and 15 650 t, respectively, in 1990.

In North America, the USA is the leading producer of apricots, but they are produced to a limited extent in Canada and Mexico. Canadian apricot production is located primarily in the western part with some small production near the Great Lakes. In Mexico, apricots are grown in the high desert east of the Sierra Madre mountain range. In the USA, California is the leading apricot-producing state, followed by Washington and Utah with a smattering of production in Michigan, Colorado, Texas, New Jersey, Idaho, New York, and the Carolinas.

In California, there are approximately 19 000–23 000 acres (7689–9308 ha) planted. Nonbearing acreage accounts for approximately 500–1000 acres (202–405 ha) of that total. Stanislaus county is the leading apricot-producing region in California, with

over 7000 acres (2833 ha). Other important apricot-producing counties in California include Contra Costa, Fresno, Kern, Kings, Madera, Merced, San Benito, San Joaquin, Santa Clara, Tulare, and Yolo-Solano.

Varieties

The most popular apricot varieties in California are described below, and some of their bearing acreages in 1990 are listed in Table 2. The Patterson apricot is being planted more widely and is a multiuse apricot, utilized primarily for canning (processing), but also frozen, dried, and eaten fresh.

Castlebrite

Released as a very-early-ripening, fresh-shipping variety, the fruit is yellow-orange and attractive, with a red blush. It is firm, medium in size, but does not possess finest eating quality. The cultivar suffers from inconsistent production, probably because the chilling requirements are not satisfied.

Derby

Derby or Derby Royal is principally grown in Yolo County, California. It originated from a chance seedling and was first planted in 1895. Derby is suitable for fresh shipping, but not for drying because the stone can cling to the flesh. The fruit may ripen unevenly. At least two distinct strains of the Derby have been recognized around Winters, California area with differing fruit characteristics.

Earlicot and Poppy Cot

Earlicot and Poppy Cot are varieties introduced by Zaiger Genetics of Modesto, California. They are among the earliest ripening apricots grown in California. They are large, firm, and yellow-orange in color with a red blush occasionally found on the skin. They are slightly acidic with a fair flavor overall and are suitable for commercial shipment.

Table 2 California acreage of selected apricot varieties in 1990

Variety	*Acres (ha)*	*Harvest time*
Blenheim/Royal	7303 (2955)	17 June
Castlebrite	986 (399)	7 May
Derby Royal	221 (89)	25 May
Flaming Gold	157 (64)	21 May
Improved Flaming Gold	118 (48)	21 May
Katy	319 (129)	15 May
Modesto	578 (234)	1 June
Patterson	3404 (1378)	12 June
Tilton	5922 (2397)	18 June
Westley	174 (70)	25 June
Other	584 (236)	

Flaming Gold

Originated in Modesto, California, by Floyd Zaiger, Flaming Gold was introduced in 1967 and was a seedling of Perfection. The fruit ripens early and has been used primarily for fresh shipping.

Goldbar and Goldstrike

Goldbar and Goldstrike originated from the breeding program of Dr Tom Toyama at Washington State University in Prosser, WA. Both fresh-market apricots are large-sized, with early maturity (after Castlebrite and before Patterson). They may require cross-pollination and they appear to be cross-compatible. They have smooth, orange skin often with a red blush and orange flesh. The eating quality is good.

Helena

Formerly K210-35, Helena originated from the breeding program of the United States Department of Agriculture (USDA) in Fresno, CA. The fresh-market apricot ripens near the time of Patterson. It is relatively large, firm, and has yellow-orange skin and flesh. It is of fair eating quality.

Katy

Large- to-medium-sized fruit developed by Floyd Zaiger, the Katy is yellow, firm, and an early-ripening fruit used for fresh shipping.

Lorna

Formerly K505-50, Lorna originated from the breeding program of the USDA in Fresno, CA. The fresh-market apricot ripens early in the season ahead of Patterson and is large, with orange skin and flesh. It may often have skin with a blush of red. The eating quality is good.

Modesto

Originated in Le Grand, California, by FW Anderson, the variety was introduced in 1964 and was an F_2, open-pollinated seedling of Perfection. The fruit is firm-fleshed, medium- to-large-sized, often with a red blush, and orange-fleshed. The tree bears regularly, and the fruit ripens about the time of Royal and several days ahead of Patterson. Modesto is resistant to pit burning.

Patterson

Originated in Le Grand, California, by FW Anderson, the Patterson was introduced in 1968 and was an F_2 seedling of Perfection $\times$ unknown. The variety is

firm; it has orange flesh and skin, and is sometimes found with a red blush. The fruit is medium to large, and produces consistently good crops. It appears to be less affected by mild winters than the Tilton variety, and the fruit ripens evenly. Patterson is resistant to pit burning. It is a good variety for processing (canning, freezing), makes a good dried product, and is fair for fresh-eating fruit. The Patterson is the apricot production leader in California.

Robada

Formerly, K106-2, Robada originated from the breeding program of the USDA in Fresno, CA. The fresh-market apricot is early-maturing, ripening ahead of Patterson, and has a very nice orange skin, often with a red blush. This fairly large fruit has orange flesh, which is firm and has good eating quality.

Royal and Blenheim

The Royal and Blenheim varieties are considered together because they have lost their separate identities. The variety was utilized for fresh market and canning, but currently is used for drying and juice. It tends to bear alternately and unless properly thinned may have small fruit. It has excellent flavor when fully matured. It is rather soft and difficult to ship. The flesh is orange, and the skin is yellow-orange; it often has a red blush. The fruit tends to pit burn and is not well adapted for the interior valleys of California. It can develop a condition known as fog spot in the coastal regions of California.

Tilton

The variety originated as a seedling in Kings County, California by JE Tilton in 1885. Tilton was once a leading apricot for processing in California but it has currently been replaced by Patterson. Tilton was used for canning, drying, and shipping, but the fresh flavor is only fair. Tilton is now mostly used for concentrate. The tree tends to bear alternately and is affected by mild winter temperatures. When properly thinned it may bear medium- to large-sized fruit. The fruit is orange to yellowish, ripening late in the season.

Tomcot

The Tomcot originated from the breeding program of Dr Tom Toyama at Washington State University in Prosser, WA. The fresh-market apricot is early-maturing (ahead of Goldbar and Goldstrike, but after Castlebrite). It is not large but adequate and firm. It has very highly colored orange skin and flesh, and the skin often has a red blush. It normally requires hand thinning to insure adequate fruit size and it has good eating quality.

Tri Gems

Developed by Zaiger Genetics, Tri Gems is a firm, medium-sized apricot that yields high-quality canned fruit. It ripens before Patterson and has a yellow-orange skin and flesh. If fruit are removed by hand thinning it can be sold fresh and dried.

Westley

Originated in Le Grand, California, by FW Anderson, the variety was introduced in 1973 and was an F_2, of Perfection × Tilton. The fruit is medium-firm, with good flavor, and is used for some fresh markets and drying. The tree tends to bear alternately.

Rootstocks

Apricots are grown commercially on apricot seedling, peach (*P. persica*), and plum (*P. cerasifera*, myrobalan seedling and 29C; *P. cerasifera* × *P. munsoniana, marianna* 2624) roots. The main plum rootstocks include myrobalan seedling, myrobalan 29C and marianna 2624. Plum rootstocks are characteristically resistant to wet and poorly drained soil conditions. The union between apricot and plum root reportedly is not as sound as apricot on peach or apricot root and occasionally some apricot varieties break off at the union during heavy wind storms. Apricots growing on plum roots may not be as productive as those grown on apricot or peach roots. Peach root for apricot is quite popular. The stocks include those propagated from Lovell, Nemaguard, and Nemared seedling. Apricots grown on peach are productive, but peach cannot tolerate wet and poorly drained soil conditions as well as plum. Peach roots are very susceptible to *Phytophthora* root and crown rots. Apricots grown on apricot seedling roots are not as common as those on peach roots. Apricot roots are not as resistant to wet soil or *Phytophthora* as plum and also do not have the resistance to nematodes as does Nemaguard peach root. However, apricot roots are thought occasionally to impart better fruit quality and productivity to apricots. (*See* **Peaches and Nectarines**.)

A rootstock, developed by Floyd Zaiger and named Citation, is a peach × plum hybrid. It has been shown to increase fruit size and advance fruit maturity of Royal/Blenheim but did not alter the production characteristics of Patterson apricot when compared to marianna 2624. The rootstock may impart some tree size control to selected apricot varieties. However, apricots growing on Citation have shown reduced levels of zinc and nitrogen which suggested reduced uptake of those nutrients by the rootstock and possibly reduced vigor.

Morphology and Anatomy

Botany and Biology

The apricot belongs to the *Rosaceae* family and most cultivated apricots belong to the species *Prunus armeniaca* L. Closely related species include *P. mume* Sidb. and Zucc., the Japanese apricot, *P. dasycarpa* Ehrh., the black apricot, *P. brigantiaca* Vill., the Briancon apricot from the French Alps, *P. ansu* Komar, *P. sibirica* L., and *P. mandshurica* (Maxim.). The apricot is diploid ($2n = 16$, $\times = 8$). Flowers are borne singly or doubly at a node on very short stems (peduncles). Flowers have about 30 stamens with one pistil. The solitary flowers are white or pinkish. Most commercial cultivars in the USA are self-fertile, but Perfection and Riland are examples of self-incompatible cultivars. Trees generally branch well and produce vigorous upright growth, but not as upright as plum. Floral initiation occurs in summer (late May or June) and most of the flowers which set into fruit are produced on spurs. Spurs are productive for several (3–5) years. The highest-quality fruit is borne on younger spurs. Apricots are the first deciduous fruit trees to produce flowers in the spring after almond, and because of that are subject to frost damage. Trees bloom over a period of approximately 1–2 weeks, depending upon weather conditions. Flowers are followed by the appearance of leaves, which are simple, alternate, and serrated, round-ovate to ovate, and sharp-pointed. Apricot cultivars currently available require approximately 450–1200 h of chilling (temperatures at or below 7.2 °C). Vegetative buds require less chilling than reproductive (flower) buds. In those years with insufficient winter (December and January) chilling, flower bud drop can occur leading to reduced cropping, flowering and leaf emergence may occur over an extended period, fruits may develop with few leaves, and small fruits may not persist until harvest. Apricots produce more flowers than are needed to insure the production of an adequate crop and often require the removal of small fruit (thinning) to insure adequate fruit size. The apricot is a stone fruit (drupe). Other stone fruits in the genus *Prunus* include almond, cherry, nectarine, peach, and plum. Other drupe fruit include olive, coconut, mango, etc. Botanically a drupe fruit is a fleshy, one-seeded fruit that does not split open of itself, with the seed enclosed in a stony endocarp, which is called a pit. The fruit of apricot consists of a stony endocarp, a fleshy mesocarp, and an outer exocarp (skin). (*See* individual fruits.)

Approximately 80% of all California apricots are processed (Table 3). California represents nearly 100% of commercially processed fruit in the USA.

Table 3 Volume shares of apricots produced in California, USA in 1998

Product type	*Metric tonnage (t)*	*Percentage of total*
Canned[a]	36 340	40
Dried	8036	9
Fresh	16 518	18
Frozen	9286	10
Concentrate	21 161	23
Total	91 341	

[a]Source: Apricot Producers of California, Modesto, CA. Statistics vary from season to season.

Basic grower production is sold for processing to five different sources: canners, nectar (juice) processors, driers, freezers, and baby food processors. For the purpose of describing these processing methods, only canning, drying, and freezing will be included since nectar and baby food processing are basically similar to the process for producing apricot concentrate of purée by canners.

Processing Apricots in Europe

Canned apricots comprise the major processed product for apricots in Europe, followed by fruit purée and dried fruit last. Fruit for canning must be round, and uniform in shape, size, and maturity. Fruits are pitted by slicing along the suture line of the fruit with rotating knives; stones sticking to flesh are problematic. Often apricots are peeled (the skin is removed) before canning, and this appears to reduce fruit softening. Dipping in hot (boiling) lye (at least 4% concentration) is used for peeling and within 1 min most apricot cultivars are well-peeled. Fruits are packed in cans, glass jars, and plastic bags. Polyvinyl chloride (PVC) bags are covered by thin metallic sheets in order to reduce permeability to oxygen and sterilized with γ-irradiation. Various techniques have been developed to maintain the color, firmness, texture, and flavor of processed apricots.

Apricot fruit used for purée can be harvested with a higher degree of maturity to insure higher organoleptic quality. Stabilization of color and viscosity are essential to maintaining quality of product. Fruit purée is mainly used in baby food, fruit nectars, and jams.

Canned Apricots in California

The majority of apricots for canning are grown in Stanislaus and San Joaquin county. One major canner is located in this area and another operates in the Santa Clara Valley. Most canning apricots consist of

the Patterson and Tilton varieties, with the Patterson predominating.

Canners' prices to the growers are negotiated between the canners and the growers' bargaining association. Current prices are based upon a price per (UK) ton for 'US no. 1s' with a downward sliding scale of five grades below this level. Grading is carried out by a third-party inspection program approved by both parties.

Fruit is picked either by hand or, to a lesser extent, mechanically, and dumped into 272-kg bins. These bins are delivered to a weighing station where they are inspected for grade and weighed. The apricots are then delivered to the canning plant, where they are mechanically dumped into a water bath containing chlorinated water. They travel down an inspection belt for removal of any materials other than apricots (leaves, sticks, stones) or immature, green, overripe or rotted fruit. The apricots are then graded for size; the small fruits, unsuitable for canning, are collected and directed towards eventual use in concentrate and/or nectar-type product items.

The fruit is delivered to mechanical apricot cutters; these machines align the fruit in such a way that the cutting will take place on the apricot suture. Cut fruit is then opened and the loose pits drop through a stainless-steel plate. Cut, pitted fruit is delivered to the sizer/grader to be mechanically sorted, resulting in uniformly sized fruit. Once the cans have been filled, a topping medium such as sugar water or fruit juice is added, then immediately sealed. The product is then ready to be cooked, rendering it commercially sterile. Later, when the product reaches the warehouse it will be labeled and cased as per the customer's request. Canned apricots are packed in heavy syrup, light syrup, juice pack (apricot or pear), and water pack.

Back in the processing plant, fruit that is unsuitable for cutting is delivered to a thermal screw, where it is heated to 98.9 °C and delivered to a pulping unit, which will remove the pit. The heated pulp is pumped through a series of finishers that will remove some of the fibrous material, such as the skin of the apricot. Finished juice is then ready for the evaporation process or delivered to the nectar room where it is mixed with sugar, water, and citric acid. The nectar is filled and sealed, similar to the cut-fruit canning process, and delivered to the warehouse. Fruit juice destined for the evaporator will be condensed, resulting in 32 ° Brix (32%) fruit concentrate. The product is canned in 3.25-l cans or aseptically filled in 250-l drums. The concentrated product is ideally suited for nectar reconstitution or as an ingredient in various sauces.

There are a very few marketers of apricot nectar that purchase off-grade apricots directly from the grower and process their own concentrate or purée according to their own particular specifications. The concentrates are then diluted to an acceptable level as a drinkable apricot juice called nectar.

Dried Apricots

Dried apricots are produced from the plump, ripe, fresh fruit. The fruit is picked and sun-dried in June through early August in California. The Blenheim and Patterson apricots are the principal varieties used for drying. Other varieties are dried but most do not have the unique combination of high flavor density and solids-to-acid ratio that create the luscious, sweet-tart flavor of the California dried apricot.

Sun-Drying of Fruits

The drying of apricots parallels methods used for processing other dried fruits (figs, peaches, pears, etc.). Stage of maturity of the fruit is important in selecting fruits for drying. If the fruit is picked too early, color and flavor are lacking in the final product. When overripe, the final product loses shape and becomes slab-like in appearance. Much of the fine flavor of California dried apricots results from the fact that the dried fruit can be produced from fully tree-ripened fruit.

Preparation of the fresh fruit for sun-drying is simple. The common predrying treatments applied to apricots are as follows: (1) selection and sorting of fresh fruit; (2) washing; (3) cutting into halves and removal of pits; (4) spreading of fruit on drying trays with the cut surface upward; (5) sulfuring with burning sulfur or gaseous sulfur dioxide; (6) placing of trays in full sun in the dry yard. (*See* **Drying**: Drying Using Natural Radiation.)

Sulfuring For many years sulfur dioxide (SO_2) has been used to preserve the color of dried fruits. It is the only chemical added to dried apricots. Sulfur dioxide is recognized as safe for use in dried fruits by the US Food and Drug Administration (FDA). Apricots prepared for drying are usually exposed to gaseous SO_2 before being put in the sun for drying, but treatment with fumes of burning elemental sulfur is also practiced.

In addition to preventing enzymatic browning, SO_2 treatment reduces the destruction of carotene and ascorbic acid which are valuable natural nutrients in apricots; thus, nutritional qualities are preserved.

Sulfured, dried apricots will contain a SO_2 level of about 2500 p.p.m. The amount of SO_2 must also be controlled because regulations on levels of SO_2 permitted vary from one country to the next. Sulfur dioxide in the fruit begins to dissipate as soon as

applied and continues to diminish throughout storage, distribution, and retail shelf-life of the product.

Sun-drying After sulfuring, the trays are placed in the drying yard for sun-drying. Sun-drying is complete when the apricots have a moisture content of 15–20%. Drying time can vary depending on the condition of the fruit, air moisture, and constancy of sun exposure. During drying the cut and sulfured fruit is left in full sun for 5–10 days, followed by further drying away from direct sunlight for a sufficient time to bring moisture to the desired level.

After drying, the apricots are transferred to boxes for curing and for bringing about equilibrium of moisture content. This requires from 2 to 3 weeks or even longer. The dried apricots are then ready for grading and final preparation for packing.

Screening, Inspection, and Washing

Size grading is required to obtain the desired piece size in the end product. Size grading is accomplished by passing the dried product over a shaking perforated metal screen and collecting the fractions separately. Each size fraction passes on to the final inspection operation.

Prior to packing, chopping, or grinding, the apricots are rigorously washed to remove dust, leaf particles, etc. Washing consists of a presoak in water, followed by mechanical scrubbing and rinsing. After washing, the fruit is spread on trays for a second treatment with SO_2 in the finished product to meet shelf-life requirements, or requirements specified by the customer of bulk packs.

Storage

Dried apricots are protected from product decomposition caused by microbial or enzymatic deterioration. The relatively low moisture level, high natural sugar level, high acid content, SO_2 level, and low pH preclude these types of spoilage. (*See* **Storage Stability**: Mechanisms of Degradation; Parameters Affecting Storage Stability.)

The loss of SO_2 cannot be eliminated entirely, but it can be controlled so that it is of little consequence in normal commercial storage. The single most important factor in determining the storage life in dried fruit is temperature of the storage space. Temperature is so critical that the storage life is cut approximately in half: for every 11 °C increase it is about 4.4 °C.

The following conditions and tips will help to obtain maximum storage life for dried fruits:

1. Store dried fruit at 4.4 °C and 75% relative humidity for excellent keeping for at least 6–9 months (for washed and resulfured apricots).
2. Keep temperatures and humidity constant.
3. Be sure that the product is well wrapped and not exposed to air.
4. Protect dried fruit from strong direct light.

Frozen Apricots

Apricots for freezing include the Patterson and Blenheim varieties, with Patterson predominating.

Frozen apricots are processed for three different product types: sliced halves, slices, and a multiple scored apricot that is not completely sliced. The former two types are sold primarily to bakers, ice-cream makers, and frozen-dessert makers. The latter type are processed for use in jams and jellies and are called 'machine-pitted.'

Receiving

Apricots are received in approximately 363-kg bins. There are normally 48 bins per truckload. Each truckload is weighed and assigned a lot number. Bins from each lot are visually sampled for quality. The apricots are checked for ripeness, insect penetration, rot, flesh damage, and excess foreign materials such as leaves. Fruits are placed in high-temperature cold storage or left in receiving for ripening. As needed, bins of fruit are brought to the processing plant by truck.

Leaf Roller

The apricots are dumped on to a conveyor and pass over a series of parallel rollers. The rollers are separated by small gaps through which leaves and twigs may fall. A worker is stationed there to remove leaves, foreign material, rot, and green fruit. The green fruit are held for rerunning when properly ripened.

From the leaf roller the apricots fall into the shaker-washer which agitates the apricots in water and propels them under fresh-water sprays.

The shaker-washer discharges the apricots on to the first inspection belt. The fruit is examined for rot, leaves, and green color. From the first inspection belt, the fruit drops on to a cleated elevator which carries the fruit to a cross-belt. The cross-belt delivers the apricots to one of two apricot halvers. A shaker-feeder receives the apricots. Rotating scrubbers clean the apricots and single-file them into five lanes. The apricots from the five lanes are fed into pick-up pockets. The pick-up pockets feed the apricots to V trough belts in time with orienting fingers. The orienting fingers cause the apricots to rotate so that the suture is aligned with blades which cut the apricot in half in line with the suture.

A pit remover at the end of the blade is used to separate the pit from the two halves as they pass

through. Approximately 85% of the pits are removed at this point.

A cross-belt carries the apricot halves to a conveyor, which transports them to a cup-up pit shaker. As the apricot halves move across the shaker pan they pass over holes which permit the remaining pits to fall through as they are shaken loose. As the apricot halves are discharged from the cup-up pit shaker they are aligned with the pit cavity, facing up.

The cup-up pit shaker distributes the apricot halves on to the pit inspection belt. On the belt the apricots are inspected for pits and soft fruits. Soft fruits are placed into sort-out buckets and used to make purée. From the pit inspection belt the apricots are transported to a gang blade slicer. The slicer has parallel circular blocks separated by a 1.27-cm gap. The slicer cuts the halves into strips.

The sliced apricots fall on to a final inspection belt. The apricots are inspected for pits, blemishes, and harmless extraneous material. Fruit from the final inspection belt is carried to a fill-weight station. The fruit is placed in prelabeled tins and weighed. A depressor is placed on top of the fruit and 60° Brix syrup with ascorbic acid is added. The container is weighed again. A lid is placed on the can and it is passed through a can washer. The cans are coded, loaded on pallets, and tagged. The completed pallets are promptly moved to cold storage for freezing.

Apricot Usage

At the height of California apricot production in the 1930s and 1940s, the major usage was dried apricots. This was primarily because of the dried product's ability to remain shelf-stable for a relatively long period of time, its versatility as an out-of-hand snack, cooking and baking ingredient, and its sweet-sour flavor.

After World War II, the canning industry began its dynamic growth. Dried apricots gave way to the canned version because of a growing acceptance of canned fruits and vegetables as convenient and economical products, as well as the apricots' greater similarity to the fresh fruit. The dried apricot continued to be the largest usage type through the late 1940s but lost its position to canned apricot products (which included baby food, purée, and nectar) in 1950 and never regained its plurality. Recently, sales of dried apricots have been declining due to foreign competition.

Frozen apricots were introduced to the American public in 1943, diverting about 4046 t out of a total processed crop of 79 248 t, the smallest crop recorded up to that time. Apricots going into frozen production peaked in 1945 at 26 822 t out of a total of 161 544 t and have never regained that level. Today frozen apricots account for less than 10% of the pack.

Apricots sold fresh in retail and food-service outlets have been slow in developing into major usage. Their high point in sales was reached in the disastrous 1943 crop year, with 21% of total production. Most years since 1909 have held at around 10% of the total crop. Since 1984, however, with substantially more marketing effort behind them, fresh apricots have been maintaining a 14–20% share of saleable tonnage.

In 1998, the California Apricot Producers reported 91 341 t by use-type, distributed as shown in Table 3.

Nutrition

Weight for weight, apricots provide more than three times the carotene of peaches, and three times the

Table 4 Nutritional composition (per 100 g fruit) of apricots[a]

ARSENIC

Contents

Properties and Determination

N Hata, I Kasahara, S Taguchi and K Goto, Toyama University, Toyama, Japan

Background

Arsenic is located in group 5A of the periodic table and has an atomic number of 33 with an atomic weight of 74.922. The electron configuration is $(1s)^2(2s)^2(2p)^6(3s)^2(3p)^6(3d)^{10}(4s)^2(4p)^3$.

Chemical Properties

The structures of some of several important arsenic compounds and their acid dissociation constants (pK_a) are shown in Figure 1.

Inorganic arsenic (As) occurs in four oxidation states, As(V) as in arsenate (AsO_4^{3-}), As(III) as in arsenite (AsO_3^{3-}), As(0), and As(-III) as in arsine (AsH_3). In aerated water, arsenate is a stable form. Since As(III) is considerably more toxic than As(V), the form in which arsenic exists, whether as arsenate or arsenite, is important. Doses of 70–180 mg of arsenic trioxide (As_2O_3) are fatal. Arsenic acid is a fairly strong acid, while arsenous acid behaves in water practically as a weak, monobasic acid (see Figure 1).

Arsenic forms a variety of organoarsenic compounds. Arsenic compounds of the types, R_3As, $RAs(OH)_2$, R_2AsOH, $RAsO(OH)_2$, $R_2AsO(OH)$, and $R_4As^+X^-$ are called arsines, arsenous acids, arsinous acids, arsonic acids, arsinic acids, and arsonium salts, respectively. It is believed that organoarsenic compounds are much less toxic than the inorganic arsenic compounds. Biochemical conversion of inorganic arsenic compounds to organoarsenic compounds has been known for more than 100 years.

Occurrence

Arsenic is distributed everywhere in the environment. The use of arsenic is decreasing gradually but is still important. Commercial elemental arsenic is mainly employed as an additive for alloys. High-purity arsenic (at least 99.999%) is employed in electronics as gallium arsenic (GaAs) or indium arsenic (InAs). Furthermore, arsenic has been used in wood preservation, medical supplies (Salvarsan), pigment (Scheele's Green: $CuHAsO_4$, Paris's Green: $3Cu(AsO_2)_2{\cdot}Cu(CH_3COO)_2$), agricultural chemicals, food additives (arsanilic acid, $H_2NC_6H_4AsO(OH)_2$), and poison gas (lewisite). British anti-lewisite (BAL), which was developed as an antidote for lewisite, is also one of the antidotes for heavy metal poisoning.

Arsenic occurs naturally in the earth's crust (1.5–2 mg kg^{-1}). Hot-spring and well waters sometimes contain appreciable quantities of arsenic, mostly in

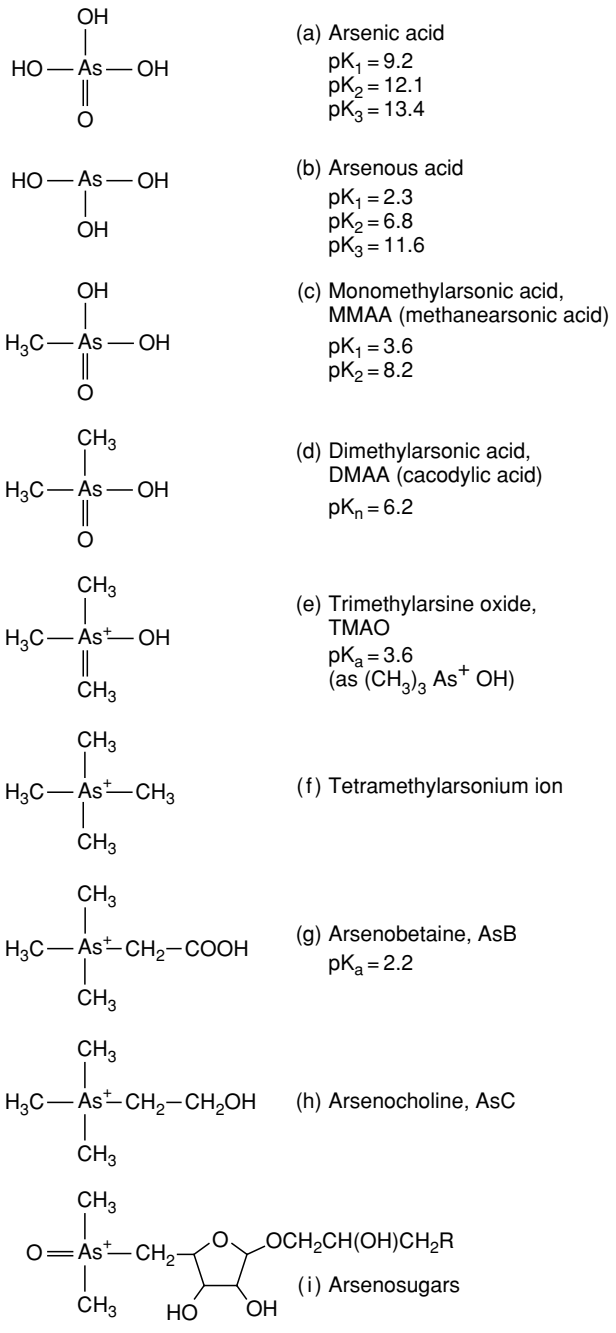

Figure 1 Structure of some important arsenic compounds and their acid dissociation constants. (i1) R = -SO_3H, 2-hydroxy-3-sulfopropyl-5-deoxy-5-(dimethylarsinoyl)-β-ribofranoside; (i2) R = -OH, 2,3-dihydroxypropyl-5-deoxy-5-(dimethylarsinoyl)-β-ribofranoside; (i3) R = -$OPO_3HCH_2CH(OH)CH_2OH$, 3-'glycerophosphoryl'-2-hydroxy-1-[5-deoxy-5-(dimethylarsinoyl)-β-ribofranosyloxy] propane; (i4) R = -OSO_3H, (2S)-3-[-5-deoxy-5-(dimethylarsinoyl)-β-D-ribofranosyloxy]-2-hydroxypropyl hydrogen sulfate.

the form of arsenate. Arsenic is associated with sulfide ores. Waste water discharged from sulfide mines and ore-dressing plants often contains arsenic in appreciable quantities. Arsenic contamination caused by flue gases from lead and copper smelters has been frequently reported. Most authorities adopt a value of $10\,\mu g\,l^{-1}$, measured as total arsenic, as the maximum permissible concentration in drinking water.

The arsenic levels in ocean water are around $2\,\mu g\,l^{-1}$, and although arsenate is the stable form in aerated waters, ocean water sometimes contains appreciable proportions of arsenite. It is believed that some bacteria are able to reduce arsenate to arsenite.

Because arsenic compounds have been used as insecticides, herbicides, and animal-feed additives, some soils, vegetation, swine, and poultry may be contaminated with arsenic. The value of $1\,mg\,kg^{-1}$ as As_2O_3 has been the maximum allowable limit for fruits and vegetables in Japan. Soil containing more than 15 mg of arsenic per kilogram is considered unsuitable for agriculture.

Edible marine organisms, such as lobsters, shrimps, and brown kelps, contain considerable concentrations of arsenic frequently in the $mg\,kg^{-1}$ range, occasionally at concentrations as high as several tens of $mg\,kg^{-1}$ on a wet-weight basis. Fortunately, however, the arsenic is mostly in the form of organoarsenic compounds, which are rapidly excreted and therefore relatively nontoxic to humans. On average, about 80% of the arsenic in marine organisms is found in the water-soluble fraction. Mostly, arsenobetaine (AsB) is the predominant arsenic species in marine animals, with arsenosugars in marine algae and some marine bivalves. Concentrations in freshwater plants and animals, and terrestrials are usually lower than in marine species. Arsenic has been found in mushrooms (*Agaricus bisporus*): As(III), 0.07 $mg\,kg^{-1}$; As(V), 0.14 $mg\,kg^{-1}$; monomethylarsonic acid, 0.05 $mg\,kg^{-1}$; dimethylarsinic acid, 0.28 mg kg^{-1}; and AsB, 0.46 $mg\,kg^{-1}$.

In 1900, there was an outbreak of arsenic poisoning among beer-drinkers in England. The cause of poisoning was traced to the use of invert sugar produced using arsenic-contaminated sulfuric acid. In 1955, there was an outbreak of unusual disease and fatalities in Okayama and Hiroshima Prefectures in Japan among infants drinking arsenic-contaminated milk. The arsenic content of the powdered milk that caused this disaster was estimated to be 15–24 $mg\,kg^{-1}$ as As. The dose of arsenic in the infants was estimated to be 1.3–3.6 $mg\,day^{-1}$ and the source of arsenic was traced to arsenic-contaminated sodium phosphate added as a stabilizer. The sodium phosphate had been produced from waste bauxite processing liquor and renamed by resale, but it contained about 3% arsenic.

Recently, a large number of fatal arsenic intoxications were traced from drinking water contaminated

by inorganic arsenic species. The main sources of arsenic contamination of drinking water are natural, and high concentrations of arsenic in drinking water are found in various parts of the world. In Taiwan, patients with blackfoot disease are found in areas where drinking water contains arsenic. In Bangladesh and West Bengal in India, arsenic poisoning became evident in the 1980s, and tens of millions of people are estimated to be at risk. The survey is not complete because the survey area is so large. The source of arsenic is geological.

Speciation of Arsenic in Food and Water

Various arsenic species show large differences in their toxicity. Their acute toxicity decreases in the following order: As(-III) (AsH_3) >> arsenite {As(III)} > arsenate {As(V)} >> dimethylarsinate > monomethylarsonate >> arsenobetaine and arsenocholine (organoarsenic compounds in seafoods). Therefore, speciation of arsenic is required for reliable toxicological estimation. Arsenic in seafoods has been well studied and is mostly in the form of organoarsenic compounds, including arsenobetaines and arsenosugars.

Extraction and purification are needed, especially for speciation of arsenic. For the speciation of organoarsenic compounds in seafoods, the samples are usually extracted with methanol or a methanol–water mixture. The samples are then purified with a C_{18} cartridge, centrifugation, and/or filtration. The purified sample is subjected to gel-permeation chromatography, ion-pair chromatography, ion-exchange chromatography, and preparative thin-layer chromatography. Buffered ion-exchange chromatography, close to neutrality, is necessary to prevent decomposition of the compounds to dimethylarsinic acid occurring at extremes of pH.

Arsenic compounds extracted with methanol from sea animals (cockle, trough shell, tuna, crab, sea cucumber, squid, etc.) have been separated by liquid chromatography. No single column has been found to be satisfactory for separating all organoarsenic compounds present in the seafoods. Four compounds (**Figure 1f**, **g**, **i2**, **i3**) have been found in animals. Arsenobetaine (**Figure 1g**) was found in all sea animals tested. There is considerable evidence that arsenocholine and arsenobetaine are rapidly excreted and almost nontoxic to humans.

Van Elteren and Šlejekovec investigated the stability of several arsenic compounds in food treatment procedures. Under usual food treatments (microwave treatment of 300 W of power for 120 min and boiling on a hot plate for 100 min), aqueous solutions of monomethylarsonic acid (MMAA), dimethylarsinic acid (DMAA), arsenobetaine (AsB), and tetramethylarsonium ion remained stable. Using γ-irradiation treatment with a dose of 10 kGy, 5% of AsB decomposed to trimethylarsineoxide (TMAO), and 1.5% of MMAA and 1% of DMAA decomposed to inorganic arsenic. After dry heating for 30 min at 160 °C, 10% of AsB decomposed to TMAO, 9% of MMAA to As(III), 6% of DMAA to MMAA, and tetramethylarsonium ions remained stable. Under unusually harsh treatments, however, decomposition of some compounds was found.

Sample Preparation

To determine total arsenic, the sample must be brought into solution. Care must be taken during the destruction of the sample to ensure that no arsenic is lost by vaporization of trivalent arsenic halides. Loss can usually be avoided by oxidizing the arsenic at an earlier stage by boiling with nitric acid under reflux.

In determining arsenic at trace levels in food, the Association of Official Analytical Chemists (AOAC; Article 9.1.01 D) recommends that a sample be digested with HNO_3 (heated in an oven at 150 °C oven for 2 h) in a closed system. In the closed system, a sample is placed in a digestion vessel (or cylinder), usually constructed of a fluorinated polymer such as polytetrafluoroethylene (PTFE) or perfluoroalkoxy (PFA). After the addition of digestion reagents, the cylinder is tightly sealed. The microwave-assisted alkali digestion with tetramethylammonium hydroxide ($(CH_3)_4NOH$, TMAH), which is used as a tissue solubilizer, is useful for the pretreatment of various biological samples prior to analysis. A mixture of nitric, sulfuric, and perchloric acids is also used for wet ashing of food samples. Monomethylarsonate, dimethylarsinate, arsenobetaine, and phenylarsonate are decomposed to inorganic arsenate. Dry ashing at 600 °C with magnesium nitrate for the destruction of meat and poultry is also used. The ash is dissolved in dilute hydrochloric acid.

To examine arsenic contamination of soils in Japan, arsenic is extracted by shaking the soil with 1 M hydrochloric acid (50 ml per 10 g of sample) for 30 min at 30 °C. The mixture is filtered through dry paper and subjected to hydride generation atomic absorption spectrometry.

Low levels of arsenic in water can be enriched by coprecipitation with ferric hydroxide after being oxidized to the pentavalent state with potassium permanganate. Triton X-100 has been used to aid the formation of large precipitates. It is claimed that both arsenate and arsenite are coprecipitated with iron hydroxide.

Methods of Analysis

There are several methods available for the determination of low levels of arsenic, and various analytical methods for determining arsenic in various concentrations are shown in Figure 2.

High-performance Liquid chromatography

High-performance liquid chromatography (HPLC) separation is most frequently employed for the speciation of arsenic species. Gas chromatography (GC) separation can also be used but requires complicated analyte derivatization steps to form volatile derivatives. Ion-pair chromatography in reverse mode, ion-exchange chromatography, and gel-permeation chromatography are often used. In reverse mode, C_{18} columns and polymer resin columns such as Hamilton polymer reversed-phase (PRP) are commonly used. Ion-pair chromatography is based on the distribution of ion-pairs between the aqueous mobile phase and the hydrophobic stationary phase. A quaternary ammonium ion such as tetrabutylammonium ion is often adopted for the separation of the anionic species. An alkyl sulfonate such as hexanesulfonate is often adopted for the separation of cationic species. Detection can be by UV absorption, conductivity, or

hyphenated techniques (atomic absorption and mass spectrometry).

Hydride Generation Method

There are two approaches for hydride generation (HG). The first is a selective HG for speciation followed by detector and is limited to the determination of the hydride-forming arsenic species. Differentiation of several arsenic species is possible in the HG technique with sodium borohydride as a reductant. Inorganic arsenic, monomethylarsonic acid, and dimethylarsinic acid are reduced, in acid solution, to arsine, monomethylarsine, and dimethylarsine, respectively, and collected in a cold trap. Differentiation of these arsenic compounds is possible by fractional volatilization of the arsines collected in the cold trap, because there are great differences in boiling point between arsine (AsH_3, $-55\,^{\circ}C$), monomethylarsine (CH_3AsH_2, $2\,^{\circ}C$) and dimethylarsine ($(CH_3)_2AsH$, $36\,^{\circ}C$). The choice of a proper packing material in the cold trap is important for the mutual separation of these arsines. A silanized diatomaceous earth impregnated with phenylmethylsilicon (15%) or hydrofluoric-acid-etched glass beads (0.3 mm) has been used. Arsenite (As(III)) (pH 6) and arsenate (As(V)) (pH 1) can be separated by pH-selective HG. Hydride generation for differentiation of arsenic species is becoming obsolete because very stable organoarsenic compounds such as arsenobetaine cannot form arsine.

The second removes total arsenic from the matrix and is generally combined with HPLC followed by decomposition (microwave digestion or UV decomposition) as a postcolumn prior to detector. The generated arsines are often concentrated by introduction to a cold trap before detection. The HG technique is used in combination with many different detection systems, including atomic absorption spectrometry (flame, quartz furnace, and graphite furnace), atomic emission spectrometry, mass spectrometry, atomic fluorescence spectrometry, spectrophotometry, and colorimetry. The HG technique is incorporated into the Gutzeit method and silver diethyldithiocarbamate (AgDDC) method.

Arsenic is reduced in acid solution by zinc or sodium borohydride to form arsine (AsH_3), which is volatile and is stripped by the hydrogen generated during the reduction; it can be collected by a trap cooled in liquid nitrogen or by a dilute iodine or bromine solution. With zinc as the reductant, prior reduction of arsenic to arsenite is necessary for the conversion of arsenate into arsine. A mixture of potassium iodide and tin(II) chloride also helps the reduction of zinc. In a strongly acid solution, both arsenate and arsenite are converted into arsine by sodium borohydride.

Gutzeit Method (Colorimetry)

The Gutzeit method is becoming obsolete, although it is highly sensitive and has been employed for many years for the detection and semiquantitative determination of traces of arsenic in foods, soils, and fertilizers. The sample is brought into solution by wet ashing or by other means. Arsenic is reduced to arsenite with potassium iodide and tin(II) chloride and further to arsine with zinc in acid solution. The arsine is stripped by the hydrogen formed during the reduction with zinc, and passed through a tube containing a strip of $HgBr_2$-impregnated paper. The paper darkens on reaction with arsine, and the length of the darkened area is proportional to the amount of arsenic.

In the field kit based on this method, the paper turns yellow on reaction with arsine, the concentration of arsenic is determined by comparison on a color chart, and its detection limit is sub-mg kg^{-1} levels.

Spectrophotometry

Spectrophotometric methods used for the determination of arsenic are based on either the formation of heteropolymolybdate, e.g., the molybdenum blue method, or the formation of arsenic diethydithiocarbamate. Only arsenic(V) reacts with molybdic acid to form heteropolymolybdate. For the determination of total inorganic arsenic, prior oxidation of arsenic(III) to arsenic(V) is required.

In the molybdenum (Mo) blue method, arsenic(V) reacts with molybdic acid in the presence of a reducing agent to form heteropolymolybdenum blue. Since this method is interfered with phosphate and silicate, it is used after isolation of arsenic by the hydride generation method. First, arsenic is converted into arsine. The arsine is then passed through an arsine trap solution containing sodium hypobromite. An ammonium molybdate–sulfuric acid solution is added to the arsine trap solution to react as follows:

$$AsO_4^{3-} + 12MoO_4^{2-} + 24H^+ \rightarrow AsMo_{12}O_{40}^{3-} + 12H_2O.$$

After reduction with hydrazinium sulfate, absorbance at 845 nm is measured. The color develops slowly (~ 75 min) at room temperature but is stable.

The silver diethyldithiocarbamate ($(C_2H_5)_2$ NCSSAg, AgDDC) method involves arsine generation and bubbling the arsine formed through a trapping solution in pyridine. Figure 3 shows an example of the apparatus used in this method. The glass wool in the sulfide scrubber is moistened with lead acetate

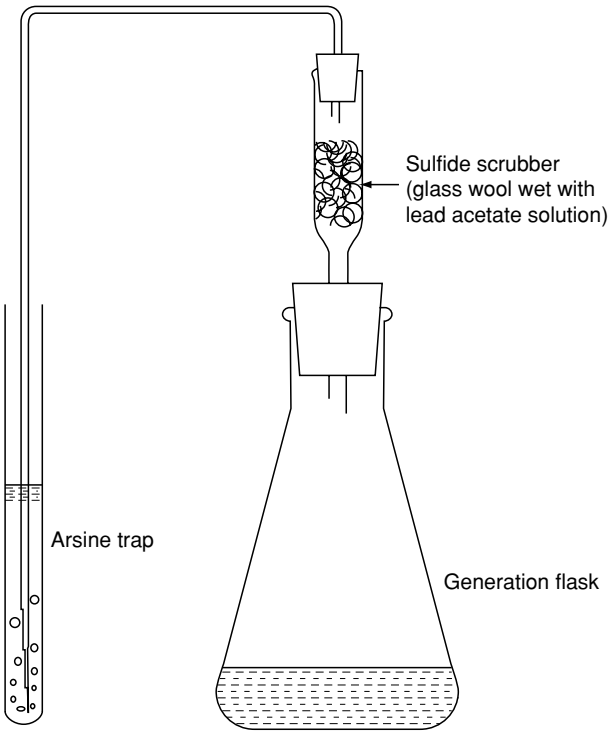

Figure 3 Apparatus for silver diethyldithiocarbamate method.

solution, and AgDDC–pyridine solution is placed in the arsine trap.

An appropriate volume of sample solution is placed into an arsine generator flask, and hydrochloric acid, potassium iodide, and tin(II) chloride are added to the flask. The mixture is allowed to stand for more than 15 min at room temperature. Zinc metal is added, and the generator flask is immediately sealed and the tube connected as illustrated. The solution is then allowed to react for 30 min. The trap is disconnected, and the trapping solution is mixed by gently drawing back and forth five times with an aspirator assembly. The absorbance based on an intense red color is measured at about 522 nm. The wavelength for the absorption maximum changes slightly with the composition of the trapping solution. If AgDDC–brucine–chloroform solution is used as a trapping solution, to prevent the production of foul-smelling pyridine, an appropriate volume of chloroform should be added to the trapping solution at the end of the trapping operation to compensate for the loss of chloroform evaporation.

Atomic Absorption Spectrometry

A hollow cathode lamp or an electrodeless discharge lamp can be employed as a light source. The primary absorption line is 193.7 nm.

Direct nebulization of extracts into a flame atomic absorption spectrometry is impractical at low concentrations because the flame strongly absorbs radiation at the wavelengths of sensitive absorption lines. Better sensitivity is obtained by the hydride generation technique, in which arsenic (as arsine vapor) is introduced into a hydrogen–argon reducing flame or into a heated tube for measurement of atomic absorption.

Graphite furnace atomic absorption spectrometry (GF-AAS) can also be employed. Arsenic sublimes at 613 °C and arsenic trichloride ($AsCl_3$) boils at 130 °C, but nickel arsenide melts at 968 °C. Successful results are obtained when nickel nitrate is added as a modifier to prevent loss of arsenic during the ashing process and to reduce interference. Similarly, magnesium nitrate, palladium and magnesium nitrates, and zirconyl nitrate can also be used as modifiers.

Instead of GF-AAS, quartz furnace atomic absorption spectrometry coupled with HG is also employed. The temperature in the quartz furnace is elevated to 900 °C.

Inductively Coupled Plasma Atomic Emission Spectrometry

Inductively coupled plasma atomic emission spectrometry (ICP-AES) is a simultaneous multielement analysis technique with a dynamic range. In ICP-AES, arsenic can be measured simultaneously in various emission lines (188.979, 180.042, 193.696, 197.192, or 228.812 nm) with different sensitivities. Atomic emission at 193.7 nm is less subject to interference, giving a detection limit of c. 0.02 mg l^{-1}. At 228.8 nm, cadmium interferes. Atomic emission at 188.979 nm, which is recommended in recent years, is giving a detection limit of μg 1^{-1} levels.

At 228.812 nm cadmium interferes. Arsenic (V) is converted into an arsenomolybdate, which is sorbed by the filter as the ion-associate with tetrapentylammonium ion, and the filter and the arsenomolybdate sorbed are dissolved in concentrated sulphuric acid, diluted with water and nebulized into the plasma torch. An emission line at 228.812 nm can be used. Interference from cadmium is eliminated because cadmium is not collected on the filter. Arsenic (III) dose not form arsenomolybdate and is not determined.

The sensitivity of conventional direct nebulization ICP-AES for arsenic is high but not sufficient to determine traces of arsenic. The sensitivities of ultrasonic nebulization ICP-AES for arsenic are about ten times better than that of conventional direct nebulization ICP-AES, but matrix (salt concentration) effect becomes larger. The sensitivity of ICP-AES can be improved by using HG techniques because of a

more efficient sample introduction and matrix removal. A continuous hydride generator is convenient. The detection limits of HG-ICP-AES for arsenic are about two orders in magnitude better than that of conventional direct nebulization. ICP-AES is possible to use a continuous monitoring. Do *et al*. investigated the speciation of arsenic in urine by HPLC-HG-ICP-AES. The limits of quantification were found to be 36 μg l^{-1} for AS(III), 9 μg l^{-1} for DMA, 57 μg l^{-1} for MMA, and 101 μg l^{-1} for As(V), applying a 100 μl sample injected for analysis.

Inductively Coupled Plasma Mass Spectrometry

Inductively coupled plasma mass spectrometry (ICP-MS) uses an inductively coupled plasma as an ion source and is one of the most sensitive methods for elemental determination. Arsenic is a monoisotopic element, that is, 100% of arsenic is ^{75}As.

The determination of arsenic using ICP-MS is interfered with by any molecular ion having a mass/charge ratio (*m/z*) equal to ^{75}As. Thus, the $^{75}As^{+}$ ion is interfered with by $^{40}Ar^{35}Cl^{+}$ formed by the combination of plasma gas and chloride ions, and so separation of the arsenic species from chloride ions is often required. The removal or reduction of argon from the excitation source by the addition of nitrogen gas or helium gas also eliminates, or significantly reduces, the formation of $^{40}Ar^{35}Cl^{+}$. Before ICP-MS, an HG method or a high performance liquid chromatography (HPLC) coupled with ICP-MS is required for the determination of arsenic species. The concentration of organic solvents must be lower because the introduction of organic solvents destabilizes the inductively coupled plasma.

Other Methods

Atomic fluorescence spectrometry (AFS) combined with HG is also available for trace arsenic determination. With LC (anion and cation exchange, liquid chromatography)–UV (decomposition)–HG–AFS system, six arsenic species (As(III), DMAA, MMAA, As(V), AsB, tetramethyarsonium ion) can be separated, with detection limits of about 0.5 μg of As per liter (100 μl injected). The limits of determination for arsenic in AFS, neutron activation without chemical separation, and pulse polarography are 0.8, 0.02, and 0.004 mg l^{-1}, respectively.

Certified Reference Materials

For quality control, the adoption of certified reference materials (CRM) is the best choice. A number of CRM for total arsenic are available, although only a few are available for speciation. Several easily available CRM for arsenic, relating to foods, are as follows: NIES CRM 9 Sargasso (certified value: 115 ± 9 mg kg^{-1}), BCR CRM 422 cod muscle (21.1 ± 0.5 mg kg^{-1}), NIST SRM 1566 oyster tissue (14.0 mg kg^{-1}), BCR CRM 279 *Ulva lactuca* (sea lettuce) (3.09 ± 0.20 mg kg^{-1}), NIST SRM 1548 total diet (0.20 ± 0.020 mg kg^{-1}), NIST SRM 1570a spinach leaves (0.068 mg kg^{-1}), BCR CRM 185 bovine liver (0.024 ± 0.003 mg kg^{-1}), NIST SRM 8433 corn bran (0.002 mg kg^{-1}). CRM are produced by several institutions:National Research Council of Canada, Community Bureau of Reference EC, Brussels, Belgium (Standards, Measurements and Testing Programme), International Atomic Energy Agency, Vienna, Austria, National Institute of Environmental Studies, Tsukuba, Japan, and National Institute of Standards and Technology, Gaithersburg, Maryland, USA.

Arsenic in the Environment

Arsenic is widely distributed in the natural environment. Virtually all soils and waters contain a variety of different arsenic compounds. As a byproduct of melting copper, lead, and several other metals, as well as from coal-fired power plants, high quantities of this metalloid are emitted into the atmosphere. Arsenic compounds are also used by the metallurgical and chemical industry. Phosphate fertilizer, as well as many herbicides, fungicides, wood preservatives, insecticides, and rodenticides, contains arsenic. Thus agriculture contributes significantly to arsenic pollution. Legislation in countries with developed conservation systems attempts to minimize the quantity of these pesticides as well as other sources of arsenic pollution.

Both the trivalent (arsenite) and the pentavalent (arsenate) state of arsenic can be detected in biological material. The biochemically important forms of arsenic are however methylated compounds: dimethylarsenic acid, methylarsonic acid, trimethylarsine oxide, trimethylarsonium ion, arsenocholine, arsenobetaine, and unstable arsenyl esters.

Arsenic accumulated in the environment can be subject to various biotransformations – reduction, oxidation, and methylation – performed by microorganisms. Methylation of inorganic arsenic in methanogenic bacteria under anaerobic conditions may be a detoxification mechanism for arsenic. Also marine algae transform arsenate into nonvolatile methylated arsenic compounds (methanoarsenic acid and dimethylarsenic acid) in seawater. These less toxic compounds are concentrated in higher marine organisms consuming the plankton. Several fungi are able to transform aerobically inorganic and organic arsenic compounds into very toxic volatile methylarsines.

Owing to the ubiquity of arsenic in the environment, foodstuffs of plant and animal origin as well as drinking water also contain arsenic. The maximally permissible arsenic concentration in drinking water, vegetables, fruits, and meat is regulated by law in most industrially developed countries. The US drinking water standard, for example, is fixed at $50\,\mu g\,l^{-1}$. However, several springs and spa waters contain 0.5–1.3 mg of arsenic per liter.

The range of arsenic levels in foodstuffs in the absence of significant pollution is as follows: cereals $0.05–0.4\,mg\,kg^{-1}$, fruits $0.03–1.0\,mg\,kg^{-1}$, vegetables $0.05–0.8\,mg\,kg^{-1}$; meat $0.05–1.4\,mg\,kg^{-1}$; dairy products $0.01–0.23\,mg\,kg^{-1}$. Higher concentrations – $1.5–15.3\,mg\,kg^{-1}$ – are registered in seafoods because marine organisms accumulate arsenic in the form of nontoxic organic compounds. The average daily intake of arsenic is estimated in the range of 12–40 μg. When diets contain substantial amounts of seafood, as is usual in Japan, 70–170 μg could be the realistic daily intake. (*See* **Shellfish**: Contamination and Spoilage of Molluscs and Crustaceans.)

Arsenic Metabolism

Intestinal Absorption

Arsenic is generally well absorbed by the gastrointestinal tract, although the solubility of the compounds seems to correlate with the rate of absorption. Intestinal absorption of most inorganic and organic compounds of arsenic is a quick process. However, some unusual compounds, such as Na-P-N-glycolylarsenilate, given orally to humans, are poorly absorbed.

Some investigations in chicks, mice, rats, and rabbits indicate that arsenate as well as arsenocholine readily penetrates both the mucosal and the serosal surfaces of the epithelial membrane and that arsenate and phosphate do not share a common transport pathway. Both arsenic compounds are apparently absorbed by simple diffusion following a concentration

gradient. On the other hand, *in vivo* and *in vitro* experiments in rats revealed a saturable transport process for pentavalent arsenic which was significantly reduced by phosphate. This result might indicate that arsenic and phosphate share the same secondary active carrier-mediated transport system.

Arsenic in Human Tissues

Once absorbed, arsenic is quickly distributed to all organs and tissues, probably as a complex with α-globulins. Apart from inorganic arsenic, blood also contains methylated metabolites formed in the liver.

If the uptake of arsenic is low, no significant accumulation in the soft tissues occurs. However, in unexposed humans relatively high arsenic concentrations are usually found in skin, nails, and hair. Because hair levels correlate with arsenic in the air as well as with renal arsenic excretion, hair concentration has often been used as an index of contamination with toxic amounts of arsenic. The median arsenic content of human hair was found to be $0.51\,\mu g\,g^{-1}$. The hair of workers at plants with arsenic-containing emissions was found to be 10–31 μg of arsenic per g of hair. Values greater than $3\,\mu g\,g^{-1}$ indicate toxic levels of uptake.

Arsenic Excretion

In general, the biological half-life of arsenic is short: the metalloid is excreted mainly in urine with a little in feces. Some compounds, such as arsenobetaine, which is the form found in marine animals, pass through into the urine unchanged. For this reason, despite the high arsenic content, intoxication by seafood is unlikely. Different methylated compounds are the major urinary metabolites.

Excretion via the bile is low after dietary intake of arsenic, but can significantly increase when drugs containing arsenic are administered intravenously. The hepatobiliary transport of arsenic is glutathione-dependent and associated with a profound increase in biliary excretion of glutathione; thus, hepatic glutathione depletion and diminished glutathione conjugation result.

Biotransformation of Arsenic

Inorganic arsenic is methylated in the liver with S-adenosylmethionine as methyl donator. As the first step, arsenate is reduced to arsenite by using glutathione. Arsenite is methylated to dimethylarsenic acid with monomethylarsenic as a precursor. Investigations with germfree animals have shown that methylation is mainly performed by the liver cells, with little contribution from the intestinal microflora.

The rate of methylation of inorganic arsenic varies considerably between species and individuals. As shown by studies in human volunteers exposed to specific doses of inorganic arsenic, the rate of renal excretion of arsenic increases with methylation efficiency. It could be assumed that the variations in interindividual susceptibility to arsenic in humans could be due to differences in the capacity of arsenic methylation.

Some organic compounds, especially arsenobetaine, are excreted unchanged. Arsenocholine can be incorporated into phospholipids, replacing choline, but the major part of this compound is excreted by the kidney.

Some mold species are able to produce volatile neurotoxic compounds by biotransforming arsenical pigments contained especially in wallpapers. Some lethal poisoning cases have been described resulting from such toxic products of aerobic and nonaerobic fungi as well as other primitive organisms.

Biochemical Function and Essentiality of Arsenic

Although a specific function for arsenic on a molecular level is unknown, some evidence has been accumulated indicating a distinct role for this element in several metabolic processes.

This could be the case in CH_3-group metabolism. Almost all organic forms of arsenic produced *in vivo* are methylated compounds. One of the trimethylated ones is arsenocholine, which can be incorporated into phospholipids, replacing choline. Choline is a methyl donator for different methylation reactions in intermediary metabolism. There is some evidence indicating that arsenocholine might have a similar function in labile methyl metabolism. As some experiments have shown that arsenic deprivation in the rat, chick, and hamster affects labile methyl metabolism, it could be speculated that the role of arsenocholine cannot be fulfilled by choline.

Arsenic binds strongly to sulfydryl groups which are known to participate in hundreds of enzymatic reactions. In this context it behaves like heavy metals that impair enzymatic catalysis. It is likely that the biochemical basis is the inhibition of a wide range of SH-enzymes by arsenic. But it cannot be ruled out in advance that such an interaction is not only of toxicological but also of biological significance.

Some investigators have reported that arsenic can provide partial protection from chronic selenosis, with the vitamin E level influencing the incorporation of selenium into the tissues. It has been shown that selenium toxicity for cultured mice fibroblasts can also be counteracted by arsenic. Interactions between

arsenic and cadmium have also been shown. Considering the common mode of action that these elements have at the cellular level, especially through interaction with SH-groups, these facts are not surprising. (*See* **Cadmium**: Toxicology; **Selenium**: Physiology.)

Studies with chicks suggest that arsenic is closely related to the metabolism of zinc. Depressed growth caused by arsenic deprivation was alleviated when dietary zinc was given in excess. It seems, however, not only that interactions between arsenic and zinc exist but also that the arginine status of the chicks plays a distinct role in these complicated correlations between the two trace elements and the amino acid. There is support for the possibility that arsenic participates – in a way that has yet to be clarified – in utilizing amino acids for protein synthesis, or in protein degradation, as well as in uric acid metabolism. (*See* **Zinc**: Physiology.)

Effects of arsenic on carbohydrate metabolism have been observed in experiments with guinea pigs. The most prominent finding after repeated arsenic (As_2O_3) administration was a marked decrease in total carbohydrate content of the liver, mainly owing to depletion of glycogen. (*See* **Carbohydrates**: Digestion, Absorption, and Metabolism.)

Some other biochemical facts in connection with arsenic – used in physiological as well as toxicological amounts – have been registered in the last few years. We are far from being able to classify the frequently conflicting facts and their significance for metabolism.

Since 1975, some conclusive evidence has been published supporting the suggestion of nutritional essentiality of arsenic. An element is considered essential if a dietary deficiency consistently results in a suboptimal biological function that is preventable or reversible by intake of a physiological amount of that element. Signs of arsenic deprivation were studied in four animal species – chick, goat, miniature pig, and rat. Safe and adequate intakes of arsenic for these species are not precisely defined. However, a diet containing less than 50 μg of arsenic per kg is denoted as an arsenic-deficient ration in these animal experiments, whereas 350–500 $\mu g\,kg^{-1}$ is considered a normal arsenic supply and 3.5–5 $mg\,kg^{-1}$ as a therapeutic dose.

The essentiality of arsenic has been systematically investigated in growing, pregnant, and lactating goats, as well as in miniature pigs and their offspring. Deficient rations contained less than 10 μg of arsenic per kg of semisynthetic diet, and control rations 350 $\mu g\,kg^{-1}$.

The following deficiency symptoms were described: feed consumption was reduced and this was correlated with diminished growth rates and milk production; a high abortion rate for goats and increased perinatal mortality for miniature pigs and rats were also registered; intrauterine arsenic depletion in goats, miniature pigs and rats resulted in significantly reduced birth weight of the offspring. The decreased milk-fat concentration could be a consequence of lowered triglyceride concentration in the blood serum of arsenic-deficient goats.

Histological changes, accompanied by ultrastructural alterations of the mitochondria, have been seen, especially in skeletal muscles, the myocardium, and liver tissue. Some modifications in the mineral composition of different organs with a remarkable retention of manganese were also connected to arsenic deficiency.

Many recent findings from studies with sophisticated new techniques have revealed possible sites of essential action of arsenic. It seems to have an important role in the conversion of methionine to different metabolites, e.g., S-adenosylmethionine, S-adenosylhomocysteine, and taurine. Additionally, arsenic affects the formation of the polyamines spermine, spermidine, and putrescine from arginine and the metabolism of labile methyl groups.

As shown in recent studies, arsenic induces the cellular synthesis of certain heat shock or stress proteins. This event is controlled at the transcriptional level and may involve changes in the methylation of core histones. Thus, arsenic seems to regulate gene expression. Arsenic also enhances DNA synthesis in unsensitized and in stimulated human lymphocytes.

Beneficial effects of arsenic preparations have been known – or at least believed – for centuries. Arsanilic acid used to be incorporated into pig and poultry feed in pharmacological doses as a growth-promoting agent. Intake of relatively high amounts of inorganic arsenic salts by humans and horses was reported from several parts of Europe. 'Arsenic eaters' were convinced that these preparations had protective effects against diseases, and increased physical condition and virility. Regular daily intakes of 0.5 g of arsenic have been reported; this kind of dose can only be tolerated once you are accustomed to arsenic for a long time. (*See* **Trace Elements**.)

Nevertheless, there is as yet no convincing evidence that arsenic is essential for humans, but the possibility cannot be ruled out. For definitive judgment of essentiality of arsenic, further critical investigations are necessary.

Only data from animal studies are available for estimating the approximate amount of arsenic required by humans, if it is essential for humans at all. Cautious assessments support a daily requirement of about 12–15 μg for persons consuming 8.4 MJ per

day. This amount is guaranteed by a mixed-food diet. But the evidence is too limited or controversial to recommend an ambiguous apparent beneficial intake for arsenic.

Toxicity of Arsenic

Arsenic has traditionally been associated with the poisoner and it was of interest to forensic medicine as a poison which is frequently used in suicide and homicide. Nowadays, intoxication mostly results from accidental intake of arsenic-contaminated food or beverages, or from environmental pollution. Depending on the dose, the nature of compounds, and the health status of the individual incorporating the poison, arsenic can cause both acute and chronic poisoning.

Acute Toxicity

The smallest lethal dose reported is 130 mg of arsenic, but total recovery can occur even if the ingested dose is several times higher. Signs of intoxication can appear a few minutes after ingesting a solution containing arsenic, but when the arsenic is taken in solid form signs may be delayed for up to 10 h. After ingestion of a lethal dose, death occurs after 12–24 h.

Depending on the severity of exposure to arsine (AsH_3), hemolytic symptoms can occur in a few minutes or after about 24 h. After massive exposure nausea, vomiting, and abdominal cramps begin within 2 h, followed by hematuria and skin color turning yellow within 24 h.

Chronic Toxicity

Although acute intoxication has become rare, arsenic is still a dangerous pollution agent for industrial workers and people living in the vicinity of emission sources.

A maximum daily intake of arsenic that is well tolerated over a longer period of time without impairing health and well-being cannot be fixed precisely. The chemical form of arsenic strongly affects its toxicity and variations in individual susceptibility are large. It was reported that orchard workers ingested for years as much as 6.8 mg of arsenic per day, i.e., about 500 times the estimated daily requirement, without any signs of intoxication. The ratio of the toxic to nutritional dose for rats was found to be about 1250.

The rank order of cytotoxicity of arsenic compounds – based on cell culture experiments – is as follows: arsenite > arsenate > dimethylarsenic acid > trimethylarsine oxide. Arsenobetaine, arsenocholine, and the tetramethylarsonium ion reveal only weak toxicity. Glutathione plays a significant role in protecting the cells from the effects of the toxic arsenic compounds.

The mode of incorporation of arsenic can be by respiration, by oral intake with drinking water and food, and by skin. For incorporation by skin arsenic trichloride is the only compound of importance. Irritations of the respiratory tract are common in areas surrounding coal-burning power stations, especially in eastern Europe where stations use coal containing up to 200 times as much arsenic as average coal. Human exposure to arsenic in the air is likely to increase in the future.

In some areas of the world the concentration of arsenic in drinking water exceeds the fixed standards. However, the correlation of different disorders with drinking water containing arsenic in a range above the drinking water standards of 50 $\mu g\, l^{-1}$ (0.6–6.0 mg l^{-1}) remains questionable. Most of the researchers (California, Oregon, Alaska) reported no adverse health effects; however, investigators form Minnesota, Taiwan, and Chile presented data supporting circulatory and skin disorders from arsenic consumption through drinking water. Reasons for these regional differences may be the additional exposure to other chemicals and/or fungi that potentiated the observed effects. In addition, differences in the nutritional status of the populations investigated remains at issue.

Contamination of foodstuffs with arsenic can result from air pollution, soil pollution by agricultural measures, or by accidental pollution. Use of arsenics as pesticides in vineyards resulted, in some cases, in poisoning by arsenic-contaminated wine. Cirrhosis of the liver in vine-growers was assumed to have at least partially been caused by arsenic.

Until the first decades of the 20th century a preparation of inorganic arsenic known as Fowler's solution was used for the treatment of dermatoses and even as a tonic against anemia. The treatment often lasted several years and caused signs of chronic arsenic poisoning, especially on the skin, with a high incidence of skin cancer.

Clinical symptoms of long-lasting arsenic intoxication develop over weeks and months. The first signs occur in the skin, mucous membranes, gastrointestinal tract, and neural system. The liver and circulatory system are affected later, if at all. The symptom complex resembles that of other progressive diseases, thus arsenic intoxication is difficult to diagnose. For this reason arsenic was one of the most common homicidal poisons for centuries.

Classical initial symptoms of chronic intoxication with arsenic are as follows: loss of appetite and, subsequently, weight; weakness; nausea; vomiting; dry

throat; fatigue; gastrointestinal symptoms; icterus and skin erythema. As the disease progresses, further symptoms can be found: loss of hair, fragile and pigmented nails, eczema, hyperkeratosis, and desquamation of the skin on hands and feet. Later, severe conjunctivitis, bronchitis, neurological symptoms, hearing disturbances and vascular disorder can occur. Some of the symptoms are reversible when exposure is interrupted, but individual variability is great, and neurological symptoms are particularly long-lasting.

Exposure to arsenic has been associated for decades not only with the development of different types of cancer but also with noncarcinogenic injuries, such as diabetes, peripheral neuropathy, and cardiovascular diseases. Some results about the biochemical mechanism of carcinogenesis induced by arsenic were obtained in the last few years. But, there are very few reliable data concerning the specific mechanism(s) of arsenic action on cellular level in context with noncarcinogenic effects. This is astonishing in so far as arsenic is assumed to inhibit more than 200 enzymes. But, direct enzyme inhibition seems not to be the common toxic effect of arsenic.

Therapeutic Measures

The most common antidote to arsenic poisoning is 2,3-dimercaptopropanol (BAL), which is a dithiol binding one arsenic molecule with its two SH-groups. Owing to the fact that this binding is more stable than binding of arsenic to the SH-groups of the amino acid residues, arsenic can be eliminiated via renal excretion.

Successful treatments with BAL have been reported, especially in cases of dermatitis caused by arsenic intoxication. After injection of the drug a powerful stimulation of renal arsenic excretion is registered during the first 3–6 days, accompanied by an improvement of the skin lesions. A further chelating agent recommended in cases of arsenic poisoning is D-penicillinamine. In severe cases of acute intoxication, exchange transfusion or hemodialysis may be necessary.

Teratogenic and Mutagenic Effects

Large doses of arsenic are reported to cause teratogenic alterations in different animal species. Embryotoxic effects of arsenite (1–40 $\mu mol\,l^{-1}$) and arsenate (10–400 $\mu mol\,l^{-1}$) on the development of mouse embryos during early organogenesis have been registered in the form of growth retardation and malformations of the central nervous system and of the extremities. Although no direct evidence exists for embryotoxicity of arsenic in humans, it cannot be conclusively ruled out that this toxic element may be involved in unaccountable early abortions and malformations claimed to be attributable to the toxicity of heavy metals.

Careful studies performed in the last decade point to the mutagenic potency of arsenic. Induction of chromosomal aberrations and sister chromatid exchanges have been described. A role of arsenic as a potential synergist to ionizing radiation, as well as inhibition of DNA repair by this element have been supposed.

The ability of arsenic to induce gene amplification may relate to its carcinogenic effects in humans since amplification of oncogenes is observed in many human tumors. (*See* **Mutagens**.)

Arsenic and Carcinogenesis

A number of epidemiological studies have been performed to elucidate the correlation between chronic arsenic exposure and cancer. The results are controversial. (*See* **Cancer**: Epidemiology.)

Inorganic arsenic causes a variety of benign skin lesions, including hyperpigmentation and hyperkeratosis. Some hyperkeratotic lesions and squamous cell carcinomas-*in-situ* may progress to invasive carcinoma and metastasize. Locally invasive but nonmetastasizing basal cell carcinomas may also occur. A dose–response relationship has been described between medicinally administered arsenic and the frequency of various skin lesions. Chronic intake of arsenical preparations for psoriasis is reported to cause malignant lesions in skin, lung, and liver.

A high incidence of carcinoma of the respiratory tract was registered in several epidemiological studies dealing with populations in areas highly polluted with arsenic. Factory workers exposed simultaneously to arsenic and sulfur dioxide ran a very high risk of developing multiple carcinoma.

In 1970 the occupational Safety and Health Administration of the US government fixed the maximum concentration of inorganic arsenic in the air to 10 $\mu g\,m^{-3}$ for occupational exposure. On the basis of several studies performed in factories causing arsenic pollution, the same institution predicted that the risk of lung carcinoma would rise exponentially with increasing pollution.

During the last decade, several research groups were engaged in clarifying the molecular basis of the carcinogenic effect of arsenic without being able to furnish a homogeneous interpretation.

It is generally recognized that arsenic is a human carcinogen or promoter of carcinogenesis. Arsenite acts as a comutagen by interfering with DNA repair, although a specific DNA-repair enzyme sensitive to arsenic has not been identified. Apparently only a few sensitive enzymes are responsible for arsenic-induced cellular toxicity. Thus, arsenic-induced

comutagenesis and inhibition of DNA-repair are probably not the result of direct enzyme inhibition, but may be an indirect effect caused by arsenic-induced changes in cellular redox levels or alterations in signal transduction pathways and consequent changes in gene expression. Cellular glutathione level was found to be the most important determinant of arsenic sensitivity in cancer cells.

Arsenic was shown to inhibit ubiquitin-dependent proteolysis. This suggests that a tumor suppressor gene product or some other aspect of the ubiquitin system may be a target for arsenic toxicity and that disruption of the ubiquitin system may contribute to the genotoxicity and carcinogenicity of arsenite. Alteration of DNA methylation by arsenic offers a further plausible hypothesis for the carcinogenic mechanism of arsenic effect.

Areas considered in need of future research are: interaction of arsenic with cellular constituents, especially with genetic material; interaction of arsenic with other metals; and development of animal models and/or cell systems to study the effects.

ASCORBIC ACID

Contents

Properties and Determination

M A Kall, Danish Veterinary and Food Administration, Søborg, Denmark

Background

Vitamin C has both enzymatic and chemical functions, and it is a cofactor for several enzymatic reactions involving metabolism of collagen and amino acids, for example. Vitamin C was discovered as an antiscorbutyric factor less than one century ago. The trivial name of the active component L-ascorbic acid was adopted to reflect the antiscorbutyric effect of vitamin C. Ascorbic acid (AA) is a water-soluble vitamin, and under most physiological conditions, it is present in the mono-protonated form. It is considered to be the most important antioxidant in the extracellular compartment. As an antioxidant, AA donates electrons to both intercellular and extracellular reactions. The oxidation product of such reactions, dehydroascorbic acid (DHAA), forms a reversible redox system with AA, and this is an important characteristic of the reactions involving vitamin C. Moreover, AA has scavenger properties and can eliminate free radicals under the formation of semidehydroascorbic acid, a nonreactive radical. The antioxidative properties of AA are frequently utilized in the food industry. Ascorbic acid is widely

used as a food additive to improve taste and color, and to restore the vitamin C lost during processing and storage.

Both AA and DHAA are very unstable in aqueous solution, and measurable degradation may occur within minutes to hours, because of oxidation caused by a wide range of chemical compounds and enzymes. Vitamin C is present in most foodstuffs of vegetable origin but in varying concentrations. In order to determine vitamin C, it is important to take into consideration the reactivity and lack of stability of AA and DHAA. Over the last three decades, numerous methods have been published describing extraction and analyses of vitamin C in foodstuffs and physiological samples. These methods cover a wide range of analytical principles from direct colorimetric determination or redox titration to modern, advanced high-performance liquid chromatography (HPLC) techniques, and furthermore, they cover a wide range of objectives and different requirements.

This article will focus on the HPLC determination of vitamin C in foodstuffs and physiological samples, and will discuss some important considerations regarding the handling of samples and choice of analytical procedures (see **Table 1**).

Chemical Properties

In aqueous solutions, AA is a strong reductant and is rapidly and reversibly transformed into DHAA in a two-electron oxidation. This reaction may be catalyzed by a variety of oxidative compounds such as molecular oxygen, heavy metal ions, halogens, and enzymes, e.g., ascorbate oxidase. The oxidation of AA to DHAA *in vitro* can be reversed by thiol-containing reductants such as cysteine, homocysteine, glutation, mercaptoethanol, dimercaptopropanol, or dithiothreitol (DTT). Dehydroascorbic acid also has reducing properties, especially in alkaline solutions, and may be irreversibly oxidized to 2,3-diketogulonic acid and further to several other compounds like threonic acid and oxalic acid. The oxidation and ring-opening process of the lactone ring of DHAA causes an irreversible loss of both the vitamin C activity and the antioxidant properties.

Ascorbic acid is a dibasic acid with an enoldiol group built into a five-membered heterocyclic lactone ring. The AA molecule contains two chiral carbon atoms, C4 and C5 (**Figure 1**), and theoretically, three stereoisomers of L-ascorbic acid therefore exist: D-ascorbic acid, D-isoascorbic acid, and L-isoascorbic acid. In the human organism, L-ascorbic acid is the only active form. The synthetic isomer D-isoascorbic (IAA) acid has the same chemical properties as AA, but this enantiomer of L-ascorbic acid has only approximately 5% vitamin C activity compared with AA. D-Isoascorbic acid is often used as an antioxidant additive in processed foods.

The overall reaction for oxidation of AA by dioxygen is given in eqn (1).

$$2AA + O_2 \rightarrow 2DHAA + 2H_2O. \qquad (1)$$

As mentioned previously, AA is easily oxidized, forming an intermediate radical of low reactivity. Ascorbic acid can scavenge very reactive species such as the superoxide anion (O_2^-), hydroxyl radical (HO•), alkoxyl radicals (RO•), and peroxyl radicals (ROO•). The poor reactivity of the semidehydroascorbic acid radical (AA•) (see **Figure 1**) may account for the antioxidant effect of AA. In foods, a free radical (X•) can start a chain reaction and cause damage to the food product (see eqns (2) and (3)).

$$X\bullet + RH \rightarrow R\bullet + XH \qquad (2)$$

$$R\bullet + O_2 \rightarrow ROO\bullet \qquad (3a)$$

$$ROO\bullet + RH \rightarrow ROOH + R\bullet. \qquad (3b)$$

Ascorbic acid can intercept these radicals and stop the chain reaction and, by disproportionation of the formed ascorbic radical, eliminate the unpaired electron (eqn (4)).

$$\begin{aligned} &R\bullet + AA \rightarrow RH + AA\bullet \\ &ROO\bullet + AA \rightarrow ROOH + AA\bullet \\ &2AA\bullet \rightarrow AA + DHAA. \end{aligned} \qquad (4)$$

Vitamin E can also act as a radical scavenger, and AA plays an important role by regeneration of vitamin E after oxidative attack and by elimination of the radical (eqn (5)).

$$\begin{aligned} &\text{Vit-E} + ROO\bullet \rightarrow \text{Vit-E}\bullet + ROOH \\ &\text{Vit-E}\bullet + AA \rightarrow \text{Vit-E} + AA\bullet. \end{aligned} \qquad (5)$$

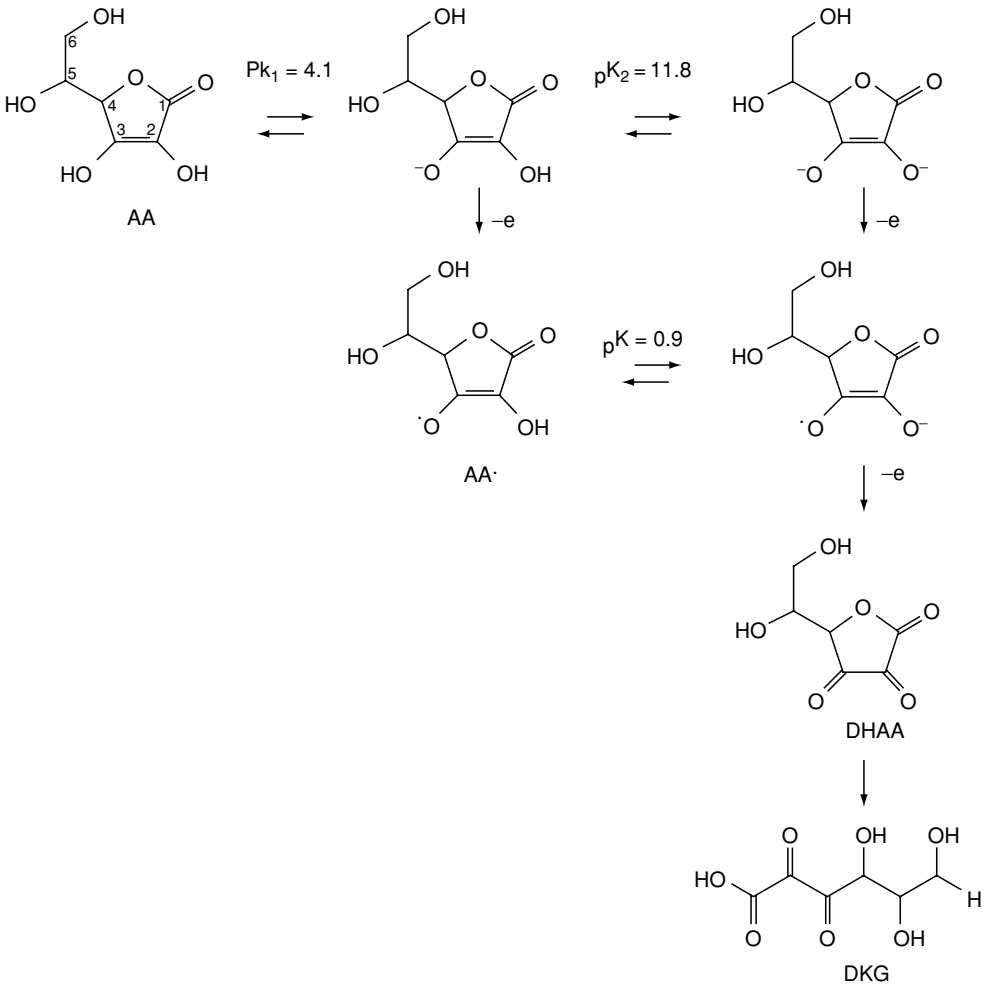

Figure 1 Reaction pathways for oxidation of ascorbic acid. AA, ascorbic acid; AA•, semidehydroascorbic radical; DHAA, dehydroascorbic acid; DKG, 2,3-diketogluconic acid.

Ascorbic acid may also have prooxidative properties. When metal ions are present, AA can stimulate the formation of free radicals. The oxidation of AA by dioxygen (eqn (1)) is very strongly catalyzed by Cu(II) and Fe(III) ions but may also be catalyzed by other metal ions capable of undergoing redox reactions between two valence states. According to eqns (6) to (8), reduction of dioxygen by AA catalyzed by Fe(III) may lead to formation of the hydroxyl radical.

$$\mathrm{Fe(III) + AA + O_2 \rightarrow Fe(III) + DHAA + H_2O_2} \quad (6)$$

$$\mathrm{Fe(III) + AA \rightarrow Fe(II) + AA\bullet} \quad (7)$$

$$\mathrm{Fe(II) + H_2O_2 \rightarrow Fe(III) + OH\bullet + OH^-}. \quad (8)$$

The hydroxyl radical is extremely reactive, and reacts with all organic substances.

Considering analytical aspects of AA, avoidance of oxidation during storage, extraction, and analysis is by far the most challenging aspect of the analysis. Metal ions catalyze the oxidation of the mono-anion of AA only (see Figure 1). Thus, pH has a marker effect on the oxidation rate, especially near the first pK_a value at 4.17. In order to ensure full protonization of AA during extraction of samples and storage of extracts, the pH should not exceed 2. The autooxidation of AA catalyzed by metal ions (eq (6)) is a first-order reaction with regard to AA, metal ions, and oxygen concentrations. Evacuation of dissolved oxygen from samples and solutions is important in preventing oxidation of AA. The catalytic autooxidation can be further eliminated by complex formation of the metal ions with adequate chelators. Complexes tend to stabilize the higher oxidation states of coordinated metal ions, e.g., by lowering the redox potential, and oxidation reactions by complex bound metal ions are therefore generally much slower than reactions with the metal ion aqua complexes. Addition of a chelating agent, such as ethanediaminetetraacetic acid (EDTA) or oxalic acid, to the extraction buffer will in most cases prevent metal-ion-catalyzed

autooxidation or direct oxidation of AA. In several cases, however, it has been reported that the presence of EDTA in sample extract in fact increases oxidation of AA caused by Fe(III) instead of preventing it. One plausible explanation could be the formation of OH• generated by the reaction in (eqn (8)) and that OH• oxidizes AA to AA•. For several ligands examined at neutral pH, it has been found that iron complexes with a high stability were better catalysts for AA oxidation than iron complexes with a low stability. The opposite was found to be true for copper complexes. These trends have been attributed to the change in redox potentials and to the rate of reoxidation of the metal ion. It has been shown that the Fe(II)–EDTA complex reacts with hydrogen peroxide approximately 100-fold faster than the Fe(II) $(H_2O)_6$ complex, i.e., in eqn (8) (see Table 4).

Occurrence in Food

The vitamin C contents of several important food sources are listed in Table 2. The data originate from the Danish Composition of Foods and reveal a large variation in the amount of vitamin C between sources but also notable variations within the sources. This variation within species is known to be true for many vitamins in fruit and vegetables and may be due to different genetic properties as well as different growths conditions, e.g., soil, exposure to sun light, and fertilization. Storage conditions may also affect the content. From Table 2, it is clear that any processing of the food may cause loss of vitamin C. Table 3 shows the amount of vitamin C in some foods distributed as AA and DHAA, and some examples of the occurrence of IAA and DHIAA in processed foodstuffs.

Occurrence and Stability in Physiological Samples

The concentration of AA and DHAA in blood plasma samples may depend on the nutritional status of the individual. In general, women have higher plasma concentrations of total AA than men, and non-smokers have higher plasma concentrations of total AA than smokers. The plasma concentrations of total AA reported in most studies are in the range from approximately 40 to 85 $\mu mol\,l^{-1}$, corresponding to 7–15 $\mu g\,ml^{-1}$. The stability of AA in plasma is limited to approximately 5 h at 4 °C, but addition of 1:1 of 10% MPA to the plasma can prolong the stability of AA as well as DHAA up to 6 months by storage at − 80 °C. The stability of total AA may be prolonged further to several years by addition of DTT prior to lyophilization of the plasma sample and subsequent storage at − 80 °C.

Measurement

Measurement of AA may be accomplished by several slightly different principles, but in order to choose the optimal analytical conditions, the method by which to determine vitamin C should be considered. Dehydroascorbic acid is not directly measurable by any common HPLC detector principle and has to be transformed prior to measurement. If the sample extract is treated with a reducing agent, DHAA is reduced to AA and can be measured by UV- or electrochemical detection. In the case where determination of the ratio between AA and DHAA is required, samples should be analyzed with and without reduction, and DHAA can be calculated as the difference between the AA concentrations measured in the two analyses. This method is often referred to as the 'subtraction method.' Another possibility is to determine AA and DHAA simultaneously, but this method requires a more complex analytical procedure.

Moreover, one should consider differentiation between AA and IAA, and between DHAA and dehydroisoascorbic acid (DHIAA). Before choosing an appropriate method, it is important to define the objectives for the study and the requirements to the results. For example, in a study of degradation of vitamin C during production or storage of a foodstuff, it may be interesting to determine DHAA as well as AA. However, in order to collect data regarding food composition, to conduct a survey of the occurrence of vitamin C in a customary diet, or to control the declared content of vitamin C in a fortified foodstuff, it may be relevant to determine only the amount of total AA.

Both the capacity and costs of the analysis are important considerations. Different measurement principles often demand different sample preparations, and not all preparation procedures result equally in stabilization of AA. Studies on vitamin C in physiological samples may require determination of DHAA and AA separately, but because of a usually very low DHAA concentration compared with AA, the stability of both AA and DHAA in the extract is important.

Extraction

Regardless of the choice of measurement principle, AA has to be liberated from the sample matrices prior to analysis. The extraction procedure should be able to eliminate oxidative degradation of AA caused by dissolved oxygen, metal ion, and enzymes, and also be able to minimize hydrolysis of DHAA. Owing to the instability and high polarity of AA and DHAA, actual sample clean-up is difficult to perform. Fortunately, suspension or dilution of the sample in diluted acid with subsequent centrifugation and filtration provides a sufficient extraction of AA and DHAA from most matrices. In order to protect AA and DHAA from degradation during the extraction, different extraction solutions have been described in the literature, e.g., metaphosphoric acid (MPA), acetic acid, trichloroacetic acid, and perchloric acid. Optimal stabilization of AA and DHAA is obtained at pH values below 2. The majority of papers dealing with extraction of AA recommend MPA in concentrations ranging from 1 to 10% (w/v), but the addition of a chelating agent may often be necessary in order to complex bind metal ions. Chelators such as EDTA and oxalic acid are often used. As mentioned previously, EDTA may in some cases promote Fe(III)-catalyzed oxidation of AA instead of preventing it (see Table 4).

Oxidation of AA can be reduced further by handling the samples in a N_2 or CO_2 atmosphere, by reducing the temperature, and by light protection.

Determination

The classic chemistry associated with spectroscopic methods can be divided into two general categories: methods using redox indicators and methods involving formation of chromofor or flourofor derivatives. The principal reactions for some classical methods of direct determination of vitamin C are briefly reviewed, but HPLC methods will be discussed in detail.

Redox Reactions

2,2′-Dipyridyl This method is based on the reduction of Fe(III) to Fe(II) by AA. Fe(II) forms a complex with 2,2′-dipyridyl that can be quantified colorimetrically. Other chromogen formation Fe(II) complexing agents exist, e.g., ferrozine and 2,4,6-tripyridyl-*S*-triazine.

2,6-Dichloroindophenol This method is based on reduction of 2,6-dichloroindophenol by AA. In acidic solution, 2,6-dichloroindophenol has an absorption maximum at 518 nm and, when reduced by AA, this chromophor disappears. The specificity of this method is limited owing to the presence of naturally occurring reductants of 2,6-dichloroindophenol in fruits and vegetables. This method will typically determine 5–10% higher amounts of AA in fruit samples than a HPLC method.

Derivatization Reactions

2,4-Dinitrophyl hydrazine Ascorbic acid has to be oxidized to DHAA prior to the derivatization. The reaction between DHAA and 2,4-dinitrophenyl hydrazine results in the formation of the bis-2,4-dinitrophenylhydrazone derivative, which can be measured at 520 nm. The specificity of the method is limited, owing to unspecific reactions of 2,4-dinitrophenyl hydrazine with 5- and 6-carbon, sugar-like, nonascorbic compounds.

***o*-Phenyldiamine** Ascorbic acid has to be oxidized to DHAA prior to the derivatization. The reaction between DHAA and *o*-phenyldiamine (OPD) results in the formation of an intensive fluorophore: 3(1,2-dihydroxyethyl)furo[3,4-b]quinooxaline-1-one (DFQ) (see Figure 2). The fluorophore can be measured by the emission wavelength at 430 nm when excited at 350 nm. This reaction can be applied to direct measurement or to a chromatographic method. Some interference should be expected from naturally occurring fluorescing compounds if the method is used for direct measurement.

HPLC Determination of Vitamin C

For common foodstuff analysis and control analysis, the amount of vitamin C usually exceeds 1 mg per 100 g of sample, and in this case, a HPLC system coupled with ultraviolet (UV) detection provides adequate sensitivity. In foodstuffs with amounts less than 1 mg per 100 g and in physiological samples, where the concentration often is below 1 μg ml^{-1}, it may be necessary either to use an electrochemical detector or to transform AA into a fluorescent compound in order to increase the sensitivity by fluorometric measurement. In addition, the electrochemical and fluorescent detection are more specific than the UV detection.

In principle, three different strategies for determination of vitamin C by HPLC exist:

1. reduction of DHAA to AA followed by measurement of total AA;
2. oxidation of AA to DHAA followed by measurement of total DHAA; and
3. simultaneous determination of AA and DHAA, by pre- or postcolumn derivatization of DHAA, perhaps with additional postcolumn oxidation of AA.

As mentioned previously, extraction with MPA provides the most efficient protection of AA during extraction and subsequent analysis. However, MPA may cause serious analytical interactions with silica-based column materials. Ion-pair reversed-phase chromatography with C18 column material or pseudonormal-phase chromatography with an aminopropyl column material provide separation of AA and IAA and potential coeluting compounds with high efficiency and selectivity, but the use of MPA in the extraction buffer may affect the robustness of the

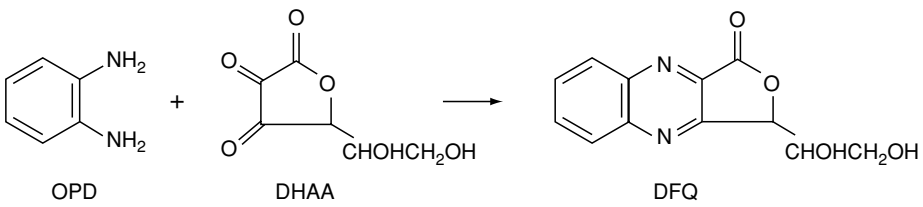

Figure 2 Reaction of DHAA with *o*-phenyldiamin (OPD) under formation of 3(1,2-dihydroxyethyl)furo[3,4-b]quinooxaline-1-one (DFQ).

chromatographic performance. The interactions may result in incomplete separation of the four compounds and cause a variation in retention time of the compound peaks. Furthermore, the use of EDTA in extraction buffers may result in a time-consuming analysis owing to a long retention time of the ligand. The interference problems with the silica-based polymer column materials caused by injection of MPA may be solved by using a polystyrene divinyl benzene (PLRP-S) polymer column material. An effluent based on 0.2 M phosphate buffer applied to the PLRP-S column performs adequate separation of AA and IAA. The PLRP-S column is compatible with injection of MPA in high concentrations in sample extracts and provides a very stable system for separation of the compounds without baseline- and retention drift. However, the efficiency and selectivity of the PLRP-S column are low with regard to AA and coeluting compounds and particularly DHAA and DHIAA, and the column should be used in combination with electrochemical or fluorescence detection only (see Figure 5).

Determination of vitamin C as total ascorbic acid Dehydroascorbic acid is reduced to AA at neutral pH in the presence of thiol-containing reducing agents such as cysteine, homocysteine, 2-mercaptoethanol, and DTT. During incubation of the sample extract with a reductant, DHAA should be transformed quantitatively into AA. Addition of a reducing agent to the sample extract will prolong the stability of vitamin C in the sample extract during the extraction procedure as well as the storage period in the autosampler during HPLC analysis. Ascorbic acid is protected against oxidation, and since DHAA is reduced to AA, DHAA is protected from hydrolyses to 2,3-diketogulonic acid. Opposite AA and DHAA, thiol-containing reductants have both a low stability and a low reducing capacity in acidic environments. Sample preparation is often carried out by MPA extraction at low pH followed by adjustment of the pH to neutral, and incubation with a reductant. Subsequently pH has to be reduced, to ensure the stability of the AA. This procedure is more laborious, and as a result of the degradation of reductants at a low pH, the reducing sample environment, and thus stabilization of the AA in extracts, is maintained for less than 24 h. It should be noted that a similar stability of AA and DHAA without addition of a reductant can be obtained by optimizing the extraction buffer, regarding pH and temperature, and the concentrations of MPA, and chelator.

Recently, tris[2-carboxyethyl]phosphine (TCEP) has been described as a promising reductant of DHAA in physiological samples. The major advantage of this compound is a high stability and a high reductive capacity at a low pH, in contrast to the commonly used reductants. It has been shown that the stabilization of AA in sample extracts can be maintained for at least 96 h and that TCEP may not cause any interference with the chromatographic system (see Figure 3).

Determination of vitamin C as total dehydroascorbic acid This principle is based on oxidation and derivatization prior to HPLC analysis. The quinoxaline derivatives are more hydrophobic than AA and DHAA, and it is possible to obtain a reversed-phase HPLC method with a high efficiency, selectivity, and baseline separation of the two quinoxaline derivatives corresponding to AA/DHAA and IAA/DHIAA. In order to obtain adequate retention times, an organic modifier has to be added to the mobile phase in concentrations that will eliminate the interaction between injected MPA and the column material, as described previously. Preparative oxidation of AA to DHAA during extraction may be accomplished by addition of iodine or heavy metal ions at a low pH or by addition of ascorbate oxidase at neutral pH. Dehydroascorbic acid is much less stable than AA, and therefore the derivatization should be carried out directly after the oxidation. The stability of the quinoxaline derivatives, however, is also limited. A stability of 8–12 h is described for the quinoxaline

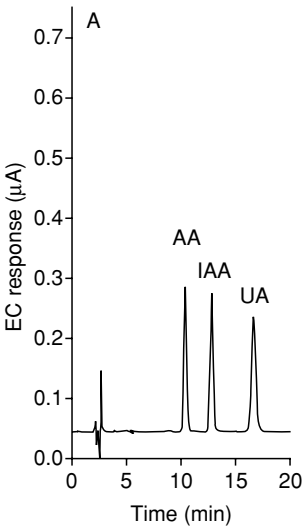

Figure 3 Chromatographic separation of AA and IAA on a C18 column with electrochemical detection. From Lykkesfeldt J (2000) Determination of ascorbic acid and dehydroascorbic acid in biological samples by high-performance liquid chromatography using subtraction method: Reliable reduction with Tris[2-carboxyethyl]phosphine hydrochloride. *Analytical Biochemistry* 282: 89–93 with permission.

derivatives in sample extracts. Further, the preparation of the quinoxaline derivative during extraction requires additional labor compared with the postcolumn derivatization.

In spite of the high selectivity, lack of interaction with MPA, and high sensitivity and specificity, the method is not recommended for purposes involving assay of many samples because of the low stability of the quinoxaline derivatives in the extracts (see Figure 4).

Simultaneous determination of ascorbic acid and dehydroascorbic acid In general, simultaneous determination of AA and DHAA requires more equipment than the other two principles, but it may require less instrumentation. Under the right conditions, oxidation of AA to DHAA is an instantaneous reaction in contrast to reduction of DHAA to AA, which, even under optimal conditions, is a relative slow reaction. In order to determine AA and DHAA simultaneously, it is therefore necessary to perform online, postcolumn oxidation of AA to DHAA and subsequently measure both compounds as DHAA. The oxidation may be performed by addition of a solution containing Cu(II), Hg(II), bromine, or iodine to the effluent after the HPLC column. Alternatively, the effluent can be led through an electrochemical cell or through a solid-state oxidation column packed with active charcoal. In a second postcolumn step, DHAA is mixed with a solution of OPD to form the fluorophore derivative, DFQ (see Figure 2). Another possibility is to measure AA directly and only use the second postcolumn step to measure the original DHAA (see Figures 5 and 6).

In contrast to the subtraction method, the simultaneous determination procedure provides data on AA as well as DHAA from a sample in the same analytical run. The procedure needs no reduction, oxidation, or derivatization prior to the HPLC analysis. However, DHAA spontaneously hydrolyzes to 2,3-diketogulonic acid at pHs as low as 3.2–3.5, and it may be difficult to preserve DHAA in the extracts for 24 h. Furthermore, the concentration of DHAA in most foodstuffs and physiological samples is low compared with AA, and even small degree of oxidation of AA during extraction or in autosampler vials will result in a pronounced increase in the DHAA concentration. Consequently, this analytical principle requires careful handling of samples during extraction and storage.

Ascorbic acid has a number of chemical properties responsible for the biological reactions that characterize vitamin C. Usually, these characteristics are positively associated with the benefits provided by this vitamin. Paradoxically, these properties provide difficulties in the analysis of ascorbic acid in foods and physiological samples.

Physiology

G F M Ball, Wembley, UK

Background

Ascorbic acid (vitamin C) has many diverse functions as a reducing agent in the body. It keeps the bound iron or copper ions of several hydroxylating enzymes in the necessary reduced state, and aids the intestinal absorption of iron by forming soluble ferrous–ascorbate complexes. Vitamin C helps in the fight against cancer by reducing harmful free radicals to harmless nonradical species, and inhibiting the formation of

carcinogenic *N*-nitroso compounds in the stomach. There is increasing evidence that vitamin C is involved in the human immune system and in the regulation of prostaglandin synthesis.

Metabolism

Humans and other primates, guinea-pigs, and fruit-eating bats lack the enzyme gulonolactone oxidase, which catalyzes the final step in the biosynthesis of ascorbic acid, and thus rely on their diet to provide the vitamin. Other animal species can synthesize ascorbic acid from glucose and have no need for dietary vitamin C.

Intestinal Absorption

The overall system of intestinal transport and metabolism in humans is shown in Figure 1. Ascorbic acid is ionized within the pH range of the intestinal contents, and therefore, it is the ascorbate anion (specifically L-ascorbate) that is transported. At physiological intakes, ascorbate must move across the brush-border membrane of the intestinal epithelium from a region of lower concentration in the lumen to one of higher concentration in the cytoplasm of the absorptive cell (enterocyte). Such 'uphill' movement requires active transport – a mechanism that depends ultimately upon the expenditure of metabolic energy, i.e., the energy released from the hydrolysis of adenosine triphosphate produced during cellular metabolism. The precise mechanism of ascorbate absorption is secondary active transport in which a transmembrane protein (inappropriately called a carrier) mediates the sodium-coupled transfer of ascorbate across the brush-border membrane. The carrier spans the membrane in a weaving fashion and effects solute transfer through a conformational change in its molecular structure. The immediate energy source for the transport mechanism is the concentration gradient of sodium across the brush-border membrane. The gradient is maintained by the constant extrusion of sodium from the enterocyte by the action of the sodium pump at the basolateral membrane. The sodium pump is driven by metabolic energy and is the primary driving force for ascorbate absorption.

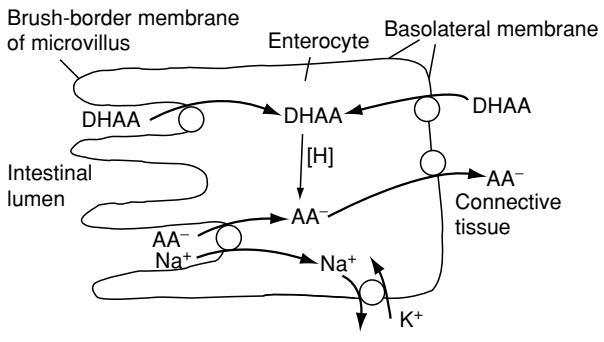

Figure 1 Model of intestinal transport of the L-ascorbate anion (AA^-) and uncharged dehydro-L-ascorbic acid (DHAA) in vitamin C-dependent animals. Thick arrowed lines indicate directional pathways; [H] signifies enzymatic reduction.

An electrical potential difference ranging from −30 to −90 mV (cell interior negative) typically exists across cell membranes. This membrane potential influences the active transport of charged solutes across membranes. Using isolated brush-border membranes from the intestines of guinea-pigs, it has been shown that ascorbate transport is unaffected by changes in the membrane potential. The transport system is therefore electroneutral, indicating a 1:1 cotransport of Na^+ and $ascorbate^-$ by the same carrier. L-Ascorbic acid leaves the enterocyte by sodium-independent facilitated diffusion at the basolateral membrane.

Dehydro-L-ascorbic acid is taken up from the bloodstream across the basolateral membrane of enterocytes as well as being absorbed across the brush-border membrane. The transport mechanism in both cases is sodium-independent facilitated diffusion driven by the steep concentration gradient maintained by the intracellular reduction of dehydroascorbic acid.

The efficiency of vitamin C absorption of foods over a range of usual intakes (20–120 mg per day) is approximately 90%. Absorption by the sodium-coupled secondary active transport mechanism reaches its maximum rate at a relatively low luminal concentration. The higher concentrations resulting from ingestion of vitamin C supplements are absorbed additionally by passive diffusion, which proceeds at a very low rate. Absorption therefore becomes progressively less efficient with increasing dose levels, the efficiency falling from 50% of a single 1.5-g dose to 16% of a single 12-g dose. Absorption efficiency is increased by the ingestion of several spaced doses throughout the day, rather than the ingestion of a single megadose. Ingesting the vitamin in a sustained release form also improves absorption efficiency. Ascorbic acid bioavailability from fruits and vegetables is not significantly different to that from synthetic ascorbic acid, indicating that the bioavailability in these natural food sources is high.

Intestinal absorption of ascorbate is adaptively regulated in a transient and reversible manner by the level of dietary ascorbate. The mechanism of regulation is an increase or decrease in the number of carriers at both brush-border and basolateral membranes in response to low or high concentrations of ascorbate in the blood. The rationale for adaptive

regulation is that carriers are most needed at low dietary ascorbate levels; at excessive levels, the required amount of ascorbate can be absorbed by fewer carriers, aided by passive diffusion. As ascorbate does not provide metabolizable energy, there is nothing to gain from the cost of synthesizing and maintaining carriers when the vitamin supply is in excess.

Postabsorptive Metabolic Events

Vitamin C circulates in the bloodstream mainly as free (nonprotein-bound) ascorbic acid. The kidney actively reabsorbs ascorbate present in the glomerular filtrate, thereby maximizing vitamin C conservation in the body and helping the intestine to maintain the circulating vitamin in its useful, reduced state. Contrary to the intestinal transport system, the renal system is present also in species for which ascorbate is not a vitamin (e.g., rat, rabbit). Renal uptake of the L-ascorbate anion at the brush-border membrane of the absorptive cell of the proximal convoluted tubule is a sodium-coupled, secondary active transport system. Unlike the corresponding intestinal transport system, the renal system is affected by experimental changes in the membrane potential, indicating an electrogenic mechanism with a Na^+/ascorbate$^-$ coupling ratio of 2:1. As the loaded carrier bears a net positive charge, its transport is accelerated by the negative membrane potential. Rapid renal reabsorption of ascorbate is important, as the transit time in the proximal tubule is only about 10 s.

Many cells and tissues can accumulate ascorbate against a concentration gradient. Particularly high concentrations of the vitamin are found in leukocytes (white blood cells), lung tissue, the adrenal and pituitary glands, and compartments of the eye. Skeletal muscle contains much of the body's pool of ascorbate, although the concentration is relatively low. The ultimate metabolic fate of vitamin C is urinary excretion of ascorbic acid or metabolites.

Effect upon Absorption of Inorganic Iron

The iron present in natural foodstuffs exists in two forms, heme iron and inorganic iron. Heme iron is obtained from the hemoglobin and myoglobin present in meat, fish, and poultry. Inorganic iron is found primarily in plant foods; it provides 85–90% of iron in a mixed diet and is the only source of iron in a vegetarian diet. The mechanisms of absorption of heme iron and inorganic iron differ. Unlike heme iron absorption, absorption of inorganic iron is affected by the presence of vitamin C and other constituents of the diet.

Dietary inorganic iron is largely in the ferric (Fe^{3+}) state, which is poorly soluble in the alkaline environment of the small intestine where absorption of iron takes place. Ferrous iron (Fe^{2+}), however, is soluble at alkaline pH. The amount of inorganic iron absorbed by the intestine is influenced by stimulatory and inhibitory factors of either dietary or endogenous origin. Ascorbic acid both reduces and chelates iron, forming ferrous–ascorbate complexes that are readily absorbed. Other weak organic acids (e.g., citric acid), certain sugars, and sulfur-containing amino acids have similar properties, but are less effective. Meat, fish, and poultry also enhance the absorption of inorganic iron, apparently because of the binding of iron by cysteine-containing peptides that result from the digestion of muscle tissues. Phytates that occur in cereals (especially in the bran fraction) bind inorganic iron and retard its absorption. The same is true for tannins (polyphenols) that are found in some vegetables and in tea.

Supplemental ascorbic acid consistently enhances absorption of inorganic iron from single meals, as indicated by incorporation of iron into red blood cells. In one study, 500 mg of ascorbic acid taken with the meal increased iron absorption about sixfold. The most pronounced effects of ascorbic acid are found in meals containing a high content of phytates and/or tannins. This finding has led to the suggestion that ascorbic acid enhances iron absorption by counteracting the influence of inhibitory substances.

Biochemical Functions

Ascorbic acid acts as a cofactor for eight mammalian enzymes (Table 1) by keeping enzyme-bound iron or copper ions in the necessary reduced state. Other reducing agents are far less effective as cofactors

Table 1 Ascorbic acid-dependent mammalian enzymes

Enzyme	*Function*
Prolyl-4-hydroxylase (EC 1.14.11.2)	Collagen synthesis
Prolyl-3-hydroxylase (EC 1.14.11.7)	Collagen synthesis
Lysyl hydroxylase (EC 1.14.11.4)	Collagen synthesis

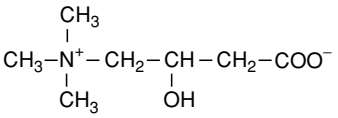

Figure 3 L-Carnitine.

in vitro, and so these enzymes are considered to be ascorbic acid-dependent. The roles of such enzymes in four biochemical processes are discussed below.

Biosynthesis of Collagen

Collagen is the major macromolecule of most connective tissues. It forms a triple helix and is highly cross-linked to give a rigid and inextensible structure. The amino acid composition is unusual among animal proteins, with an abundance of proline and 4-hydroxyproline and a few residues of 3-hydroxyproline and hydroxylysine. The hydroxyproline residues are necessary for proper structural conformation and stability; hydroxylysine residues take part in cross-linking and facilitate subsequent glycosylation and phosphorylation.

Free hydroxyproline and hydroxylysine are not incorporated into procollagen during its synthesis. The presence of these two unusual amino acids in procollagen (the precursor of collagen that contains additional 'propeptides') arises through the post-translational hydroxylation of particular proline and lysine residues in the polypeptide chain. Within the cisternae of the rough endoplasmic reticulum, the newly synthesized procollagen chains encounter three hydroxylating enzymes. Two of these enzymes, prolyl-4-hydroxylase and prolyl-3-hydroxylase, convert proline residues to 4-hydroxyproline or 3-hydroxyproline, respectively, and the third, lysyl hydroxylase, converts lysine residues to hydroxylysine. Each of these enzymes contains an iron ion (maintained in the ferrous state by ascorbate) and requires molecular oxygen and α-ketoglutarate as cosubstrates (Figure 2). In addition to the posttranslational modifications of procollagen, ascorbate stimulates transcription of the type I procollagen gene. The absence of wound healing is one of the features of scurvy that can be attributed to impaired collagen synthesis arising from lack of vitamin C.

Biosynthesis of Carnitine

Carnitine (3-hydroxy-4-*N*-trimethylaminobutyric acid, Figure 3) is essential for the β-oxidation of long-chain fatty acids, producing energy in the mitochondria. Neither free fatty acids nor fatty acid coenzyme As can penetrate the inner membranes of mitochondria, but acylcarnitine can readily do so. The translocation of fatty acids from the cytosol to the β-oxidation site in the matrix of the mitochondrion is therefore dependent upon carnitine.

The synthesis of carnitine commences with the conversion of specific peptide-linked lysine residues to trimethyllysine within certain proteins. Proteins in which trimethyllysine has been found include histones, myosin, calmodulin, and cytochrome c. Free trimethyllysine released by proteolytic cleavage is converted to carnitine in a number of steps, which include two hydroxylations. The enzymes responsible for these hydroxylations are ε-*N*-trimethyllysine hydroxylase and γ-butyrobetaine hydroxylase. Like the hydroxylases involved in collagen biosynthesis, both enzymes contain ferrous ion and require molecular oxygen and α-ketoglutarate as cosubstrates.

Vitamin C deficiency results in a variable decrease in carnitine levels of skeletal muscle, heart muscle, liver, and kidney. Carnitine status depends on dietary carnitine intake, a modest rate of carnitine biosynthesis, and efficient conservation of carnitine by renal reabsorption. The rate of carnitine synthesis in scorbutic guinea-pigs is much higher than the rate

in normal guinea-pigs, and therefore impaired synthesis is not responsible for carnitine depletion. The responsible factor is, in fact, increased urinary excretion resulting from inefficient renal reabsorption.

Biosynthesis of Noradrenaline

As a neurotransmitter, noradrenaline (norepinephrine) is synthesized in the nerve terminals of postganglionic sympathetic neurones, referred to as adrenergic neurones. As a hormone, noradrenaline, along with adrenaline, is synthesized in the chromaffin cells of the adrenal medulla. The final and probably rate-limiting step in the biosynthetic pathway – the conversion of dopamine to noradrenaline (Figure 4) – is catalyzed by dopamine β-hydroxylase in the presence of molecular oxygen. Dopamine β-hydroxylase is a tetramer, each monomer containing two copper ions maintained in the cuprous (Cu^{+}) state by ascorbate. The enzyme is localized within storage vesicles in both adrenergic neurones and adrenomedullary chromaffin cells. Intravesicular ascorbate is maintained in the reduced state by electron transport across the vesicle membrane, cytosolic ascorbate being the most likely electron donor. Cytosolic semidehydroascorbate generated in the extra- to intravesicular electron transfer reaction may be reduced by the outer mitochondrial membrane enzyme, semidehydroascorbate reductase (EC 1.6.5.4), to complete the ascorbate regeneration cycle. In this manner, a stable rate of noradrenaline biosynthesis can be maintained in the absence of exogenous ascorbate.

Amidation of Peptides to Hormones and Hormone-releasing Factors

A large number of peptides act as hormones and hormone-releasing factors. The vast majority of these peptides are initially synthesized as larger, inactive precursor molecules, which are converted to their active forms through a series of posttranslational modifications. One such final step of activation is carboxy-terminal α-amidation, which is essential for biological activity. Examples of α-amidated peptides include α- and γ-melanotropins, calcitonin, pro-ACTH, vasopressin, oxytocin, cholecystokinin, gastrin, gastrin-releasing peptide, and releasing factors for growth hormone, corticotropin, and thyotropin. Direct precursors to α-amidated peptides have glycine as the carboxy terminal amino acid. The enzyme responsible for the amidation is the bifunctional peptidylglycine α-amidating monooxygenase (PAM), which is found in secretory granules in many neuroendocrine tissues. PAM is actually a precursor protein that undergoes endoproteolytic cleavage to generate two enzymes, peptidylglycine α-hydroxylating monooxygenase (PHM) and peptidyl-α-hydroxyglycine α-amidating lyase (PAL). The two-step nature of the amidation is shown in Figure 5. Step 1 requires molecular oxygen, cuprous ion, and ascorbate as the reductant.

Antioxidant Role

Ascorbic acid helps to fight diseases such as cancer by scavenging harmful free radicals. A free radical can be

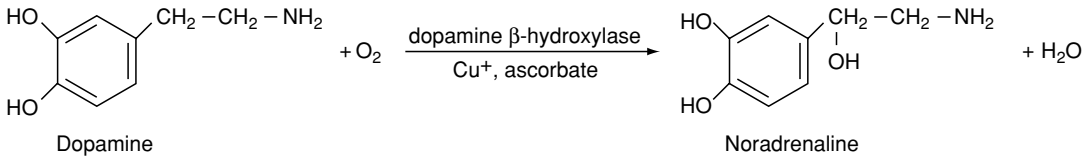

Figure 4 Hydroxylation of dopamine.

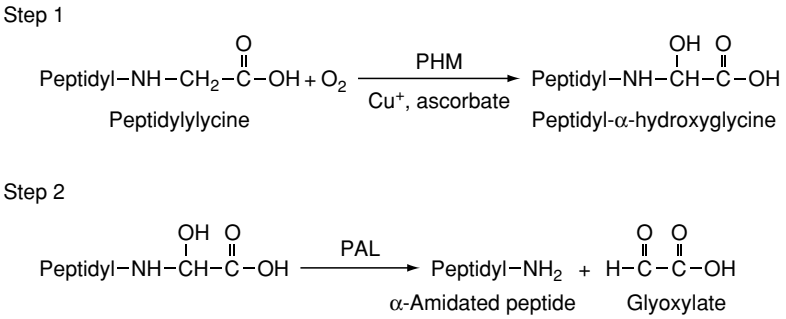

Figure 5 Amidation of peptidylglycine.

defined as an atom or molecule capable of an independent existence that contains an unpaired electron in its outer orbit. A superscript dot is used to denote free radical species; the superoxide anion radical with its two unpaired electrons is usually represented by $O_2^{\cdot-}$. Owing to their unstable electronic configuration, free radicals are much more reactive than nonradicals. They readily extract electrons from other molecules with which they collide, and these molecules in turn become free radicals. Thus, a chain reaction is propagated.

Free radicals can be generated anywhere within the cell by a variety of processes: spontaneous autoxidation reactions (e.g., flavin oxidation), phagocytosis during infection, metabolic processing of foreign compounds (e.g., constituents of tobacco smoke, drugs, pesticides, solvents, and pollutants), ultraviolet irradiation of the skin, and ionizing radiation. Among free radicals of biological importance are the hydroxyl ($HO^{\cdot}$), peroxyl ($ROO^{\cdot}$), superoxide ($O_2^{\cdot-}$), and nitric oxide ($NO^{\cdot}$) radicals.

Many, or perhaps most, free radicals that are generated in the body are metabolized to nonradicals by enzymes such as superoxide dismutase (EC 1.15.1.1), which catalyzes the reduction of the superoxide radical to hydrogen peroxide and water (1).

$$O_2^{\cdot-} + O_2^{\cdot-} + 2H^+ \rightarrow H_2O_2 + O_2. \qquad (1)$$

Although hydrogen peroxide is relatively unreactive, it can traverse biological membranes and cause intracellular damage through the production of hydroxyl radicals catalyzed by ferrous or cuprous ions (2).

$$Fe^{2+}(\text{or } Cu^+) + H_2O_2 \rightarrow Fe^{3+}(\text{or } Cu^{2+}) + HO^{\cdot} + OH^-. \qquad (2)$$

Two enzymes remove hydrogen peroxide in mammalian cells: catalase (EC 1.11.1.6) (eqn (3)) and glutathione peroxidase (EC 1.11.1.9) (eqn (4)), which uses hydrogen peroxide to oxidize reduced glutathione (GSH) to oxidized glutathione (GSSG).

$$2H_2O_2 \rightarrow 2H_2O + O_2 \qquad (3)$$

$$H_2O_2 + 2GSH \rightarrow GSSG + 2H_2O. \qquad (4)$$

Enzymes do not completely prevent the formation of free radicals, and various secondary antioxidants fulfill the role of free-radical scavengers. Ascorbate is one such antioxidant within the aqueous environment of the cytosol and extracellular fluids, and at the water–lipid interface of cellular and subcellular membranes. Figure 6 shows a possible scheme in which ascorbate can be recycled after trapping a free radical. Ascorbate (AH^-) donates an electron to the free radical ($R^{\cdot}$), forming detoxified product (R), and

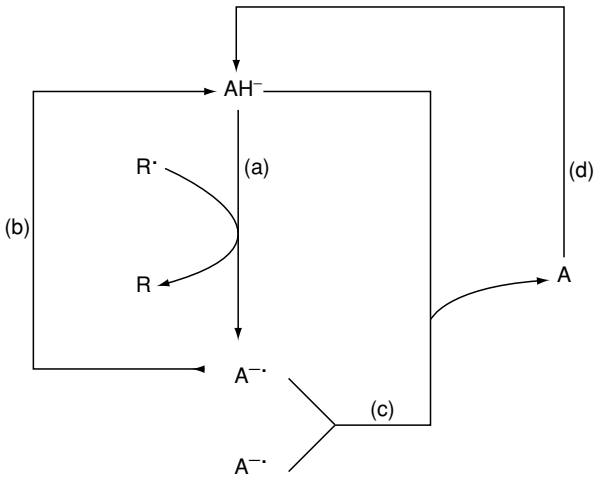

Figure 6 Recycling of ascorbate during the process of free radical scavenging. AH^-, ascorbate; $A^{\cdot-}$, ascorbyl free radical (semidehydroascorbate); A, dehydroascorbic acid; $R^{\cdot}$, free radical species; R, detoxified species. (a) Single-electron transfer; (b) semidehydroascorbate reductase; (c) nonenzymatic dismutation of ascorbyl free radical; (d) dehydroascorbic acid reductase.

is itself oxidized to the ascorbyl free radical ($A^{\cdot-}$), also known as semidehydroascorbate. Pairs of ascorbyl free radicals disproportionate to form one molecule each of dehydroascorbic acid (A) and ascorbate. The high disproportion rate constant of the ascorbyl free radical prevents substantial interaction with other substances. Dehydroascorbic acid can be reduced to ascorbate by either a glutathione-dependent or an NADPH-dependent reductase.

In the lipid environment of cellular and subcellular membranes and plasma lipoproteins, vitamin E (tocopherol, TOH) protects the lipids from peroxidation by reacting with peroxyl radicals, forming the tocopheroxyl radical ($TO^{\cdot}$) and lipid hydroperoxide (ROOH), thereby terminating the chain reaction (eqn (5)). The potentially harmful lipid hydroperoxide can be converted enzymatically to a fatty acid alcohol. Like the ascorbl radical, the tocopheroxyl radical has a low reactivity and can be converted back to tocopherol by enzyme systems.

$$ROO^{\cdot} + TOH \rightarrow ROOH + TO^{\cdot}. \qquad (5)$$

In model *in-vitro* systems, ascorbate regenerates vitamin E by reducing the tocopheroxyl radical back to tocopherol, producing the ascorbyl radical (eqn (6). However, any vitamin E sparing effect exerted by vitamin C *in vivo* is negligible in comparison with other metabolic processes.

$$TO^{\cdot} + AH^- \rightarrow TOH + A^{\cdot-}. \qquad (6)$$

Ascorbate can exert pro-oxidant properties *in vitro* through interaction with iron or copper ions and

hydrogen peroxide to produce hydroxyl radicals. In the healthy human body, these metal ions are largely sequestered in forms unable to catalyze free radical reactions, and so the pro-oxidant properties of ascorbate would not normally be expected to be biologically significant.

Inhibition of *N*-nitroso Compound Formation

Nitrosating agents, for example nitrous anhydride (N_2O_3), are derived from nitrite (eqns (7)–(9))

$$NO_2^- + H^+ \rightleftharpoons HNO_2 \quad (7)$$

$$HNO_2 + H^+ \rightleftharpoons H_2NO_2^+ \quad (8)$$

$$H_2NO_2^+ + NO_2^- \rightleftharpoons N_2O_3 + H_2O. \quad (9)$$

In the acidic contents of the stomach, nitrosation reactions take place between nitrosating agents and secondary amines or *N*-substituted amides to form *N*-nitrosamines (eqn (10)) or *N*-nitrosamides, collectively called *N*-nitroso compounds.

$$\begin{matrix} R_1 \\ \diagdown \\ \quad NH \\ \diagup \\ R_2 \end{matrix} + N_2O_3 \rightleftharpoons \begin{matrix} R_1 \\ \diagdown \\ \quad N-N=O \\ \diagup \\ R_2 \end{matrix} + HNO_2. \quad (10)$$

N-Nitroso compounds are implicated in cancer of the stomach, esophagus, and nasopharynx. Nitrite is present naturally in some foods and is added as a preservative in cured meats. Nitrosatable amines and amides may be ingested as drugs, food additives, or natural constituents of foods. Ascorbic acid is added to the curing brine in the production of bacon and other cured meats in order to prevent the subsequent formation of *N*-nitroso compounds in the stomach. Presumably, the vitamin acts by reducing nitrous anhydride to nitric oxide (eqn (11)), which is not a nitrosating agent.

$$AH^- + N_2O_3 \rightleftharpoons A + 2NO + H_2O. \quad (11)$$

For ascorbic acid to be effective, it must be present in sufficient quantity, since nitric oxide can be oxidized to nitrogen dioxide, and these two species can combine to form nitrous anhydride (eqn (12)).

$$NO + NO_2 \rightleftharpoons N_2O_3. \quad (12)$$

Immune Function

Vitamin C possesses antihistamine activity and is implicated in a variety of immune functions, including neutrophil chemotaxis, T lymphocyte proliferation, natural killer cell activity, and activation of the complement component C1q. Neutrophils and lymphocytes (types of leukocytes) concentrate vitamin C at levels up to 100 times higher than in plasma, suggesting that the vitamin has a physiological role in these immune-system cells.

Antihistamine Activity

In the initial stages of an immune response, histamine amplifies immunoresponsiveness by increasing capillary permeability and smooth muscle contraction, enhancing the flow of immune factors to the site of injury or infection. Subsequently, histamine suppresses the immune response by inhibiting neutrophil lysosomal enzyme release. Excess histamine has a negative effect, and antihistamine therapy is well known for alleviating conditions such as hay fever and inflammatory skin disorders. Ascorbic acid degrades histamine *in vitro*. In humans, chronic oral administration of vitamin C results in a lowering of blood histamine levels, whereas low blood levels of ascorbate are associated with increased histamine levels.

Neutrophil Chemotaxis

Neutrophils (polymorphonuclear leukocytes) destroy pathogenic organisms by phagocytosis (engulfment) and intracellular enzymatic degradation. If foreign materials are too large to be engulfed, enzymes and reactive oxygen species are released extracellularly. Neutrophil chemotaxis refers to the response of neutrophils to chemical signals produced at sites of infection. Histamine lowers the chemotactic responsiveness of neutrophils by elevating intracellular levels of cyclic adenosine 3′,5′-monophosphate (cyclic AMP). A rise in cyclic AMP is associated with depressed neutrophil motility. Data from a study using healthy human subjects suggest that vitamin C at doses of 2 g per day for 2 weeks may indirectly enhance neutrophil chemotaxis through its antihistamine activity.

Proliferation of T Lymphocytes

Vitamin C regulates proliferation of T lymphocytes, which are responsible for destroying viruses that reside and multiply inside living cells of the body. Specialized types of T lymphocyte exert immunoregulatory and effector functions through the secretion of lymphokines such as interferon. Cytotoxic T lymphocytes kill viruses by attaching to the infected cell through recognition of viral antigens and releasing granules whose contents cause perforation of the host cell membrane. The granules also contain substances that induce apoptosis – genetically programmed cell death by fragmentation of nuclear DNA. Since death by apoptosis does not result in the release of the cell's contents, killing by this mechanism may prevent the spread of infectious virus into other cells.

Natural Killer Cell Activity

Natural killer cells are large nonphagocytic leukocytes that kill tumor cells by cell membrane perforation and apoptosis. The cytotoxic activity of killer cells is spontaneous, unlike that of cytotoxic T lymphocytes, which only develops after an immune response has been initiated. An *in-vivo* effect of ascorbic acid on enhancement of human natural killer cell activity has been reported at a dosage of 60 mg per kilogram of body weight.

Regulation of the Complement Component C1q

Complement is a collective term for at least 25 plasma and cell membrane proteins that are important in the host's immune system. Following initial activation by antigen–antibody complexes, the various complement components interact, in a highly regulated enzymatic cascade, to generate various reaction products. Some of these products induce localized vasodilation and attract phagocytic cells chemotactically. Other products coat the foreign particle, enabling it to be recognized by phagocytic cells that bear receptors for these complement products. Finally, the terminal components of the complement system generate the membrane–attack complex, which lyses bacteria and membrane-enveloped viruses.

The first complement component to be activated in the classical cascade pathway is the C1 complex, in which C1q is one of three proteins. When guinea-pigs were fed tissue-saturating amounts of vitamin C, C1q concentrations were significantly higher than in those animals fed only enough ascorbate for adequate growth and for the prevention of scurvy. C1q is a hydroxyproline-containing protein, and so the observed effect is consistent with the known role of vitamin C in hydroxyproline synthesis.

Prostaglandin Synthesis

The prostaglandins (PG) are a group of hormone-like lipids formed in the body from derivatives of essential fatty acids, particularly arachidonic acid (20:4*n*-6). Prostaglandins have a vast range of effects and modulate cardiovascular, pulmonary, immune, and reproductive functions. Vitamin C stimulates the formation of PGE_1 from dihomo-γ-linolenic acid in human platelets. This effect occurs over the physiological range of vitamin C concentrations and is desirable because PGE_1 is an inhibitor of platelet aggregation. PGE_1 is also required for T lymphocyte formation, regulation of collagen and cholesterol metabolism, and regulation of responsiveness to insulin. There are sufficient data to suggest that some of vitamin C's biological actions could be explained by a regulatory effect on prostaglandin synthesis.

Dietary Intake and Supplementation

Recommended Dietary Allowance (RDA)

In the USA, the 1989 RDA for vitamin C is 60 mg per day for adults. At this level, saturation of tissue binding and maximal rates of metabolic and renal tubular absorption seem to be approached. The RDA of 100 mg per day for smokers is higher because the plasma concentration of vitamin C is lowered by the use of cigarettes. Plasma ascorbate levels of women decrease during pregnancy, and the RDA includes a 10 mg per day increment for pregnant women. A daily increment of 35 mg is recommended during the first 6 months of lactation and 30 mg thereafter. Assessments of human vitamin C status are based upon measurement of ascorbate concentrations in plasma and leukocytes.

Deficiency

Scurvy, the classical vitamin C deficiency disease, can occur under circumstances of poor diet, such as arises in chronic alcoholism.

Toxicity

Ascorbic acid is generally regarded as being nontoxic at high intakes. Once the plasma concentration of ascorbate reaches the renal threshold, it is excreted more or less quantitatively with increasing intake. Excessive daily intakes of vitamin C can cause an increased production of oxalic acid in some individuals, leading to an increased risk of kidney stone formation.

Rebound Scurvy

Theoretically, the absorption of ascorbic acid could be impaired on resumption of normal vitamin C inputs following megadosing (> 1 g per day), because of insufficient carriers in the enterocyte cell membranes. Based on experiments with guinea-pigs, it is considered likely that, in humans, renewed synthesis of carriers will take place well before the onset of scurvy. During megadosing, reduced ascorbate absorption is accompanied by increased rates of ascorbate catabolism. In adult guinea-pigs, the accelerated catabolism is not reversible after more than 2 months on subnormal uptake of ascorbate. Guinea-pigs are thus susceptible to a systemic conditioning effect known as rebound scurvy, caused by an induction of ascorbic acid-metabolizing enzymes by high dietary vitamin C. The body stores of vitamin C are depleted more rapidly in juvenile guinea-pigs than in adults,

increasing the likelihood of rebound scurvy in juveniles. In human infants, rebound scurvy could possibly occur, despite an adequate daily intake of vitamin C, if the mother has received large supplements of the vitamin during pregnancy. Reported cases of rebound scurvy in adult humans are rare.

Treatment of the Common Cold

Vitamin C supplementation has been suggested for the prevention of the common cold and the alleviation of its symptoms. Reviews of numerous studies generally conclude that vitamin C megadoses have no consistent effect on reducing the incidence of colds in people in general. However, in four studies with British male schoolchildren and students, a statistically high significant reduction in common cold incidence was found in vitamin C-supplemented groups. This could be interpreted as a correction of a marginal deficiency in the study subjects, rather than an effect of the high dosage. Placebo-controlled studies have consistently shown that high doses of vitamin C alleviate common cold symptoms, although the validity of some of these studies has been questioned.

ASPARTAME

M B A Glória, Federal University of Minas Gerais, Belo Horizonte, Minas Gerais, Brazil

Background

Aspartame is an intense nutritive sweetener discovered accidentally in 1965 by the chemist James Schlatter from G.D. Searle and Co. It was introduced in 1981 and has been assigned the INS number of 951. At present, it is available under the brand names of Nutrasweet®, Equal®, and Canderel®. Aspartame is a caloric substance because it is a dipeptide that is completely digested after consumption. However, its intense sweetness allows functionality to be achieved at very low levels, providing very few calories.

Aspartame has been approved for food, beverage, pharmaceutical, and tabletop sweetener use in more than 100 countries. Currently, it is the most widely consumed high-intensity sweetener. It is used in approximately 6000 different products and consumed by hundreds of millions of people in countries around the world.

The synthesis of aspartame can be performed by chemical or chemoenzymatic methods. There are over 70 patents on the manufacturing process. It can be made from pure amino acids and is not extracted from any food, and so it is kosher. It is also parve, which means that it contains neither dairy nor meat products. Although kosher and parve, other ingredients in a product containing aspartame must be checked for their kosher status. Aspartame sold for commercial use must meet all requirements of the Food Chemical Codex.

Physical and Chemical Characteristics

Aspartame is a dipeptide composed of two amino acids, L-aspartic acid and L-phenylalanine methyl ester. Its chemical structure is shown in Figure 1. Chemically, aspartame is *N*-L-α-aspartyl-L-phenylalanine methyl ester or 3-amino-*N*-(α-carboxyphenethyl)succinamic acid *N*-methyl ester. It has a molecular formula of $C_{14}H_{18}O_5N_2$ and a molecular weight of 294.30. It is a white, odorless, crystalline powder, with a melting point of 246–247 °C and $[\alpha]_D^{22} = 2.3°$ (1 mol per liter of HCl).

Aspartame is slightly soluble in water (about 1.0% at 25 °C), sparingly soluble in alcohol, and insoluble in fats and oils. The solubility in water is affected by temperature and pH. It increases as the pH is lowered and the temperature is increased.

Sensory Characteristics

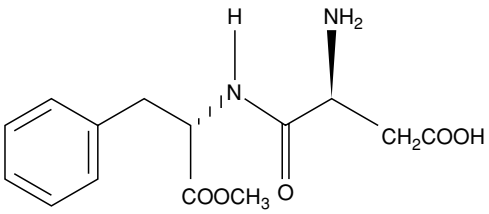
Aspartame is described as having a sweet, clean taste and sweetness profile similar to that of sucrose, without any bitter or metallic aftertaste often associated with other high-intensity sweeteners. At concentrations of 0.10–0.89 g l^{-1}, aspartame has no off-tastes. However, it displays a slow onset of sweetness coupled with a lingering sweet taste.

Aspartame has 100–200 times the sweetness of sucrose, depending on the food system. For example, its sweetness potency in flavored yogurt is 175–220 times that of sucrose. The relative sweetness is also affected by pH and the amount of sucrose or other sugars being replaced.

The perception of aspartame sweetness increases linearly with its concentration. However, increasing the ethanol content causes a reduction in the perceived sweetness.

Aspartame extends and intensifies flavors, particularly enhancing fruit flavors, such as orange, lemon, grapefruit, cherry, and strawberry. This flavor-enhancing property, as observed with chewing gum, produces a longer-lasting sweetness and flavor up to four times longer. Such a characteristic is important in many food applications.

Aspartame exhibits synergism, a superior taste profile, and an improved stability when combined with other sweeteners, such as saccharin, cyclamate, acesulfame-K, and stevioside. The flavor-enhancement quality of aspartame masks bitter flavors, even at subsweetening levels. Its use is thus recommended in blends with sweeteners that possess potentially undesirable or more complex taste profile.



$C_{14}H_{18}N_2O_5$ (FW 294.30)
N-L-aspartyl-L-phenylalanine-1-methyl ester
ASPARTAME

Figure 1 Chemical structure of aspartame.

Food and Beverage Applications

Aspartame provides many opportunities for formulating new products while lowering or limiting calories and sugar consumption. Other benefits of using aspartame are cost reductions in packaging, shipping, and storage. Furthermore, aspartame is generally cheaper than powdered sugar. It has a lower cost per unit sweetness than sucrose.

Aspartame is approved for use as a prepackaged sugar substitute tablet. Its use as a sweetener and flavor enhancer is also approved. It has a potential for a wide range of food applications, including carbonated soft drinks, fruit drinks, dry beverage bases, instant tea, hot chocolate, gelatin, puddings, fillings, yogurt, icecream, frozen novelty, hard candy, confectionery, breath mint, breakfast cereals, chewing gums, dairy products, and toppings.

Aspartame is widely used both as a dry powder and as an aqueous solution. The largest application is in soft drinks followed by dry mix products. The main products in the dry mix market are sweetener tablets and sachets, cold beverage mixes, and instant desserts. In these products, aspartame's sweetness should be released rapidly and evenly throughout the product for maximum performance. In order to insure uniformity of the final product, stability against segregation, and proper reconstitution upon preparation, agglomeration processes are used either as a re-wet or a straight through process (the dry mix is dissolved and spray-dried). Another way to overcome this problem would be by coating food ingredients such as citric, fumaric, and lactic acids, sucrose, dextrose, fructose, oligo-fructose, and maltodextrin with fine-grade aspartame.

Blends or combinations of sweeteners are often used to achieve the desired level of sweetness in food and beverage products that traditionally have been sweetened with single sweeteners. In the USA, almost every major soft-drink manufacturer now uses a combination of aspartame and saccharin in diet drinks. The blending of these two noncarbohydrate sweeteners reduces the cost and helps to prolong the shelf-life of the beverages compared with aspartame alone.

Aspartame hydrolyzes slowly at the low pH values characteristic of soft drinks. Therefore, products containing exclusively aspartame become less sweet on prolonged storage.

When aspartame is substituted for sugar in food products, the sugar bulk must be replaced. Although gums can be used as a thickening agent, modified food starch may be a better choice.

Sucrose can be replaced in nondiet carbonated soft drinks by aspartame–glucose syrup formulations, which mimic sucrose properties in soft drinks. Products containing this blend are liked as much as, or more than, all-sucrose drinks by consumers. They are also significantly cheaper since aspartame has a lower per-unit sweetness than sucrose.

Aspartame may be used as total sugar replacements in whey beverages, resulting in a significant reduction in the amount of carbohydrate present. The amount required to produce a sweetness level equal to that of a beverage containing 10.5 g per 100 ml of invert sugar is 0.25 g l^{-1}. When used together with acesulfame-K, synergism results in a 25% reduction in the total amount of sweetener required.

Stability

In the dry state (e.g., table top sweetener, powdered drinks, dessert mixes), aspartame is quite stable. However, when used in aqueous solutions or intermediate moisture systems, it is susceptible to hydrolysis, other chemical reactions, and microbial degradation, thus limiting its shelf-life.

In aqueous solution, aspartame undergoes decomposition and racemization, forming a variety of products. Degradation is also significantly affected by the pH, temperature, and storage period of the food or beverage. These factors cause a degradation reaction of first-order kinetics.

Aspartame is stable in the pH range of 3–5, which is characteristic of most foods. At 25 °C, the maximum stability is reported at pH 4.3. The good stability observed during refrigerated storage of yogurt is due to its pH, which ranges from 4.0–4.5. A frozen dairy dessert may have a pH ranging from 6.5 to 7.0, but, because of the frozen state, the rate of reaction is dramatically reduced.

The influence of temperature on aspartame depends on the composition and water activity of the food. Maximal stability is observed in the lower temperature range used for refrigerated and frozen storage. The activation energy decreases above and below the isoeletric point, pH 5.4. Aspartame can withstand the heat processing used for dairy products and juices, aseptic processing, and other processes in which high-temperature short-time and ultrahigh temperature conditions are used. However, under conditions of excessive heat, aspartame may hydrolyze or cyclize, limiting its applications. An encapsulated form of aspartame is now available to improve heat stability.

The initial microbial load and subsequent growth of contaminants in yogurt and milk chocolate can affect the rate of aspartame degradation. The stability of aspartame has been observed to be similar for different strains of *Lactobacillus bulgaricus* and *Streptococcus thermophilus*, suggesting that strain differences do not affect stability. To improve stability, aspartame should be added to yogurt after fermentation.

Aspartame can react with aldehydes, which are the principal flavor compounds used in chewing gums and in some soft drinks. However, the reactivity varies with aldehyde type, owing to differences in reaction pathway.

Nonenzymatic browning via the Maillard reaction is another important pathway for aspartame degradation in foods. Owing to its dipeptide structure, aspartame can react with reducing sugars in the presence of water. This reaction is favored at alkaline pH values, because nonprotonated amine groups on the molecule are more available. This interaction may result in off-flavors, loss of sweetening power or undesirable color changes. Another example of carbonyl-amino reactions has been shown for vanillin, resulting in the loss of vanilla flavor. Both temperature and water content during storage can affect reaction rates, which have been observed to follow zero-order kinetics.

Decomposition Products

As indicated in Figure 2, aspartame decomposition [1] results in hydrolysis of the methylester with loss of methanol forming 3,6-dioxo-5-phenylmethyl-2-piperazineacetic acid – diketopiperazine. This compound is then hydrolyzed [2], yielding aspartylphenylalanine, which is eventually hydrolyzed [3] to the free amino acids aspartic acid and phenylalanine. At acid pH values [4], products such as phenylalanine methyl ester and aspartic acid are formed. The first is hydrolyzed [5], forming phenylalanine and methanol. Another degradative pathway involves base-catalyzed hydrolysis with loss of methanol [6] forming α-aspartylphenylalanine, which undergoes further hydrolysis [3] to give phenylalanine and aspartic acid. Racemization of α-aspartame [7] and its degradation products has also been observed.

The major degradation products are diketopiperazine and aspartylphenylalanine. None of the decomposition products have a sweet taste or aftertaste. Therefore, when these compounds are formed in the

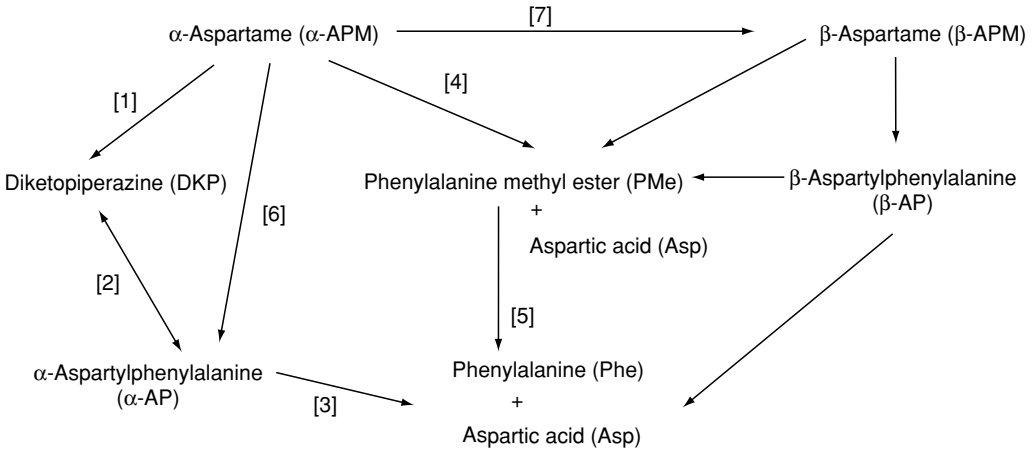


Figure 2 Decomposition products of aspartame.

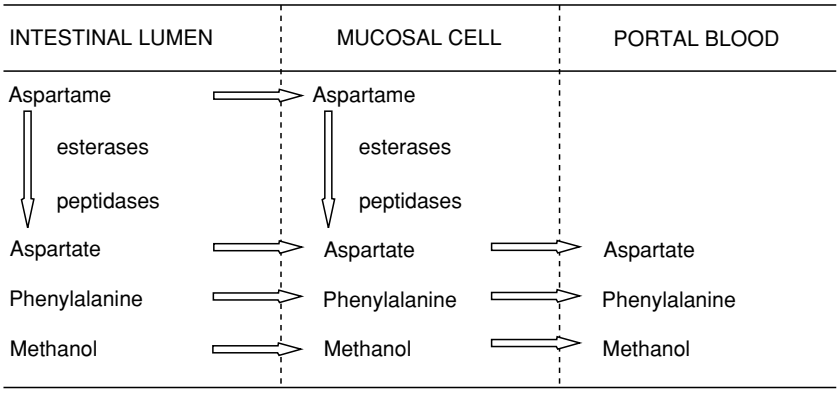

Figure 3 Diagram of aspartame metabolism. From Burini RC and Caballero B (1992) Metabolismo do aspartame em humanos. *Cadernos de Nutrição* 4: 38–47, with permission.

food, a loss of sweetness is perceived. Several investigators have monitored aspartame in different food products in the market and observed that levels varied from 52 to 107% of the value declared on the label.

Metabolism

Metabolism studies in numerous species, including humans, demonstrated that aspartame is rapidly and completely metabolized to its individual constituents phenylalanine, aspartic acid, and methanol. Consequently, it has the same caloric value of proteins – 4 kcal g^{-1}. However, because of its intense sweetness, the amount of aspartame used in foods is small enough for the sweetener to be virtually nonnutritive, providing negligible energy. It is noncariogenic and produces little glycemic response.

Aspartame may be absorbed and metabolized in one of three ways (Figure 3). It may be hydrolyzed in the intestinal lumen by proteolytic and hydrolytic enzymes to form aspartate, phenylalanine, and methanol. These hydrolysis products are absorbed from the intestinal lumen and reach the systemic circulation in a manner similar to that of amino acids, peptides and methanol arising from the digestion of dietary proteins and polysaccharides. Aspartame may be absorbed directly into mucosal cells by one of the peptide transporter systems, with subsequent hydrolysis within the epithelial cells to aspartate, phenylalanine, and methanol. Aspartame may also be de-esterified in the intestinal lumen to yield methanol and aspartylphenylalanine, which is taken up by enterocytes via a peptide transport system and further hydrolyzed to aspartate and phenylalanine. Once absorbed, these components are metabolized, utilized, and/or excreted by the body through similar pathways as when they are derived from any other dietary source.

Safety

Aspartame has been the subject of extensive investigation in animals and humans. Prior to the marketing of aspartame, numerous studies were done to evaluate its metabolism and tolerance in healthy subjects and various subpopulations, including phenylketonuric heterozygotes, children, lactating and pregnant women, and individuals with renal and liver disease. Postmarketing, numerous additional studies were performed, including the evaluation of alleged sensitivity to aspartame. The results of extensive scientific research investigating these allegations did not show any causal relationship between aspartame and adverse effects.

Aspartame has undergone extensive clinical testing prior to its regulatory approval, including acute and long-term studies in the general population and in populations that may be extensive users of a high-intensity sweetener, such as diabetics and obese subjects. In addition, pharmacokinetic and metabolism studies, including radiolabeled studies, were carried out in normal subjects, subjects with a somewhat reduced capacity to metabolize phenylalanine (i.e., heterozygotes for phenylketonuria), and subjects with an almost complete inability to metabolize phenylalanine (i.e., phenylketonurics). Following the approval of aspartame, additional studies were undertaken to further evaluate the safety of aspartame in special populations.

The safety of aspartame has been extensively tested in animal and human studies. Undoubtedly, it is the most thoroughly studied of the high-intensity sweeteners. Its safety has been affirmed by numerous scientific bodies and regulatory agencies, including the Joint Expert Committee on Food Additives (JECFA) of the Codex Alimentarius (Food and Agriculture and World Health Organizations), the Scientific Committee for Food of the Commission of European Communities, the United States Food and Drug Administration, and the regulatory agencies of more than 100 other countries around the world.

On the basis of the results of comprehensive safety studies, a no observed-effect level of more than 2000–4000 mg per kilogram of body weight was established for aspartame. Based on this information, an acceptable daily intake (ADI) of 40 mg per kilogram of body weight per day for aspartame was set by JECFA. On the basis of both animal and human data, the United States Food and Drug Administration set an ADI for aspartame of 50 mg per kilogram of body weight per day. An ADI value of 7.5 mg per kilogram of body weight was given for its metabolite diketopiperazine. The use of aspartame appears to be unanimously authorized in different foods and beverages.

However, products containing aspartame have to be labeled to warn people with phenylketonuria. Methanol released from aspartame does not constitute an excessive metabolic load. Numerous studies have shown that aspartame and diketopiperazine are not associated with any serious adverse health effects.

Estimation of Consumption

Aspartame has been the subject of extensive postmarketing surveillance of consumption. Data from surveys in the USA indicate that approximately 40% of the population is consuming aspartame-containing products. From 1984 to 1992, the 90th percentile 14-day average consumption of aspartame in the general population ranged from 1.6 to 3.0 mg per kilogram per day. This is approximately 5–10% of the US ADI. The consumption by children aged 2–5 years and from all age groups ranged from 2.6 to 5.2 and from 5.2 to 8.5 mg per kilogram per day, respectively. Aspartame consumption by diabetics ranged from 2.1 to 3.4 mg per kilogram per day. Therefore, persons with diabetes who would likely be frequent users of aspartame consume quantities well below the ADI.

In Canada, three different methods to estimate potential aspartame intake have been used. In the first method, it was estimated that aspartame consumption would be 11 mg per kilogram per day if it replaced per-capita disappearance of sugar. In the second method, it was estimated that aspartame consumption would be approximately 4 mg per kilogram per day if it replaced sugar in major types of foods on a per-capita disappearance basis. In the third method, based on a 24-h dietary recall survey of food consumption in over 13 000 individuals, it was estimated that potential aspartame use in these foods would result in an intake ranging from 3.2 to 7.4 mg per kilogram per day. In a survey with over 5000 individuals in 1987, it was observed that 45% of the individuals consumed products with aspartame. Consumption at the 90th percentile for the general population was 5.5 and 5.9 mg per kilogram per day during the winter and summer months, respectively. Intake by diabetics was 5.5 and 11.4 mg per kilogram per day during the winter and summer months, respectively. In addition, the consumption by all age groups of children was below 10 mg per kilogram per day.

In the UK, in a study based on the consumption of saccharin, it was estimated that aspartame consumption by diabetics would be approximately 5.5 mg per kilogram per day at the 90th percentile. In another study, potential aspartame intake in children from soft-drink consumption would be approximately

6.6–6.8 mg per kilogram per day at the 90th percentile.

Nearly 73% of the diabetic children surveyed in Finland consumed aspartame-containing products with a mean intake of 1.15 mg per kilogram per day. Aspartame intake in France from 1991 to 1992 was 0.6 mg per kilogram per day and in Germany, consumption in 1988–1989 was 2.75 mg per kilogram per day at the 90th percentile. The average intake of aspartame among Italian teenagers users of diet products was 0.03 mg per kilogram per day, with a maximum of 0.39 mg per kilogram per day.

In Brazil, data on potential intake of aspartame have been based on questionnaires to users of sweetener in the cities of Campinas, state of São Paulo, and Curitiba, state of Paraná, during the winter of 1990 and summer of 1991. Data showed that 40% of the population consumed aspartame alleging reasons of weight-control diet (36%), diabetes (35%), and weight loss (23%). Table-top sweeteners were the major source, followed by soft drinks. The median daily intake by users represented 2.9% of the ADI. Diabetics had a much higher intake within the studied population.

Although survey methodologies differed among these evaluations, aspartame intake is remarkably consistent across studies and well below the IDA.

Because aspartame is metabolized to common dietary components – aspartate, phenylalanine, and methanol – it is useful to evaluate the impact of its consumption on the normal dietary intake of these components. At the current 90th percentile 14-day average levels of consumption, aspartame contributes approximately 1.5 and 3% of an adult's daily dietary intake of aspartate (80 mg per kilogram per day) and phenylalanine (52 mg per kilogram per day), respectively.

Aspartame yields approximately 10% methanol by weight. This amount is well below the normal dietary exposure to methanol from many fruits, vegetables, and juices. Therefore, normal diets provide several times more methanol than that from foods sweetened with aspartame. For example, tomato juice provides approximately six times more methanol than an equal volume of aspartame-sweetened beverage. Whereas methanol exposure at the 90th percentile of chronic aspartame consumption is 0.3 mg per kilogram per day, the FDA has established acceptable levels of exposure to methanol at 7.1–8.4 mg per kilogram per day for 60-kg adults.

Methods of Analysis

Many analytical procedures have been proposed to check food labeling or to measure the degree of aspartame decomposition during manufacturing and storage of food products. Several types of methods have been described for the analysis of aspartame, including spectrophotometric, enzymatic, titrimetric, capillary isotachophoretic, thin-layer chromatography, and liquid and gas chromatographic methods.

HPLC is by far the most frequently used technique to monitor aspartame, intermediates formed during its synthesis, and decomposition products formed during manufacture and storage of food products. It is also used to check for amounts declared on food labels.

Sample Preparation

Sample preparation generally depends on the type of food matrix. Samples can be directly injected into the HPLC or after minimal pretreatment. However extraction, clean-up, and/or purification might be necessary, depending on the complexity of the matrix, in order to eliminate any interference.

Clarification with Carrez solutions can be used to eliminate any interfering compounds. Purification, isolation, or concentration of the extract can also be performed by solid-phase extraction with C8 or C18. Sep-Pak C18 cartridges can be used for the separation of aspartame from its degradation products. The use of ion-exchange cartridges, such as Bond Elut SCX, Bond Elut C18, and Amberlite CG-120, has also been described.

Separation of Aspartame from Other Sweeteners

During HPLC analysis of aspartame, the most commonly used stationary phase is reverse-phase C18. Two main types of mobile phase have been used: an alcohol (methanol or isopropanol) associated with acetate or phosphate buffer or acetonitrile associated with phosphate buffer. In both cases, the pH is adjusted to 3.0–4.5. Ion-pair chromatography has also been used to separate aspartame from other sweeteners.

Separation of Aspartame from Synthesis Intermediates, Stereoisomers and Degradation Products

The most commonly used stationary phase for the separation of aspartame from synthesis intermediates, stereoisomers and degradation products, is the reverse-phase C18 column. The main type of mobile phase used is a phosphate buffer at a pH ranging from 2.5 to 5.0, associated with acetonitrile. Reverse-phase HPLC with gradient elution of acetonitrile in phosphate buffer has also been used.

Ion-pair chromatography has also been used to separate aspartame from synthesis intermediates and

degradation products. The method using sodium hexanesulfonate and gradient elution to separate aspartame from two decomposition products and seven related synthesis byproducts has been used routinely for the control of aspartame synthesis and as a check for the purity of both finished bulk and mother liquor. Chiral chromatography can also be used to obtain the resolution of stereoisomers from aspartame, its precursors, and its degradation products.

Detection Systems

Aspartame has been quantified by UV detection (254, 200–217 nm). However, because aspartame has a relatively low extinction at 254 nm, quantification at lower wavelengths provides an increased response. Detection can also be performed with increased specificity by fluorescence after postcolumn derivatization with *o*-phthaldehyde. In order to improve the detection sensitivity, aspartame can also be separated by HPLC as a fluorescent derivative. Fluorescamine derivatives are separated on LiChrosorb RP-8 using acetonitrile in 50 mM acetate buffer, pH 6, 22:78, v/v or on Spherisorb S5 ODS-2 RP using 0.2 M phosphate buffer (pH 9):acetonitrile:methanol, 2:1:1, v/v. Detection is performed at 397 nm excitation and 482 nm emission.

ATHEROSCLEROSIS

A H Lichtenstein, Jean Mayer USDA Human Nutrition Research Center on Aging at Tufts University, Boston, MA, USA

Introduction

Atherosclerosis is the leading cause of death and disability in developed countries and its rates are rising rapidly in developing countries. The disorder is characterized by the thickening of artery walls. There are three major types of atherosclerotic lesions; fatty streaks, fibrous plaques, and complicated lesions. The latter two are raised and because they are on the surface of a blood vessel they result in decreased lumen size and impeded blood flow (ischemia). The blood vessel involved, location of the lesion(s), and extent of ischemia determine the clinical manifestations of the disorder. Primary risk factors for atherosclerosis include elevated low-dens-

ity lipoprotein (LDL) cholesterol levels, male gender, increased age, positive family history, current cigarette smoking, hypertension, diabetes mellitus, and low high-density lipoprotein (HDL) cholesterol levels. This article emphasizes dietary modification as a nonpharmacological approach to treating the major risk factor for atherosclerosis, elevated LDL cholesterol levels. The topics discussed include saturated fat, omega-3 fatty acids, *trans* fatty acids, dietary cholesterol, and soluble fiber.

The term atherosclerosis describes a subgroup of arteriosclerotic disorders characterized by the presence of fatty plaque (atheromas) within the intima and media of medium and large arteries. The word atherosclerosis is derived from a combination of the Greek words *athere*, gruel, and *skleros*, hardening. The World Health Organization defines atherosclerosis as a 'variable combination of changes in the intima of the arteries involving focal accumulations of lipids and complex carbohydrates with blood and its constituents accompanied by fibrous tissue formation, calcification and associated changes in the media.' The American Heart Association defines atherosclerosis as 'a process that leads to a group of diseases characterized by a thickening of artery walls.'

Incidence

In the late 1990s, 15 million deaths were attributed to cardiovascular disease worldwide. This accounted for about 30% of all the deaths reported. In industrialized countries, the rate of cardiovascular disease has been declining for a number of years. However, it still accounts for about 50% of all deaths. In developing countries and eastern Europe, the rate of cardiovascular disease has been increasing. It accounts for about 25% and 60% of all deaths, respectively. As compiled by the American Heart Association from World Health Organization data, the mortality rates for coronary heart disease, stroke, and total cardiovascular disease, relative to total deaths, are shown in Table 1.

Pathology

The development of atherosclerotic lesions is relatively slow and the etiology has yet to be fully elucidated. Evidence suggests that there are multiple factors which independently impinge on lesion progression. Atherosclerotic lesions are frequently subdivided into three categories: fatty streaks, fibrous plaque, and complicated lesion. The first to appear, fatty streaks, are flat or slightly raised accumulations of lipid-rich macrophages and smooth-muscle cells. Fatty streaks are ubiquitous in humans and appear early in life. They rarely impede blood flow and their presence goes largely unnoticed. Although some fatty streaks can progress to fibrous plaque, their distribution suggests this is not always the case.

Fibrous (atherosclerotic) plaque is made up of macrophages which have accumulated lipid and are transformed into what are commonly referred to as foam cells. These lesions are elevated and composed of a core of cholesteryl ester, cellular debris, and cholesterol crystals, and a fibrous cap made up of smooth muscle and foam cells, collagen, and lipid. Due to their raised nature, fibrous plaques frequently obstruct the arterial lumen and impede blood flow. Rupturing of the cap may lead to clot formation and occlusion of the artery.

Fibrous plaque frequently progresses to complicated lesions. Complicated lesions severely or even completely obstruct the arterial lumen, with consequent ischemia or infarction. They are frequently associated with mural thrombosis (frequently leading to complete obstruction), ulceration, hemorrhage into the lesion, and calcification.

There are a number of theories on how and why both fibrous plaques form and progress to complicated lesions. The lipid hypothesis suggests that persistent hypercholesterolemia leads to LDL infiltration of the epithelial cells, smooth-muscle cells, and macrophages. This hypercholesterolemia not only leads to cholesterol accumulation but also activates protein growth factors which stimulate smooth-muscle cell proliferation into the media and subsequent lipid uptake. The response to injury hypothesis suggests that injury results from mechanical factors, chronic hypercholesterolemia, toxins, viruses, or immune reactions and leads to monocyte aggregation and adherence at the site of injury. Injury causes the release of growth factors which may arise from endothelial cells, monocytes, macrophages, platelet, smooth-muscle cells, and T cells. Monocytes and smooth-muscle cells carry 'scavenger' receptors which bind oxidized but not native LDL in a nonsaturable fashion. Uptake of oxidized LDL converts macrophages and smooth-muscle cells into foam cells. The immunological hypothesis suggests that an autoimmune reaction, potentially to oxidized LDL, precipitates a chain of events which results in lipid accumulation and the development of fibrous plaque.

Clinical Events

Atherosclerosis is a disorder that is slow to be detected, primarily because it is silent throughout most of its natural history. Its stealthy presentation is explained by the fact that under normal circumstances

unobstructed arteries have an excess capacity for blood flow, even under conditions of high demand, for example during prolonged physical exertion. Therefore, the gradual progression of the disease can go undetected until fibrous or complicated lesions form and blood flow is impeded to a significant extent. Because lesion development is silent, a surrogate measure of lesion progression, elevated LDL cholesterol levels, is used as a guide to determine whether individuals are at increased risk of developing atherosclerosis and whether the elevated levels, frequently in combination with other established risk factors, warrant treatment. Treatment of asymptomatic individuals with established hyperlipoproteinemia has been demonstrated to delay or prevent the onset of atherosclerotic events.

There are a number of disorders that are classified under the generic rubric of atherosclerosis. Angina pectoris (chest pain) is attributed to myocardial ischemia, at times precipitated by increased physical activity, accompanied by increased oxygen demand of the heart. A myocardial infarction describes a complete or near complete obstruction of a coronary vessel by thrombosis, hemorrhage, or ulceration of an atherosclerotic plaque or spasm of an artery, and usually involves vessels that are already partially obstructed. The result can be damage to the myocardium or sudden death. Cerebral ischemia refers to compromised blood flow to the brain due to atherosclerosis and can involve the carotid, subclavian, or vertebral arteries, as well as intracranial vessels. Clinical manifestations can include episodic cerebral ischemia with motor function, monocular blindness, or loss of consciousness. A complete occlusion results in ischemia due to thrombosis, embolism, and hemorrhage (either intracerebral or subarachnoid) of a cerebral artery and can result in neurologic deficiency. Atherosclerosis of the renal artery can lead to the development of hypertension. Occlusive atherosclerosis of the femoral, popliteal, and tibial arteries is associated with intermittent claudication and eventually gangrene. The presence of these lesions tends to correlate with atherosclerosis in other parts of the vascular tree.

Etiology

Both observational and interventional data indicate that the major contributing factors to the etiology of atherosclerosis are elevated LDL cholesterol levels, male gender, increased age, positive family history, current cigarette smoking, hypertension, diabetes mellitus, and low HDL cholesterol levels (Table 2). It is difficult to rank the relative contribution to each to the natural progression of the disease because the relative importance of each depends on severity and likely varies from individual to individual. Additional factors, albeit not always independent factors, such as elevated levels of homocysteine, lipoprotein (a) (Lp(a)), triglyceride, physical inactivity, and obesity also likely determine the course of development and rate of progress of atherosclerotic lesion formation. For this reason, the importance of devising individualized treatment plans when counseling patients cannot be overstated.

Primary Risk Factors

Nonmodifiable Risk Factors

Age Major prospective epidemiological investigations have provided strong evidence that the risk of developing atherosclerosis is increased with advancing age. These observations are consistent with what is known about the etiology of atherosclerotic lesions and the latency period between the appearance of fatty lesions and development of complicated plaque. In developed countries atherosclerosis

Table 2 Risk factors

Positive risk factors
Age
Male $\geq$ 45 years
Female $\geq$ 55 years or premature menopause without estrogen replacement therapy
Family history of premature coronary heart disease
Myocardial infarction or sudden death before 55 years or 65 years of age in parent or first-degree relative, male or female, respectively
Current cigarette smoking
Hypertension
Blood pressure $\geq$ 140/90 mmHg (should be confirmed) or taking antihypertension medication
Low high-density lipoprotein (HDL) cholesterol ($<$ 40 mg dl^{-1} (1.0 m mol l^{-1}))
Diabetes mellitus
Negative risk factor (subtract one positive risk factor)
High HDL cholesterol ($\geq$ 60 mg dl^{-1} (1.6 $mmol^{-1}$))

becomes the leading cause of death in males during the fourth decade of life and in females during the sixth decade of life. Males above the age of 45 years and females above the age of 55 years (or premature menopause without estrogen replacement therapy) are considered to be a positive risk factor.

Family history of premature coronary heart disease (genetics) Early studies have identified a trend towards familial aggregation of atherosclerosis among the relatives of individuals with established disease compared to those without disease. Similarly, studies of monozygotic and dizygotic twins provide supportive evidence for the heritability of atherosclerosis through comparisons of concordance rates of clinical events. Offspring of patients with a premature myocardial infarction have been reported to have higher circulating cholesterol levels than age-matched offspring of patients without a premature myocardial infarction. Familial combined hyperlipidemia is one of the major genetic causes of atherosclerosis within families. Numerous genetic mutations associated with different risks of developing atherosclerosis have been identified. As the methodology for screening advances, a greater understanding of how individual mutations alter the clinical progression of this multifactorial disease will emerge.

Modifiable Risk Factors

Elevated LDL cholesterol levels Elevated LDL cholesterol levels are currently considered to be the primary risk factor for the development of atherosclerosis. LDL levels below 2.57 mmol l^{-1} are classified as desirable, 2.58–3.34 mmol l^{-1} are classified in the near or above optimal, 2.35–4.41 mmol l^{-1} are classified in the borderline high, 4.12–4.89 mmol l^{-1} are classified in the high and above 4.91 mmol l^{-1} are classified as very high (Table 3). There are three categories of risk that determine LDL cholesterol lowing goals (Table 4). Risk category is determined on the basis on the presence of existing coronary heart disease (CHD) and CHD risk equivalents (other clinical forms of atherosclerotic disease such as peripheral arterial disease, abdominal aortic aneurysm, and symptomatic carotid artery disease; diabetes; or multiple risk factors that confer a 10-year risk for CHD > 20%) or the number risk factors (Table 2). Ten-year risk for CHD can be estimated using the criteria presented in Table 5. The higher the estimated risk for CHD the lower the LDL cholesterol goals. Cross-cultural comparisons have clearly identified a positive relationship between LDL cholesterol levels and the incidence of atherosclerosis. Similar observations have been made within populations. Migration studies which have resulted in elevations in LDL cholesterol levels, presumably due to environmental factors (diet and lifestyle), have supported these observations. Primary prevention trials resulting in decreased LDL cholesterol levels have led to reduced rates of atherosclerosis. More recent interest has centered on the potential for regression of atherosclerotic lesions by nonpharmacological means. Efforts in this area have been hampered by the lack of a safe, noninvasive, inexpensive, and accurate measure of atherosclerotic plaque. The primary nonpharmacological approach to reducing LDL cholesterol levels is to limit saturated fat, *trans* fatty acids, and cholesterol, increased physical activity, and maintain a healthy body weight. The goals for lowering LDL cholesterol levels as established by the National Cholesterol Education Program are shown in Table 5.

Table 3 Classification on the basis of total and LDL cholesterol levels

Total cholesterol;		
≤200 mg/dl	(≤ 5.2 mmol/L)	Desirable
201–239 mg/dl	(5.2–6.2 mmol/L)	Borderline–high
≥240 mg/dl	(≥6.2 mmol/L)	High
LDL cholesterol;		
< 100 mg/dl	(< 2.57 mmol/L)	Optimal
100–129 mg/dl	(2.58–3.34 mmol/L)	Near or above optimal
130–159 mg/dl	(2.35–4.11 mmol/L)	Borderline high
160–189 mg/dl	(4.12–4.89 mmol/L)	High
≥190 mg/dl	(4.91 mmol/L)	Very high

Current cigarette smoking A dose-dependent relationship has been observed between cigarette smoking and atherosclerotic events. The cessation of cigarette smoking is associated with a precipitous drop in the risk of a clinical event. This observation suggests that cigarette smoking, *per se*, may act as a triggering agent that results in a series of reactions culminating in an atherosclerotic event. Physiological responses associated with cigarette smoking include undesirable effects on platelet adhesiveness and clotting factors, increased heart rate, catecholamine levels, and myocardial oxygen demand, and decreased oxygen-carrying capacity of the blood. Similar effects of pipe and cigar smoking are not normally observed.

Table 4 Categories of risk and LDL cholesterol goal

Category	*LDL Goal*
CHD and CHD risk equivalents	< 2.59 mmol/L
Multiple (2 or more) risk factors	< 3.36 mmol/L
0–1 risk factors	< 4.14 mmol/L

Hypertension Elevated levels of both systolic and diastolic blood pressure (blood pressure $\geq 140/90$ mmHg) are associated with increased risk of developing atherosclerosis. The relationship appears to be linear. Recent evidence has confirmed that sodium restriction is an efficacious dietary approach to reducing blood pressure. In addition, compared to more conventional dietary patterns of developed countries, diets high in fruits, vegetables, and low-fat dairy products have also recently been demonstrated to result in lower blood pressures in both normotensive and hypertensive subjects.

Low HDL Cholesterol Levels HDL cholesterol levels are inversely correlated with the risk of developing atherosclerosis. HDL particles are involved in the process of reverse cholesterol transport, the only means by which cholesterol in peripheral tissues can be transported to the liver for metabolism and excretion from the body. Low HDL cholesterol levels ($< 1.03\,\text{mmol}\,\text{l}^{-1}$) are a risk factor for the development of atherosclerosis. High HDL cholesterol levels ($> 1.6\,\text{mmol}\,\text{l}^{-1}$) have been designated a negative risk factor (to be subtracted from the total number of risk factors when ascertaining an individual's risk profile) (Table 2). It is more difficult to raise HDL cholesterol levels than lower LDL cholesterol levels with nonpharmacological intervention. Common approaches are increased exercise, cessation of smoking, weight loss, and moderate alcohol intake. The magnitude of each intervention varies between individuals.

Diabetes mellitus Atherosclerosis is the most common cause of death in diabetic patients. Individuals with diabetes frequently have what is commonly referred to as an atherogenic lipoprotein profile: low HDL cholesterol levels and elevated triglyceride levels. In addition, insulin resistance, hyperinsulinemia, and glucose intolerance have been found to be atherogenic. Some evidence suggests that the increased risk of developing atherosclerosis observed in diabetic patients is contributed to by both the adverse lipoprotein profile and hyperinsulinemia itself. Adult-onset diabetic patients (type II) frequently present with a combination of obesity, adverse lipoprotein profile, and elevated blood pressure. This combination is frequently termed the 'insulin resistance syndrome' and is strongly associated with increased risk of developing atherosclerosis. Weight loss, in addition to the other dietary and lifestyle approaches to decreasing atherosclerosis risk, is among the most efficacious modalities of treating these patients.

Secondary Risk Factors

Certain risk factors are informally referred to as secondary risk factors, either because they are thought to be a consequence of a primary risk factor or due to insufficient evidence to classify them as a primary risk factor at the current time. The following gives details of some of these. As new data are accumulated, some may in the future shift from one category to another.

Obesity

Increased body weight for height is associated with various primary risk factors for atherosclerosis. These include hypertension, elevated LDL cholesterol levels, and low HDL cholesterol levels. Additionally, central or abdominal obesity is more strongly related to increased risk of developing atherosclerosis than overweight alone. When treating overweight patients cessation of weight gain should be the first goal and then a slow gradual approach to weight loss that combines energy restriction with increased energy output should be the second goal. Emphasis should be on permanent lifelong changes rather than drastic approaches.

Physical Inactivity

Physical inactivity has been associated with increased risk of developing atherosclerosis. It is difficult to determine whether physical fitness itself is the determining factor or whether individuals who habitually have low levels of physical activity also have a greater number of risk factors for atherosclerosis (i.e., obesity, hypertension, insulin resistance) that contribute to the clinical outcome. Regardless of the relationship, increased levels of physical activity should be encouraged. Currently, a number of health organizations are emphasizing the importance of maintaining a physically active lifestyle throughout the life cycle as a means of decreasing the risk of developing atherosclerosis and other degenerative diseases.

Elevated Homocysteine Levels

Homocysteine is a metabolite of methionine, an essential amino acid. Elevated homocysteine levels have been associated with an increased incidence of atherosclerosis. High levels of homocysteine can result from deficiencies in folic acid and vitamins B_6 and B_{12}. Since 1998 the USA has mandated that folic acid be added to all grain products. As a result there has been a secular decrease in homocysteine levels. There are ongoing studies to determine whether the decline in homocysteine levels due to folic acid supplementation or fortification will result in decreased rates of vascular disease.

Lp(a)

Lp(a) is a lipoprotein particle formed by the addition of a carbohydrate-rich protein (apolipoprotein; apo(a)) via a disulfide bond to apo B-100 on an LDL particle. High levels of Lp(a) are associated with an increased risk of developing atherosclerosis. There is a high degree of homology between Lp(a) and plasminogen. Plasminogen is converted to plasmin in plasma. Plasmin functions by dissolving blood clots. It has been hypothesized that high levels of Lp(a) compete with plasminogen, counteracting the fibrinolytic system, and increasing the risk of thrombosis. Whether Lp(a) levels are an independent risk factor for atherosclerosis have yet to be determined. Lp(a) levels are, for the most part, determined by genetics. Although dietary modification, hormone replacement therapy, and some lipids-lowering medications have been reported to alter Lp(a) levels, the changes tend to be small and, although statistically significant, may not be of a great enough magnitude to have a physiologically significant effect. More work in this area is likely to emerge in the near future.

Inflammation

Recent interest has centered on markers of inflammatory response, such as C-reactive protein and the risk of developing atherosclerosis. Epidemiological studies have noted an association between C-reactive protein and risk of an atherosclerotic event in apparently healthy males and those with a history of a prior event. Again, at this point it is premature to designate C-reactive protein as a primary risk factor for atherosclerosis. However, the results of future work will likely cause the issue to be revisited.

Dietary Modification to Decrease Risk of Developing Atherosclerosis

Diet

Current recommendations (individuals over the age of 2 years) to decrease the risk of developing atherosclerosis are to limit fat intake to 25–35 of energy, saturated fat to < 7% of energy, and cholesterol to less than 200 mg day^{-1}. This diet is termed a therapeutic lifestyle change (TLC) diet. Additional lifestyle recommendations include maintenance of body weight and regular physical activity. Table 6 includes the commonly occurring fatty acids, in both the body and food.

Saturated fatty acids Early evidence has clearly demonstrated that the consumption of foods relatively high in saturated fatty acids increases serum total cholesterol levels and that not all saturated fatty acids behave in the same way. Relatively short-chain fatty acids (C6:0 to C10:0) and stearic acid (C18:0) produce little or no change in serum cholesterol levels. Saturated fatty acids with chain lengths of C14:0, C16:0, and possibly C12:0 appear to be the most potent in increasing serum lipid levels. It has been postulated that stearic acid (18:0) is rapidly converted to oleic acid (18:1) and for this reason has a relatively neutral effect on plasma lipid levels. Subsequent work has further refined what is known about the hypercholesterolemia effect of saturated fatty acids. Dietary saturated fatty acids result in an increase in both LDL cholesterol and HDL cholesterol levels with little or no effect on triglyceride levels.

Table 6 Common fatty acids

Code	*Common name*	*Formula*
Saturated		
12:0	Lauric acid	$CH_3(CH_2)_{10}COOH$
14:0	Myristic acid	$CH_3(CH_2)_{12}COOH$
16:0	Palmitic acid	$CH_3(CH_2)_{14}COOH$
18:0	Stearic acid	$CH_3(CH_2)_{16}COOH$
Monounsaturated		
16:1*n*-7 *cis*	Palmitoleic acid	$CH_3(CH_2)_5CH{=}(c)CH(CH_2)_7COOH$
18:1*n*-9 *cis*	Oleic acid	$CH_3(CH_2)_7CH{=}(c)CH(CH_2)_7COOH$
18:1*n*-9 *trans*	Elaidic acid	$CH_3(CH_2)_7CH{=}(t)CH(CH_2)_7COOH$
Polyunsaturated		
18:2*n*-6,9 all *cis*	Linoleic acid	$CH_3(CH_2)_4CH{=}(c)CHCH_2CH{=}(c)CH(CH_2)_7COOH$
18:3*n*-3,6,9 all *cis*	α-linolenic acid	$CH_3CH_2CH{=}(c)CHCH_2CH{=}(c)CHCH_2CH{=}(c)CH(CH_2)_7COOH$
18:3*n*-6,9,12 all *cis*	γ-linolenic acid	$CH_3(CH_2)_4CH{=}(c)CHCH_2CH{=}(c)CHCH_2CH{=}(c)CH(CH_2)_4COOH$
20:4*n*-6,9,12,15 all *cis*	Arachidonic acid	$CH_3(CH_2)_4CH{=}(c)CHCH_2CH{=}(c)CHCH_2CH{=}(c)CHCH_2CH{=}(c)CH(CH_2)_3COOH$
20:5*n*-3,6,9,12,15 all *cis*	Eicosapentaenoic acid	$CH_3(CH_2CH{=}(c)CH)_5(CH_2)_3COOH$
22:6*n*-3,6,9,12,15,18 all *cis*	Docosahexaenoic acid	$CH_3(CH_2CH{=}(c)CH)_6(CH_2)_2COOH$

c, *cis*; t, *trans*.

Foods relatively high in saturated fatty acids include meat and full-fat dairy products. Saturated fatty acids tend to be solid at room temperature. The notable exceptions are the tropical oils; palm, palm kernel, and coconut. Efforts to reduce saturated fatty acid intake should include use of lean meat, trimming of excess fat or the skin of poultry, and the substitution of fat-free or low-fat dairy products for their full-fat counterparts. Judicious use of ingredient listings and nutrient labels on processed foods will help individuals achieve the goal of reducing the saturated fatty acid content of their diet.

Omega-3 (n-3) polyunsaturated fatty acids Reports of low rates of atherosclerosis in Greenland Eskimos and the inverse relationship between fish consumption and mortality from atherosclerosis raised interest in oils derived from fish and marine mammals. These oils, high in polyunsaturated fatty acids, are distinguished from other oils high in polyunsaturated fatty acids, such as vegetable oils, by the presence of *n*-3 fatty acids. As a class, *n*-3 fatty acids are defined as having a double bond at the third carbon from the methyl end of the acyl chain. In contrast, the more common *n*-6 fatty acids are defined as having a double bond at the sixth carbon from the methyl end of the acyl chain. Potential mechanisms of *n*-3 fatty acids in decreasing risk of developing atherosclerosis include decreased postprandial triglyceride levels, reduced risk of arrhythmic events, decreased blood pressure, altered endothelial function, and release of cytokines and other inflammatory mediators. The relative importance of each of these factors to the epidemiological observation of an inverse relationship of atherosclerosis incidence and fish or *n*-3 fatty acid intake has yet to be determined. The major dietary *n*-3 fatty acids from plant sources is alpha-linolenic acid (18:3*n*-3) and from marine sources are eicosapentaenoic acid (20:5*n*-3), and docosahexaenoic acid (22:6*n*-3) (Table 6). The different physiological effects of each is under active investigation at this time.

***Trans* fatty acids** *Trans* fatty acids are fatty acids that contain at least one double bond in the *trans* configuration. Dietary *trans* fatty acids occur naturally in meat and dairy products as a result of anaerobic bacterial fermentation in ruminant animals. *Trans* fatty acids are also created when liquid vegetable or fish oil is hydrogenated; this is frequently done to increase their plasticity and chemical stability for subsequent food processing. *Trans* fatty acids raise LDL cholesterol levels, similarly to saturated fatty acids. However, *trans* fatty acids do not raise HDL cholesterol levels, as do saturated fatty acids. For this reason there is concern that dietary *trans* fatty acids are worse than saturated fatty acids. Additionally, some literature suggests that *trans* fatty acids may increase Lp(a) levels. Over the past decade it appears that as a result of changes made by industry the intake of *trans* fatty acids is decreasing. Due to the considerably higher intake of saturated than *trans* fatty acids it still seems prudent to maintain emphasis on reducing saturated fat intake.

Dietary cholesterol In humans there is a positive correlation between dietary cholesterol intake, and both serum cholesterol levels and risk of developing atherosclerosis. Interpretation of the dietary cholesterol literature is complicated by the large degree of variation among studies and the tendency for responsiveness to vary over a wider range than other dietary variables. Nonetheless, the majority of evidence supports the premise that increased dietary cholesterol intake results in increased LDL cholesterol levels. The major sources of dietary cholesterol are eggs, meat, and dairy products. Since dietary cholesterol is frequently found in foods which are also relatively high in saturated fatty acids, reducing the saturated fatty acid intake should also result in a reduction in the cholesterol content of the diet.

Soluble fiber Dietary soluble fiber has been reported to have a modest hypocholesterolemic effect. A major contributor to this outcome is the β-glucan fraction of the soluble fiber. A variety of mechanisms have been proposed for the cholesterol-lowering effect, most likely relating to decreased absorption of cholesterol. There is no evidence that insoluble fiber has an effect on plasma lipid levels.

Dietary pattern It can be difficult for individuals, however well intended, to modify their diet to meet certain dietary goals, for example, to consume < 7% of energy as saturated fat. However, with the exception of high-risk individuals who need more individualized instruction provided by a qualified professional, the general recommendation to consume a diet high in fruits, vegetables, and whole grain which also includes nonfat or low-fat dairy products, fish, poultry, and lean meat is consistent with the more technical recommendations and should be consistently encouraged on a population-wide basis. Additionally, it is important to couple such dietary recommendations with a prescription that further encourages a pattern of regular activity, through the life cycle, that matches levels of physical activity to energy intake with the expressed intent of avoiding overweight or obesity.

Summary

Atherosclerosis is a disorder of blood vessels characterized by a thickening of the arterial wall. This process frequently leads to partial or total occlusion of the vessel to blood flow. The location of the impeded or blocked blood flow determines the clinical consequence of the disorder. A major contributing factor to the development of atherosclerotic lesions is elevated LDL cholesterol levels, followed by other risk factors. The primary risk factors include advanced age, family history of premature atherosclerosis, current cigarette smoking, hypertension, lower HDL cholesterol levels (high HDL cholesterol levels are classified as a negative risk factor), and diabetes mellitus. Sometimes referred to as secondary risk factors, either because they are thought to be a consequence of a primary risk factor or due to lack of sufficient evidence to classify them as a primary risk factor at the time, are obesity, physical inactivity, elevated homocysteine levels, elevated Lp(a) levels, and elevated inflammation markers. With the intent of lowering LDL cholesterol levels, the major dietary interventions are decreased saturated fat, cholesterol, and *trans* fatty acid intakes, and increased *n*-3 fatty acid intakes and soluble fiber. These changes from the current diet of developed countries can best be achieved by encouraging the consumption of a diet high in fruits, vegetables, and whole grain which also includes nonfat or low-fat dairy products, fish, poultry, and lean meat. Additionally, these recommendations should be coupled with a pattern of regular activity that is matched to energy intake to avoid overweight or obesity.

AVOCADOS

A K Cowan, Stockholm, Sweden
B N Wolstenholme, University of Natal, Scottsville, South Africa

Background

The fruit of the avocado is regarded as one of the most nutrient-dense fruits available. Although its high oil content has been mistakenly thought of as a disadvantage, closer scrutiny of the nutritional facts reveals that avocado eaten in moderation does not contribute to weight gain, contains large quantities of the desirable unsaturated and monounsaturated fatty acids, and is rich in fiber, protein, vitamins, antioxidants, and minerals. This nutrient-rich fruit is therefore without rival and, in many respects, a veritable fruit of paradise.

In this chapter, brief descriptions of avocado production, emphasizing the 'subtropical' ecotype, and processing are provided. These are followed by an account of the nutritional status of avocado as a food source. Data on nutrient, fat, vitamin, antioxidant, mineral, and sugar content and composition are supplied and are synthesized based on minimum and maximum values published in the literature. The nutritional benefit of a diet containing avocado is also discussed. Reference is also made to the major allergen in avocado that is relevant in the 'latex-fruit syndrome' that affects latex-allergic individuals.

Avocado Fruit Production

History, Cultivation, and Fruit Growth

Avocado originated in central America, and the fruit has been consumed as part of the diet by the indigenous peoples of that region for more than 5000 years. The word 'avocado' derives from a corruption of the Spanish words 'ahuacate' or 'aguacate,' which are adaptations of the Aztec 'ahuacatl.' The fruit of the first vegetatively propogated cultivar 'Fuerte' is pear-shaped, and this characteristic probably resulted in the inappropriate colloquialism, 'avocado pear.' However, the horticulturally and agriculturally correct term for the fruit is simply avocado.

The botanical name for avocado is *Persea americana* Mill., and three ecological races (today regarded as botanical varieties or subspecies) are recognized; *Persea americana* var. *drymifolia* (Mexican ecotype), *Persea americana* var. *guatemalensis* (Guatemalan ecotype), and *Persea americana* var. *americana* (West Indian ecotype). Fruits of the West Indian ecotype are usually large with a thick peel and have a low oil content (< 8%) and higher water and sugar content. Trees of the Mexican ecotype yield fruit with a high oil content (up to 30%). Those of the Guatemalan ecotype are recognized as having the most horticulturally desirable traits, have an intermediate oil content, and are characterized by a 'nutty' flavor. Amongst the most important commercial cultivars of the 'subtropical' avocado are 'Hass,' 'Fuerte,' 'Ettinger,' and 'Pinkerton,' which, are all chance seedlings with superior fruit quality. Several countries have extensive selection and breeding programs which are starting to produce fruit of improved quality. 'Hass' is the most sought after subtropical cultivar, having almost eclipsed 'Fuerte' in California, and forms the basis of the subtropical avocado export industry to Europe.

The Mexican and Guatemalanm ecotypes, whose progeny today form the basis of the technologically advanced 'subtropical' avocado industries, are indigenous to subtropical and tropical highland climates. So-called 'West Indian' avocados are lowland tropical in origin. Mexico (by far the largest producer), California, Israel, Spain, Chile, South Africa, and Australasia all have industries based on Guatemalan and Guatemalan × Mexican hybrid cultivars. However, virtually all subtropical countries grow avocados to some extent. Large crops of 'West Indian' and 'West Indian' × Guatemalan hybrid avocados are also produced in tropical countries, from less technologically advanced industries. Tropical avocado industries, with the conspicuous exception of Florida, USA, are usually based on seedling (not grafted) trees. The fruits, although making a substantial contribution to the diets of mostly poor, tropical lowland peoples, are horticulturally and nutritionally inferior to the selected subtropical cultivars.

The avocado tree is evergreen and flowers in early spring, and fruitlets are usually visible by late spring/early summer. Typically, careful and correct orchard management practise is required to ensure production of quality fruit. Amongst the most important ecophysiological factors that affect fruit production are irradiance, temperature, water stress, and salinity. Botanically, the fruit of the avocado is described as a berry. Fruit growth continues for anything from 20 to 60 weeks, depending on the cultivar, environment, and cultural practice, and the fruit is harvested when horticulturally mature as it does not ripen on the tree. Harvested fruit are washed, graded, often

waxed, and packed in cartons typically holding 4–6 kg of uniform fruit. European markets prefer the individual fruit weight to be in the range of 200–350 g, for which higher prices are paid. It is now known that the final fruit size of avocado is the result of the number of cell divisions during flower set and fruit growth and that cell division is dependent on isoprenoid biosynthesis, carbohydrate metabolism, and maintenance of plant hormone homeostasis. Zinc, boron, magnesium, and calcium are considered important elements in the production of quality fruit. Nitrogen is a 'manipulator element' used to control tree vigor, and must be appropriately managed as excessive tree vigor is counterproductive to good fruit quality.

Maturity

Oil content and/or dry matter of the fleshy mesocarp, which surrounds the single large seed, is used by most producers to determine harvestable maturity and consumer acceptability. For the cultivar 'Fuerte,' a minimum oil content of 8% (dry mass) was applied in California for many years, but today, this has been replaced by a minimum dry matter standard of *c*. 21%, depending on the cultivar and region. This is based on the percentage moisture (determined using a microwave oven), which is an indirect measure of oil content based on the cultivar-specific constant of the sum of percentage moisture and percentage oil. By 1983, percentage dry matter (or its reciprocal, percentage moisture) had become standard for the determination of avocado fruit maturity and is now used worldwide.

Ripening

Avocado fruit are classified as climacteric (i.e., fruit that can be harvested unripe and then undergo normal ripening). Although detachment of the fruit is not a prerequisite for ripening of most climacteric fruit, avocado fruit do not ripen while attached to the tree. Postharvest, the fruit ripen within 5–10 days at temperatures between 15 and 24 °C. Both ripening and fruit softening are delayed by precooling the fruit immediately after harvest to 5–6 °C, and this strategy is used by most producers to maintain fruit quality during transport/export of fruit. A return to ambient temperature after a period of cold storage sees the acceleration of the ripening process. Ripening in avocado can also be stimulated by exposure to the plant hormone, ethylene.

During ripening, the fruit undergoes marked changes in a variety of biochemical processes. These include an increase in respiration (i.e., consumption of oxygen and release of carbon dioxide), increased ethylene production, changes in texture (i.e., fruit softening), and the production of volatiles such as β-caryophyllene (28% of total volatiles), α-copaene (11%), α/β-cubebene (8%), α-farnesene (6%), decanal (6%), and heptanal (3%), which impart flavor. The substrate for respiration in avocado appears to be carbohydrate and not oil. However, some degradation of oils does take place. An increase in ethylene biosynthesis is typical of climacteric fruits such as avocado, and the maximum ethylene production usually coincides with the maximum respiration rate (amount of carbon dioxide released). Cold storage reduces this climacteric rise in respiration.

Fruit softening is a consequence of changes in cell-wall metabolism resulting from alterations in cellulase (EC 3.2.1.4), polygalacturonase (EC 3.2.1.15) and pectinesterase (EC 3.1.1.11) activities. In some varieties (e.g., 'Hass'), the color of the peel changes from green to purple/black owing to the accumulation of anthocyanin pigments. Other changes include a slight increase in the concentration of glucose and fructose in the fruit flesh.

Processing of Avocado

Avocado is usually consumed fresh in salads, as a savory dish, as a sandwich filling, as guacamole, or sweetened as a dessert. It was the extraction of oils from avocado and the production of guacamole that really started avocado processing. Apparently, the production of guacamole on a commercial scale was started as long ago as 1964 in California, and by 1981, 6000 tonnes of fresh avocado was being processed annually.

For processing, the preferred cultivar is 'Hass' because of its superior flavor, mesocarp color, 'keeping' quality, and year-round availability. Fruit with a 25% dry matter content (or 13% oil) are considered ideal for processing. Avocado flesh is also marketed frozen, processed into a sauce, dehydrated to a powder, and extracted for its oil.

Guacamole, Avocado Sauce, and Oil

Before processing can take place, fruit are uniformly ripened at 22 °C in the presence of ethylene gas for 2–5 days. When the fruit are soft, they are cooled to 5 °C and surface-sterilized in 200 mg of hypochlorite per liter. After removal of the stems (pedicels) and seed, the pulp (mesocarp) is mechanically separated from the peel. The pulp is then mixed with the ingredients (usually includes lime or lemon juice, salt, and salsa or Picante) to yield a uniform textured guacamole. The guacamole is then placed in containers and stored frozen.

The process for the production of avocado sauce is similar to that used for the preparation of guacamole up to pulp extraction. For sauce, the pulp is sheared in a high-speed blender with water, emulsifiers, and spices. Sauces are usually packaged in polyethylene containers and then stored frozen.

Dehydration of avocado is either by spray- or drum-drying in much the same way as for the preparation of milk powder, but the product is less attractive than that of sugar-storing fruits.

Oil is extracted from avocado with organic solvents, hydraulically (pressing), or by centrifugation. The last method is more desirable as the product is free from solvent residue. Nevertheless, solvent extraction enables the extraction of various fractions, some of which are used in the pharmaceutical industry. For example, avocado unsaponifiables (including hydrocarbons, tocopherols, triterpenes, sterols, and other unidentified compounds), which seem to be beneficial in the treatment of periodontal and osteoarticular diseases, function by stimulating deposition of repair material in affected areas by enhancing transforming growth factor β (TGF β) in articular cartilage. Avocado oil is also used in cosmetic preparations such as skin moisturizers and body lotions.

Nutritional Status

Avocado is considered a nutritious fruit and contains higher quantities of soluble and insoluble fiber and protein than many other fleshy fruits. Avocado is also a rich source of potassium and the vitamins E and C, and β-carotene (provitamin A). Although low, a vitamin A value of 150 μg RE (retinol equivalents) per kilogram has been reported. Furthermore, the monounsaturated fatty acids in avocado effectively reduce blood levels of the undesirable low-density lipoprotein (LDL, cholesterol) while increasing levels of the beneficial, high-density lipoprotein (HDL). (*See* **Cholesterol**: Factors Determining Blood Cholesterol Levels; **Vitamins**: Overview.)

Nutrient Composition/density

Unlike foods that are described as providing 'empty calories,' the avocado is a nutrition-rich 'protective' fruit. The energy content per 100-g serving has been estimated at 800 kJ, depending on the cultivar and growing conditions. A detailed analysis of the composition of avocado mesocarp (the edible portion of the fruit) of a typical subtropical cultivar has revealed a nutritional status, which is summarized in Figure 1.

Avocado contains approximately 2.3% protein on a fresh-weight basis, which is between two and 10 times that of most other fleshy fruits and vegetables analyzed. Although avocado contains all of the essential amino acids (i.e., it is 'complete'), it is not generally regarded as nutrient-dense for protien, certainly not in comparison to meat or eggs, for example. A mixture of soluble and insoluble fiber is ideal in the diet, and avocado contains appreciable quantities of both (2.1 and 2.7%, respectively).

In avocado, the sum of percentage water plus percentage oil is constant in the range 88–91%, and for each gram of water lost, there is a 1 g increase in oil, in fruit containing between 8 and 22% oil. Changes in oil content are also associated with changes in fiber and protein. Therefore, the energy value of avocado is almost entirely due to its oil content, and any variation is due solely to changes in the percentage oil. It is probably this observation that led to the mistaken idea that consuming avocado increases body mass. On the contrary, addition of avocado to the diet has been shown to cause a small but significant average weight loss. One possible explanation is that avocado speeds up the basal metabolic rate in humans. Another hypothesis relates to the type of oil, and avocado is rich in the beneficial monounsaturated fatty acids.

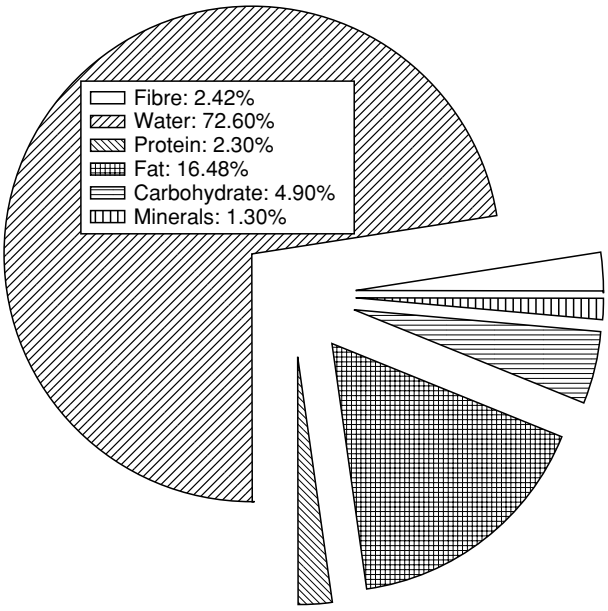

Figure 1 Nutrient content and composition of subtropical fruit flesh. Data are the average between the minimum and maximum values reported by Ahmed EM and Barmore CD (1980) Avocado. In: Nagy S and Shaw PE (eds) *Tropical and Subtropical Fruits: Composition, Properties and Uses*, pp. 121–156. Westport, CT: AVI; Seymour GB and Tucker GA (1993) Avocado. In: Seymour GB, Taylor JE and Tucker GA (eds), *Biochemistry of Fruit Ripening*, pp.53–81. London: Chapman & Hall; Slater GG, Shankman S, Shepherd JS and Alfin-Slater RB (1975) Seasonal variation in the composition of Californian avocado. *Journal of Agricultural and Food Chemistry* 23: 468–474, and references cited therein.

The fatty acid content and composition of avocado have been iterated in most texts on the physiology and biochemistry of fruit growth and ripening. Avocado lipids can be divided into the following fractions: (1) neutral lipids (tri-, di-, and monoacylglycerols), (2) phospholipids, (3) glycolipids, and (4) free fatty acids. The neutral lipid fraction constitutes 96% of the total lipid content of avocado, and the majority are triglycerols. The major triglycerols identified in avocado are dioleyl palmitin, triolein, dioleypalmitolein, linoleyl oleyl palmitin, and linoleyl diolein. Within each of these triglycerols, 18:1, 18:2, 16:0, and 16:1 are the major fatty acids present, and the relative concentration (percentage of total lipid) of each is in the range 59–81% (18:1), 7–14% (18:2), 7–22% (16:0), and 3–11% (16:1). These values are comparable with those for olive oil, making avocado which is easily digested, an ideal substitute for olive oil in cooking, and in the preparation of salad dressings, although it is currently more expensive.

Unsaturated fats are either mono- or polyunsaturated, and the ratio of polyunsaturated fatty acids to saturated fatty acids (P/S), which is used as an indicator of nutritional value by nutritionists, is about 0.74 for avocado. A diet high in polyunsaturated fatty acids reduces the level of the undesirable LDL, whereas a high dietary level of monounsaturated fatty acids also maintains levels of the desirable HDL. Thus, it should not be surprising that results from trials in which the monounsaturate-rich avocado was used as a dietary component revealed a significant decline in total cholesterol with preservation of the HDL level. Likewise, substituting avocado for butter, margarine, and cheese significantly reduced blood cholesterol levels, and increased HDL up to 16%. Accordingly, avocados have gained acceptance by the Heart Foundations of several countries, and can even be prescribed for convalescent heart patients.

Fat- and Water-soluble Vitamins, and Antioxidants

The vitamin content and composition of avocado are shown in Table 1. Although vitamin D has been identified in avocado, no values have been published. It has been reported, however, that the vitamin D content of avocado is higher than that of butter and eggs. Vitamins C and E and provitamin A (β-carotene) are believed to function as antioxidants and protect against damage from oxygen 'free radicals.' Although oxygen is essential to life processes, it is also damaging if converted to reactive oxygen species (e.g., the superoxide anion or the hydroxyl radical), which can cause cell mutation and contribute to aging, cancers, arthritis, and heart disease. The three antioxidant vitamins are effective at disarming these reactive oxygen species, and it has been stated that for each of the three, and for any given daily kJ proportion, the avocado provides about twice the proportion of this nutrient.

Table 1 Vitamin content and composition of avocado fruit flesh

Component (per 100 g fresh weight)	*Concentration range*[a]
β-Carotene (provitamin A) (IU)	370–750
α-Tocopherol (vitamin E) (IU)	1.6–2.4
Ascorbic acid (vitamin C) (mg)	1.6–30.0
Biotin (μg)	3.2–10.0
Choline (mg)	17–22
Folacin (μg)	30–62
Niacin (mg)	1.4–3.5
Pantothenic acid (mg)	0.25–1.14
Pyridoxine (vitamin B_6) (mg)	0.22–0.62
Riboflavin (vitamin B_2) (μg)	95–230
Thiamine–HCl (vitamin B_1) (μg)	60–240
Phytyl menaquinone (vitamin K) (μg)	0–8
Calciferols (vitamin D)	Unknown

[a]Concentration is dependent on the cultivar and stage of ripening. Values were derived from data published by Ahmed EM and Barmore CD (1980) Avocado. In: Nagy S and Shaw PE (eds) *Tropical and Subtropical Fruits: Composition, Properties and Uses*, pp. 121–156. Westport, CT: AVI; Seymour GB and Tucker GA (1993) Avocado. In: Seymour GB, Taylor JE and Tucker GA (eds), *Biochemistry of Fruit Ripening*, pp. 53–81. London: Chapman & Hall; Slater GG, Shankman S, Shepherd JS and Alfin-Slater RB (1975) Seasonal variation in the composition of Californian avocado. *Journal of Agricultural and Food Chemistry* 23: 468–474, and references cited therein.

In addition to the antioxidant vitamins, 2(R)-(12Z, 15Z)-2-hydroxy-4-oxoheneicosa-12,15-dien-1-yl acetate and persenone A and persenone B have been isolated from avocado mesocarp as inhibitors of superoxide and nitric oxide generation. These compounds do not scavenge reactive oxygen species (like the vitamins) but rather suppress free-radical generation and may therefore be effective chemopreventive agents in inflammation associated carcinogenesis. Thus, the consumption of avocado may be one way of ingesting more of the antioxidants that help to protect against cancers, heart disease, and aging.

Mineral Composition

The mineral content and composition of avocado are presented in Table 2. As shown, avocado is a rich source of potassium, which is purported to protect against the risk of strokes in humans and reduces the incidence of strokes by up to 40%. One of the confounding factors in the cause of strokes is increased blood pressure, which has been associated with a high intake of sodium. The avocado is as low in sodium as it is high in potassium. (*See* **Minerals – Dietary Importance**.)

Phosphorus, calcium, and magnesium are abundant minerals in avocado. Most other minerals, including iron, occur in amounts of less than 1 mg per gram fresh weight of edible fruit.

Table 2 Mineral content and composition of avocado fruit flesh

Mineral (mg per 100 g fresh weight)	*Concentration range*[a]
Potassium	340–723
Magnesium	40–60
Phosphorus	20–80
Calcium	10–15
Sodium	5–15
Iron	0.5–2
Boron	1–3

[a]Concentration is dependent on the soil type, cultivar, and cultural practice. Values were derived from data published by Ahmed EM and Barmore CD (1980) Avocado. In: Nagy S and Shaw PE (eds) *Tropical and Subtropical Fruits: Composition, Properties and Uses*, pp. 121–156. Westport, CT: AVI; Slater GG, Shankman S, Shepherd JS and Alfin-Slater RB (1975) Seasonal variation in the composition of Californian avocado. *Journal of Agricultural and Food Chemistry* 23: 468–474, and references cited therein.

Table 3 Sugar content and composition of ripe avocado fruit flesh

Sugar (mg per 100 g fresh weight)	*Concentration range*[a]
Glucose	0.14–1.28
Fructose	0.08–0.65
D-*Manno*-heptulose	0–3.82
Perseitol	0–2.06

[a]Concentration is dependent on the cultivar and stage of ripening. Values were derived from data published by Liu X, Robinson PW, Madore MA, Witney GA and Arpaia ML (1999) 'Hass' avocado carbohydrate fluctuations. II. Fruit growth and ripening. *Journal of the American Society of Horticultural Science* 124: 676–681; Seymour GB and Tucker GA (1993) Avocado. In: Seymour GB, Taylor JE and Tucker GA (eds), *Biochemistry of Fruit Ripening*, pp. 53–81. London: Chapman & Hall, and references cited therein.

Carbohydrates

During avocado fruit ripening, there is an increase in the concentration of glucose and fructose. In addition to these monosaccharides, avocado also contains several unusual sugars including the seven-carbon sugar alcohol, perseitol, and its reduced form, D-*manno*-heptulose. The sugar content and composition of avocado are given in Table 3. (*See* **Carbohydrates**: Classification and Properties.)

Studies in the 1940s indicated that ingestion of avocado could lead to the presence of sugar in urine. It was later discovered that *manno*-heptulose, the major reducing sugar in avocado, could induce hyperglycemia when administered to humans and other animals orally. Even so, this author knows of no unequivocal information linking the consumption of avocado with diabetic symptomology. In fact, the *manno*-heptulose content of the edible portion of avocado declines by up to 80% as the fruit ripens. Thus, any amounts of *manno*-heptulose ingested are likely to be very low, and some cultivars appear to have none in harvested fruit.

Interestingly, *manno*-heptulose is regarded as an inhibitor of hexokinase activity in plants. This enzyme phosphorylates glucose during glucose metabolism to give glucose-6-phosphate, which is then metabolized in the glycolytic pathway to provide energy and organic substrates. Whether this biochemical pathway is affected by a diet rich in avocado (and therefore some *manno*-heptulose) in humans is unknown.

Nutritional Benefits and Costs

Nutrient Density

The extraordinary nutrient density, at least of the fruits of subtropical avocado cultivars which form the basis of world trade and of consumption in the affluent first world, has been noted, and the subtropical avocado has been described as very nutritious of all fleshy fruits. Thus, comparatively small amounts of avocado are extremely helpful in upgrading the quality of the diet in an increasingly health-conscious world. Furthermore, the relatively small amounts consumed per serving (80–100 g) are no cause for concern where affluence has contributed to overweight or even obesity. The problem in poor, mostly tropical third world countries is very different, and here the energy and nutrient density of the fruit, even of less nutritious cultivars, can make a substantial contribution to guarding against malnutrition.

Protection from Coronary Heart Disease

Coronary artery disease results from the build-up of cholesterol and other lipids in coronary arteries. Cholesterol is carried by lipoproteins, and LDL causes the most damage. HDL, however, protects vessel walls from atherosclerosis. Monounsaturated fatty acids increase the blood level of HDL. Avocado is high in monounsaturated fats and contains no cholesterol. A diet rich in avocado therefore has a favorable effect on blood fats, decreases cholesterol, and preserves HDL. Trials have revealed that a diet rich in avocado causes a decline in total serum cholesterol of 16% in healthy individuals. In hypercholesterolemic subjects, a decrease in serum cholesterol of 17%, LDL-cholesterol of 22%, and triglycerols of 22% was observed, while HDL-cholesterol increased by 11%. There has, therefore, been a welcome change in attitude towards avocado consumption in people at risk of coronary heart disease. (*See* **Coronary Heart Disease**: Prevention.)

Hypersensitivity

Hypersensitivity occurs in latex-allergic individuals who react to avocado (and other fruits including

banana and kiwifruit) within 60 min of ingestion and typically display one or more of the following symptoms: mouth irritation, angiodema, urticaria, asthma, nausea, vomiting, diarrhea, rhinitis, or anaphylaxis. Allergy to avocado is increasing, especially in the USA and Mexico, and has been estimated at around 1% of the general population. Avocado allergy is of particular importance in the 'latex-fruit syndrome' observed in at least 40% of latex-allergic individuals. As mentioned above, the allergens elicit diverse immunoglobulin E-mediated reactions in sensitized individuals. Many of the known plant food allergens are in fact proteins produced in plants either following pathogen attack or after induction of the plant stress syndrome. These are called pathogenesis-related proteins (PR), and 14 families are now recognized. The major allergen in avocado has been identified: a 32-kDa protein known as '*Prs a 1*,' which has endochitinase activity and is recognized by 15 out of 20 avocado and/or latex-allergic individuals. This allergen belongs to the PR-3 family of pathogenesis-related proteins and is induced in plants by ethylene treatment, but allergic activity is lost in heating. This probably explains why plant foods containing this allergen that are consumed after cooking (e.g., green beans) are not usually associated with the latex-fruit syndrome.

BACILLUS

Contents

Occurrence

R Leuschner, Central Science Laboratory, York, UK

Systematics and Ecology of *Bacillus* Species

Aerobic endospore-forming bacteria are currently assigned to four genera in the family Bacillaceae. Within this family, the genus *Bacillus* was established to include the rod-shaped bacteria that grew in the presence of air, thus distinguishing them from the strictly anaerobic *Clostridium* spp. It is possible to allocate many *Bacillus* species to one of six taxa that have distinguishable physiologies and this is generally consistent with the devision of the genus based on spore morphologies. The six groups are: *B. polymyxa* group (I), *B. subtilis* group (II), *B. brevis* group (III), *B. sphaericus* group (IV), and thermophiles (V and VI). In group I all species are facultative anaerobes and grow strongly in the absence of oxygen. Acid is produced from a variety of sugars. Endospores are ellipsoidal. The group II species (*B. subtilis* group) are phylogenetically and phenetically consistent. *B. subtilis* is an appropriate representative of the taxon that includes many common names. All these bacteria produce acids from a range of sugars and some, *B. cereus* and *B. licheniformis*, are facultative anaerobes. *B. licheniformis* grows poorly anaerobically and can use glucose only under anaerobic conditions. Although *B. subtilis* is generally regarded as an aerobe, it can grow and sporulate slowly under strict anaerobic conditions. Given glucose, with nitrite as a terminal electron acceptor, it grows strongly anaerobically. These bacteria are therefore an intermediate stage between the true facultative anaerobes of the group I strains and the strict aerobes in groups III and IV. This is reflected in their production of acid from several sugars. All these bacteria produce oval endospores that do not swell the mother cell and are generally located centrally or subterminally. Group III represents strict aerobes that generally do not produce acid from sugars, with the exception of two species. They produce ellipsoidal spores that swell the mother cell. In group IV all species produce spherical spores that may swell the mother cell and contain L-lysine or ornithine in the cell wall. All species are strictly aerobic, but some have limited ability to produce acid from sugars. Group V represents thermophilic species that grow optimally at $> 50\,^{\circ}C$. Physiologically and morphologically, they are heterogeneous, but most produce oval spores that swell the mother cell. In group VI are thermophilic, acidophilic species with membraneous ω-alicyclic fatty acid.

Occurrence in the Environment and Food

Members of the genus *Bacillus* have a ubiquitous environmental distribution. The endospore is important for the dispersion of *Bacillus* spp. Spores are readily blown about in dust and air currents and are prevalent in animal feces. Bacteria related to *B. subtilis* are commonly encountered and easily identified. The soil is the reservoir of these bacteria. From the soil, they are transferred to various associated environments, including plants and plant materials, foods, animals, and marine and fresh-water habitats. *B. cereus*, *B. licheniformis*, *B. pumilus*, and *B. subtilis* are prevalent in soils, particularly low-nutrient soils. They are also common on straw and cereals, including rice and pulses, which they presumably colonize

from wind-blown soil particles and dust. Endospores of bacilli represent a metabolically inactive survival form. They are characterized by high resistance against heat, dryness, irradiation, and other unfavorable environmental conditions. The success of the endospore for the survival of the species depends on an effective mechanism to resuscitate and enter the vegetative cell cycle to multiply. It is usually the case that spores resuscitate under good environmental conditions that allow germination and cell growth. Food of various origin and compositions can offer these conditions and this can lead to spoilage or even food poisoning due to growth of bacilli in food.

Spores and vegetative cells of *Bacillus cereus* and other food-poisoning *Bacillus* spp. occur widely in soils (10^5–10^6 CFU g^{-1}) and may be found in raw materials and processed foods which were not sterilized by heat or irradiation. They constitute a major portion of the microbial flora of raw milk and easily contaminate various dairy products, causing spoilage with their proteolytic, lipolytic, and saccharolytic activities. *B. cereus* was detected and enumerated in milk, vegetable, and meat-based products (Table 1). *B. cereus* is a problem to the dairy industry because it contaminates the udders of cows while they graze in the fields and can be introduced into milk. *B. licheniformis*, *B. pumilus* and *B. subtilis* were the most commonly isolated *Bacillus* species in bakeries and milk (Tables 2 and 3). The incidence of *B. cereus* and *B. subtilis* in various food products was investigated in the Netherlands. The total number of products was 229 samples and *B. cereus* and *B. subtilis* were isolated at contamination levels between 10^2 and 10^6 CFU g^{-1} or ml in a wide range of food products such as milk, yeast, flour, pasta products, cocoa, chocolate, bakery products, meat products, and herbs and spices. *B. cereus* was present in 48% and *B. subtilis*

in 25% of all samples examined. In spoiled bread that developed symptoms of ropiness after 2 days' storage at ambient summer temperatures, identified species were *B. subtilis* (70%), *B. licheniformis* (24%), *B. pumilus* (2%), and *B. cereus* (2%).

Food Spoilage and Poisoning

The occurrence of *Bacillus* species in raw materials used for food processing is generally below the infectious dosis required to affect negatively the well-being of consumers: this is normally above 10^5 cells g^{-1} or ml^{-1} food (Table 4). This indicates that *Bacillus* cells or spores must have the opportunity to multiply in the food environment to enable them to cause food spoilage and poisoning.

B. cereus food poisoning is principally associated with the storage of cooked foods at temperatures and times that allow growth and result in cell numbers above 10^6 CFU g^{-1} or ml^{-1}. Rapid cooling of cooked food below 10 °C is generally an effective control measure. Low-pH foods (< pH 5.0) and dry foods will not support the growth of *B. cereus*, although many dried foods will be contaminated with spores of this microorganism. Spores are more hydrophobic than spores of other *Bacillus* spp., which enables them to adhere particularly well to many types of surfaces. This makes them difficult to remove during cleaning and a difficult target for disinfection.

B. cereus can cause infections and intoxications. In addition to foodborne diseases, *B. cereus* causes septicemia, meningitis, and ocular infections. It can cause two types of food poisoning: the emetic disease, characterized by a short incubation period (1–5 h) displaying symptoms such as nausea, vomiting, and stomach cramps, and the diarrheal disease, characterized by an incubation period of 8–16 h with symptoms including abdominal pain, watery diarrhea, and rectal tenesmus. Usually both types of food poisoning are relatively mild and last for less than 24 h.

B. subtilis was reported to be the cause of illness in meat dishes with elements of vegetables, seafood and rice, bread and pastry products, sandwiches, and pizza. The infectious dose was > 10^5 CFU g^{-1} with an incubation period of 10 min to 14 h and a duration of illness of 2–8 h. Symptoms were vomiting (80%), diarrhea (49%), abdominal pain/cramps (27%), and nausea, headaches, flushing, and sweating. Bacilli are capable of causing food spoilage in bread, and this is known as ropiness. *B. subtilis* has been described to be the main cause of the bread spoilage 'ropiness.' Ropiness is the most important spoilage of bread after moldiness and occurs particularly during the summer when the climatic conditions favor growth of the bacteria. This involves mainly *B. subtilis*. *Bacillus* counts in white and wholemeal wheat loaves produced without preservatives or sourdough were consistently 10^6 CFU g^{-1} after 2 days of storage at ambient summer temperatures.

B. licheniformis was identified in meat dishes with elements of vegetables, bread, and pastry products, and chicken as a cause of food poisoning. The infectious dose was > 10^6 CFU g^{-1}, the incubation period 2–14 h and the duration of illness 6–24 h. Symptoms were vomiting (54%), diarrhea (92%), and abdominal pain/cramps (46%). *B. pumilus* in meat products, sandwiches, and canned tomato juice was found to be responsible for food poisoning. The infectious dose was > 10^6 CFU g^{-1} and the incubation period 15 min to 11 h. Symptoms were vomiting and diarrhea.

B. stearothermophilus and *B. coagulans* were reported to be the cause of flat sour spoilage in evaporated milk.

Growth Characteristics and Resistance of Bacilli

Knowledge about the resistance and growth characteristics of *Bacillus* species is important to enable food manufacturers and consumers to avoid handling practice that enable spores to germinate and vegetative cells to multiply in a food.

Psychrotrophic strains of *B. cereus* were able to grow and produce diarrheal toxin at temperatures down to 4 °C. Most mesophilic strains are able to grow in low-acidic foods at temperatures between 15 and 55 °C, with an optimum range of 30–40 °C. Growth can generally occur between pH 5.0 and 8.8,

Table 4 Infective or intoxication dosis food poisoning caused by *Bacillus* species

Bacillus *species*	*Intoxication dosis*	*Infective dosis*
B. cereus (emetic toxin)	12–32 μg kg^{-1} toxin (*Suncus murinus*: a small monkey)	10^5–10^8 cells g^{-1} food
B. cereus (diarrheal disease)		Usual 10^5 g^{-1} or ml^{-1}
B. subtilis		> 10^5
B. licheniformis		> 10^6
B. pumilus		> 10^6

Modified from Leguerinel I and Mafart P (2001) Modelling the influence of pH organic acid types on thermal inactivation of *Bacillus cereus* spores. *International Journal of Food Microbiology* 63: 29–34.

with an optimum between 6.0 and 7.0. Spores are variable in their heat resistance, which is normally moderate, but can be increased by fat components. The emetic toxin is very heat-resistant and can survive heating at 126 °C for 90 min. The diarrheal toxin is heat-sensitive and is inactivated at 56 °C after 5 min. Growth of *B. cereus* was found at water activities of 0.93 depending on the acidulant and humectant. Other food-poisoning *Bacillus* spp. have similar growth and resistance characteristics to *B. cereus*. *B. licheniformis* and *B. subtilis* were not found to grow at pH 4–4.2; however, growth in tomato juice at a pH of 4.4 in the presence of oxygen was reported. Spores of thermophilic bacilli such as *B. stearothermophilus* are far more heat-resistant and are used to test sterilization effectiveness. Heat resistance of bacilli spores is dependent on the temperature during spore formation and on the pH of the food. Further dependence was observed on various acidulants (Table 5).

Sterilization will inactivate all *Bacillus* spores. This is however also imposing a harsh treatment towards other valuable food ingredients. The development of novel and milder food preservation technologies, such as high-pressure and electromagnetic fields, have proven to be effective in *Bacillus* spore inactivation. Pressure treatments of 400 MPa for 25 min at 30 °C resulted in a 0.45 log inactivation of *B. cereus* spores. Pressure treatments at lower temperatures were less effective. Spores of *B. subtilis* proved to be more resistant to ultraviolet B range (280–330 nm) than spores of *B. cereus*. An exposure of 30 min reduced the viability of spores of *B. cereus* by 50% and that of *B. subtilis* spores by 10%. Levels of resistance to ultraviolet B of spores from different *Bacillus* species appear to be related to the quantity and quality of small acid-soluble proteins and to activities of DNA repair systems. The novel, milder nonthermal preservation technologies need further evaluation with particular emphasis on spore inactivation mechanisms and synergistic effects by combination of various techniques in food systems.

Detection

L A Shelef, Wayne State University, Detroit, MI, USA

Background

The genus *Bacillus* is large, comprising more than 60 species that are mostly saprophytes, widely distributed in nature, spreading from soil to water, plants, and animals. The genus shows a great diversity of strains and species. The organisms are Gram-positive or Gram-variable spore-forming bacilli, mostly catalase-positive, that may be motile by peritrichous flagella. Most are mesophiles, but some are psychrothrophs and thermophiles. *Bacillus* contains strict aerobes (e.g., *B. megaterium*), as well as facultative anaerobes (e.g., *B. cereus, B. licheniformis*). The vegetative cells are rods ranging from $0.5 \times 1.2\,\mu m$ to $2.5 \times 10\,\mu m$, and the endospores are in the central or paracentral, subterminal or terminal position. Survival of the organism results from the resistance of the spores to adverse conditions.

Of the identification schemes proposed, that of Gordon and co-workers divides the genus *Bacillus* into three groups, according to cellular morphology and physiological properties. Group 1 consists of

Gram-positive species that form ellipsoidal or cylindrical spores that do not appreciably distend the sporangia. This group is further divided according to the vegetative cell dimensions and presence of lipid globules in the protoplasm of the species. The 'large-celled' group 1 *Bacillus* species have a cell width greater than 0.9 μm and include *B. megaterium, B. cereus, B. cereus* var. *mycoides, B. thuringiensis*, and *B. anthracis*. The 'small-celled' species have a cell diameter < 0.9 μm, and lipid globules are not formed. They include *B. subtilis, B. pumilus, B. licheniformis*, and *B. coagulans*. Organisms of groups 2 and 3 are characterized by swollen sporangia and either ellipsoidal (group 2) or spherical (group 3) spores. Studies of DNA composition and other studies suggest that the genus *Bacillus* consists of some bacterial families that will necessitate further classification of the genus.

Most *Bacillus* species are harmless saprophytes characterized by their proteolytic and saccharolytic properties and are rarely associated with human or animal disease. However, several species are proven or suspect pathogens. Of these, *B. cereus* is a recognized food pathogen, and other species, particularly those of the *B. subtilis* group (*B. subtilis, B. licheniformis*, and *B. pumilus*), have been implicated in foodborne illnesses. *B. brevis*, also identified as a causative agent of foodborne disease, has been split and transferred to the new genus *Brevibacillus*. *B. anthracis* is the agent of anthrax. Five *Bacillus* species, *B. thuringiensis, B. popilliae, B. sphaericus, B. larvae*, and *B. lentimorbus*, are insect pathogens, the first three being used in commercial insecticides for the control of crop insects.

Of the *Bacillus* species associated with foods, detection and identification methods have focused on *B. cereus* as a recognized food pathogen. Spores and vegetative forms of *B. cereus* are frequent inhabitants of soils, sediments, dust, natural water sources, vegetation, and many foods such as grains, dairy products, dried foods, spices, meats, and vegetables. Examination of various raw and processed foods shows contamination levels ranging from 10^1 to 10^6–10^7 cells per gram or milliliter. It is estimated that *B. cereus* accounts for ~2–3% of reported foodborne outbreaks in the USA. In the UK, a single outbreak was reported during the period of October–December, 2000. In this outbreak, 30 people became ill after consuming contaminated soup with cream in a canteen, and a statistical association was established between consumption of the food and the cause.

Detection of *B. cereus* and its toxins and differentiation between the species within the *B. cereus* group are presented in this chapter. Following a brief review of the properties of the organism and its toxins, traditional and novel detection of the organism and its toxins are discussed.

Properties of *B. cereus*

Cells of *B. cereus* are large, Gram-positive rods that are motile by means of peritrichous flagella. They are typically 1.0–1.2 μm in diameter and 3.0–5.0 μm in length. Endospores are in either the central or paracentral position without distention of the sporangium. The organism sporulates freely on many media under aerated conditions. The optimum growth temperature is 28–35 °C, with a minimum of 5 °C and a maximum of 48 °C, and the pH for growth is 4.9–9.3. *B. cereus* strains are able to utilize glucose, fructose, and trehalose. Sucrose, salicin, maltose, mannose, glycerol *m*-inositol, and lactose are utilized by some, but not all, members of the species. Pentoses, mannitol, and many of the sugar alcohols are not metabolized. Urease is produced by few strains. Most of the strains produce acetylmethylcarbinol (Voges–Proskauer-positive), reduce nitrate to nitrite, hydrolyze soluble starch, tyrosine, gelatin and casein, and produce a neutral metalloprotease. *B. cereus* and *B. thuringiensis* produce a broad spectrum of β-lactamase and are, therefore, resistant to penicillin, ampicillin, and cephalosporins. Their ability to grow on agar containing penicillin aids in differentiating them from *B. anthracis*. Certain strains have been reported to synthesize a dehydropeptide reductase that catalyzes cleavage of the bacteriocins nisin and subtilin. In contrast to *B. megaterium, B. cereus* strains are not sensitive to lysozyme.

The organism elaborates a number of toxins with distinct diarrheal and emetic syndromes. The diarrheal syndrome is caused by bacterial growth and toxin formation in the small intestine, whereas the emetic syndrome is caused by preformed toxin resulting from growth of the pathogen in the food. Of the enterotoxins responsible for the diarrheal syndrome, hemolysin, designated BL, comprises three heat-labile peptides, B (37.8 kDa), L_1 (38.5 kDa), and L_2 (43.2 kDa), and the genes that encode for these components have been cloned. The L_1 and L_2 peptides appear to be responsible for binding to erythrocytes and the B component for lysing them. Cereolysin (56 kDa), a cytolytic protein responsible for hemolysis, consists of phospholipases that hydrolyze phosphatidylinositol, some of which are metalloenzymes requiring divalent cations for activity, and sphingomyelinase, also a metalloenzyme that has hemolysin-like activity, but shows no phospholipase activity. The nonhemolytic enterotoxin is heat-labile, comprising three proteins (39, 45, and 105 kDa). Cereulide is a putative emetic toxin. It has been

isolated and identified as a small (1.2 kDa), heat-stable dodecadepsipeptide, structurally related to the ionophore valinomycin, producing a vacuole response in HEp-2 cells. Psychrophilic strains of *B. cereus* capable of producing toxins at refrigerator temperatures have been reported.

Isolation and Identification of *B. cereus*

Standard Agar Media

The characteristics of *B. cereus* and of the culturally similar *B. mycoides*, *B. thuringiensis*, and *B. anthracis* are summarized in Table 1. Most procedures for the isolation, identification, and enumeration of *B. cereus* involve direct plating techniques. Media developed for the identification of the organism provide conditions for the organism to exhibit fermentation properties, hemolysin production, lecithinase activity, and morphological characteristics. Selective agents to inhibit competitive microorganisms, such as antibiotics (most often 10 μg of polymyxin per milliliter), are normally incorporated into the media.

MYP agar Mannitol–egg yolk-polymyxin agar (MYP) was the first selective medium, introduced in 1967 by Mossel and coworkers. It relies on lecithin hydrolysis (the egg-yolk reaction), negative mannitol reaction for differentiation of *B. cereus* from other commonly occurring *Bacillus* species, and polymyxin B. The agar plate is surface-inoculated, and typical colonies of *B. cereus* after 20–24 h of incubation at 30–32 °C have a dry, flat, 'ground-glass' appearance, translucent to creamy white with a violet–red background surrounded by a readily visible zone of egg-yolk precipitate (Figure 1). Less commonly, colonies may be large (5 to over 10 mm in diameter), amorphous, spreading, and highly irregular. MYP remains to date a popular choice for the isolation of *B. cereus* and is available commercially. Plates can be stored for up to 7 days at 4 °C.

Table 1 Characteristics of *Bacillus cereus* and other members of the *B. cereus* group

Reaction	B. cereus	B. mycoides	B. thuringiensis	B. anthracis
Egg-yolk reaction	+[a]	+	+	(+)[b]
Acid from mannitol	−	−	−	−
Catalase	+	+	+	+
Gram reaction	+	+	+	+
Motility	±[c]	−[d]	±	−
Hemolysis (sheep RBC)	+	(+)	(+)	−
Rhizoid growth	−	+	−	−
Production of toxin crystals	−	−	+	−
Anaerobic utilization of glucose	+	+	+	+
Nitrate reduction	+	+	+	+
VP reaction	+	+	+	+
Tyrosine utilization	+	(+)	+	(+)
Resistance to lysozyme	+	+	+	+

[a] +, 90–100% of strains are positive.
[b] (+), usually weakly positive.
[c] ±, 50–90% of strains are positive.
[d] −, < 10% of strains are positive.

KG agar In 1971, Kim and Goepfert developed the Kim–Goepfert (KG) medium with a similar sensitivity and selectivity to MYP. It contains no carbohydrates and low levels of peptone to promote free spore formation within 24 h of incubation at 37 °C. Surface colonies of *B. cereus* after overnight incubation at 37 °C are flat, dry, and of a rough appearance, similar to the appearance of the colonies on MYP agar. The composition of KG agar allows direct confirmation of lecithinase-producing organisms by microscopic examination, differentiation of *B. cereus* from *B. thuringiensis* based on production of parasporal crystals of δ-endotoxin by the latter species during sporogenesis, and the use of fluorescent-labeled antibodies to spore-coat antigens as a rapid and specific serological test for confirmation of identity. *Bacillus* spp. that may produce lecithinase, such as *B. polymyxa* and *B. laterosporus*, are unable to do so under the nutritionally poor KG medium.

PEMBA medium Polymyxin–pyruvate–egg yolk–mannitol–bromothymol blue agar (PEMBA), developed by Holbrook and Anderson in the early 1980s, also relies on the mannitol-negative, lecithinase-positive properties of the organism. The medium contains pyruvate to reduce the tendency of *B. cereus* to form rhizoid colonies, improve the egg yolk reaction, and enhance sporulation. After 18–24 h of incubation at 37 °C, *B. cereus* strains form flat, crenate to rhizoid, turquoise–peacock blue colonies, 2–5 mm in diameter, with a 'ground-glass' surface appearance. After a further 24 h of incubation at ambient temperature, all colonies turn peacock blue. *B. cereus* is differentiated microscopically from other mannitol-negative species by microscopic examination of the stained cells for the presence of lipid granules and spores in the cytoplasm.

PEMPA medium Polymyxin–Pyruvate–egg yolk–mannitol–bromocresol purple agar (PEMPA), a modified agar, gives comparable results to PEMBA after shorter incubation times (18–24 h).

Figure 1 Typical colonies of *B. cereus* on plates of MYP agar (left) and BCM® agar (right).

Blood agar On 5% horse blood agar, after 24 h at 35–37 °C, *B. cereus* colonies are 3–8 mm in diameter, flat to low convex, gray–white to gray–green, with a matt 'ground glass' surface. Growth is also associated with a strong 'mouse-like' odor. Hemolytic reactions on the medium vary from partial lysis of erythrocytes to complete β-hemolysis. Small colonies, 2–3 mm in diameter, form during anaerobic incubation. The irregular, β-hemolytic colonies resemble those of *Clostridium perfringens* and require further identification.

Of the plating media, MYP agar is the official medium in the USA (Association of Official Analytical Chemists), Canada, France, and several other countries. PEMBA is widely used in the UK. These plating media do not differentiate between *B. cereus* and *B. thuringiensis* organisms (Table 1). In general, the numbers of *B. cereus* recovered from foods are sufficiently high for direct plating, and preenrichment is unnecessary. However, preenrichment may be required when low viable counts or damaged cells are present. The most probable number (MPN) technique, using trypticase soy-polymyxin B broth and incubation for 48 h at 30 °C, is recommended for estimation of *B. cereus* numbers in foods expected to contain less than 10 cells per gram. Tubes showing growth are streaked on to MYP agar. On egg-yolk-containing agar plates, zones of egg-yolk precipitation from individual colonies tend to coalesce if high levels of the organisms are present (Figure 1), and enumeration of colonies may become difficult. Further dilutions of samples to three to 30 colonies are therefore recommended in quantitative analyses.

Chromogenic Agar Media

Chromogenic substrates that utilize specific enzymatic activities are increasingly used for rapid detection and identification of microorganisms. Their incorporation into selective agar media facilitates identification of colonies, improves the accuracy of the test and reduces the need for isolation of pure cultures and confirmation. The enzyme inositol-specific phospholipase C (PI-PLC) was first reported in culture filtrates of *B. cereus* in 1965, and a similar enzyme was later identified in *B. thuringiensis*. On a chromogenic, selective, and differential plating medium that detects the enzyme phosphatidylinositol-specific phospholipase C (PI-PLC) in *B. cereus* and *B. thuringiensis* (BCM® *Bacillus cereus* and *Bacillus thuringiensis*, Biosynth, Staad, Switzerland), these organisms form large, 2–7-mm, turquoise, flat colonies with or without turquoise halos on the medium. Other *Bacillus* spp. form white, 1–2-mm colonies or are inhibited; some *Listeria* strains form colonies less than 1 mm in diameter, white or turquoise on the medium. Comparison with MYP agar has shown a significantly higher inhibition of Gram-positive non-*B. cereus*/*B. thuringiensis* organisms that interfere with enumeration of small numbers of *B. cereus* in heavily contaminated samples. Typical colonies of *B. cereus* on the chromogenic agar plate are shown in Figure 1. The shelf stability of the chromogenic agar plates (3 months at 2–5 °C) is superior to that of MYP plates. As with other procedures, the chromogenic medium does not differentiate between *B. cereus* and *B. thuringiensis* organisms.

Confirmatory Procedures

The specific confirmation tests that distinguish *B. cereus* from the other members of the *B. cereus* group include motility, toxin crystal formation, rhizoid growth, and hemolysin activity (Table 1).

Motility is determined by stabbing the center of a tube of semisolid medium and incubating for 18 h at 30 °C. The motile organisms (most *B. cereus* and *B. thuringiensis*) diffuse out from the stab, forming an opaque growth pattern. The only established difference between *B. cereus* and *B. thuringiensis* strains is the presence of genes encoding for the insecticidal toxins, usually present on plasmids. The ability of *B. thuringiensis* to form toxin crystals is determined by inoculating nutrient agar slants with the overnight culture and incubation for 2–3 days at room temperature. Toxin crystals appear on a smear of a microscope slide stained with 0.5% basic fuchsin as dark-staining diamond-shaped objects after their release from the sporangium upon lysis. The test is inconclusive if the release is not observed. Rhizoid growth, characteristic of *B. mycoides*, is observed by the production of hair- or root-like structures projecting from an agar plate inoculated with the organism and incubated for 48–72 h. Rhizoid growth may be lost by the organisms. All three species show strong hemolytic activity on trypticase soy–sheep blood agar plates inoculated with an overnight culture and incubated at 35 °C for 24 h.

A rapid confirmatory staining technique for the identification of *B. cereus* developed by Holbrook and Anderson uses colonies grown on PEMBA medium and a combined spore and intracellular lipid stain. Only the *B. cereus* group bacilli produce the intracellular lipid globules.

The US Food and Drug Administration confirms presumptive *B. cereus* colonies from MYP agar plates by anaerobic production of acid from glucose, reduction of nitrate to nitrite, production of acetylmethylcarbinol, decomposition of L-tyrosine, and growth in the presence of 0.001% (wt/vol) lysozyme. Additional tests for rhizoid growth, hemolysis of sheep erythrocytes, motility, and production of parasporal δ-endotoxin crystals enable differentiation of *B. mycoides, B. thuringiensis*, and *B. anthracis*. The Central Public Health Laboratory, London, UK confirms presumptive *B. cereus* by testing motility, hemolysis, rhizoid growth, susceptibility to γ-phage (*B. cereus*-negative; *B. anthracis*-positive), and fermentation of ammonium salt-based glucose, but not of mannitol, arabinose, or xylose, after 5 days of incubation at 36 °C.

Serological Tests

The serological relationships within the genus *Bacillus* are not as well defined as for other genera, and the development of serological procedures for use as diagnostic aids has met with limited success. Studies with spore antigens have shown cross-reactions with other *Bacillus* species. The multiplicity of spore surface antigens in a single strain of *B. cereus* has also been demonstrated. Some of the problems in the use of spore antigens stem from contamination of their preparations with vegetative cell debris and formation of antivegetative cell immunoglobulins, germination of spores during serum production, which also results in the formation of antivegetative cell immunoglobulins, and *in-vitro* spore germination during immunoassay.

Forty-two flagellar (H) and 13 somatic (O) antigens have been identified. A serological typing scheme for *B. cereus* strains based on flagellar antigens was developed by Gilbert and coworkers and is used routinely by the Food Hygiene Laboratory, Central Public Health Laboratory, Colindale, London, UK for investigations of food-poisoning outbreaks and for serotyping strains from nongastrointestinal infections. It is composed of 42 H antigens raised against prototype strains of diverse origin. Twenty-three of the 42 H serotypes are linked to illness, and serotype H1 is dominant and contains both emetic and diarrheal strains. A system similar to that used in the UK was also developed by the Tokyo Metropolitan Research laboratory of Public Health in Japan.

B. thuringiensis strains have been classified on the basis of their flagellar antigens. A serological typing scheme for this species has been developed, and 14 serotypes have been recognized. There is evidence that certain strains of *B. cereus* and *B. thuringiensis* share common antigens.

Rapid Identification Methods

The term *rapid methods* refers to a variety of tests, which can shorten the analysis time and reduce labor (i.e., by automation). Some eliminate the need for confirmation, whereas others require enrichment prior to testing, which limits the assay speed but provides more reliable identification of the target organism. All require pure culture isolates of the bacteria. Rapid methods applicable to *B. cereus* are discussed below.

Miniaturized biochemical kits to identify *Bacillus* species have been developed to produce standardized test media that improve reproducibility, have a long shelf-life, are rapid and convenient to use, economize the use of media, and are inexpensive. The API 20E and 50 CHB strips (bioMérieux, Marcy l'Etoile, France; Hazelwood, MO, USA), are ready-to-use microtube systems that contain dehydrated media for standard biochemical tests. The API 50 CHB for the identification of the genus *Bacillus* tests the fermentation of 49 carbohydrates, and the phenotypic profile obtained from these tests is used to identify the

strain. The API 20E strips are used for the identification in the Vitek automated identification system, which eliminates the need for manual identification. Incubation for 24–48 h at 30 or 37 °C (mesophiles) is required before reading the results. Other manual and automated systems for identification of *Bacillus* based on biochemical properties are available. MicroLog™ microbial carbon-source utilization (Biolog Inc., Hayward, CA) generates an identity profile based on the ability of the organism to oxidize different carbon sources based on changes in the redox potential following respiration of the viable bacterial cells. Oxidation is determined colorimetrically with a tetrazolium-based compound, and the color change data measured automatically by a spectrophotometer are fed into a computer. Bacteria are identified by comparison with a reference data base. The BBL Crystal™ Gram-positive Identification System (Beckton Dickinson, Sparks, MD) is another example of miniaturized identification method for Gram-positive aerobes employing modified conventional, fluorogenic, and chromogenic substrates.

Another approach for the identification of the organism is based on its fatty acid profile. Analysis of the cellular fatty acid composition is carried out by gas chromatography following extraction of pure cultures and injection into a gas chromatograph (Microbial Identification System, MIS, Microbial-ID, Newark, DE). The cellular fatty acid profile is analyzed by computer and compared with database values to provide the best-match identification of the organism.

Other diagnostic schemes include polyacrylamide gel electrophoresis analysis, pyrolysis mass spectrometry, and Fourier-transform infrared spectroscopy. Classification and identification based on differences in rRNA are available commercially for food pathogens including *B. cereus*. Ribotyping (RiboPrinter® Microbial Characterization System, DuPont Qualicon, Wilmington, DE) generates precise fingerprints that can be used to classify isolates at the species level and trace them to the contaminated source. Steps of the identification, from cell lysis to data capture and database comparisons, are automated. All of the above identification methods require large updated databases. DNA sequence data for the design of specific primers for *B. cereus* are being investigated. The design of primers within the coupled sequences for phospholipase C and sphingomyelinase of *B. cereus* has been reported, and PCR tests with these primers are positive only with isolates of the *B. cereus* group. Moreover, positive results have also been observed with an egg-yolk-negative *B. cereus* isolate, suggesting that the primers could be specific for atypical *B. cereus*.

Phage typing of *B. cereus* strains is another epidemiological tool in outbreaks of *B. cereus* food poisoning. Phages are used in routine test dilution, and drops are deposited on bacterial lawns on nutrient agar plates that are incubated overnight at 32 °C and examined for lysis. A typing scheme using a set of 12 phages selected on the basis of host range, stability, and reproducibility of reaction showed that most isolates of the pathogen were typeable. A good correlation (80–100%) was observed between phage types of strains isolated from specimens of suspected foods and from symptomatic patients. Most *B. thuringiensis* strains were also typeable by the same set of phages.

Detection of *B. cereus* Toxins

In-vivo and *in-vitro* methods for the detection of *B. cereus* diarrheal and emetic toxins are summarized in Table 2. *In-vivo* methods for the detection of *B. cereus* diarrheal enterotoxins include the rabbit or guinea-pig ileal loop test, dermonecrotic test in guinea-pig, mouse lethality test, vascular permeability test, and Rhesus monkey feeding trials. In the ileal loop assay, the lower portion of the intestine of the animal is surgically exposed to allow ligation, usually of the ileal regions, thereby testing different samples in a single animal. The sample is injected into a ligated section, and fluid accumulation is monitored with time and compared with control sections. Animal feeding trials (Rhesus monkey and *Suncus marinus*) and lethality tests (mouse and *Suncus marinus*) are used to detect the presence of the emetic toxin. Animals (a set of six) are observed for about 5 h after samples have been introduced

Table 2 Detection methods of *B. cereus* toxins[a]

In-vivo *methods*	In-vitro *methods*
Diarrheal syndrome	
Rabbit or guinea-pig ligated ileal loop	Gel-diffusion assays
Guinea-pig dermonecrotic test	Cell cytotoxicity (hemolysin BL)
Mouse lethality test	BCET-RPLA kit (L_2 of BL)

using a stomach tube. An emetic response in two of the six animals is considered positive for the toxin.

The disadvantages of bioassays are the time to complete the assay, the need for special animal facilities, the cost, as well as the concern about the use of experimental animals in research. Alternatives to the *in-vivo* tests are *in-vitro* assay methods that include diffusion techniques, enzyme-linked immunosorbent assays (ELISA), and cell cytotoxicity tests. The gel diffusion assay detects hemolysin BL, producing a discontinuous hemolysis pattern on blood agar plates. The microslide immunodiffusion assay and the fluorescent immunodot assay detect enterotoxin by line of identity and fluorescence, respectively.

Two immunoassay kits are available commercially for the detection of the *B. cereus* diarrheal toxins. These include the *B. cereus* enterotoxin-reversed passive latex agglutination (BCET-RPLA) assay (Oxoid, Unipath, Basingstoke, UK), and the *Bacillus* diarrheal enterotoxin visual immunoassay (BDE-VIA) (TECRA Diagnostics, Batley, UK). The RPLA procedure uses latex particles to amplify the antibody: antigen reaction. The antibody detects the L_2 component of hemolysin BL, and can provide a semiquantitative measure of the enterotoxin in foods. In the TECRA immunoassay, a sandwich ELISA is used, in which the antibody is absorbed on the solid phase, and the enterotoxin is added. The colorimetric reaction detects the 45-kDa and 105-kDa proteins of the nonhemolytic enterotoxin and other proteins. The presence of preformed toxin is detected in 4 h, and production of the toxin in samples containing enterotoxigenic *Bacillus* spp. is detected after overnight enrichment. Since these two kits detect components in the different enterotoxins, isolates should be tested by both methods. Many *B. cereus* strains have been shown to react with both the Oxoid and the TECRA detection kits, suggesting that they are able to produce both enterotoxin complexes.

B. thuringiensis, B. subtilis, B. licheniformis, and *B. pumilus* strains have been involved in foodborne illnesses. Although the nature of their toxins is not well defined, reaction with antibodies to *B. cereus* enterotoxins in both the Oxoid and the TECRA detection kits has been demonstrated for some of them.

Cell cytotoxicity techniques have been used for both the diarrheal toxin and the emetic toxin. Cell lines used include HeLa, HEp-2, Vero, and others, and cellular responses in the presence of the toxin range from morphological changes (subjective), to more specific, e.g., metabolic status of the cells and detection of lactate dehydrogenase release from damaged cells.

Taxonomic Relationship of *B. cereus*, *B. thuringiensis*, and *B. anthracis*

The lower end of the GC range of the genus *Bacillus* (32–38%) is occupied by *B. cereus* and the closely related species *B. anthracis*, *B. mycoides*, and *B. thuringiensis*. It was suggested in 1952 that there are no consistent phenotypic properties that differentiate these species and that these three species be designated varieties of *B. cereus*. However, this has not been accepted for *B. anthracis* and *B. thuringiensis* because of their pathogenic qualities. The high homology between DNA from *B. anthracis*, *B. thuringiensis*, and *B. cereus* suggests that organisms in these taxa should have the same name. Recently, researchers used multilocus enzyme electrophoresis and sequence analysis of nine chromosomal genes to provide further evidence that *B. anthracis* should be considered a lineage of *B. cereus*. Evidence of the close taxonomic relationship of *B. cereus*, *B. thuringiensis*, and *B. anthracis* was indirectly obtained from serological studies that showed extensive cross-agglutination between the spores of the three species.

The only established difference between *B. cereus* and *B. thuringiensis* strains is the presence of genes encoding for the insecticidal toxins, usually present on plasmids. None of the detection methods discussed above distinguishes between the two species.

Table 1 Different *Bacillus* species involved in food poisoning[a]

Species	
B. cereus	Frequently involved in food poisoning
B. anthracis	Has caused food poisoning (see text)
B. thuringiensis	Involved in food poisoning
B. mycoides	Might have been involved in food poisoning
B. weihenstephanensis	Might have been involved in food poisoning
B. pseudomycoides	Might have been involved in food poisoning
B. brevis	Involved in food poisoning
B. circulans	Probably not involved, but has been shown to produce *B. cereus*-type enterotoxin
B. licheniformis	Involved in food poisoning
B. pumilus	Involved in food poisoning
B. sphaericus	Involved in food poisoning
B. subtilis	Involved in food poisoning

[a]The first six species belong to the *B. cereus* group and are very closely related.

Food Poisoning

P E Granum, The Norwegian School of Veterinary Science, Oslo, Norway

Background

There are several *Bacillus* species that have been involved in food poisoning (**Table 1**) although the only species that frequently causes problems is *Bacillus cereus*. There are six species that belong to the *B. cereus* group including *B. anthracis*. All of these species can cause food poisoning and in most cases are not distinguished in routine food laboratories, apart for *B. anthracis*, which is usually not hemolytic and is sensitive to penicillin. It has also been suggested that these species are so closely related that they should be considered as one species. In this article, the *B. cereus* group (apart from *B. anthracis*) is dealt with mostly as one species, although *B. thuringiensis* and *B. weihenstephanensis* are dealt with separately. *B. cereus* is a food-poisoning bacterium of growing concern, although it does not cause the types of illness that makes newspaper headlines. However, outbreaks of both the emetic- and the diarrheal type have caused some deaths in recent years. In some countries, where relatively few outbreaks of campylobacteriosis and salmonellosis are recorded, a steady increase in *B. cereus* food poisoning cases has been observed. As the Norwegian reference laboratory for the spore-forming food-poisoning bacteria, we can follow this trend closely. The same increase in *B. cereus* outbreaks is probably hidden behind the usually more serious outbreaks caused by other bacteria in Europe and the USA. And indeed it has been reported to be the most important cause of foodborne disease in The Netherlands, together with *Salmonella* spp., in the years between 1985 and 1991.

Bacillus cereus is a Gram-positive, spore-forming, motile, aerobic rod that also grows well anaerobically. It is a common soil saprophyte and is easily spread to many types of foods, especially of plant origin, but is also frequently isolated from meat, eggs, and dairy products. *B. cereus* and other members of the *B. cereus* group can cause two different types of food poisoning: the diarrheal type and the emetic type. The diarrheal type of food poisoning is caused by complex enterotoxins produced during vegetative growth of *B. cereus* in the small intestine, whereas the emetic toxin is preformed during the growth of cells in the food. For both types of food poisoning, the food involved has usually been heat-treated, and the surviving spores are the source of the food poisoning. *B. cereus* is not a competitive microorganism but grows well after cooking and cooling ($< 42–50\,^{\circ}C$). The heat treatment will cause spore germination, and in the absence of competing flora, *B. cereus* grows well. Invasion by psychrotolerant strains from the *B. cereus* group in the dairy industry has led to increasing surveillance of *B. cereus* in recent years.

B. cereus food poisoning is a nonreportable disease in all of Europe and the USA. Because of this, and because it is usually a relatively mild and short lasting

disease (< 24 h), it is highly underreported in official statistics. However, occasional reports have described more severe forms of the diarrheal type of *B. cereus* food poisoning, including a necrotic enteritis type causing three deaths. A Swiss boy also died after eating spaghetti containing large amounts of emetic toxin a few years ago.

The closely related *B. thuringiensis* is reported to produce enterotoxins and has been shown to cause food-poisoning symptoms when given to human volunteers. It has also been reported to cause food poisoning in regular outbreaks. The extensive use of this organism as a protective agent against insect attacks on crops may be part of the increasing problems with organisms of the *B. cereus* group observed in the food industry. Normal procedures for confirmation of *B. cereus* would not differentiate between the two species, if at all possible from heat-treated food products, since *B. thuringiensis* frequently will throw out insecticidal plasmids when grown above 30 °C. This makes it difficult to investigate the real numbers of food-poisoning cases caused by commercially used *B. thuringiensis*. To assure safe spraying with *B. thuringiensis*, the organism in use should be unable to produce food-poisoning toxins. The Health & Consumer Protection Directorate-General (European Commission) has already accepted that only non-toxin-producing *Bacillus* spp. should be allowed to be used in animal nutrition. *B. weihenstephanensis* is the psychrotolerant species within the *B. cereus* group, and most of the strains of this species are non- or low toxin producers, although there are exceptions. There are also *B. cereus* strains that are able to grow temperatures as low as 4 °C.

The other *Bacillus* species that might cause food poisoning are all isolated from soil and foods. However, in contrast to the members of the *B. cereus* group, only a small number of isolates of these species have the ability to produce toxins (harboring toxin genes) that can result in food poisoning.

Taxonomy of the *B. cereus* Group

The aerobic endosperm forming bacteria have traditionally been placed in the genus *Bacillus*. Over the past three decades, this genus has expanded to accommodate more than 100 species. Analysis of 16S ribosomal RNA sequences from numerous *Bacillus* species has indicated that the genus *Bacillus* should be divided into at least five genera or rRNA groups. The species treated in this text (Table 1) do all still belong to the genus *Bacillus*.

Bacillus anthracis, B. cereus, B. mycoides, B. thuringiensis, and, more recently, *B. pseudomycoides* and *B. weihenstephanensis* comprise the *B. cereus* group. These bacteria have highly similar 16S and 23S rRNA sequences, indicating that they have diverged from a common evolutionary line relatively recently. Extensive genomic studies of *B. cereus* and *B. thuringiensis* have shown that there is no taxonomic basis for separate species status. Nevertheless, the name *B. thuringiensis* is retained for those strains that synthesize a crystalline inclusion (Cry protein) or δ-endotoxin that may be highly toxic to insects. The *cry* genes are usually located on plasmids, and loss of the relevant plasmid(s) makes the bacterium indistinguishable from *B. cereus*. It is now clear that most strains in the *B. cereus* group, including *B. thuringiensis*, carry enterotoxin genes.

Foodborne Outbreaks Caused by the *B. cereus* Group

B. cereus is now well recognized as a food-poisoning organism. Outbreaks can be divided into two types according to their symptoms. The diarrheal type is far more frequent in Europe and the USA, whereas the emetic type appears more prevalent in Japan. Typical foods implicated are stews, puddings, sauces, and flour and rice dishes. When expressed as a proportion of all reported food poisonings, outbreaks ascribed to *B. cereus* seem to be concentrated in Scandinavia and Canada (10–47% of the total) and less frequent in Central Europe, UK, USA, and the Far East (1–5% of the total). Although these differences might partly be due to different consumer habits, they are also not comparable, because of dissimilar reporting practices. Thus, in the Netherlands, in 1991, *B. cereus* was responsible in 27% of outbreaks in which the causative agent was identified. However, the incidence was only 2.8% of the total, since the majority of cases of food poisoning were of unknown etiology. In addition, when the number of food poisoning cases ascribed to *B. cereus* are expressed on a per capita basis, many of the large regional differences in incidence disappear. Examples of foods involved in different outbreaks are listed in Table 2.

Characteristics of the *B. cereus* Disease

The emetic toxin results in vomiting, and the second type, caused by enterotoxins, leads to diarrhea. In a small number of cases, both types of symptoms are recorded, probably due to ingestion of preformed emetic toxin together with living *B. cereus* cells that may produce enterotoxins in the small intestine. There has been some debate about whether or not the enterotoxin(s) can be preformed in foods and cause intoxication. From a review of the literature, it is clear that the incubation time is slightly too long

Table 2 Examples of the variety of foods involved in *Bacillus cereus* food poisoning

Type of food	*Country*	*Number of people involved*	*Type of syndrome*
Barbecued chicken	Many countries		E, D
Cooked noodles	Spain	13	D
Cream cake	Norway	5	D
Fish soup	Norway	20	D
Lobster pâté	UK		D
Meat loaf	USA		D
Meat with rice	Denmark	> 200	D
Milk	Many countries		E, D
Pea soup	The Netherlands		D
Sausages	Ireland, China		D
School lunch	Japan	1877	E
Scrambled egg	Norway	12	D
Several rice dishes	Many countries		E, D
Stew	Norway	152	D
Turkey	UK, USA		D
Vanilla sauce	Norway	> 200	D
Wheat flour dessert	Bulgaria		D

E, emetic syndrome; D, diarrheal syndrome.

for that (> 6 h; average 12 h), and in model experiments, it has been shown that the enterotoxins are degraded on the way to the ileum. Although the enterotoxin(s) can be preformed, the number of *B. cereus* cells in the food would need to be at least two orders of magnitude higher than that necessary to cause food poisoning, and such products would no longer be acceptable to the consumer. The characteristics of *B. cereus* food poisoning are listed in Table 3.

In recent years, food poisoning resulting from ingestion of *B. anthracis*-infected meat has been reported in three continents (Asia, Africa, and America). Patients who do not develop anthrax symptoms instead develop diarrhea, sometimes bloody, with fever and rashes. It is not yet known whether the enterotoxins known from *B. cereus* are at least partly involved in such symptoms. However, it is known that enterotoxin genes (*nhe*) are present in *B. anthracis* (from the total genome sequence), although the positive regulator for enterotoxin production (see Table 4) is nonfunctional, but in other strains, this might not be the case.

Infectious Dose of *B. cereus* Group

Counts ranging from 10^4 to 10^9 per gram (or milliliter) *B. cereus* have been reported in affected foods after food poisoning, giving total infective doses of about 5×10^4–10^{11}. The variation in the infective dose is partly due to the differences in the amount of enterotoxin produced by different strains (at least two orders of magnitude) and partly due to the difference in infective dose between vegetative cells and spores, since all the spores will survive the stomach-acid barrier. Thus, any food containing more than 10^3 *B. cereus* per gram cannot be considered completely safe for consumption.

Virulence Factors/Mechanisms of Pathogenicity

Very different types of toxins cause the two types of *B. cereus* food poisoning. The emetic toxin, causing vomiting, is a ring-formed small peptide, whereas the diarrheal disease is caused by several different enterotoxins (Table 4).

Emetic toxin

The emetic toxin causes emesis (vomiting) only, and for many years, its structure was a mystery, as the only detection system involved living primates. The discovery that the toxin could be detected (vacuolation activity) by the use of HEp-2 cells led to its isolation and structural determination. The emetic toxin has been named cereulide, and consists of a ring structure

Table 3 Characteristics of the two types of disease caused by *Bacillus cereus*

	Diarrheal syndrome	*Emetic syndrome*
Infective dose	10^5–10^7 (total)	10^5–10^8 (cells per gram food to produce enough emetic toxin)
Toxin produced	In the small intestine of the host	Preformed in foods
Type of toxin	Protein(s)	Cyclic peptide
Incubation period	8–16 h (occasionally > 24 h)	0.5–5 h
Duration of illness	12–24 h (occasionally several days)	6–24 h
Symptoms	Abdominal pain, watery diarrhea (occasionally bloody diarrhea) sometimes with nausea	Nausea, vomiting, and malaise (sometimes followed by diarrhea, due to additional enterotoxin production?)
Foods most frequently implicated	Meat products, soups, vegetables, puddings/sauces and milk/milk products	Fried and cooked rice, pasta, pastry, and noodles

Table 4 Toxins involved in food poisoning produced by *Bacillus cereus*

Toxin	*Type/size*	*Food poisoning*
Hemolysin BL (Hbl)	Protein, three components transcribed from one operon: HblC (L_2-component), HblD (L_1-component) and HblA (B-component); the proteins have a molecular mass of 37–46 kDa	Probably
Nonhemolytic enterotoxin (Nhe)	Protein, three components transcribed from one operon: NheA, NheB, and NheC; the proteins have a molecular mass of 36–41 kDa	Yes
Cytotoxin K (CytK)	Protein, one component, 34 kDa	Yes, three deaths
Emetic toxin (cereulide)	Cyclic peptide, 1.2 kDa	Yes, one death

of three repeats of four amino-and/or oxy-acids: [D-*O*-Leu-D-Ala-L-*O*-Val-L-Val]$_3$. This ring structure (dodecadepsipeptide) has a molecular mass of 1.2 kDa and is chemically closely related to the potassium ionophore valinomycin. The emetic toxin is resistant to heat, pH, and proteolysis, but is not antigenic. The biosynthetic pathway and mechanism of action of the emetic toxin still have to be elucidated, although it has been shown recently that it stimulates the vagus afferent through binding to the 5-HT$_3$ receptor. It has just been shown that cereulide is synthesized non-ribosomally by a peptide synthetase.

Cereulide was responsible for the death (fulminant liver failure) of a 17-year-old Swiss boy a few years ago. A large amount of *B. cereus* emetic toxin was found in the residue from the pan used to reheat the food (pasta) and in the boy's liver and bile. In a recent experiment, mice were injected i.p. with synthetic cereulide, and the development of histopathological changes was examined. At high cereulide doses, massive degeneration of hepatocytes occurred. The serum values of hepatic enzymes were highest on days 2–3 after the inoculation of cereulide, and rapidly decreased thereafter. General recovery from the pathological changes and regeneration of hepatocytes was observed after 4 weeks.

Enterotoxins

As shown in Table 4, three different enterotoxins, believed to be involved in food poisoning, have been characterized to date. The three-component hemolysin (Hbl; consisting of three proteins: B, L_1, and L_2) with enterotoxin activity was the first to be fully characterized. This toxin also has dermonecrotic and vascular permeability activities, and causes fluid accumulation in ligated rabbit ileal loops. Hbl has been suggested to be a primary virulence factor in *B. cereus* diarrhea. Convincing evidence has shown that all three components are necessary for maximal enterotoxin activity. It has been suggested, from studies of interactions with erythrocytes, that the B protein (HblA) is the component that binds Hbl to the target cells, and that L_1 (HblD) and L_2 (HblC) have lytic functions. More recently, another model for the action of Hbl has been proposed, suggesting that the components of Hbl bind to target cells independently and then constitute a membrane attacking complex, resulting in a colloid osmotic lysis mechanism. Substantial heterogeneity has been observed in the components of Hbl, and individual strains have been shown to produce various combinations of single or multiple bands of each component.

More recently, a nonhemolytic three-component enterotoxin (Nhe) has been characterized. The three components of this toxin are different from the components of Hbl, although there are similarities. The three components of Nhe enterotoxin were first purified from a *B. cereus* strain isolated after a large food-poisoning outbreak in Norway in 1995. Binary combination of the components of this enterotoxin shows some biological activity, but not nearly as high as when all the components are present.

Almost all tested *B. cereus*/*B. thuringiensis* strains produce Nhe, and about 60% produce Hbl. At present, we do not know how important each of them is in relation to food poisoning. There are several food-poisoning strains that do not produce Hbl, but none that do not produce Nhe.

The newly discovered cytotoxin K (CytK) is similar to the β-toxin of *Clostridium perfringens* (and other related toxins) and was the cause of the symptoms in a severe outbreak of *B. cereus* food poisoning in France in 1998. In this outbreak, several people developed bloody diarrhea, and three died. This could be considered an outbreak of *B. cereus* necrotic enteritis, although it is not nearly as severe as the *C. perfringens* type C food poisoning.

There is significant sequence identity between the three proteins of Nhe and between the Nhe and Hbl proteins. The identity is highest in the N-terminal third of the proteins. The most pronounced gene

sequence similarities are found between *nheA* and *hblC, nheB* and *hblD*, and *nheC* and *hblA*. This is not only in direct comparison of the sequences, but also in predicted transmembrane helices for the six proteins. NheA and HblC have no predicted transmembrane helices, whereas NheB and HblD have two each. Finally, NheC and HblA have one predicted transmembrane helix each, in the same position in the two proteins. Although there are some similarities among the components of Hbl and Nhe, they cannot be substituted for each other to give biological active complexes.

Other Possible Virulence Factors

The *B. cereus* spore is more hydrophobic than any of the other *Bacillus* spp. spores, which makes it adhesive to several types of surfaces. This makes it difficult to remove during cleaning and a difficult target for disinfection. The *B. cereus* spores also contain appendages and/or phili that are, at least partly, involved in adhesion (Figure 1). These properties of the *B. cereus* spore not only allow them to survive sanitation, and thus become available for contamination of different foods, but also aid adherence to epithelial cells. Experiments have shown that spores, at least from one strain isolated after one outbreak, can indeed adhere to Caco-2 cells in culture and that these properties are linked to hydrophobicity and possibly to the appendages. A longer incubation period is observed in this case, as expected, as the spore would first have to germinate.

Commercial Methods for Detection of the *Bacillus cereus* Toxins

Neither of the two available commercial immunoassays can quantify the toxicity of the enterotoxins from *B. cereus*. The assay from Oxoid measures the presence of the HblC (L_2) component, whereas the Tecra kit mainly detects the NheA protein. However, if one or both of the commercial kits react positively with proteins from *B. cereus* supernatants, it is likely that the strain is enterotoxin-positive, specifically if the strains are cytotoxic on epithelial cells. If the supernatants are shown to be cytotoxic, the strains can be regarded as enterotoxin-positive. At present, there is no commercial method available to detect CytK, and, unfortunately, no commercial method to detect the emetic toxin either. However, a specific, sensitive, semiautomated, and quantitative Hep-2 cell culture-based 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide assay for *B. cereus* emetic toxin has been developed.

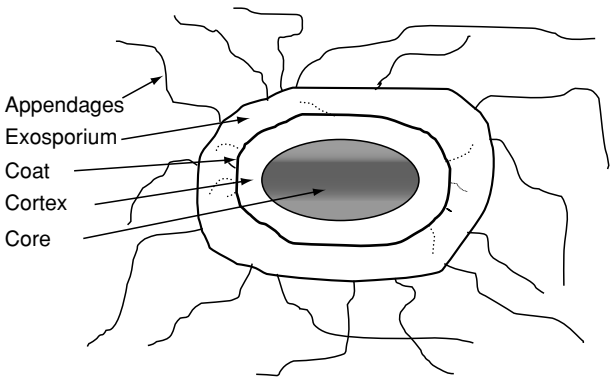

Figure 1 *Bacillus cereus* spore with the different layers and appendages.

Other Bacillus Species

Of the other *Bacillus* species involved in food poisoning, only three have been involved frequently enough to give a relatively clear picture of the diverse food-poisoning symptoms (Table 5). For *B. sphaericus* and *B. brevis*, only a few cases have been recorded. The infective dose variation for these species is not clear, although they are probably quite high ($> 10^6$). From the data in Table 5, it is clear that many types of toxins are involved. For incubation periods shorter than 6 h, preformed toxins are expected. Enterotoxins similar to those of *B. cereus* have been detected from several of the other *Bacillus* species (Table 1) using immunological methods and polymerase chain reaction-based methods. However, until the toxins have been isolated and characterized, there structure and function are mostly speculative.

One of the toxins has been well characterized. From a strain of *B. licheniformis* isolated for milk powder (which caused the death of a young child), a toxin similar to the *B. cereus* emetic toxin was isolated. This toxin was also found in 13 out of 210 isolates (6%) of *B. licheniformis* from different sources (mainly from foods). The toxins isolated from three strains of different origins contained the same component each of which had the same amino acid residues L-Gln, L-Leu, D-Leu, L-Val, L-Asp, D-Leu, and L-Ile, in that order. Toxins were identified as lichenysin A, a cyclic lactonic heptalipopeptide in which the main 3-hydroxy fatty acids are 13–15 carbons in length. The molecular mass of this toxin is about 1 kDa.

Prevention and Control of *Bacillus* Food Poisoning

Prevention and control of *Bacillus* spp. is relatively easy, apart from in the dairy industry, where *B. cereus*

Table 5 Characteristics of the illness caused by the three *Bacillus* species other than *B. cereus* causing food poisoning

	Bacillus subtilis	*Bacillus licheniformis*	*Bacillus pumilus*
Foods involved	Meat dishes with elements of vegetables Seafood with rice Bread and pastry products Sandwiches Pizzas	Meat dishes with elements of vegetables Bread and pastry products Chicken	Meat products Sandwiches Canned tomato juice
Infective dose	$> 10^5$	$> 10^6$	$> 10^6$
Incubation period	10 min to 14 h	2–14 h	15 min to 11 h
Duration	2–8 h	6–24 h	
Symptoms:			
Vomiting	80%	54%	Yes
Diarrhea	49%	92%	Yes (not all)
Abdominal pain/cramps	27%	46%	?
Other symptoms	Nausea, headaches, and flushing/sweating	Not reported	Not reported

Table 6 Factors determining the growth of the four most common food-poisoning *Bacillus* species

Species	*pH range*	*Temperature range*	*Other factors*
Bacillus cereus	4.3–9.3	4–50 °C	Growth at a_w to 0.92 Inhibited by 0.2% sorbic acid (pH < 5.0) Growth in 7% NaCl
Bacillus subtilis	5.0–8.5	10–50 °C	Growth in 7% NaCl Growth with only glucose and ammonium
Bacillus licheniformis	5–?	> 15–55 °C	Growth in 7% NaCl
Bacillus pumilus	5–?	10–45 °C	Growth in 7% NaCl

causes major problems. There are also a growing number of precooked long-life products on the market that are difficult to produce completely free from *Bacillus* spp. spores. The growth characteristics of the four most common food-poisoning *Bacillus* spp. are listed in Table 6. If foods are not kept at 6–60 °C for too long, no spore germination and growth of these species will occur. Rapid cooling and proper reheating of cooked food are essential if the food is not consumed immediately. Long-term storage must be at temperatures below 8 °C (or preferably 4–6 °C to prevent growth of *B. cereus*). Low-pH foods (pH $\leq$ 4.3) can be considered safe from growth of the food-poisoning *Bacillus* spp. *Bacillus* spores are commonly isolated from spices, cereals, and dried foods. For example, during 1960–8, *B. cereus* was the third most common cause of food poisoning in Hungary, and meat dishes were frequently involved. The reason for this was the preference for well-spiced meat dishes in Hungary. Several cases of *B. cereus* food poisoning, (involving many people) resulting from consumption of meat-containing dishes have also been reported recently in Norway.

The emetic syndrome of *B. cereus* food poisoning is often connected with the consumption of rice in Chinese restaurants. The predominance of cases in Chinese restaurants is linked with the common practice of saving portions of boiled rice from bulk cooking. The boiled rice is then stored, usually at room temperature, overnight and *B. cereus* is then able to multiply. The same problem may occur when foods such as pasta and pizza are stored for long periods of time at room temperature.

At present, the main problem with *B. cereus* seems to be in the dairy industry, where the keeping quality of milk is determined by the number of *B. cereus* cells/spores in the product. The bacterium may cause aggregation of the creamy layer of pasteurized milk, known as bitty cream, which is explained by the lecithinase activity of *B. cereus*. Further, *B. cereus* is responsible for sweet curdling (without pH reduction) in both homogenized and nonhomogenized low-pasteurized milk. It seems impossible to completely avoid the presence of *B. cereus* in milk where it already infects raw milk at the farm. Soiling of the udders of cows is the principal source of contamination of milk with *B. cereus*. Soil has been shown to contain 10^5–10^6 spores per gram. It is very important, therefore, that the udder and the teats are cleaned to reduce the contamination of raw milk. Transport and further storage in the dairy may result in further

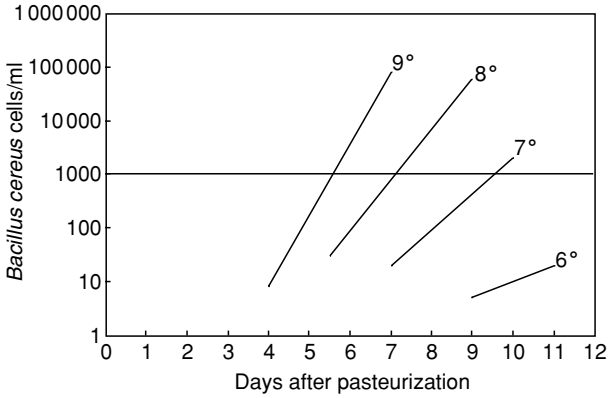

Figure 2 Growth rate of *Bacillus cereus* cells in milk stored at 9, 8, 7, and 6 °C.

contamination of the raw milk from *B. cereus* spores already present (adherent) in the tanks or pipelines. The vegetative bacteria are killed in the pasteurization process, but the spores survive. Pasteurization might activate at least some of the spores (heat activation), which might start germinating.

To control *B. cereus* in milk and milk products, it is very important to trace the presence of spores from farmer to package. The storage temperature is the most important factor in keeping *B. cereus* numbers to a minimum. Figure 2 shows the number of days required before milk contains more than 10^3 *B. cereus* per milliliter at different temperatures. An increase of just 2 °C during storage, from 6 to 8 °C, increase the growth rate substantially. At the dairy, the milk is generally kept at 4 °C, thus ensuring a good keeping quality. However, during distribution, where the energy costs are often valued higher than food quality, temperatures up to 8 °C and above are common. Further, the consumer often exposes milk to higher temperatures for longer periods, for example at the breakfast table. The majority of the strains from the *B. cereus* group that grow at low temperatures (including *B. weihenstephanensis*) are usually low in enterotoxin production, although there are exceptions.

As mentioned before, the spores of *B. cereus* are very adhesive to different hydrophobic surfaces (such as glass and stainless steel), and for this reason, *B. cereus* is often found in food plants and kitchen environments. The strong adhesion of *B. cereus* spores is mainly due to three characteristics: the high relatively hydrophobicity, the low spore surface charge, and the spore morphology (appendages). At present, the only way to overcome this problem, when first introduced, is through the use of hypochlorite (0.2% at pH 7–8) or UVC light, since neither low- nor high-pH cleaning is sufficient to control the problem.

BANANAS AND PLANTAINS

J W Daniells, Queensland Department of Primary Industries, Queensland, Australia

Introduction

Bananas and plantains (*Musa* spp.) are grown extensively throughout the tropical and subtropical regions of the world. Together they represent the number-one fruit crop in the world, in terms of both production and trade, exceeding oranges by 37×10^6 t per year for production and by 10×10^6 t per year for trade. Most of the exported fruit, which makes up only 15% of the total, are Cavendish-type dessert bananas. However, bananas and plantains that are cooked account for almost half of the world production. This article describes their global distribution and importance, the morphological and nutritional characteristics of the fruit, handling and storage, and other uses of fresh and processed fruit. (*See* **Fruits of Temperate Climates:** Commercial and Dietary Importance.)

The terms 'bananas' and 'plantains' require clarification. 'Bananas' refers to all the members of the genus *Musa*. In the narrow sense, plantains are a defined group within this genus which have the AAB genome and are characterized by the orange-yellow color of both the compound tepal of the flower and the fruit pulp at ripeness. When ripe, a relatively high proportion of starch (10–25% of fresh weight) is present in the pulp. The fruits are slender, angular to pointed, and are generally palatable only after cooking. Plantains, in the broad sense, include other members of the genus *Musa* that are starchy at ripeness but which lack the other characteristics. In this article, plantains are referred to in the narrow sense, except when global production figures are discussed, as these refer to plantains in the broad sense.

Global Distribution

Before international trade began a little over 100 years ago, bananas in temperate regions were merely a curiosity. Bananas are grown in commercial plantations, but more often in household gardens because of their almost universal appeal as a food, ease of growing, quick production, and attractive plant appearance.

Bananas and plantains are suited to the warm, high-rainfall regions of the lowland tropics. They originated in South-east Asia (including Papua New Guinea) and have been spread to other regions of the world in the past 2000 years. They are now grown from the equator to about 35 °N and 30 °S, and within these latitudes they may be grown in semiarid locations with irrigation or in large plastic greenhouses.

Bananas for export are produced mainly in Central and South America as well as the Philippines (**Tables 1–4**). Most exported fruit goes to North America, Europe, and Japan, and in 2000 was valued at $\$4.306 \times 10^9$. Exports of plantains have increased in importance in recent years but still represents less than 2% of the combined total exports of bananas and plantains. Other major areas of banana production are South-east Asia and East Africa (according to Food and Agriculture Organization (FAO) statistics*) but little of this is exported. Plantain production is most important in East and West Africa as well as South America.

Average world consumption of bananas and plantains in 2001 was about 16 kg per person per year. However, in much of Africa and Latin America it is 5–10 times this amount, and it is as much as 450 kg

*FAO production statistics need careful interpretation because the meaning of the words 'bananas' and 'plantains' differs among countries, particularly in East Africa. For instance information from Burundi on bananas largely refers to plantains used for cooking purposes.

per person per year in some parts of East Africa. The major export production areas are located close to the equator, where an even supply of fruit throughout the year is possible, and where they are less damaged by cyclones or typhoons.

The optimum temperature range for bananas is about 22–31 °C. Chilling injury of fruit occurs when the latex coagulates at temperatures below 13 °C. Bananas are susceptible to frost and in subtropical regions are often planted on hillsides to avoid it. The growth cycle is greatly prolonged outside the tropics and productivity is generally reduced. The industries that have developed in the subtropics have largely done so because of proximity to markets.

Varieties

All the edible bananas belong to the Eumusa (sometimes referred to as Musa) section of the genus *Musa*, except for the Fe'i bananas of the Pacific region which belong to the Australimusa section (Figure 1). The Fe'i bananas are characterized by erect bunches and pink-red sap, and an orange, slimy fruit pulp that generally requires cooking. There are numerous wild seeded species in each of the *Musa* sections.

Edible bananas and plantains belonging to the Eumusa section are believed to contain genomes from two wild species, *M. acuminata* (A) and *M. balbisiana* (B). Most cultivated bananas are triploid and are classified according to characteristics estimating the contribution of the two parent species. Because the binomial Latin nomenclature for edible varieties, e.g., *Musa cavendishii* cultivar (cv.) Williams, proved unsatisfactory, they are referred to as, for example, *Musa* spp. (AAA Group, Cavendish Subgroup) cv. Williams. There are about

500 varieties of bananas and plantains in existence, but only 150 or so are primary clones and the remainder are somatic mutants.

Bananas for export now come almost entirely from varieties of the Cavendish subgroup. From the 1940s to 1960s, these replaced cv. Gros Michel, which was devastated by a soil-borne fungus called Panama disease (fusarium wilt) in one of the largest disease epiphytotics that has ever occurred in crop plants. The greatest diversity of varieties occurs in Southeast Asia where particular varieties are especially favored for various culinary uses (Figure 2).

The leaf disease, black Sigatoka, and new races of Panama disease currently pose major threats to world banana and plantain production. As resistant varieties are developed by conventional breeding programs, somacloning and genetic engineering, further changes in the varieties cultivated can be expected.

Fruit Morphology and Anatomy

The banana plant is a large, tree-like, determinate perennial herb with a basal rhizome, a pseudostem composed of leaf sheaths, and a terminal crown of large leaves (Figure 3). The terminal inflorescence is initiated near ground level and is then thrust up the center of the pseudostem by elongation of the true stem. The basal flower clusters (hands) are female and form the fruit bunch. Distal flower clusters are male, do not produce fruit, and are commonly deciduous. The banana has the largest inflorescence of any plant grown as a crop. The world record for a mature fruit bunch is 144 kg, obtained in the Canary Islands.

Banana bunches have from one to 20 hands and take 2–6 months to reach maturity. Bunches are pendant or subhorizontal and usually weigh between 10

and 60 kg. Individual fruits (fingers) can number up to 300 on a bunch. Fingers of different varieties can be anywhere from 6 to 60 cm in length and from 50 to 1000 g in weight, but are more usually 15–30 cm long and weigh 50–200 g. The curved shape of the fruit is caused by a negative geotropic growth response. Immature bananas are usually green, and when mature they ripen to a yellow color. Young fruits are somewhat angular, but this disappears with maturity in the AAA varieties. AAB and ABB varieties may still be angular at maturity.

The fruit is a berry that develops from the inferior ovary of the female flower. It is parthenocarpic, i.e., it develops without the stimulus of pollination. The ovules shrivel early but can still be recognized as brown specks in the center of mature fruit. Most varieties are sterile or have very low fertility. If a pollen source, such as a wild species, is nearby, some varieties will set an occasional dark hard seed about 3–5 mm in diameter. These are a hazard to the teeth of consumers so it is fortunate that seeds are an extremely rare event.

In the growing fruit, the pulp-to-peel ratio of fresh weight varies from about 1:1 to 4:1, depending upon variety and maturity at harvest. When the mature fruit ripens, the pulp-to-peel ratio increases, and this is thought to be in part as a result of water movement from the peel to the pulp associated with the hydrolysis of starch to osmotically active sugars.

Nutritional Composition

Ripe dessert bananas are considered by many to be a complete food if taken in association with a protein source such as milk. They are favored as food for young babies and elderly people because they are easily digested and are very nutritious. They are excellent for people with stomach complaints, particularly ulcers, and are ideal for diets with low levels of cholesterol, fats, and sodium. The potassium concentration is about 350 mg per 100 g of fresh pulp with trace amounts of sodium (Table 5). Bananas are also recommended in the treatment of infant diarrhea, celiac disease, and colitis. They are a good source of vitamins C and B_6 (Tables 5 and 6). A major feature is the high sugar-to-acid ratio (ranging from 100 to 180) compared with 7–10 for citrus. This is confirmed by the carbohydrate concentrations shown in Tables 5 and 7. If we assume 20% of the fresh banana pulp is sugar and 76% water, then 83% of the dried solids are sugar (Tables 5 and 7). This is why bananas have recently received much attention from people in sport because of the high carbohydrate content, capable of rapidly releasing energy necessary for vigorous sporting events. The sugars are almost entirely glucose, fructose, and sucrose, in a ratio of 20:15:65. The high sugar concentration of ripe bananas is exceeded in fresh fruit only by that of dates, jujube, tamarind, and carob. Requirements; **Infants**: Nutritional Requirements.) *See also* individual nutrients.

The characteristic aroma of bananas has received considerable attention, with more than 350 volatile compounds having been identified. The major constituents appear to be amyl and isoamyl esters of acetic, propionic, and butyric acids.

The major differences between bananas and plantains are: (1) the lower moisture percentage of the pulp in green plantains compared with ripe bananas (Tables 5 and 7); (2) the lower sugar concentration in ripe plantains compared with ripe bananas; and (3) plantains are a much richer source of vitamin A than bananas (Tables 5 and 6). These differences are valid for the edible product, but are less important if fruits are compared at the same stage of ripeness. For example, the moisture percentage can increase from about 60% in preclimacteric banana fruit to 70% after ripening and 75–80% at the stage of senescence. In addition, there are major inconsistencies in the literature regarding the conversion of starch to sugar in plantains, with some references indicating only traces of starch in the ripe fruit. Some of the differences are probably due to different ripening conditions and the stage of ripeness selected for measurement. (*See* **Ripening of Fruit**.)

Fresh Fruit Handling and Storage

Handling procedures vary substantially in the different banana-producing countries and depend upon whether fruit is to be exported. This discussion is based largely on procedures adopted in commercial plantings producing fruit for export because it provides an understanding of the factors involved.

Bananas travel best and receive a minimum of mechanical damage while they are in a hard, green condition. It is necessary to transport the fruits to the marketplace in this hard, green state so that they can be uniformly ripened with ethylene gas (1000 mg l^{-1}) in humidified rooms at 15–18 °C. This greatly facilitates marketing. Fruits can take from a few days to 3 weeks to reach the marketplace, and so must have sufficient greenlife (the period after harvest for which the fruit stays in a hard green condition) to survive this journey. No postharvest treatment can improve upon the inherent greenlife, but treatments can reduce its rate of decline. In general, the earlier the harvest in the life of the fruit, the greater is the fruit greenlife, but any gain in greenlife must be balanced against the loss in bunch weight (5–10% per week). A bunch that would ripen in the field 5 months after it emerged may be harvested and ripened satisfactorily as early as about 10 weeks (pulp-to-peel ratio of 1:1), when the fingers are still quite thin. A key to profitable banana growing is to maximize yield without premature ripening occurring. Other considerations

Figure 4 (see color plate 2) Bananas for export are usually transported to the packing shed by cableways to minimize skin blemishes due to mechanical damage. Reproduced from Bananas and Plantains. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

are that greater fruit maturity leads to a higher proportion of edible pulp and possibly an increase in fruit flavor. In practice, maturity standards are varied, so that more mature bunches are harvested for nearer markets and less mature ones for more distant markets.

Maximum greenlife for a particular finger diameter (grade) at harvest is achieved by manipulating the plant and environment to obtain the maximum possible rate of fruit filling. Finger diameter, bunch age, and degree of fruit fullness (loss of angularity) are used as criteria for harvest. The combination of age-grade control for determining time of harvest insures the production of high-quality fruit with sufficient greenlife at harvest. To minimize the risk of premature ripening after harvest, it is important to keep the fruit as cool as possible (but above 13 °C to prevent chilling injury) and not to expose it unnecessarily to light.

Banana bunches are harvested by hand and usually carried on the shoulder to nearby cableways (Figure 4) or tractor-drawn, padded trailers. The plastic sleeve, known as a bunch cover, that is applied to the young bunch to improve fruit quality is retained to minimize mechanical damage during handling. In the packing shed, the bunch cover is removed, the bunches are dehanded, usually into tanks of water, and then fruit is sorted, graded, divided into clusters of 4–10 fingers, weighed, labeled, and packed into fiberboard cartons containing plastic liners. Fungicide may be applied in a separate operation before the fruit is packed. Cartons hold from 12 to 18 kg of fruit. The packed fruit is sent by refrigerated transport to the marketplace and usually involves transport by rail, road, and sea. The transport system is highly integrated and regular (at least weekly) so that fruit of uniform maturity is marketed. This has the effect of avoiding the need for storage beyond the shipment period. (*See* **Fungicides**.)

Bananas are usually consumed within 3–4 weeks from the day of harvest, with no long-term commercial storage possible, as for citrus and pome fruits. It is possible to delay the onset of ripening by a few weeks by the use of modified atmosphere storage with high carbon dioxide (5%) and low oxygen (2%) and with ethylene scrubbers, such as potassium permanganate, but because banana fruit is available year round there is usually no advantage in doing this. However, in places where the expensive technology of refrigeration is not available, this technique may be valuable for marketing fruit in distant markets.

Once the fruit ripens, the period over which it may be eaten, its shelf-life, is relatively short. It is usually of the order of 2–10 days depending upon variety and ambient temperature. The extremely perishable nature of banana is associated with its high rate of metabolism – the rate of respiration during the climacteric is 100–180 ml of oxygen per kg of fruit per h and 40–60 ml kg^{-1} h^{-1} whilst green. This is higher than apples and pears, which have a respiration rate of 6–40 ml of oxygen per hour at similar temperatures. Lower temperatures will reduce the metabolic rate. A reduction of 10 °C usually halves the rate. Chilling injury occurs when the fruit is kept for a long period below 13 °C.

Fruit Utilization

Almost half of the bananas and plantains produced are eaten raw as a dessert fruit; the other half is cooked, usually by frying, boiling, roasting, or baking. Virtually all varieties of bananas and plantains may be either eaten raw when ripe, or cooked when either green or ripe. Cultural preferences govern the choices made.

Bananas can be processed in various ways so that they may be stored and utilized for other purposes. Fruits that are unmarketable because of small size or some peel blemishes are suitable for processing.

Banana purée is the most important processed product made from the pulp of ripe fruit. The purée is canned and used as an ingredient in dairy desserts, bakery items, drinks, processed foods, and sauces, and as a part of special diets in hospitals and nursing homes. Ripe bananas are also sliced and canned in an acidified syrup and are used in desserts, fruit salads, cocktail drinks, and bakery items.

Chips are made by deep-frying thin slices of unripe fruit, with the optional addition of various flavorings, and sold as a snackfood like potato crisps. Ripe banana may be dried (known as banana figs in some regions) and is said to store satisfactorily for over 10 years without the addition of preservatives. This would presumably be due to the high sugar content, which is in excess of 50%. The ripe fruit is ideal for ice-blocks (water ices, ice lollies), when peeled and frozen, with the optional addition of toppings such as chocolate and chopped nuts. It is an excellent base for icecreams because of its creamy consistency.

The other major processed products are flour made from dried unripe fruit, and essence which is extracted from the pulp of ripe fruit. When ripe fruit is fermented it makes a low-alcohol beer. Beer manufacture is confined to East Africa, with consumption being as much as 1.2 l per person per day in Rwanda. Less important processed products include a clarified juice, powder, jams, flakes, freeze-dried slices, ketchup 'filler', vinegar, and wine. Unripe bananas have been used to make starch, but none is currently produced.

Green banana fruit, pseudostems, and foliage are suitable as animal feed. They provide a source of energy and require supplementation with a protein source. Bananas are only economical as a source of animal feed when the livestock are nearby, because of the high cost of transport. The corms, shoots, and male buds find widespread use as an animal food in Asia and Africa.

Conclusion

Bananas have become the major fresh fruit consumed around the world, even in the temperate zone where they are not grown, despite the fact that they cannot be stored for more than a few weeks. This has been possible because they can be produced all year round, are competitively priced, come packed in an hygienic, easily opened peel, are extremely convenient to eat in virtually all situations and, as William Forsyth put it, 'The suave melting texture of a fully ripe banana combined with its distinctive mellow flavour makes a delicious combination.'

BARLEY

A W MacGregor, Canadian Grain Commission, Winnipeg, Manitoba, Canada

Introduction

Barley is one of the major cereal crops in the world. This article reviews its origin, botany, distribution, chemical composition, and uses as food and feed. Utilization of barley in the malting and fermentation industries (brewing, distilling, alcohol production) is covered in other articles.

Botany

Barley is a member of the grass family Gramineae, the subfamily Festucoideae, the tribe Hordeae and the genus *Hordeum*. Cultivated barleys belong to the subspecies *vulgare*, whereas the wild forms of barley belong to the subspecies *spontaneum*. The basic chromosome number of the genus *Hordeum* is 7, and all cultivated barleys are self-fertilizing, diploid annuals ($2n = 14$).

The spike or head of barley consists of a series of spikelets that are attached – in sets of three – at nodes to alternating sides of the rachis. Each spikelet contains a floret. In six-rowed barley (Figure 1a), each floret is fertile and develops into a kernel, leading to the formation of six rows of kernels. Only the central kernel in each triplet is symmetrical; the lateral kernels are twisted to varying degrees. Therefore, two-thirds of the kernels in a sample of six-rowed barley will be nonsymmetrical. In two-rowed barley, the lateral florets are not fertile, so that only the central floret in each triplet develops into a kernel (Figure 1b), leading to the formation of two rows of symmetrical kernels in the mature spike. All cultivated barleys are either two- or six-rowed, but some six-rowed cultivars appear to have only four rows of kernels; thus, reference is sometimes made to four-rowed barleys, although these are really six-rowed barleys.

The barley kernel consists of many different tissues; some of these are shown in Figure 2. Outer layers of the kernel and the area between the embryo and the starchy endosperm are shown in detail in Figure 2a and **b**. In botanical terms, the barley seed is that part of the kernel enclosed by the testa. Hence, the testa is often referred to as the seed coat. Surrounding the testa and fused tightly to it is the pericarp, the outer tissue of the grain or caryopsis. Since a caryopsis is a fruit, barley is a fruit containing a seed. The hull or husk completely surrounds the grain and adheres tightly to the pericarp in most barley cultivars. In some cultivars, however, the so-called naked or hull-less types, the hull is loosely attached to the grain and is removed during threshing. (*See* **Wheat**: Grain Structure of Wheat and Wheat-based Products.)

Origin, Adaptation, and Production

Neither the place of origin nor the progenitor of cultivated barley is known with certainty. There is archeological evidence that from about 7000 BC barley was cultivated in the fertile crescent of the Middle East. This area includes present-day Israel, Jordan, Syria, and Iran. There is evidence also that barley may have been cultivated even earlier than that in the Nile Valley of Egypt, but considerably later in India and China. It is probable, but by no means certain, that two-rowed *Hordeum spontaneum* is the ancestor of cultivated barley, but this subspecies

From *Canadian Grains Council Statistical Handbook* (2001). Winnipeg: Canada Grains Council.

may be an intermediate between the actual barley progenitor and cultivated barley. Six-rowed forms of barley are thought to have developed from early two-rowed forms through mutation and hybridization.

Barley is a widely adapted crop and grows under a wider range of environmental conditions than any other cereal. It appears to require fewer heat units than other cereals to reach physiological maturity and can therefore be grown successfully at higher latitudes and altitudes than other cereal crops. Barley is relatively tolerant to drought and to alkaline and salt conditions but grows best in temperate regions of the world where growing seasons are long, cool, and moderately dry.

Winter barley is less cold-tolerant than either winter wheat or winter rye. Nevertheless, in some countries with temperate climates, such as the UK, most of the barley is grown during winter. In countries such as Australia and Spain, which experience hot summers, a significant proportion of the barley is grown during the winter. Conversely, the harsh winters of North America preclude the growing of winter barley, except for some areas in the southern USA.

Over the past 10 years, world-wide production of barley has averaged 51.0×10^6 t (Table 1). This places barley fourth after wheat, maize, and rice in terms of total annual production. In 2000, barley accounted for 8.4% of the world's total cereal production. The former USSR is the largest producer of barley, but it is all consumed internally. Canada, the USA, and Australia each produce much smaller quantities but they, as well as members of the EU, are major barley exporters. (*See* **Cereals**: Contribution to the Diet.)

Composition

The major constituent of barley kernels is starch, which is present in the endosperm in the form of discrete granules (Figure 2) and represents, on average, 60–64% of the weight of the kernel (Table 2). Starch consists of two high-molecular-weight polymers of glucose: amylose and amylopectin. Amylose is composed of long chains of glucose residues linked by α-(1,→4) bonds with a few side-chains joined to the main chains through α-(1,→6) bonds. Amylopectin contains much shorter unit chains of α(1,→4)-linked glucose residues that are inter-linked through α-(1,→6) bonds. In other words, amylose is lightly branched, and amylopectin is heavily branched. In general, barley starch contains about 75% amylopectin and 25% amylose. However, starch from 'waxy' barley cultivars contains 95–100% amylopectin, and starch from high-amylose barley cultivars may contain more than 40% amylose. These starches have different functional properties, but they have not yet been utilized widely in the food industry.

The major component of endosperm cell walls is the polysaccharide, (1,→3), (1,→4)-β-D-glucan, which

Table 2 Barley composition

Component	*Content (%, dry weight)*
Starch	60–64
Arabinoxylans	4.4–7.8
β-Glucans	3.6–6.1
Cellulose	1.4–5.0
Simple carbohydrates (glucose, fructose, sucrose, maltose)	0.41–2.9
Oligosaccharides (raffinose, fructosans)	0.16–1.8
Proteins	8–15
Lipids	2–3
Minerals	2–3

Barley also contains small quantities of the B-complex vitamins, including thiamin (B_1), riboflavin (B_2), nicotinic acid, pyridoxine (B_6) and pantothenic acid, biotin, folic acid, and vitamin E.

forms highly viscous, aqueous solutions. These high viscosities may cause filtration problems during brewing and digestive problems when untreated barley is fed to chickens. Conversely, there is substantial evidence that ingestion of β-glucan can lead to lowered levels of serum cholesterol and of glucose and insulin responses. These are all beneficial responses. Arabinoxylans, which are polymers of xylose and arabinose, are present, in both soluble and insoluble forms, mainly in the cell walls of endosperm and aleurone tissues. They absorb many times their own weight of water and also form viscous solutions in water. Small amounts of cellulose are present in the outer tissues of barley kernels.

Only small amounts of the simple sugars, glucose and fructose, are present in the kernel; the major sugars are sucrose and raffinose, which are present mainly in the embryo. Varying amounts of fructosans, which are fructosyl polymers of sucrose, are also present in the mature kernel.

Barley contains a large number of proteins, which can be separated into four major groups on the basis of solubility. Albumins and globulins (15–30% of barley protein) are soluble in water and salt solutions, respectively; hordeins (35–50% of barley protein), the major storage proteins in barley, are soluble in aqueous alcohol solutions; glutelins (15–20% of barley protein), a mixture of storage and structural proteins, are soluble in alkali. Although aleurone cells are rich in protein, mainly globulins, most of the barley protein is in the endosperm, especially in the subaleurone region.

About 70% of barley lipid is present in the endosperm, 20% is in the embryo, and the remainder is in the outer layers of the kernel.

Minerals such as magnesium, sulfur, sodium, potassium, zinc, and calcium are concentrated in the outer layers of the kernel. Phosphorus is present, mainly, as phytic acid in the aleurone. Refer to Individual nutrients (*See* **Cereals**: Dietary Importance.)

Uses

Animal Feed

The largest use of barley, world-wide, is as animal feed, especially for cattle and pigs. Barley provides a good balance of high energy, because of its starch content, and reasonable protein quality and content. Hulled barley is less desirable than other cereal grains, such as maize, for chicken feed formulations because of its relatively high fiber content. There is increasing interest in developing hull-less barleys for feeding to pigs.

Malting, Brewing, and Distilling

The proportion of the total barley production used for malting varies widely among countries, but world-wide utilization is about 15% of total production. This aspect of barley utilization is discussed more fully in another entry. (*See* **Beers**: Wort Production; **Malt**: Malt Types and Products; Chemistry of Malting.)

Human Food

Less than 5% of total barley production is used for human food in most developed countries, but in some countries in the Far East, Middle East, and North Africa, barley products form an important part of the diet. The most common products are blocked, pot and pearl barley, barley flakes, and barley flour. Blocked barley is prepared by lightly scarifying the grain between abrasive disks to remove the husk. More severe treatment (pearling) results in removal of the outer kernel layers and rounding of the grain to produce pot barley, which amounts to about 65% of the starting material. Extensive pearling leads to removal of the outer endosperm layers and the embryo to leave pearled barley, which is only about 35% of the original barley. These products are used in soups, breakfast cereals, and stews, as tea or coffee substitutes after roasting, and as rice extenders. They can also be milled into flour and used in baby foods, porridge, and some baked goods when blended with wheat flour. Barley may be puffed by heating it under pressure to gelatinize the starch and then releasing the pressure suddenly. The loss in pressure allows rapid expansion of the water vapor and significant puffing of the grain. Barley flakes are made by cooking the barley, rolling the hot, moist product between heavy rollers, and drying the flakes to about 10.5% moisture content. (*See* **Cereals**: Breakfast Cereal.)

Nutrients are not distributed uniformly throughout the barley kernel. Vitamins, minerals and lipids are concentrated in the outer layers and embryo of the grain, and peripheral regions of the endosperm have significantly more protein than central regions. During pearling, therefore, the nutritive value of the product decreases as the outer layers of the kernel are removed. Pearl barley, for example, is nutritionally inferior to pot barley because it does not contain the embryo or any of the nutritionally rich outer layers of the kernel. Hull-less barley may offer some advantages over hulled barley in the food industry.

Sound, bright, uniformly plump kernels with a high test weight ($> 60\,kg\,hl^{-1}$) are preferred for all barley uses. In general, barley cultivars possessing yellow aleurones are also preferred. There is a small, decreasing demand for malts prepared from blue-aleurone barley.

Storage

The end-use quality of grain stored under high moisture conditions deteriorates through loss of viability and attack by insects and microorganisms. The temperature recommended for safe storage depends on the moisture content of the grain. Dry grain (12–13% moisture) can be stored safely at 17 °C, but grain at higher moisture contents deteriorates and should be dried with cool, dry air before storage. Barley intended for malting should not be dried at temperatures over 45 °C because the germination potential of the grain may be damaged. For food and feed uses, however, temperatures up to 60 °C may be used without impairing quality of the grain. Ideally, barley should be stored at about 12% moisture and at 15 °C or less. Grain may be treated with insecticides and pesticides, but some of these may leave unacceptable residues on the grain. It is possible to store grain under anaerobic or low oxygen conditions (e.g., under carbon dioxide or nitrogen), thus slowing down or inhibiting the development of microorganisms and insects. Such treatment does not impair the germination potential of the grain, nor does it leave residues on the grain. (*See* **Cereals**: Handling of Grain for Storage; Bulk Storage of Grain.)

BARRELS

Contents

Beer Making

E R Partington, Nickel Development Institute, London, UK

History

The art of brewing, which became highly developed in most English monasteries, can be traced back to Roman times. For 2000 years beers have been produced and stored in wooden vessels which have been lined with a variety of materials such as pitch to help seal them against leakage. Originally, beer was brewed to meet the needs of small communities and was consumed at the production site but, as demand for it grew, and beer had to be taken to more distant points of sale, transportable casks were required and these, too, were made from wood. The most common size of cask held one 'barrel,' a brewing unit which, in Medieval times, was a volume of 32 imperial gallons (145.5 l) but which is now standardized at 36 imperial gallons (164 l). This volume naturally gave its name to the cask of that capacity but was eventually adopted colloquially for all sizes of cask, despite their having their own names; the 4.5 gallon (20.5-l) 'pin,' the 9-gallon (41-l) 'firkin,' the 18-gallon (82-l) 'kilderkin,' and the 54-gallon (246-l) 'hogshead.' Wooden casks were made from vertical strips of oak, or staves, held tightly together by horizontal steel hoops. For this arrangement to be watertight, the staves were not only tapered so that together they created a circular cross-section but also bowed so that steel hoops could be forced down from the circular end to squeeze them together. This gave rise to the bellied shape of casks, which offered the practical advantages that even the hogshead, which weighed nearly one-third of a ton when full, could be easily rolled and steered along the ground with a stick or by gentle kicking. Then, when it needed to be lifted up to, and laid horizontally on, the rack (or 'stillage') in the customer's cellar, the bellied shape allowed the container to be rocked backwards and forwards longitudinally until it could be lifted smoothly on to its end and then swung completely over and on to the stillage (see Figure 1). There, it was stored until the natural conditioning processes were complete and the beer was ready for drinking. The belly also retained the yeast sediment, which settled during conditioning such that, even as the level in the cask fell, the beer was constantly drawn off from above the sediment, keeping it clear and 'bright.'

Eventually, with the advent of brewing on an industrial scale, metallic materials were introduced for the production vessels, but these were selected essentially for their strength. From the middle of the nineteenth century (with little recognition of the effects of corrosion and the resultant product contamination) process tanks were made out of soldered copper sheet and massive open fermenting chambers were lined with lead. Vessels were sometimes named after the materials that the industry had begun to use and the ingredients for beer are even today boiled in 'coppers.' However, until the mid-1900s, wood remained the only material commonly used for casks for storage, distribution and dispense, with the advantage that staves damaged by impact during delivery could be replaced individually by the cooper.

Although, from 1934, Flowers' Indian Pale Ale was, for a short time, exported in experimental steel casks, it was not for another quarter-century that metals became extensively used for the bulk packaging of beers. Stainless steel was introduced in the late 1950s for the smaller sizes of cask, the dimensions of which mimicked as far as possible those of the traditional oak ones so that they could operate side by side with them, and the weights of which were less than those of wooden casks of the same strength. In the early 1960s, aluminum alloys were introduced because they offered the advantage that, for an equivalent size and strength of container, they were approximately 30% lighter even than stainless steel.

Terminology

'*Beer*' is the generic name encompassing ales, lagers and stouts. '*Container*' is the generic term including all sizes of both casks and kegs (definitions below) (although all are often colloquially referred to simply as 'barrels').

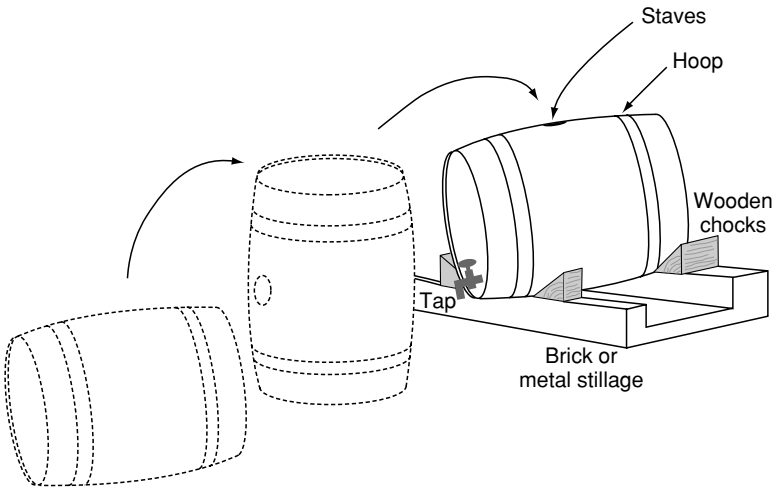

Figure 1 Cask of traditional beer, stillaged and tapped.

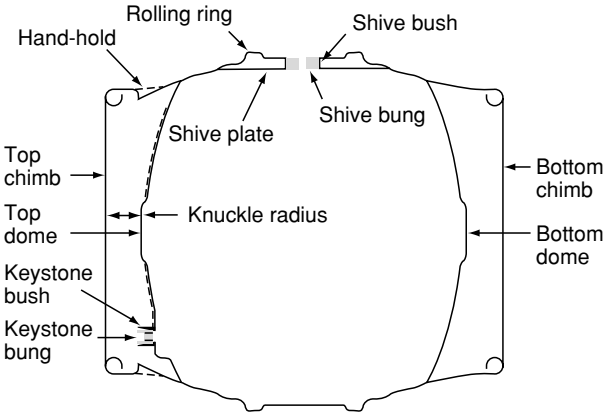

Figure 2 Typical cask for traditional beers.

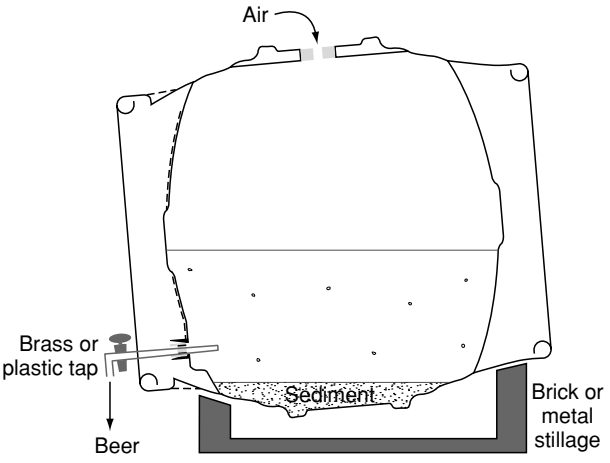

Figure 3 Dispense of beer from a traditional cask.

Traditional ales complete their conditioning in the containers in which they have been transported to the sales outlet. Typically, they have a low carbon dioxide content and can therefore be packaged into dual-aperture containers which, since at least as far back as 1727, have been called *casks*. Originally these were wood, but they are now almost all metallic (see Figure 2) and they are sealed only by tapered wooden (or, latterly, plastic) bungs driven into *shive* (inlet) and *keystone* (outlet) bushes. These bungs are removed when the empty cask returns for washing and are renewed before reuse. Figure 3 shows a cross-section through a cask during dispense.

Pasteurized beers (both ales and lagers) are conditioned in the brewery and have a relatively high gas content (which may be carbon dioxide or a mixture of this gas with nitrogen). In the packaging of these beers, the superior ability of metallic containers to contain a gas pressure becomes of paramount importance, as it is essential to maximizing the shelf-life of the product. Such beers are therefore packaged into single-aperture metal *kegs* (see Figure 4), first developed in the UK in the early 1960s, which incorporate a semipermanent '*extractor*' (or 'spear,' 'closure,' or 'valve'). This is commonly screwed into a '*Barnes Neck*' welded to the keg body (and named after its inventor, Australian Roy Barnes, who was employed by one of the major UK container manufacturers). The extractor remains in the keg whilst it is being cleaned, filled and subsequently emptied. It sits on a synthetic sealing-gasket in the neck and features two concentric, spring-loaded valves (see Figure 5), through the outer of which a gas pressure can be applied at dispense to force the beer up the downtube and through the inner valve to the dispense point on

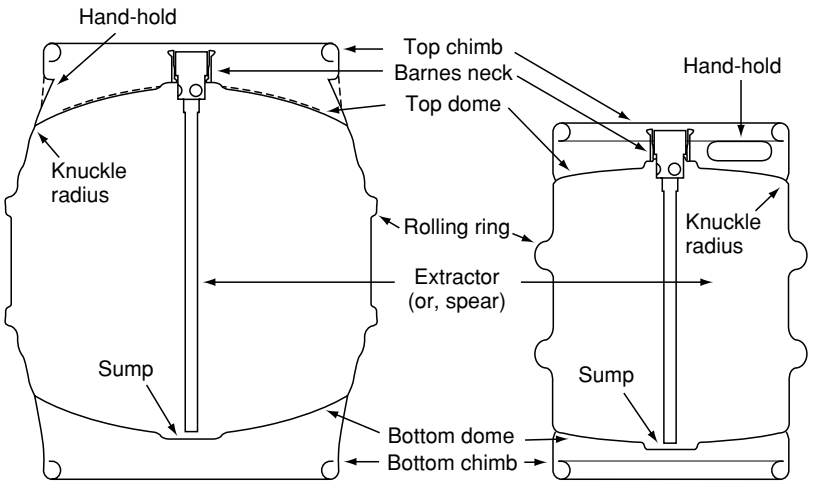

Figure 4 Typical kegs for pressurized beers.

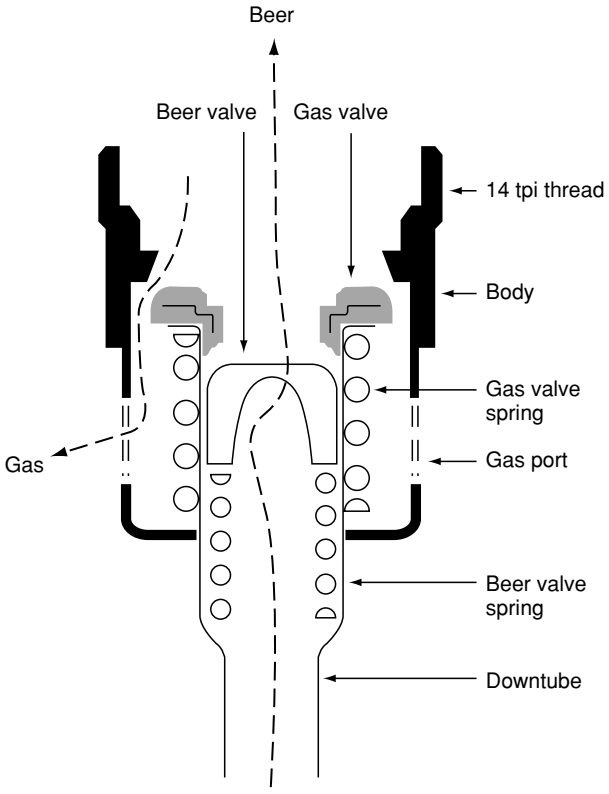

Figure 5 Typical extractor.

the bar (see Figure 6). It is because of this extractor that cleaning and filling can be mechanized and the costs of packaging significantly reduced.

Similar kegs and extractors (with slight design and material modifications to accommodate the more aggressive environment) are also used to package ciders.

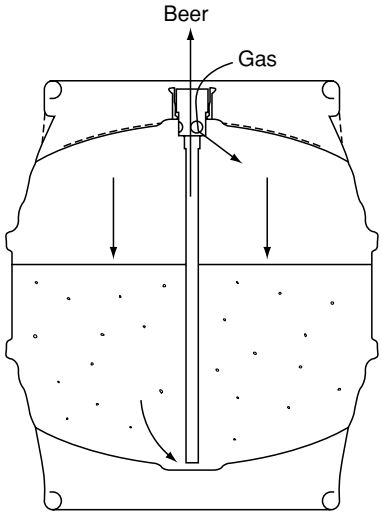

Figure 6 Dispense of beer from a pressurized keg.

Regulations and Codes of Practice

The then-Ministry of Agriculture, Fisheries and Food stipulated that materials must not 'react with, or alter the organoleptic properties of, the foods with which they come into contact.' This legislation has necessitated much research into materials, including the epoxy resins used to line aluminum containers, higher grades of stainless steels, and the synthetics used for the gaskets and valves of the extractors.

The UK Brewers' and Licensed Retailers' Association (now the British Beer and Pub Association) issues the instruction that all pressure kegs 'shall be tested at the manufacturer's works to at least 1.5 times their Safe Working Pressure,' this SWP being 'the maximum gauge pressure to which equipment

should be subjected and which must not be exceeded by any planned method of working.' It further stipulates that the 'maximum test pressure should not subject the material to stresses in excess of 90% of the minimum specified yield for the material [and] shall be maintained for a sufficient length of time to permit a thorough examination to be made of all seams and joints.' In practice, the industry voluntarily applies these same procedures to the manufacture of traditional casks and, in view of this self-regulation, beer kegs and casks are currently exempt from all EU legislation applicable to the design, manufacture and testing of pressure vessels.

Design Considerations

Existing Standards

Few design standards currently exist for beer containers. In the absence of any liaison between brewing companies or container manufacturers in the early days of container production, as many slightly different designs were created as there were customers. Even with the introduction by a significant number of UK brewers of the European cylindrical 11-gallon (50-l) stainless steel keg in the late 1980s, there was little industry-wide standardization of dimensions as each brewer's keg had to meet slightly different operational constraints, particularly those of compatibility with their preexisting packaging, handling, storage and transportation systems. In 1984, however, the major UK brewers came together to form the InterBrewer Technical Liaison Group (INTEL), and this body recommended procedures for materials selection and standards for the performance testing of kegs. In conjunction with INTEL, the UK Brewers' and Licensed Retailers' Association issued in the early 1990s detailed specifications for the two most common designs of Barnes Neck.

Compatibility with Existing Machinery and Equipment

In view of the extent to which the operation of both kegs and casks are now mechanized, it is essential that their designs are compatible with the plant on which they will be cleaned and filled (the 'washer/racker'), the machinery that will palletize them, the cradles, boards or pallets on which they will be stored, the road vehicles on which they will be transported and the dispense environment, including stillages for casks and extractors in kegs.

Strength

Almost all damage to kegs happens in the distribution cycle. Drop tests can simulate a container falling the 4 ft 6 in (1.4 m) from the bed of a delivery vehicle on to a concrete pavement, and evaluate the strength of the rolling rings and the chimbs (the end-rings on which containers stand when vertical and by which they are usually picked up), particularly when a container falls at 45° onto its handholds.

Testing the strength of domes can simulate static loads, such as 'topping.' This is the practice of stacking a small container horizontally on top of a larger, vertical container. Whilst this can save space on a delivery vehicle bed, it can also damage the Barnes Neck or the keystone bush of the lower container.

When a keg is to be cleaned and refilled in the brewery, the washer/racker effects a seal between the washing/filling head and the rim of the Barnes Neck by means of a pneumatically operated clamp. However, a 3-in (75-mm) air-ram at 50 psig (3 bar) exerts a force of nearly 500 lbf (0.25 tonne) axially on to the keg neck – when applied gently. If, however, the head impacts the neck suddenly, the effect can be equivalent to a far higher static force.

If, during the cleaning process, steam injected to purge the detergent is followed by rinse-water, the steam in the keg will condense rapidly to water, creating a vacuum. A hard vacuum applies a force of 700 lbf (300 kgf) to the end-domes of an 11-gallon (50-l) keg, which may cause them to collapse inwards.

Design features such as impressed stars (or, 'cruciforms') spanning most of the diameter of end-domes can significantly increase their resistance to deflection without any increase in weight (see **Figure 7**).

Weight

The strength of a container can be improved by increasing the thicknesses of its materials, but this will increase both its tare weight and its cost, and

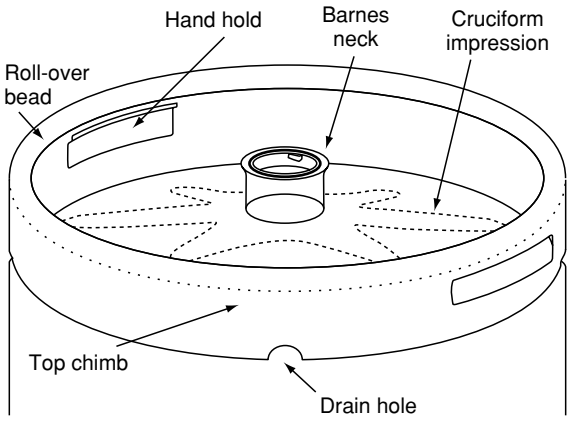

Figure 7 Top dome of a typical cylindrical keg.

will reduce road-vehicle payloads. The use of superior materials, such as half-hard stainless steels (some chimbs being rolled from sheet of over 1000 N mm^{-2}) and the addition of cruciforms will both permit higher specific strengths. However, it is advantageous for there to be as little variation as possible between different manufacturers' tare-weights because of the weighing scales at the end of the filling line in the brewery which automatically check for kegs not sufficiently filled.

In addition to consumer demand for a wider choice of beers at the point of sale, Manual Handling legislation is resulting in a trend towards a greater number of smaller (and, therefore, lighter) containers. Some aluminum hogsheads and barrels remain in service, but most are being phased out in favor of containers of 22 gallons (100 l) or less, which remain of an acceptable weight even in stainless steel. Table 1 shows the weights of typical metal casks. A keg of the same capacity will weigh about 1 lb (0.5 kg) more than a cask because of its extractor.

Volume

Even today, casks are filled manually through the shive bush. It is therefore possible to brim-fill them, and so the content of each cask is the same as its capacity.

Until 20 years ago, kegs were brim-filled in the upright position with the Barnes Neck uppermost, and so, again, the contents were always the same as the capacity. It is now, however, almost universal practice that the machine fills kegs in the inverted position, because the beer can be injected faster (and less turbulently) through the gas ports of the extractor than through the narrow downtube (see Figure 8). However, an inverted keg cannot be filled completely because of the gap between the tip of the downtube and the dome of the keg. There is always a mushroom-shaped gas space left, and this can account for as much as 0.5 pint (284 ml) in a 72-pint (41-l) firkin, and 0.75 pint (426 ml) in a 288-pint (164-l) barrel, depending on the shape of the dome and the distance between it and the tip of the downtube.

However, UK Trading Standards stipulate that, when a brewery fills a batch of containers all of a nominal capacity of (for instance) 18 gallons (82 l) and to be sold as '18-gallon casks' or '18-gallon kegs,' the actual contents of all of the containers in that batch must average 18 gallons (82 l) and each individual container must hold at least nominal-less-3% (17.46 gallons, 79.44 l) in the case of casks or nominal-less-2% (17.64 gallons, 80.26 l) in the case of kegs. Similarly, each individual 11-gallon (50-l) keg in a production batch must hold at least nominal-less-2% (i.e. 49 l). This 'Declaration of Contents' regulation has to be allowed for when specifying the capacities of new containers as containers can change in capacity over long periods of service. Aluminum containers with rolling-rings swaged out of the body tend to grow in length and capacity with time because the rings flatten out, but stainless steel containers tend to shrink by about 0.05% of their original capacity for every year in service because of all the small dents they accumulate. The design specification for the lower limit (i.e., nominal less manufacturing tolerance) of the volume of a container should therefore

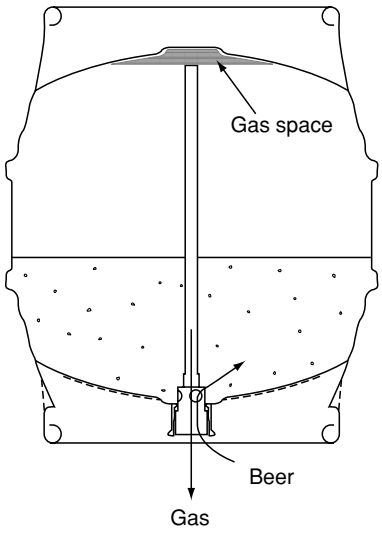

Figure 8 Filling a keg through the gas ports of the extractor.

Table 1 Weights and nominal capacities of typical metal beer casks

Cask			*Material*	*Weight*			
	Nominal capacity			*Empty*		*Full*	
	Imperial gallons	*(liters)*		*lb wt*	*(kg wt)*	*lb wt*	*(kg wt)*
Firkin	9	(41)	Stainless steel	25	(11)	119	(54)
Kilderkin	18	(82)	Stainless steel	51	(23)	236	(107)
Barrel	36	(164)	Aluminum	63	(29)	435	(197)
Hogshead	54	(246)	Aluminum	85	(39)	641	(291)

reflect both filling practice and in-service changes in shape usually by including an over-measure of approximately 1% of the nominal capacity.

Practicality

The profile of the bottom dome of a container can significantly affect both the volume of beer left in the keg after normal dispense and the effectiveness of the on-line deterging procedures. Too shallow a dome radius may result in too much beer being unextractable and, for this reason, many kegs incorporate in their bottom dome a small sump (or 'dimple') of approximately 3 in (75 mm) diameter and 0.25 in (6 mm) depth (equivalent to about one fluid ounce, or 25 ml) into which the tip of the extractor just reaches. However, if the shape of this sump is not carefully chosen, the detergents that are lanced into the inverted keg through the extractor downtube during the washing cycle may not spray evenly over all internal surfaces and clean them effectively.

Tight radii can create areas inside containers that are difficult to clean. Top chimbs usually incorporate small drain points just above the butt-weld, which attaches them to the top dome such that extraneous water drains away easily (see Figure 7).

Material Selection

Operating Environment

The conditions under which casks and kegs must operate influences the choice of the materials used for the bodies of the containers themselves, any protective interior linings they may have, the synthetics of extractor components and any plastics used for shive or keystone bungs.

Beer has a pH of about 4 when fresh, but this can drop to 3.5 or below if the beer is exposed to oxygen, such that it sours, as is inevitable in a traditional cask after dispense. Fresh ciders may have a pH as low as 3.3 and, when oxidized, even below 3. Stainless steel is generally impervious to these levels of acidity, but the oxide layer with which aluminum alloys protect themselves from corrosion is attacked by any pH less than about 4 or over 9. Aluminum alloy containers are therefore internally lined at manufacture by a sequence of steam-sealing, anodizing, and epoxy lacquering. However, if that lacquer lining is broken down (as may occur by impact to the keg during handling), not only can flakes of lacquer get into and jam the extractor valves, but also the keg itself can be corrosively attacked. This is most prevalent at exposed welds and can threaten the structural integrity of the container.

Typically, beer contains chlorides at concentrations up to 350 mg l^{-1} (p.p.m.) and sulfates at up to 300 mg l^{-1}. This environment might only be corrosive to stainless steels if combined with an abnormally high temperature (over about 55°C), which would itself be deleterious to the beer, and might affect areas such as rolling-rings, which retain high stresses from the manufacturing processess. However, for this reason, stainless steel containers should not be exposed to hot, salty conditions such as exist at the seaside in summer, even when empty.

Even during filling and dispense using mixtures of carbon dioxide and nitrogen, the pressures in kegs should rarely exceed 50 psig (3 bar). All containers made in Europe (whether kegs or casks) are designed for a working pressure of 60 psig (4 bar), and every one is tested at manufacture and after repair to 90 psig (6 bar). In practice, aluminum containers rarely fail at less than 300 psig (20 bar), and stainless steel containers commonly withstand pressures of 1000 psig (70 bar).

During the washing and refilling processes, steam at temperatures of up to 145 °C is used to sanitize kegs, and this has generally proved to be too hot for synthetics to be used as a material of construction for beer kegs. If steaming is immediately followed by a charge of inert gas to remove all oxygen before the new beer is added, the material of the container can suffer thermal shock from approximately 120 down to 0 °C. If steaming follows a cold-water rinse, the thermal shock can be from 20 to 140 °C. Such sudden changes in temperature can crack the epoxy linings of aluminum kegs, exposing the substrate to subsequent corrosion by the beer.

Commonly, hot 1% phosphoric acid is used to remove process soils from the interiors of metallic kegs and warm 4% phosphoric solution to remove normal dirt from their exteriors. Alternatively, a hot 2% caustic soda solution with ethylenedianine tetraacetic acid (EDTA) may be used to clean both the interior and exterior of stainless steel containers (but not aluminum containers as caustic soda is highly corrosive).

Some lubricants used on conveyors may embrittle synthetics.

Storage temperatures normally range between 0 and 25 °C. However, temperatures may fall to −20 °C if the container is left outside during winter, under which circumstances the 9% expansion of the water content of the beer as it turns to ice can create internal pressures in excess of 400 psig (27 bar); high enough to distend outwards the end domes of stainless kegs or burst most aluminum containers (especially at sites of corrosion) and all wooden casks. Such pressures in casks may be relieved by the shive

or keystone bungs being blown out, but this may not always happen, particularly if an ice-plug has formed beneath them first. The temperature of a container may rise to 60 °C if it is left exposed to strong sunshine for extended periods in the summer, and this can cause synthetics to soften.

In the event of a fire, the materials of containers should neither ignite easily nor support a flame.

When a container is damaged irreparably, or its design becomes obsolete, the material from which it is made must satisfy the Packaging and Packaging Waste Directive requirements for recyclability.

Materials selected

During the 1950s, attempts were made to develop containers that were stronger, cheaper to maintain and more hygienic than timber alone. A number of material combinations were tried, some more successfully than others:

- A thin stainless steel liner was encased in a wooden cask. This presented to the beer a more hygienic surface than timber alone, but the wood still broke during handling and the stainless steel liner could be dented easily.
- A stainless steel vessel was complete encased in a mild steel jacket. This was known as a 'Brown Bomber' and was strong but very heavy. External rusting of the jacket also presented a poor image of the contents.
- A thin stainless steel body had a pair of mild steel chimbs longitudinally bolted together to entrap the vessel. This was quite strong but, again, unacceptably heavy.
- A cylindrical stainless steel body had interference-fit galvanized mild steel chimbs with integral rolling-rings pressed on to each end. This 'Sunbrite' design, developed by GKN-Sankey, is still in service today.

In the 1980s and 1990s, synthetic materials were introduced:

- Polyurethane was used to jacket thin-walled stainless kegs, with the benefits of both having stainless steel in contact with the beer – but at a thinner, cheaper gauge than would be strong enough to withstand everyday handling on its own – and a synthetic exterior material that could not only be decorative and promotional but also support the stainless lining whilst making the keg considerably quieter to roll around than an all-stainless keg. However, these kegs were not only as expensive overall as all-stainless steel ones kegs, but they were also very difficult to repair, particularly if an impact dented them and delaminated the thin stainless skin from the plastic.
- Under development are all-synthetic kegs made from plastics that can withstand the high stresses imposed during manual handling and the high steam temperatures required to sterilize beer kegs before they are refilled, but which do not taint the flavor of the beer.

The two most prevalent materials now, however, are aluminum alloy and stainless steel. Aluminum alloys, borrowed from the aircraft industry for their lightness and strength, were introduced in the early 1960s. Initially, container bodies were cast, but these were found over time to deteriorate to the point where they could suffer fast fracture at normal working pressures, and so the Brewers' and Licensed Retailers' Association Code of Practice now prohibits the use of cast aluminum for pressure kegs. It may be used for the chimbs welded to the ends of the beer-containing section, but the bodies themselves are manufactured from sheet HE30, a 1% silicon, 0.7% magnesium, 0.6% manganese heat-treatable aluminum alloy. Any welded-on rolling-rings are manufactured from an extruded version of this alloy. Aluminum alloy containers have the advantage of a high specific strength but the disadvantages of high purchase and operating costs. The material requires heat treatment before and after both manufacture and repair and, to minimize its corrosion by the beer, a series of expensive processes including internal steam-sealing, anodizing, epoxy-lacquer spraying and stoving to provide a barrier between the alloy and the beer. However, this protection is still very susceptible to crazing as a result of impact damage during handling and delivery of the container. Furthermore, in the case of pressure kegs (see **Figure 4**), a special design of Barnes Neck is required to insulate the aluminum body of the keg from the stainless steel of the extractor components. It comprises an outer, aluminum bolster welded to the keg body and an interference-fit stainless steel insert (which carries in its bore a female thread for the extractor), the two being separated by an electrically insulating nylon sleeve. Failure of this sleeve, as is common in service, results in the creation of a galvanic cell, the beer acting as an electrolyte between the stainless steel and the aluminum, and this can increase the rate of general corrosion of the aluminum alloy some 30 times. There is also a significant trade in stolen aluminum beer containers, as the material is easily smelted. For these reasons, aluminum containers are almost exclusive to the UK and, indeed, up to the 22-gallon (100-l) size are being superseded by stainless steel containers.

Stainless steels are readily formed and welded, robust, totally inert in normal usage, impervious to the most effective internal and external detergents, simple and economic to repair and very safe. Deep-drawing of the bodies offers a higher strength for the same weight and at about half the cost per unit volume that was possible 10 years ago. The most common sheet material used is EN: X5 CrNi 18/10 (1.4301; AISI 304 – 17/19.5% chromium, 8/10.5% nickel), and there are now approximately 10 million stainless steel beer kegs and casks in service in the UK made from this grade. With its higher resistance to general pitting corrosion, EN: X5 CrNiMo 17/10/2 (1.4436; AISI 316 – 16.5/18.5% chromium, 10.5/13.0% nickel, 2.5/3.0% molybdenum) has been used where the environment was particularly aggressive, such as for ciders to which metabisulfite preservatives had to be added. The 1.4301 series is also used to make the Barnes Necks, but here it is important to ensure its compatibility with the materials of the extractors as two such stainless steel components, connected by fine (14 tpi) threads, may gall (or cold-weld) themselves together unless their individual chemical compositions and their surface topographies and finishes are specified correctly.

Manufacture and Repair

Processes and practices

Aluminum alloys must be solution-treated at over 600 °C before manipulation. Both stainless steel and aluminum alloy containers were originally manufactured with five major components (see Figure 9), to which the 'fittings' (Barnes Necks, shive bushes, and keystone bushes as appropriate) were attached. The center section of the body was formed from rolled sheet, longitudinally welded into a cylinder and then profiled. Two pressed domes were then circumferentially welded on and, to these, the two chimbs were also circumferentially welded. In the 1980s deep-drawing was introduced for both materials, discs being drawn into half-shells to form the center section, to which the two chimbs were attached, all three welds being circumferential (see Figure 10). For both materials, deep-drawing reduced the amount of welding necessary, but in the case of stainless steel it had the added advantage that the material was significantly work-hardened between the two knuckle radii, enhancing the strength of the cylindrical body.

After assembly, aluminum alloy containers are internally steam-sealed, anodized, and sprayed with an

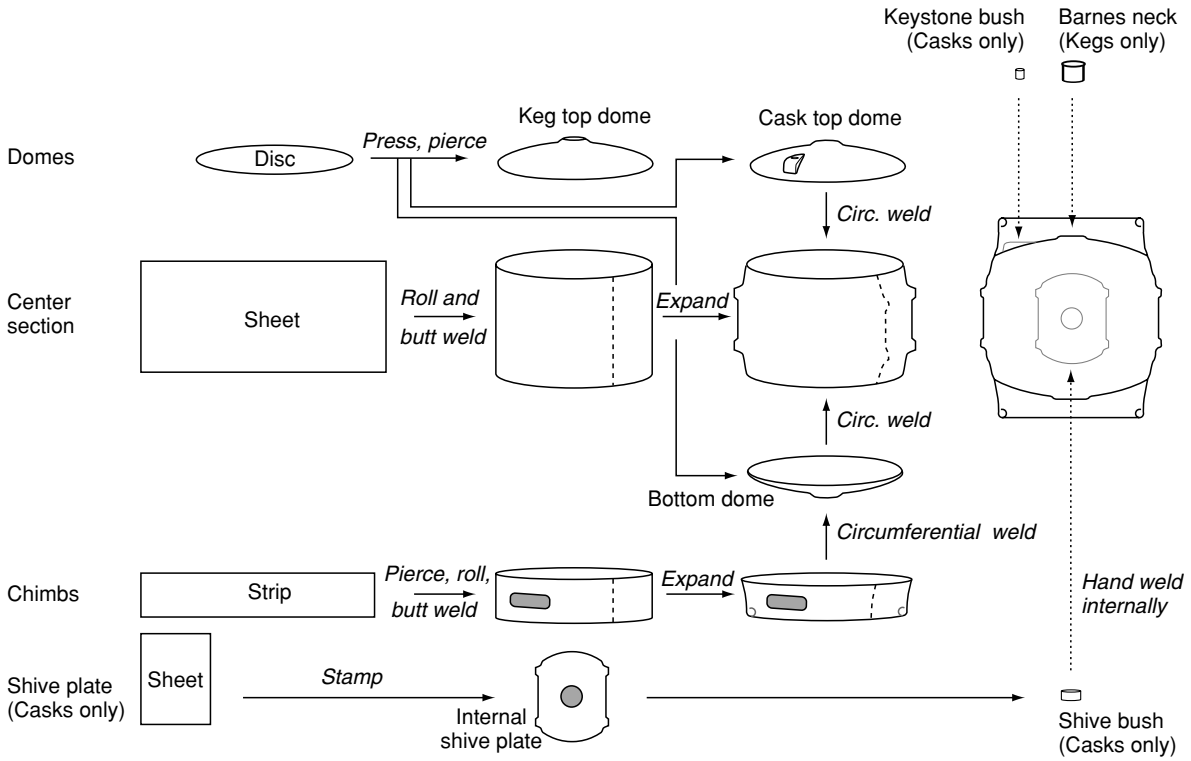

Figure 9 Manufacture of five-piece metal beer containers.

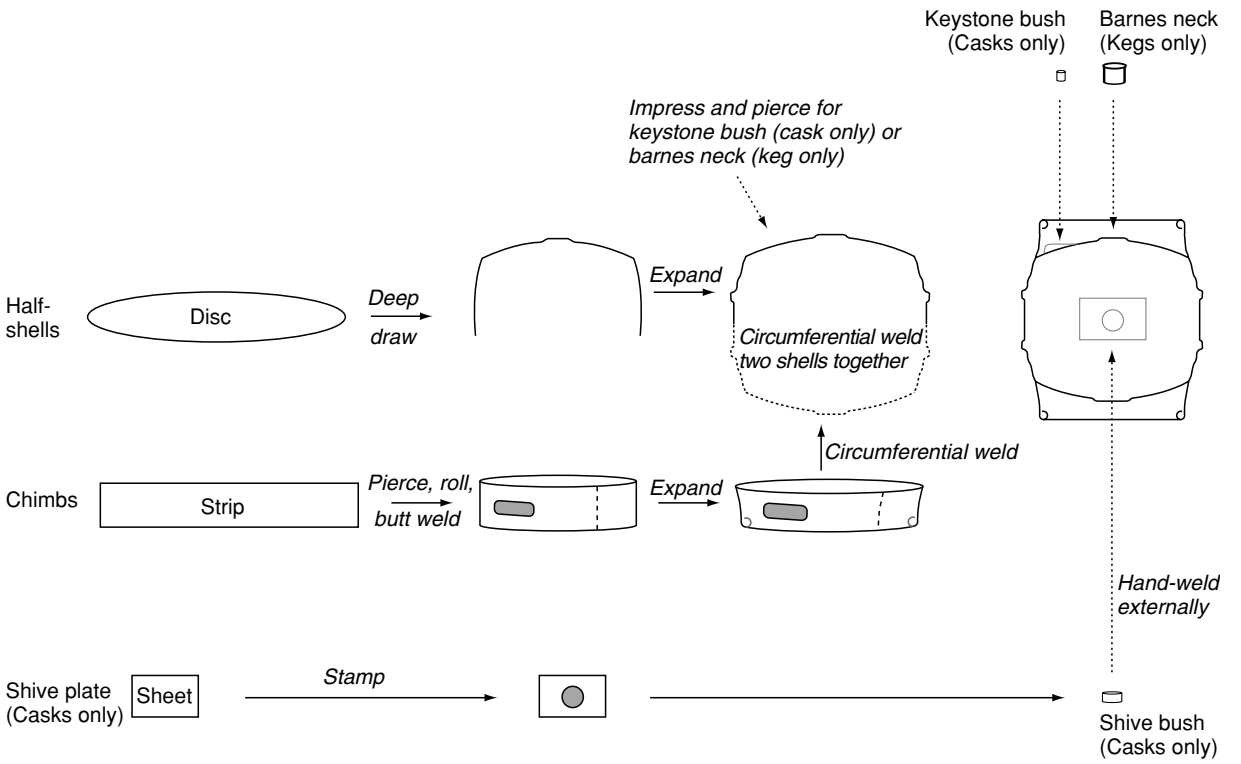

Figure 10 Manufacture of deep-drawn metal beer containers.

epoxy-resin lining. They are then heat-treated at approximately 190 °C both to cure that lining and to precipitation-harden the alloy. Stainless steel containers do not require lining, but must be pickled in a 3% hydrofluoric/10% nitric acid to descale the welds.

After manufacture, all containers are immersed in water and leak-tested to 40 psig (3 bar) with air, and then pressure-tested to 90 psig (6 bar) hydraulically.

Welding Standards

All welding of aluminum alloy containers is by Gas Metal Arc Welding (sometimes known as 'Metal Inert Gas' welding) which involves a filler wire. All welding of stainless steel containers is by Gas Tungsten Arc Welding (sometimes known as 'Tungsten Inert Gas' welding) which does not. Welding standards should control:

- the alignment of components (particularly at butt welds) and the maximum projection of the weld-bead into the beer (both to maximize cleanability);
- weld penetration (to preclude crevices that could be hygiene hazards);
- porosity (to maximize strength); and
- straightness of circumferential weld runs.

Performance in Service

Damage Repair

Although stainless steel does suffer more bending and indentation in service than aluminum alloy, it can be straightened again relatively easily and repeatedly. A cooperage (often sited beside the brewery washer/racker) can hydraulically pull a depressed keg top-dome back up and reround badly damaged chimbs. However, repairs involving capacity correction, pressure testing, welding or fitting of new parts are generally carried out by specialist companies external to the brewery.

All repairs to aluminum containers have to be carried out by specialist manufacturers/repairers, as the alloy requires re-solution-treatment to soften it before reshaping it and then re-precipitation-hardening afterwards.

Corrosion

Once the protective internal lining of an aluminum alloy container is flawed (as can result from impact damage during handling, thermal shock, or physical damage when fragments of the wooden shive or keystone bungs are spiked from inside casks), the material will suffer corrosion by the beer. Attack is

particularly prevalent at exposed welds (these effectively comprising cast material and therefore having a lower corrosion resistance than the parent plate), and ultimately this can threaten the structural integrity of the keg. In normal service, stainless steel kegs exhibit no corrosion.

The Future

To meet the continuing demand for traditional ales, most UK brewing companies still maintain large stocks of casks, these generally being of 4.5, 9, or 18 gallons (20.5, 41, or 82 l, respectively) capacity. However, existing 36-gallon (164-l) and 54-gallon (245-l) casks are generally being replaced by smaller casks, both because of their weight and because of the shorter shelf-life of traditional beers once stillaged and tapped in the cellar, which necessitates high sales volumes.

Existing 9-gallon (41-l) and 18-gallon (82-l) stainless steel kegs remain in common use, but are being supplemented by deep-drawn 30-litre, 11-gallon (50-l) and 22-gallon (100-l) stainless kegs.

Glossary

Barnes Neck A bush welded to the top dome of a metal keg to accept the extractor, which commonly screws into this neck with a 7 tpi or 14 tpi, 2 in. diameter thread (see Figure 4). Between the extractor and the neck is a synthetic sealing gasket to hold the gas in the keg.

Barrel A volume of 36 imperial gallons (163.7 l) which gives its name to a wooden or metal container holding that nominal volume of beer. However, the name 'barrel' is often applied colloquially to other sizes of beer or cider container.

Board An abbreviation of 'Locator Board'.

Cask A re-usable, dual-aperture storage and transportation container for traditional beers which are not ready to drink when they leave the brewery but must complete their conditioning both in these containers and at the sales outlet (see Figure 1). Traditional beers (sometimes referred to as 'real ales') typically have a low gas-content and can therefore be packaged into such containers which are sealed only by tapered bungs driven into their shive and keystone bushes.

Chimb An end-ring formed in a wooden cask by the tips of the staves and in a metallic container usually by a separate component welded to the body (see Figures 2 and 4). Chimbs provide stability when the container is stood upright and also protect the Barnes Necks of kegs.

Closure See 'Extractor'.

Containers The generic term for casks and kegs.

Cooper A craftsman who manufactures and repairs wooden beer containers essentially using hand tools.

Cruciform A star-shape impressed into each dome of a metal keg to enhance its strength; particularly its resistance to end-loads such as those caused by 'topping' or those applied by the 'washer/racker' (see Figure 7).

Dimple An indentation in the bottom dome of a keg to minimize the volume of beer or cider which cannot be extracted. May also be referred to as a 'sump'.

Extractor A bi-directional valve unit which is fitted into the Barnes Neck of a keg and which remains in place whilst the keg is being cleaned, filled and subsequently emptied (see Figure 4). It features two concentric, spring-loaded valves (see Figure 5), through the outer of which a gas pressure can be applied at dispense to force the beer up the downtube and through the inner valve to the dispense point on the bar (see Figure 6). May also be referred to as a 'spear' or 'closure' or 'valve'.

Firkin A beer or cider container with a nominal capacity of 9 imperial gallons (40.9 l).

Handhold An aperture pierced through the chimb of a container to facilitate its being manhandled (see Figures 2 and 4).

Hogshead A beer container with a nominal capacity of 54 imperial gallons (245.5 l).

Hoop A steel band forced down from the end of a wooden cask towards its belly in order to contain and compress the staves and ensure their water-tightness (see Figure 1).

Keg A metallic single-aperture storage and transportation container for brewery-conditioned beers or ciders which are ready to drink immediately upon arrival at the sales outlet (see Figure 4). Because such beers and ciders typically have a higher gas-content than traditional ales, they depend upon the pressure-integrity of a metal container to maintain their condition.

Keystone A wooden bung driven into the outlet bush of a cask (see Figure 2). It is replaced each time the cask returns to the brewery for washing and re-filling.

Kilderkin A beer container with a nominal capacity of 18 imperial gallons (81.8 l).

Knuckle The radius between the dome and the wall of a metallic container.

Locator Board A pallet-like component made of timber or plastic on which four or six containers are stacked on end in a rectangular array. Another board is placed on top of the containers and another array of containers on top of that, and so on. Two or three layers of containers at a time (according to their size) may be moved by a fork-lift truck which is fitted with special tines which clamp the sides of the containers

with a horizontal pincer-action. In the warehouse, stacks of containers will comprise at least six layers.

psig Pounds force per square inch (gauge) – i.e.: above atmospheric pressure.

Pin A beer container with a nominal capacity of 4½ imperial gallons (20.5 l).

Rolling rings Rings around the belly of a container transverse to its longitudinal axis to provide integral 'wheels' to facilitate its being rolled in a straight line. They are formed either by swaging them out from the material of the wall of the container or by welding on separate components (see Figures 2 and 4).

Roll-over bead The curling-over of the extremity of the chimb of a metallic container to form a bead which provides a comfortable and safe area to grasp the container, add strength to the chimb and offer a firm ring on which the container can be stood (see Figure 7).

Shive A wooden (or, latterly, plastic) bung driven into inlet bush of a cask (see Figure 2). It is replaced each time the cask returns to the brewery for washing and re-filling.

Spear See 'Extractor'.

Staves Shaped strips of oak, longitudinal to the axis of a cask and held tightly together by horizontal steel hoops (see Figure 1).

Stillage A wooden, brick or concrete cradle in the cellar of a public house on which casks are laid essentially horizontally while the conditioning process is completed and the sediment of their traditional ale settles into the belly of the cask, leaving the beer clear and ready to drink (see Figures 1 and 3).

tpi Threads per inch.

Topping The practice of stacking a small container which is horizontal on top of a larger container which is vertical (i.e.: standing on one end) in order to save space on a delivery vehicle bed.

Washer/racker The item of plant in a brewery which automatically cleans and re-fills metallic beer kegs. It manipulates the kegs and locates emptying- and filling-heads onto their Barnes Necks by means of pneumatic rams.

Valve See 'Extractor'.

Introduction

The use of oak wood for making barrels is primarily explained by its mechanical properties (strength, hardness, and flexibility) and low permeability to liquids. Nevertheless, contact with oak wood also strongly influences the flavor of barrel-stored wines and spirits. This article principally covers oak wood properties, methods of barrel construction, the organoleptic effects of oak wood, and its use for aging wines and spirits.

Oak Wood

Types of Oak

Oaks belong to the genus *Quercus*, which is divided into two subgenera, *Cyclobalanopsis* and *Euquercus*. The subgenus *Euquercus* is divided into six sections. The section *Lepidobalanus* is widely distributed, being found in Europe, Asia, North Africa, and North America, and includes the important species used in cooperage.

In Europe two species provide wood for the construction of barrels: *Quercus robur* (also known as *Q. pedunculata* or pedunculate oak) and *Q. petraea* (*Q. sessiliflora* or sessile oak). In North America, 10 species of white oak are reported to be used for oak cooperage, the most important of which is *Q. alba*. While additional oak species may be suitable for cooperage it is unlikely that their use will ever become anything other than a novelty.

Different ecological preferences characterize the two European species. *Q. robur* is a faster-growing,

pioneer species and grows best in fertile soils with good water supply. *Q. petraea*, however, is more drought-resistant and better adapted to dry, acid soils. The geographical range of *Q. robur* extends further east than *Q. petraea*, as far as the Ural mountains. However, the distribution of these species in much of Europe no longer reflects their ecological preferences due to considerable transportation and indiscriminate planting of seeds. Within most of Europe, both pure and mixed forests of the two species are observed and there is strong evidence indicating that some degree of interbreeding between the species may occur.

American oak cooperage comes from central and eastern USA, mainly from Indiana, Tennessee, and Missouri. While the dominant species *Q. alba* is found across all states, certain oak species have very localized distributions.

Wood Structure

Two different wood zones are clearly distinguishable within a cut oak tree. Beneath the bark and cambium is a layer of lightly colored sapwood generally representing 10–20 years of growth. The rest of the tree is composed of older, darker-colored heartwood and it is only from this part that wood is cut for cooperage. The transformation of sapwood into heartwood is characterized by the laying down of tyloses – membraneous growths that block large vessels and reduce wood permeability. Some oak species, notably red oak (*Q. rubra*), lack tyloses and are therefore not suitable for cooperage. Heartwood formation is also characterized by cell death, the removal of starch, and the laying down of diverse extractible compounds in the dead cells of the heartwood. Despite the lower permeability and greater durability of heartwood, the woods are structurally very similar.

Oak wood is known as a 'ring porous' wood, with each year of growth defined by clearly visible annual rings. Each of these rings consists of two types of wood: the early (or spring) wood and late (or summer) wood (Figure 1). The early wood is predominantly made up of large vessels and is laid down early in the growing season. The width of early wood tends to vary little between growing seasons. In contrast, the width of late wood, made up of mostly wood fibers and small vessels, varies according to the growth rate. Thus, the relative proportion of early and late wood is highly dependent upon the growth rate of the tree, with fast-growing trees containing a higher proportion of late wood.

Heartwood Chemistry

Wood has three main structural components: lignin, cellulose, and hemicellulose. These complex polymers are mostly insoluble in alcohol–water solutions. The remaining 5–12% of wood mass is composed of extractible compounds. This fraction consists mainly of the ellagitannins with a variety of other compounds belonging to diverse chemical classes (Figure 2).

The concentration of particular heartwood compounds varies among the different woody tissues. Furthermore, certain compounds undergo gradual transformation over the lifetime of the tree. The ellagitannins become increasingly insoluble due to

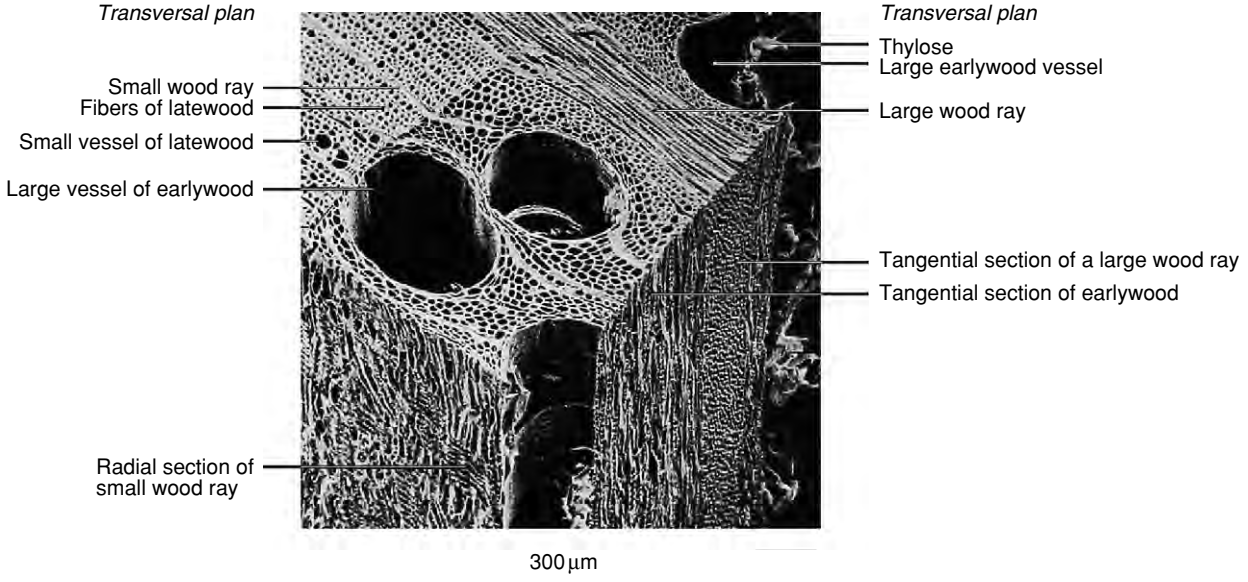

Figure 1 Oak wood anatomy.

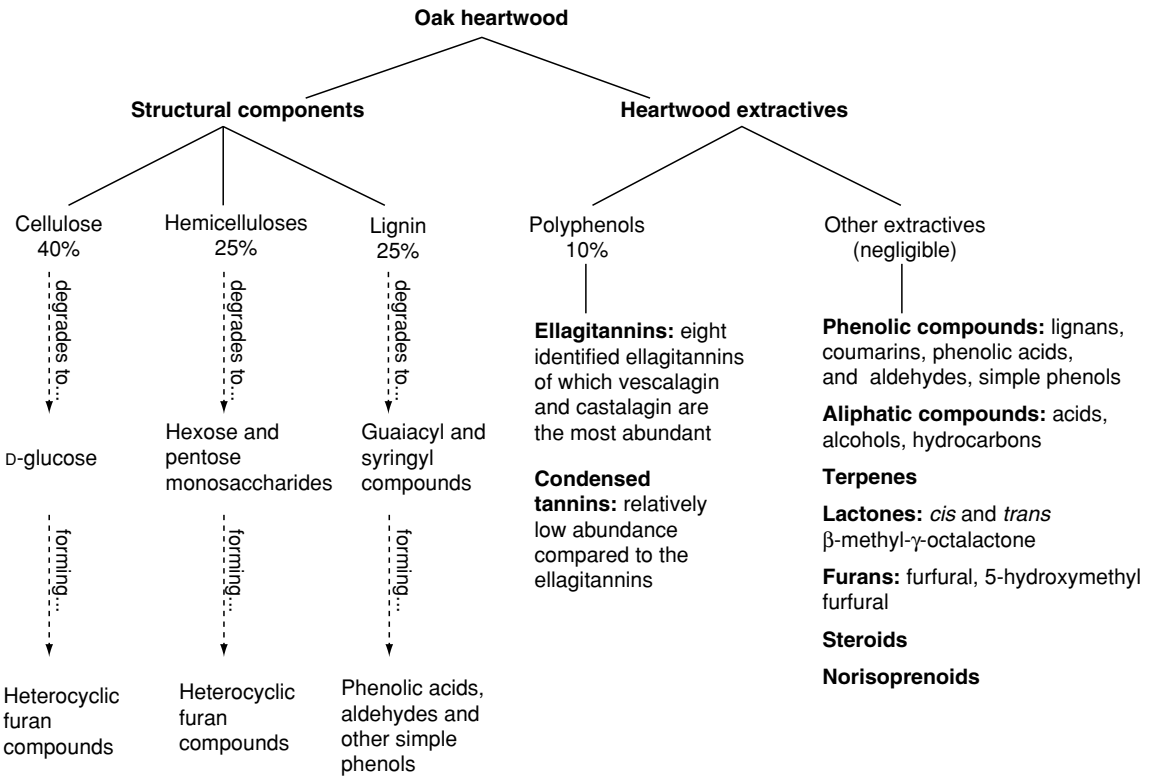

Figure 2 The major chemical constituents of oak heartwood. Percentages indicate the percentage of wood mass made up by the constituent.

polymerization and therefore levels of soluble polyphenols decline in the central, older heartwood.

Method of Manufacture

Barrels are made in several stages: preparation of the wood, making the staves, 'raising' the barrel, bending staves by heating, beveling, grooving and placing heads, hooping, and checking for defaults (Figure 3).

The Cooperage Industry

The two main sources of oak cooperage have traditionally been France and the USA, although recent years have seen a growing supply of oak wood and casks from eastern Europe.

In France, the cooperage industry is one of the most important purchasers of top-quality oak wood, with 250 000 m^3 of oak timber used in 1997, representing 400 000–450 000 barrels of an average capacity of 220 l. Over half of this production is destined for export. The cognac and armagnac market accounts for about 10% of barrel production, with the rest destined for wine aging.

In contrast, the much larger American cooperage market is dominated by the spirits industry. The much larger scale of production has also led to greater automation in cooperage methods. Nevertheless, smaller cooperages, often affiliated to French *tonnelleries*, are also found and cater in particular to wine makers.

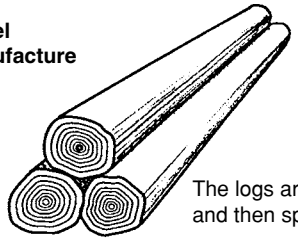
Selection and Cutting of Stave Wood

High-quality wood needed for barrel-making is cut from trees with a girth of at least 35 cm and generally 100 years old or more, depending on growth rate. Perfect straight-grained logs are used, with the timber selected for its mechanical properties, its suitability for shaping, and its porosity.

European oak is traditionally split along the grain into bolts, before quarter-sawing staves (Figures 4 and 5). The finished staves are about 3 cm thick. This method of cutting is considered to produce staves possessing the best mechanical properties and to improve the impermeability of barrels. However, 5 m^3 of logs is required to produce 1 m^3 of stave wood.

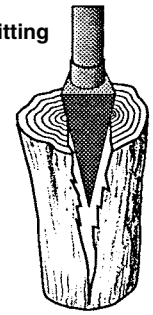
American logs are rarely initially split into bolts, but rather staves are directly sawn from cut logs. While this method is both quicker and less wasteful of wood, it is not considered suitable for European wood. The greater abundance of tyloses observed in most American oak may render it less permeable than

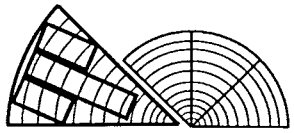
Barrel manufacture



The logs are cut to the desired length and then split into bolts

Splitting

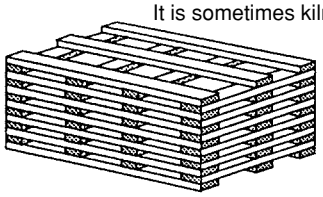




The bolts are cut into stave wood

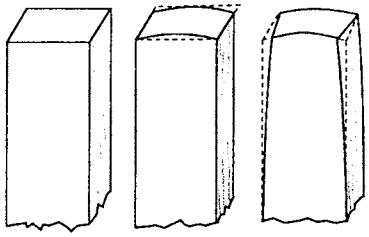
Drying

The wood is dried outdoors exposed to the weather for 3 years.
It is sometimes kiln-dried after air drying...



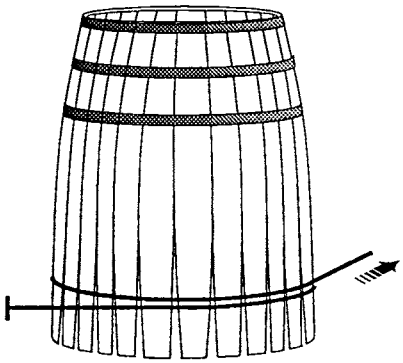
...the staves are shaped

Planing and hollowing **Shaping and jointing**

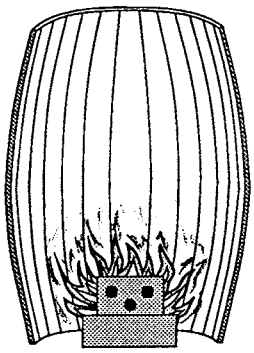


Raising the barrel and bending

This is carried out with a windlass or a bending machine...

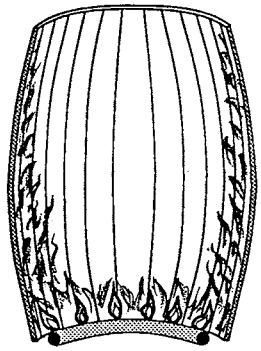


...the wood is dampened outside and heated inside



The European technique
Bending with a wood-fired brazier for about 20 min followed by further heating:

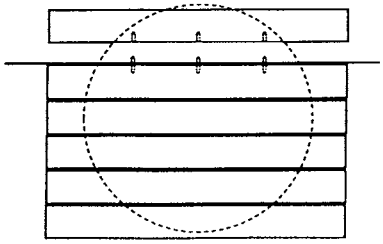
5–10 min: light heating
10–15 min: medium heating
15–20 min: heavy heating



The American technique
Steam bending followed by charring with a gas burner:

15 s: light char
30 s: medium char
45 s: heavy char

Making the heading pieces



The heads are made up of 7–9 boards assembled with dowels. Strips of reed make them liquid-tight

The final hoops are fitted and the barrel is tested with hot water

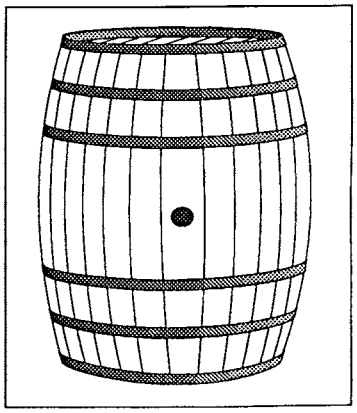


Figure 3 Barrel manufacture.

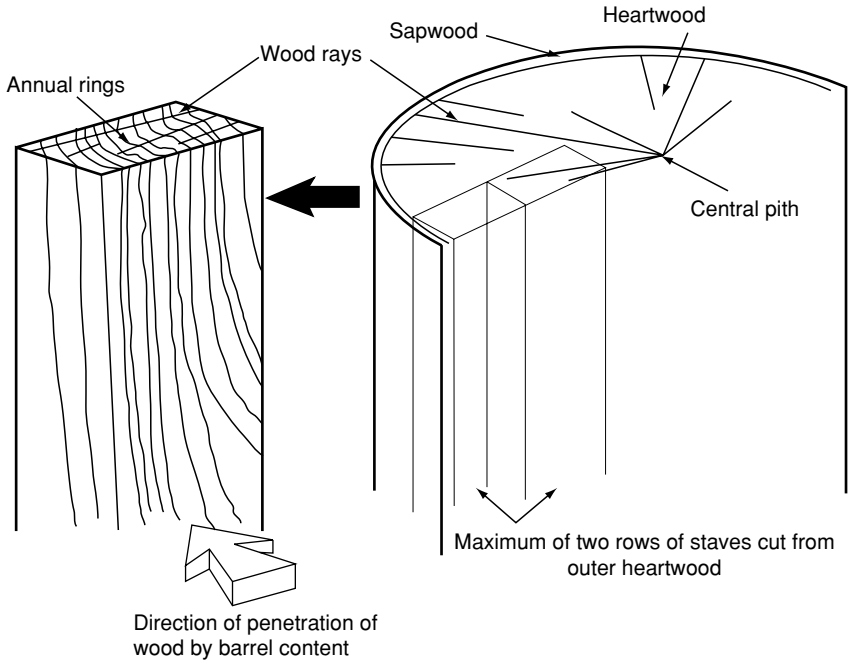

Figure 4 Quarter-sawn stave: orientation and location in the bole of the tree.

European oak wood and therefore this reduces the importance of careful splitting and cutting of barrel staves.

Drying

Wood that is dried below what is termed the fiber saturation point (about 30% water content for oak wood at 20 °C) undergoes shrinkage. The degree of shrinkage varies along the different dimensions of the wood, with radial and tangential shrinkage being much greater than longitudinal shrinkage. Oak used for barrel construction, therefore, is dried to 14–18% water content to insure that any further moisture loss will cause little dimensional change.

In France, oak wood is traditionally dried (or 'seasoned') using drying stacks (Figure 6) in the open air for about 3 years; it is considered that drying requires 1 year for each centimeter of stave thickness. During this period, changes may occur in the physical, mechanical, and biochemical properties of the wood. These modifications are influenced by the initial properties of the wood (e.g., density) and the stacking technique and climate. During air-drying, a diverse fungal flora also develops on the surface of staves, down to a depth of 3–4 mm.

An alternative drying method is by forced-convection kiln-drying. As oak is one of the most difficult types of wood to dry, the conditions of kiln-drying are very gentle (40–65 °C) to avoid any physical degradations (deformations, splitting, wood collapse). Despite the difficulties of kiln-drying oak, the greater flexibility and speed are clearly an advantage compared to the long process of air-drying. It is common for wood to be initially air-dried for 12 months or so and then kiln-dried according to need. An alternative kiln-drying method, used primarily in the USA, consists of rapidly kiln-drying the wood to a reduced moisture content of between 25 and 40%. The drying is then completed by traditional kiln or air-drying.

Barrel Assembly

An average of 28–32 staves and 12–16 head pieces are used for the construction of a barrel. The first phase of construction involves the preparation of barrel staves. After being cut to the same length, they are planed, hollowed, shaped, and jointed. Planing renders the outer surface of each stave convex. The inside of the stave is hollowed to give the barrel a regular, concave shape. The staves are shaped to make them narrower at the ends than in the middle. A typical stave is 27 mm thick at the top and 24 mm thick in the middle (the bilge). The next step of construction is 'raising' the barrel, when the staves are assembled in a 'truss hoop' before tightening.

Bending

This is a very important part of the barrel-making process as it governs, to a great extent, the quality and longevity of the barrel; poor heating can lead to defective products. In Europe, bending is traditionally

Figure 5 Splitting into bolts.

Figure 6 (see color plate 3) Stave wood drying in the open air.

Figure 7 (see color plate 4) A barrel placed over a brazier for bending.

Figure 8 (see color plate 5) Preparation for bending with a brazier.

performed over a wood fire, whereas steam is most frequently used in the USA.

In the traditional wood fire technique, the cooper burns oak chips and off-cuts in a brazier to make a fire inside the assembled barrel (Figure 7 and 8). The barrel may be turned to insure even heating of all the staves. As the barrel begins to grow hot, the cooper windlasses the base of the barrel while continuing to feed the fire. He takes care to heat the central part of the staves so that they bend without breaking and he may cover the barrel shell to concentrate the heat inside.

The wood is heated to temperatures of up to 200 °C during the operation. Such temperatures modify the thermoplasticity of certain polymeric constituents of wood (polyoses and lignin), allowing it to bend without splitting or breaking. The inside and outside of the barrel are dampened during bending to prevent warping and difficulties when the heads are inserted.

The barrel is then turned over and new hoops fitted. They are hammered on strongly while the barrel is still hot to tighten the staves and make the

joints perfectly liquid-tight. Once the barrel has been formed, coopers may continue heating the barrels (Figure 9).

Toasting and Charring of Barrels

The degree of additional heating (or 'toasting') influences the organoleptic qualities of the wood. Both the duration and intensity of heating may vary. Light and medium heating differ mainly in the duration of heating (5–10 min), with temperatures generally varying from 150 to 200 °C. Intense heating (heavy toast) occurs at higher temperatures and is stopped when exothermic reactions begin, that is to say at about 280 °C, as the barrel may catch fire at higher temperatures. Traditionally, only the barrel staves are heated. The heads, forming nearly 25% of the barrel surface in contact with the liquid contents, do not generally receive heat treatment.

In the USA, most barrel staves are more intensely treated to produce a layer of char on the inner surface of the barrel. After being assembled by steaming, barrels are then put over firing pots to dry the staves and remove the surface moisture acquired in the steam box. Next, they are sent to the charring fires where the inside of each barrel is treated for 15–45 s according to the depth of char desired. Barrel heads are also charred on a heading char machine.

Final Assembly

The heads are assembled with wooden dowels; a length of reed is fitted in each joint to give a good seal. They are cut to the required length and fitted to each end of the barrel. The barrels are crozed – a groove is cut in the ends of the staves to hold the head.

The truss hoops used during assembly are removed and replaced by the final hoops. The bung hole is drilled and boiling water or steam is injected to check for any leakage.

Figure 9 (see color plate 6) Heating barrels.

Organoleptic Properties of Oak Barrels

The cooperage industry used to manufacture barrels in chestnut or other woods such as acacia for transporting beverages or dry goods. Today, oak casks are used exclusively for the aging of wines and spirits and a few other food products (e.g., certain vinegars and sauces). The barrel plays an important role in the final flavor of the wines and spirits that it contains. (*See* **Wines**: Types of Table Wine; **Whisky, Whiskey and Bourbon**: Composition and Analysis of Whisky.)

The Effect on Flavor of Wood Constituents

The barrel directly influences flavor through the following mechanisms:

- direct extraction of soluble oak wood compounds
- partial disintegration of structural macromolecules and extraction of the resulting compounds
- transformation of extracted compounds and interactions with other wine or distillate compounds

Only a small fraction (4–5%) of lignin slowly degrades through ethanolysis and is extracted from the wood. In contrast, 55% of phenolic compounds in the wood are extracted. The most important polyphenol compounds extracted are the ellagitannins, yet these are not found in mature spirits and only very low quantities are found in oak-aged wines. Recent research has revealed that these molecules react with ethanol and form hemiketal or ketal derivatives. These derivatives have astringent properties and oak polyphenols are also responsible for the color of oak-aged spirits. Nevertheless, the exact role of polyphenolic compounds in the aging of wines and spirits remains poorly understood.

The principal volatile compound extracted from oak wood is *cis*- and *trans*-β-methyl-γ-octalactone (also known as oak or whisky lactone), and the quality of both wines and spirits has been found to be correlated with levels of this compound. Other compounds which are extracted from the wood and which may affect the characteristics of wines and spirits include volatile phenols, furans, and pyrazines. The levels of these compounds, however, are generally below individual flavor-threshold values and many are only formed in abundance as a result of the heat treatment of barrels.

The oak barrel also indirectly influences the flavor of aging beverages. The barrel defines the physical conditions of storage which will influence, among other factors, the evaporative losses of water, alcohol, and other volatile compounds. The layer of char in barrels used for aging spirits serves as an adsorbent for volatile substances formed during distillation. Storage in barrels also results in special redox

conditions, with the wood allowing continuous, if limited, interaction between the wine and the outside atmosphere.

Oak constituents of the wood may also indirectly influence flavor by chemical or physical interactions with wine and spirit constituents, influencing conditions such as pH, oxygen availability, the solubility of other volatile compounds, and the catalysis of various reactions. During the maturation of spirits, the gradual evolution of distillate compounds over the years is as important for the flavor of the final product as any direct effect of the wood.

The Influence of the Type of Wood and Barrel

Oak wood is a heterogeneous structure, the properties of which are highly variable. Furthermore, the wood used for barrels derives from different countries, species, and forests. In addition to this 'natural' variation, the method of construction also influences the properties of barrels. Different methods of wood drying and particularly barrel heating have important effects on barrel properties. It is therefore not surprising that the flavor effect of barrels has been found to be highly variable.

Natural variation of wood properties Different species of oak are characterized by different levels of heartwood extracts. The dominant American species (*Q. alba*) is characterized by low levels of oak tannins but high amounts of certain volatile compounds, notably β-methyl-γ-octalactone. American oak wood is also generally denser and has more tyloses. Of the two European species, *Q. petraea* has been found to possess levels of extracts closer to those of American oak, namely high oak lactone and low tannin concentrations, than the other European species, *Q. robur*, even when growing in the same forest (Table 1). Recent studies suggest that the heartwood properties of different American species may also vary.

Not all natural variation is explained by species differences. There is also high heterogeneity in heartwood properties among individual trees of the same species.

A recent study comparing barrels constructed from the wood of individual trees by the same cooper found that the resulting wines were very different. The heartwood concentrations of *cis*-β-methyl-γ-octalactone in the oak wood was the factor that most influenced wine flavor.

Barrel variation Differences in the method of constructing barrels may either augment or reduce natural differences in the properties of oak wood. The most important factor influencing barrel properties is the heating of the wood during construction. The various heating and charring operations during barrel construction modify the chemical composition and macromolecular structure of the wood. These changes depend on the intensity and duration of treatment.

The most susceptible polymers to heating are the oak polyphenols, followed by the hemicelluloses and finally the lignin–cellulose matrix. Thermal degradation leads to the appearance of volatile compounds which are present in only negligible quantities in unheated wood. Thermo-sensitive hemicelluloses and celluloses degrade to hexose and pentose monosaccharides which are in turn susceptible to degradation, forming furan products such as furfural and 5-hydroxymethyl furfural (Figure 2). The thermal degradation of lignins produces aromatic aldehydes (cinnamic and syringyl aldehydes). The intensity of heating influences the composition of degradation products. At higher temperatures, aromatic aldehydes give way to their respective acids and dimethoxy

Table 1 Concentrations of heartwood extractives measured in three oak species by studies of (I) barrel staves and (II) wood cores of individual oak trees. Maximum, minimum, and mean values for the sum of eight identified oak ellagitannins (mg g^{-1}) and the sum of *cis*- and *trans*-β-methyl-γ-octalactone (μg g^{-1})

(syringyl) thermolysis products become increasingly prevalent compared to methoxy (guaiacyl) compounds. (*See* **Browning**: Nonenzymatic; **Phenolic Compounds**.)

Structural modification of the wood due to the thermolysis of parietal structures also leads to increased accessibility of solvents to extractible compounds.

Wood-drying conditions also affect the chemical composition of oak wood. Air-drying leads to a greater loss of oak wood ellagitannins than does kiln-drying. The effect of kiln-drying varies according to the temperatures used, with the loss of many volatile compounds (e.g., oak lactone, eugenol) increasing at higher drying temperatures. At drying temperatures of 65 °C or more, a slight degradation in the xylan and glucomannan hemicelluloses is observed.

Barrel Use

Barrels are selected and used according to the properties of the spirit or wine being aged. The correct selection and use of barrels is essential in achieving the desired final product.

Barrel-aging Wines

The costs of barrel-aging restrict their use to only the more prestigious and expensive wines. Traditionally, red wines are aged in barrels directly after vinification, for a period of 6–18 months, before bottling. White wines are sometimes barrel-fermented, the wine being transferred to the barrel before alcoholic fermentation is completed. Both red and white wine may also undergo malolactic fermentation during barrel-aging.

Barrel selection and aging practices depend on the type of wine; the cask should contribute subtle fineness and aromatic complexity without overwhelming the inherent character of the wine. In general, the barrels used for wines are less intensely heated than those for spirits. The type of bung, the frequency of topping-up barrels after evaporation loss, the proportion of new to old barrels, and the cellar conditions will also all affect the aging process. The maintenance of good barrel hygiene is more important in wine than spirit aging due to the greater risk of bacterial contamination. Barrels may be a refuge for microbial contamination and the build-up of tartrate deposits can prevent easy cleaning.

Some wines, and especially sherry, are aged in oak butts using the 'solera' system, which is in effect a process of blending across vintages. After use, these barrels are much sought-after for aging Scotch whisky.

Barrel-aging Spirits

Both the type of cask and the duration of maturation vary widely and are often defined by legislation according to the product name. Thus, American corn whisky must be matured in new, charred barrels, while in Canada and Scotland, maturation must be for a minimum of 3 years. Therefore, the bourbon industry is the main user of new, charred American barrels, which are subsequently reused for aging Scotch whisky and rum. These spirits may remain in barrels for over 10 years. Cognac and armagnac are matured in European oak (**Figure 10**). Coarse-grain (wide annual rings) wood is preferred, as it is considered more porous and releases more tannins than fine-grain oak. Coarse-grain wood is predominantly of the species *Q. robur* and fine-grain is mostly *Q. petraea*. This difference of species is likely to explain the difference in the levels of tannins extracted. The spirits are first lodged in new barrels for several months and then transferred to old barrels. Aging periods may range from 3 years to several decades, with a minimum of $2\frac{1}{2}$ years' aging required for armagnac and cognac under European Union law. While it is in the wood, the spirit acquires color and its bouquet becomes richer and more complex. (*See* **Tannins and Polyphenols**.)

Exhaustion and Rejuvenation of Barrels

The amount of wood constituents extracted and the effect on flavor decline with repeated (or extended) barrel use. A number of methods are used to restore some of the effects lost. The most common techniques include the scraping out of the inner surface of barrels to expose new, unextracted wood, and/or reheating or recharring the inside of barrels. These techniques rarely fully restore the barrel; recharring will not restore products other than those deriving from the heat degradation of wood macromolecules.

The change from using ex-sherry casks to ex-bourbon casks for Scotch whisky maturation led some producers to adopt various cask treatments such as allowing them to absorb white wine or a very sweet, dark sherry under pressure, before using them for whisky. The beverage previously aged in the barrel is considered to influence the flavor of the whisky.

Barrel Alternatives

The use of cheaper alternatives to barrel-aging have become increasingly popular, particularly in the new-world wine and brandy sectors. The adoption of such alternatives is, however, often limited by legislation preventing their use. This is notably the case for the whisky and European wine and brandy sectors.

Figure 10 (see color plate 7) Aging spirits in oak barrels. Reproduced from Barrels *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

The simplest method of 'oak-aging' is by the use of oak chips. Many different types of chips are available according to their size, wood origin, and treatment (degree of toasting). Other barrel-alternatives include various systems of removable staves which can be simply replaced once exhausted. These systems are used in conjunction with either inert tanks or with old oak barrels. Such methods are widely used for wine-aging outside Europe.

Another barrel-alternative is oak wood extract, whose use tends to be limited to brandy production. Wood extracts (*boisés*) allowed in the production of armagnac and cognac must be obtained by extracting oak chips using boiling water and are therefore normally devoid of volatile components, consisting mostly of oak polyphenols and their degradation products. More sophisticated extracts are available as either liquids or lyophilized powders, deriving from an infusion or extraction of oak wood that may have been previously subjected to physical or chemical treatments to promote degradation.

Future Developments

Most attention has recently focused on the variability of oak barrels. There is greater interest in defining the natural properties of stave wood influencing the maturation of wines and spirits. The dominant factor appears to be the biological species, but further studies are needed to estimate the relative importance of natural variation between oak trees, forests, and species.

Coopers also continue to optimize barrel production and quality. In particular, toasting and charring processes are more carefully supervised and controlled.

One of the main unknowns is the future development of barrel-alternatives. Current systems are likely to be refined and perhaps new methods proposed that more closely simulate barrel-aging. However, despite the widespread use of barrel-alternatives for new-world wines, the demand for barrels has showed no sign of significantly decreasing. If oak chips and other systems allow an economical alternative to oak barrels, this has not prevented the continued use of barrels for the most prestigious of oak-aged wines.

Background

Throughout human history, more than 3000 species of plants have been used as foods. On a global basis, plants provide 65% of food protein and over 80% of food energy, and account for 85% of gross tonnage. Excluding the large number of fruit and vegetable species, only about 50 crop species make a significant contribution to human diet. Of these, cereals are the largest group, followed by legumes, in terms of global production. However, because legumes contain almost two to three times more protein than cereals, their dietary importance as protein source is well appreciated. Of more than 1300 species of legumes, only about 20 are most commonly consumed by humans. Among these, the common dry bean, *Phaseolus vulgaris*, is consumed in the largest quantity on a world-wide basis. Dry beans are low in fat (excluding oilseeds), low in sodium, and contain no cholesterol. They are a rich source of proteins, complex carbohydrates, fiber, vitamins, and certain minerals. On a caloric basis, dry beans are more nutrient dense than cereals. Dry beans are less expensive than animal food products and, when stored properly, have a considerably longer shelf-life than several animal, fruit, and vegetable products. Since legumes have the ability to fix atmospheric nitrogen and therefore add nitrogen to the crop–soil ecosystem, they are important in soil conservation and maintenance of soil quality.

Global Distribution, Varieties, and Commercial Importance

The word 'legume' is derived from the Latin word '*legumen*,' which means seeds harvested in pods. The term 'pulse' (from the Latin word '*puls*,' meaning pottage) is used for legume seeds that contain small amounts of fat, whereas for those containing large amounts of fat (such as soybeans and peanuts), the term 'leguminous oilseed' is used. According to the Food and Agriculture Organization (FAO), the word 'legume' is used for all leguminous plants. The legumes most commonly used as human food are listed in **Table 1**.

Although legumes have been cultivated for several thousand years, the chronology and origins of domestication of food legumes are almost impossible to reconstruct. Some legumes (lentils for example) have been dated back to 7000–6000 BC. Leguminosae (or Fabaceae) is the third largest family of flowering plants (after Compositae and Orchidaceae) in size and economic importance, and is second only to the grasses (Gramineae). Current estimates indicate that Leguminosae has about 16 000–19 000 species in about 750 genera. The subclassification is somewhat controversial. The generally accepted subclassification is shown in **Figure 1**. Almost all of the domesticated legumes used as food are members of Papilionoideae. All of the common beans belong to the tribe Phaseolaeae.

In terms of global production, legumes (including oilseeds) rank fifth in annual world grain production. Dry beans account for approximately 30% of the total world legume (pulses) production (**Table 2**). On a world-wide basis, the common beans (*Phaseolus* spp.) are the number one crop among dry beans

Table 1 Grain legume species commonly used for food purposes[a]

Botanical name	*Common name*
Aracahis hypogaea	Groundnut, peanut, monkey nut, goober pea, nguba
Cajunus cajan	Pigeon pea, arhar, red gram, tur, *toovar* Angola pea, gandal, ambre vade, alverja
C. indicus	Pigeon pea, congo pea, yellow dhal
Canavalia ensiformis	Jack bean, horsebean, gotani bean, haba de burro, chickasaw, lima
C. gladiata	Sword bean, maxima
Cicer arietinum	Chick-pea, bengal gram, chana, deshi chana, kabuli, chiche
C. minotinum	Chana, garbanzo
Cyamopsis tetragonoloba	Cluster bean, guar, aconite, cyamopse
Dolichos biflorus	Horse gram
D. lablab	Hyacinth bean, bonavist, field bean, caballeros, Indian butter bean Egyptian kidney bean,
Ervum vulgaris	Lentils, masur dhal
Faba vulgaris	Windsor bean
Glycine max	Soybean, soja
G. hispida	
G. soja	
Lablab niger	Lablab bean
L. purpureus	Kidney bean, hyacinth bean, Indian bean, lubia bean
Lathyrus sativus	Grasspea, kesari dhal, vetch, chickling vetch, chicaro
Lens esculenta	Lentils, masur dhal, red dhal, lentille, split pea, lentija
L. culinairs	
Lupinus spp.	Lupins, tarwi, tarin, pearl lupin, wolf bean, tremoco
Macrotyloma uniflorum	Horse gram, Madras gram, Kallu, Kulthi bean
Mucuna pruriens	Velvet bean, cowage, Mauritius bean, stizolobia
Phaseolus aconitifolius	Moth bean
P. acutifolius	Tepary bean, pavi, Yorimuni, dinawa
P. angularis	Adzuki bean, *feijao*
P. aureus	Mung bean, green gram, golden gram, chiroko, chicka sano pea
P. calcaratus	Rice bean, frijol arroz
P. lunatus	Lima bean, sieva bean, Madagascar bean, sugar bean, Burmabean, towe bean, pole bean, caraota, panguita
P. mungo	Mung bean, mungo bean, urd dhal, black gram, *urad*, woolly pyrol, kambulu
P. radiatus	Mung bean, golden graham, green gram
P. vulgaris	Dry bean, haricot, common bean, kidney bean, navy bean, pinto or snap bean, feijao, opoca, *rajma*, French bean, chumbinho
Pisum sativum	Dry pea, green pea, garden pea, field pea
P. angularis	
P. arvense	
Psophocarpus tetragonolobus	Winged bean (humid tropics), goa bean, asparagus bean, Colombo, four-angled bean, princess bean
Sphenostylis stenocarpa	Yam bean
Stizolobium spp.	Velvet bean
Tetragonolobus purpureus	Winged bean (Europe)
Trigonella foenumgraecum	Methi, fenugreek
Tylosema esculentum	Marama bean
Vicia faba	Broad bean, horsebean, faba bean, field bean, Windsor bean
V. sativa	Vetch
Vigna aconitifolia	Moth bean, matki, mouth bean, mat, math
V. aureus	Mung bean
V. radiata	
V. mungo	Black gram, *urd*, *urad*, kambulu, pyrol
V. sinensis	Dry cowpea
V. umbellata	Rice bean, red bean, mambi bean
V. unguiculata	Black-eyed cowpea, black-eye pea, cowpea, kaffir bean, Hindu pea, asparagus pea
Voandzeia subterranea	Bambara groundnut, Madagascar groundnut, earthpea, Congo goober, kaffir pea, jugo bean, haricot pistache

[a]Compiled from Deshpande SS and Srinivasan D (1990) Food legumes: Chemistry and technology. *Advances in Cereal Science and Technology* 10: 147–241 and Doughty J and Walker A (1982) *Legumes in Human Nutrition, Food and Nutrition Paper 20*. Rome: Food and Agriculture Organization of the United Nations.

(excluding oilseeds) in both production and consumption and are therefore economically an important crop. In 1997, the global dry bean supply in kilograms per capita per year was 2.4. Asia produces the largest quantity (48.80% of total world production) of dry beans, followed by Latin America

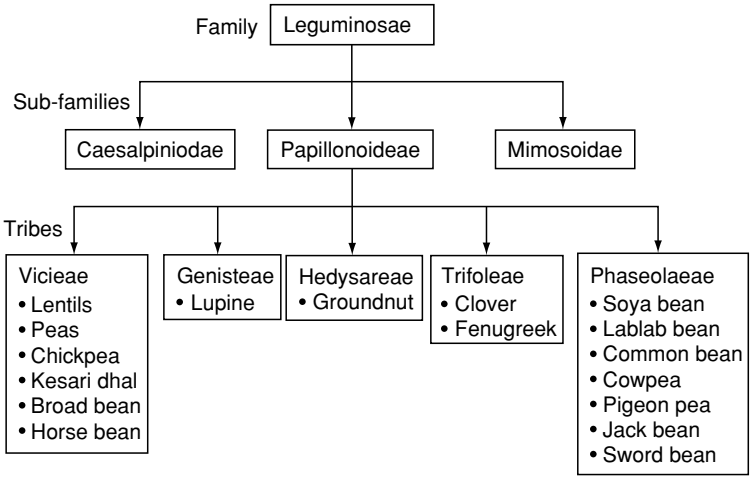

Figure 1 Botanical classification of food legumes.

and the Caribbean (26.98%), North Central America (19.07%), South America (17.19%), and Africa (11.00%). In 1998, India (17.81%), Brazil (13.06%), China (10.15%), US (8.19%), Mexico (7.48%), and Myanmar (6.40%) accounted for 63.09% of the global dry bean production. Latin America and Caribbean, Europe, and Asia, lead the world imports of dry beans in terms of dollar value (Table 2). Brazil, Mexico, Japan, Italy, France, and Venezuela, respectively, accounted for 13.18, 11.17, 8.02, 5.06, 4.55, and 4.08% of the total dollar value of world-wide imports ($1 164 946 000) of dry beans. Asia and North and Central America lead the world-wide export of pulses and dry beans (Table 2). In 1998, the leading exporting countries of dry beans were US, Argentina, China, Myanmar, and Canada, respectively, accounting for 24.37, 18.32, 15.95, 12.27, and 7.36% of the total dollar value (78.27%) of world-wide dry bean exports.

Morphology of the Pods/Seeds

Regardless of the fat content, most legume seeds have a similar structure. Mature legume seeds have three major components: the seed coat, the cotyledons, and the embryo axis. In most dry seeds, they account for 8–20, 80–90, and 1–2% of the seed weight, respectively. The majority of the nutrients are present in cotyledons. Typical seed structure and various anatomical parts of legume seeds are shown in Figure 2. The outermost layer of the seed is the seedcoat or testa. The external seed structure includes the hilum, micropyle, and raphe. The hilum is a scar-like structure (usually oval) near the middle edge where the seed breaks away from the stalk. The micropyle is the small opening in the seedcoat where, originally, the pollen tube enters the valve. The raphe is the ridge at the side of hilum opposite the micropyle and represents the base of the stalk that fuses with the seed coat upon seed maturation. In most legumes, the endosperm is short-lived and shrinks to a thin layer surrounding the cotyledons (or embryo). On soaking the seeds, the endosperm can be easily removed, along with the seed coat. The remainder (embryo) of the seed consists of shoot (which contains two cotyledons), and a short axis above and below the cotyledons and terminates in the shoot tip. The plumule or embryonic stem is well developed in the resting seed and lies between two cotyledons.

The outermost layer of seed coat is the cuticle, which has papillae or papillae-like growth in some legumes (e.g., green gram), but in most legumes, it is a smooth structure. The thickness of the seed coat is quite variable, depending upon the type of bean. Generally, seeds containing thick seed coats tend to have a high fat content. Both hilum and micropyle are important in water imbibition by testa. Palisade cells derived from the outer epidermis of the outer integument, next to the cuticle, are either loosely packed or densely packed depending upon the seed maturity and may affect seed hydration. Next to palisade cells are the hourglass cells. The shape of the hourglass cells can vary from bottle-shaped (guar) to dumbbell-shaped (broad beans) to hourglass-shaped (soybeans). Only a few legume species (such as *Dolichos*, *Cajanus*, and *Vigna*) have more than one layer of hourglass cells. The remainder of the testa contains primarily mesophyl cells.

Legume cotyledons are primarily composed of parenchyma cells, which vary in size (70–100 μm) and act as storage sites for most nutrients. Each cell of the cotyledon is bound by the cell wall and the middle lamella. Vascular bundles in cotyledons generally are devoid of any filling material. Vascular bundles

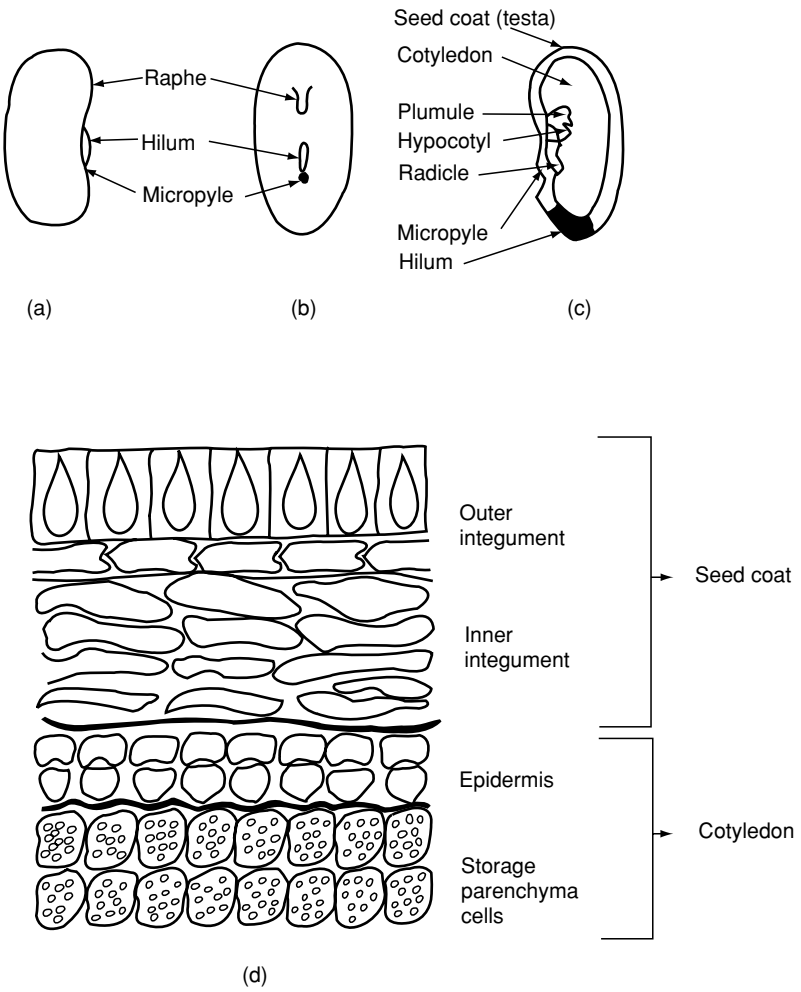

Figure 2 Dry bean (*Phaseolus vulgaris*) seed: (a) external side view, (b) external face or edge view (viewing at hilum side), (c) cross-section (one cotyledon removed), and (d) detailed cross-section across the seed coat and cotyledon.

are often used as key structures in the identification of different plant types.

Chemical and Nutritional Composition

The majority of nutrients in dry beans are primarily located in the cotyledons and account for up to 90% of the total nutritive value. Typically, dry beans provide 300–350 kcal per 100 g of dry seeds. The majority of constituents of cotyledons are proteins and carbohydrates and respectively account for 15–25% and 50–75% of the total seed weight. The remainder consists of fat, minerals, fiber, and vitamins. With the exception of oilseeds, dry beans generally contain low amounts (1–3% of seed weight) of fat. Although most minerals are present in cotyledons, some (such as calcium and iron) may be present in seed coat in significant proportion. The typical nutrient composition of several *Phaseolus* beans is shown in Table 3. Dry beans contain not only significant amounts of nutrients but also several undesirable components and attributes: inhibitors of enzymes such as trypsin, chymotrypsin, subtilisin, amylases, and elastase; lectins; phenolic compounds including tannins; phytates; toxic amino acids mimosine and djenkolic acid; cyanogenic glycosides, which produce HCN; flatulence-causing oligosaccharides raffinose, stachyose, and verbascose; lipoxygenases, which catalyze the development of rancidity, and off-odors often described as beany, grassy, painty, cardboard-like, and chalky.

Proteins

Phaseolus beans are not only important for their caloric contribution to human diet but are especially valued for their protein content, since they are a major protein contributor to the human diet on a global basis. In certain parts of the world, they are

Table 3 Proximate composition of *Phaseolus* beans[a]

[a]Data compiled from Sathe *et al*. (1984) and Salunkhe and Kadam (1989). Data expressed on a dry-weight basis.

the most important source of dietary protein. Dry bean proteins can be classified as storage and metabolic proteins. The original protein classification proposed by T. B. Osborne was based on the solubility of proteins in a series of solvents. In this scheme, the water and dilute salt soluble proteins were termed as albumins and globulins, respectively. Dry beans contain 40–60% globulins and 20–40% albumins, based on Osborne's protein classification. Globulins are exclusively storage proteins, whereas the albumin fraction contains both storage and metabolic proteins. The protein content of dry beans is usually calculated by multiplying the Kjeldahl nitrogen content by a factor of 6.25. Because dry beans contain 10–15% of total nitrogen as nonprotein nitrogen, most dry bean protein values are typically overestimated by 1–2%.

The major storage proteins in dry beans have been identified by several names, and therefore, their nomenclature is somewhat confusing. Based on the nomenclature using the ultracentrifugation sedimentation coefficient (S), dry beans contain both 7S (vicilin-like) and 11S (legumin-like) storage proteins. Depending on the bean variety, the relative proportion of these two types of proteins varies considerably. The 11S type proteins typically are nonglycosylated proteins with an estimated molecular weight (MW) in the range of 300 000–400 000. They are usually composed of six subunits (MW 60 000), each consisting of one acidic (MW 40 000) and one basic (MW 20 000) polypeptide linked by disulfide bond(s). Usually, 11S proteins are present in minor amounts in *Phaseolus* beans. The 7S globulin in *Phaseolus* beans has also been referred to as glycoprotein II, globulin 1, euphaseolin, globulin, and phaseolin. Depending on the type of bean, the 7S globulin type and quantity vary considerably. In *Phaseolus* beans, the 7S globulins are, however, the major storage proteins and account for 40–60% of the total proteins. The three major types of 7S proteins that have been identified, biochemically purified, and characterized are: (1) phaseolin, (2) lectin (also called glycoprotein II, phytoagglutinins or phytohemagglutinins, and protein II), and (3) arcelin in wild bean accessions from Mexico (named after the town Arcelia in Mexico, where some of the accessions were collected). All the 7S globulins are glycosylated and contain D-mannose and D-glucosamine as the major sugar constituents.

Phaseolin Phaseolin is the major globulin in domesticated *Phaseolus* beans. It is a trimeric, vicilin-like 7S globulin known to exhibit polymorphism. The polypeptide polymorphism is believed to be due not only to the differential glycosylation but also to phaseolin polypeptides being encoded by a small multigene

family. Phaseolin is soluble in 0.5 M NaCl at all pH values. It undergoes reversible pH-dependent dissociation–association with sedimentation coefficients of 3.0S (pH 12.0), 7.1S (pH 7.0), and 18.2S (pH 3.6) known as peptides (MW 44 000), protomers (MW 163 000), and tetramers of protomers (MW 653 000). Phaseolin consists of a group of subunit polypeptides with MWs 43 000–54 000 and isoelectric points from pH 5.6 to 5.8, depending on the phaseolin type. Among *Phaseolus* beans, three distinct types of phaseolins, named after the cultivars tendergreen (T), Sanilac (S), and Contender (C), have been identified. Screening of 107 cultivars has revealed that S-, T-, and C-type phaseolins accounted for 69, 25, and 6%, respectively, of the total cultivars. These types can be easily distinguished by one-dimensional or two-dimensional gel electrophoresis using sodium dodecyl sulfate (SDS) polyacrylamide gel electrophoresis (PAGE) for one-dimensional or isolectric focusing in the first dimension followed by SDS–PAGE in the second dimension for two-dimensional gel electrophoresis. The C-type phaseolin is believed to have originated from the T and S types. Regardless of the type of phaseolin, phaseolin contains 3–5% carbohydrates, and its amino acid composition is dominated by acidic amino acids (30–40% of the total). Typically, the N-glycosylation sites in phaseolin polypeptides occur at amino acid residue numbers 252 and 341. Sulfur-containing amino acids (notably methionine) are the limiting amino acids in phaseolin as well as other major storage proteins in *Phaseolus* beans. The secondary structure of phaseolin in 0.5 M NaCl typically has a low α-helix content (10%) and β-turns (9.0%) and a large amount of β-sheet (48.0%) and random coils (33.0%). Native phaseolin is quite resistant to digestive proteases such as pepsin, trypsin, and chymotrypsin, and is degraded to polypeptides with MWs 24 000–28 000. Heat-denatured phaseolin is easily digested by these proteases, however. (*See* **Protein**: Chemistry.)

Lectin Bean lectins agglutinate erythrocytes owing to their ability to bind with cell-surface glycoproteins and glycolipids. Although the precise function of lectins in beans is not known, they are thought to offer protection to the plant. Since lectins are toxic, they are of nutritional concern. Lectins occur in both albumin and globulin fractions. Certain bean cultivars lack lectins. When present, lectins represent 6–12% of total protein. In addition to agglutinating activity, many bean lectins have mitogenic activity. Most lectins of *Phaseolus* beans have subunits of MWs 29 000–36 500 with an isoelectric pH in the range of 4.9–7.9 (most are in the 5–6 pH range). The majority of native lectins have tetrameric nature (MWs 100 000–150 000) although some (lima beans, for example) have a dimeric nature. The majority of *Phaseolus* lectins have 4–6% carbohydrate, low sulfur-containing amino acids, and sugar specificity towards D-acetylgalactosamine. Lectins are very resistant to common digestive proteases and are slowly hydrolyzed *in vitro*, even after extensive heat denaturation. Proper moist heat denaturation can completely inactivate the biological activity of lectins and therefore can render them nontoxic. (*See* **Hemagglutinins (Haemagglutinins)**.)

Arcelin Arcelin was first discovered in wild accessions of Mexican *Phaseolus* beans. It also occurs in lines that contain phaseolin as well as lectin. Because it is present in equal or greater levels than phaseolin in certain lines, it is one of the major storage proteins in *Phaseolus* beans. The MWs of arcelin subunit polypeptides range from 35 000 to 42 000, depending on the variant, and are more basic than both lectin and phaseolin. The native arcelin has a MW of 89 000 and is therefore a dimeric protein. Arcelin has many similarities with lectin (including agglutinating activity) with respect to chemical composition.

Other proteins *Phaseolus* beans contain trypsin inhibitors (many of them also inhibit chymotrypsin), amylase inhibitors, lipoxygenases, and several other minor protein components. Most of these proteins are a part of albumins. Trypsin and chymotrypsin inhibitors in *Phaseolus* beans typically account for up to 10% of the total proteins and are generally rich in sulfur amino acids. The MWs of these inhibitors range from 2000–23 000. Most *Phaseolus* beans lack Kunitz-type (inhibitors with 170–200 amino acids with MW of approximately 20 000) trypsin inhibitors. Amylase inhibitors in dry beans have been characterized from only a few cultivars and therefore not yet extensively studied. The MW of kidney bean amylase inhibitor (a glycoprotein) has been shown to be 50 000. Appropriate moist heat treatment (such as cooking or autoclaving) can inactivate both the protease and amylase inhibitors.

Carbohydrates

Total carbohydrates in *Phaseolus* beans contribute 50–70% of the seed weight and include mono-, di-, and oligosaccharides, starch, and other polysaccharides. Starch is the most abundant nutrient in *Phaseolus* beans, accounting for up to 70–80% of total carbohydrates. Among the simple sugars, oligosaccharides (raffinose, stachyose, verbascose, and ajugose) are the major constituents (up to 10% of seed

weight) and are at least partially responsible for flatulence. Crude fiber is primarily composed of cellulose, hemicellulose, lignins (not a carbohydrate), and other nonstarchy polysaccharides such as arabinogalactans, arabinoxylans, glucomannans, galactomannans, and pectins. The hypocholesteremic effect of dry beans is partially attributed to the presence of nonstarchy polysaccharides. *Phaseolus* bean starch granules are quite variable in shape (round, oval, oblong, elliptical, spherical, kidney shape, and irregular) and size (5–60 μm) and typically contain 10–45% (of total starch) amylose. The average degree of polymerization for amyloses and chain lengths for amylopectins of *Phaseolus* bean starches range from 1600 to 1900 and 22 to 26, respectively. Based on X-ray diffraction spectra *Phaseolus* dry bean starches are mostly of the C type [a mixture of A (typical of cereal starches) and B (typical of root and tuber and high amylose cereal starches) types]. These starches have restricted swelling, a gelatinization temperature range of 60–89 °C, high solution viscosities, and good thermal stabilities. Upon gelatinization, they produce opaque gels. Dry bean starches (especially if cooked) are well digested (their digestibility is comparable with those of many cereal and tuber starches) by humans. Because dry bean starches are digested slowly, however, they are hypoglycemic and therefore useful in the diets of diabetics. (*See* **Carbohydrates**: Classification and Properties.)

Vitamins and Minerals

Phaseolus beans are a good source of B-vitamins, especially thiamin, riboflavin, niacin, and folacin. Typically, the thiamin, riboflavin, niacin, and folacin contents (on a dry-weight basis) of *Phaseolus* beans are, respectively, 0.5–1.14, 0.1–0.25, 0.4–3.14, and 0.037–0.676 mg per 100 g. The vitamin E content ranges from 0.72 to 1.97 mg per 100 g, and the B_6 content ranges from 0.2 to 0.659 mg per 100 g. *Phaseolus* beans are poor sources of vitamin A and C.

Phaseolus beans are excellent sources of several minerals, including Ca, Fe, Cu, Zn, P, K, and Mg. Typically, raw beans contain 70–260, 0.5–1.40, 3.34–13.5, 160–320, 1.0–2.1, 380–570, 1320–1780, 4.0–21.0, and 1.9–6.5 (all expressed as milligrams per 100 g, dry-weight basis) of Ca, Cu, Fe, Mg, Mn, P, K, Na, and Zn, respectively. The low sodium and high potassium content of raw beans makes them a desirable constituent of human food (especially for people with hypertension).

Antinutritional Factors

In addition to protease inhibitors and amylase inhibitors, *Phaseolus* beans contain several other antinutritional and antiphysiologic factors such as phytic acid, tannins, cyanogenic glycosides, saponins, and allergens. Because these components are usually present in small quantities (less than 5% of the total seed weight), they do not pose a serious health hazard under normal conditions (that is, when beans are a part of total diet and are properly processed prior to consumption). Of these antinutritional factors, phytates and tannins are of particular concern, because both are heat stable and cannot be easily removed from beans during normal home processing. Phytate is a general term used for mono to dodeca anions of phytate along with esters lower than hexaphosphate. Ca–Mg salts of phytic acid [myoinositol 1, 2, 3, 4, 5, 6-hexakis (dihydrogen phosphate)] are referred to as phytin. In most dry beans, phytate phosphorus accounts for up to 80% of the total phosphorus. The amount of phytate in *Phaseolus* beans ranges from 0.6 to 2.1% (by weight) of the total seed weight. Because phytates are chelating agents, they may interfere in mineral utilization. Germination, fermentation, and soaking followed by cooking (if both soak- and cook-water are discarded) are effective methods of removing phytates (50–80% reduction). (*See* **Plant Antinutritional Factors**: Characteristics.)

Tannins (especially condensed tannins) are heat-stable compounds and are present in *Phaseolus* seeds (especially in colored varieties) up to 2% of total seed weight. Because of their ionic character, they may interact with other constituents (notably proteins) and adversely affect the nutritional bioavailability of that constituent. Tannins are thought to offer protection to the plant from insects and pests. (*See* **Tannins and Polyphenols**.)

Lipids

Phaseolus beans contain 1–3% lipids (by weight), depending on the species. Neutral lipids (30–50% of total) and phospholipids (25–35% of total) are the major constituents and glycolipids may account for up to 10% of the total lipids. Regardless of the variety, *Phaseolus* bean lipids primarily contain palmitic, oleic, linoleic, and linolenic acids. Polyunsaturated fatty acids and saturated fatty acids typically account for 55–87% and 12–28% of total lipids. (*See* **Fats**: Classification.)

Beneficial Bioactive Compounds

Continuing research on raffinose oligosaccharides, phytates, tannins, simple phenolic compounds, sterols, protease inhibitors, and several other major and minor constituents of dry beans suggests that some of these compounds, under appropriate conditions, may offer beneficial effects for human health.

Long-term detailed and fundamental research is needed to fully realize the potential health benefits of dry bean consumption.

Grading, Handling, and Storage

Dry beans are usually harvested at maturity. The seeds are removed from the pods either manually or mechanically and cleaned to remove dirt, stalks, leaves, blemished, and wrinkled seeds, and packaged prior to storage. The grading of seeds is usually based on external characteristics such as color, gloss, seed size, seed soundness, seed firmness, and presence of contaminating substances. The seeds are stored at farmer, trader, or government levels. Typically, farmers hold up to 8% of harvested seeds until the next season so that they can be used as planting seeds if crop failures occur. In developed and developing nations, a majority of the seeds are stored by traders and/or governments to protect against subsequent crop failures (or low yields), price fluctuations, and fluctuations in supply (change in demand, shortages, and famines). Losses in seeds occur both pre- and postharvest. The normal preharvest losses are mainly due to birds and mammals feeding on bean plant seeds. Drought/floods, insects, rodents can also contribute to preharvest losses. In developed nations, preharvest losses are usually small (as low as 1% of the crop). A majority of the losses occur during postharvest handling and storage, and can range from 8% to as high as 50% of total crop. It is estimated that as much as 48% of food produced in the world is lost (due to pre- and postharvest losses). Factors that influence postharvest losses of legumes include moisture, temperature, respiration rate, insect damage, microbial spoilage, and damage caused by mites and rodents. Properly packaged dry beans should be stored at low relative humidity and temperature conditions. A high relative humidity and temperature favor the 'hard-to-cook' beans. These conditions also favor the growth of molds and insects. Three major insect genera that cause much of the damage to stored legumes are *Bruchus, Acanthoscelides*, and *Callosobruchus*. Dehusked, split stored pulses are also damaged by *Rhizopertha, Trogoderma*, and *Tribolium* species. Usually, pests seem to have a preference for the type of bean they infest, although the basis for such a preference (or the lack of it) has not been elucidated yet. The major microbial problem during bean storage is contamination by aflatoxin-producing molds (*Aspergillus flavus* and *Aspergillus parasiticus*). Mites can consume food up to their own weight (6–8 μg) and, because of their large numbers, can cause serious losses. Rodents cause twofold damage to stored legumes by not only consuming but also contaminating plants (up to 20 times the amount they would eat). Because rodents are carriers of many communicable diseases, they pose serious damage to stored beans. The species that most commonly cause damage include *Rattus rattus, R. norvegicus, Bandicota indica, B. bengalensis*, and *Mus musculus*.

Processing and Food Uses

Phaseolus beans are processed and used in a variety of ways. The processing of beans is mostly at the household level in developing and underdeveloped countries, whereas in most developed countries, the majority of the processing is done at the industrial level. Home processing methods include milling, soaking, cooking, frying, germination, fermentation (either alone or in combination with cereals), roasting, puffing, parching, extrusion and frying, and toasting. The method(s) used for home processing depend on the regional preference for bean variety and the desired end product. For example, mung beans in sprouted form are popular on a global scale, and therefore, germination is one of the preferred household processing methods used. Black gram, however, is extensively used for preparation of *idli*, a breakfast food popular in India and Sri Lanka, after fermenting it with rice. Industrial processing includes freezing for such beans as green French beans, snap beans, etc., milling (production of flours and high-protein flours), baking (baked beans), cooking and frying (refried beans), and canning (alone in salt water or tomato juice or in combination with meats such as beef and pork). In developing countries, dehusking and splitting to produce *dhal* are also performed on an industrial scale.

In developing and underdeveloped countries, *Phaseolus* beans are used in numerous ways, depending on the type of bean and regional preference. They may be eaten as raw, immature seeds; cooked as green vegetables (such as French beans); consumed as part of salads; used in making curry; used as a soup ingredient; cooked, mashed, mixed with condiments and spices and used as gruels and porridges; prepared as pastes to be extruded to prepare fried snack products; sprouted; puffed or roasted and eaten as snack foods; and fermented to prepare numerous fermented products.

In developed countries, *Phaseolus* beans are consumed as a salad and soup ingredient, sprouts, canned, frozen, and refried beans. They are also extensively used in the preparation of Mexican-style preparations, such as burrito, chimichanga, taco, bean dips, tamale, etc., and often canned with meats such as beef and pork. In many South American

countries, cooked black beans are a preferred part of breakfast.

Although there is a good potential for the preparation of protein concentrates and isolates and the development of food starches, *Phaseolus* beans have not been used on a large scale for such purposes. In many countries, especially the developed countries, *Phaseolus* beans have been extensively used as animal feed. In developing and underdeveloped countries, the green foliage, deseeded pods, and roots and shoots of bean plants are used as natural fertilizers, especially after composting. Because the legume roots fix nitrogen, they help conserve soil quality. For this reason, in many developing countries, they are extensively used for soil-quality conservation.

BEEF

R L Joseph, The National Food Centre, Dublin, Ireland

Introduction

Beef is 'the flesh of ox, bull or cow' (*Oxford English Dictionary*). *Boeuf* (Anglo-French) is derived from the Latin *bos, bovis* (ox), and until the eighteenth century beef meant both animal and meat. The etymology suggests that the meat was for the Norman ruling class, and was not commonly eaten by Anglo-Saxon folk even in the late thirteenth century as Middle English was forming.

Beef has enjoyed a special status since *Bos* spp. were domesticated in Neolithic times in South-west Asia. The bull was a totem for warrior nomads; eating his flesh transferred his power. The docility and strength of draft oxen, the versatile milk, the valuable hides and attractive meat have made the *Bos* genus economically vital to humans.

Today beef cattle are raised all over the world (**Table 1**). The natural environment of *Bos taurus* is temperate grasslands. *B. indicus* prefers savannah.

[a]Average per annum.
[b]Summed over FRG and GDR figures.

Crossbreeds such as Santa Gertrudis grow well in hot dry areas, such as the south-west USA.

Different breeds have been developed over the centuries to maximize returns under local conditions. The compact, early-fattening Aberdeen Angus and Hereford are productive in harsher nutritional and climatic environments. The great draft cattle of Europe, like Charolais and Chianina, put on muscle quickly in larger quantity and are heavier at slaughter. They are leaner, more productive, and are gradually replacing the earlier-maturing breeds.

Many European countries, and New Zealand, produce beef from the dairy herd, whose cows are selected mainly for milk production. Beef bulls on surplus heifers produce beef calves. Pure dairy calves may be raised for beef, in the UK, Ireland, and New Zealand, or veal, in France and The Netherlands, or pet food, in the USA.

Modern economic pressures intensify and concentrate animal production. Many once strong local rare breeds are facing extinction; in the British Isles and USA alone about 30 are listed. Their rich gene pool must be maintained so a wide genetic base will be available to accommodate future natural or market constraints on production.

Comparison of systems converting feed into saleable meat is complex. Prices of land, stock, and feed change yearly. Support schemes alter markets. Health and diet are important to consumers, so a demand for 'natural' feeding has reinforced economic pressures towards increased use of grass and less use of animal-derived feeds.

Typical Production Systems

Two-Year-Old Spring-Born Steer (Friesian/Friesian Cross)

This tightly managed semiintensive system is suitable for north-west Europe. In February, male calves are bought and finished cattle are sold. In early April yearlings start grazing 45% of the farm; 55% is closed for silage. By mid-May the calves are grazing ahead of the yearlings. In late May silage is cut, 45% of the farm is closed for a second cut, taken in mid-July, then slurry is spread. The calves are castrated in late September. Finishing cattle are housed in mid-October, weanlings in early November.

Fifty cattle may be produced off 22 ha. The main inputs per animal sold per year are the 0.45 ha of productive grassland, to provide grazing and 10 t of silage; the fertilizers are 110 kg of nitrogen equivalent, 41 kg of potassium, and 11 kg of phosphorus. Each animal receives 25 kg of reconstituted milk powder, roughage, and concentrates *ad lib*. In the first winter the weanlings are fed silage and concentrates (150 kg). Yearlings receive 600 kg of concentrates during a 150-day finishing period.

Live-weight gains are from 0.6 to 0.9 kg day^{-1}. Slaughter weight (Friesian) is about 600 kg, to give a carcass of 320 kg, with about 220 kg of saleable lean beef, some 55 kg of bone and 45 kg of fat trim. Charolais $\times$ Friesian reach 680 kg, dressed 380 kg; giving 270 kg of lean meat, 60 kg of bone, and 50 kg of fat trim.

Suckler Beef

This is extensive and more common on marginal land. Calves suckle dams; a 'cow unit' consists of cow, calf, and yearling. Cows are cross-bred Hereford or Limousin on Friesian to give adequate milk with

low maintenance requirements. Mating is to a third breed: Hereford, Aberdeen Angus, or Limousin for the first calving and large breeds, Charolais or Simmental for later pregnancies.

Calving takes place in February to April. Calves grow rapidly on the milk, reaching about 300 kg at weaning in November. Each cow unit grazes 0.32 ha in April–June, with 0.45 ha reserved for silage. Then, until August, 0.48 ha is grazed; 0.29 ha is for silage. Thereafter, 0.77 ha is grazed until housing in November. Silage is cut, in late May and late July, totaling 37 t ha^{-1}. About 175–225 kg ha^{-1} of nitrogenous fertilizer is applied yearly.

Housed yearlings have silage *ad lib* with 1 kg per head per day of concentrates. After the second summer on grass, the heifers are slaughtered, at 20 months, in November–December, finishing on silage and 3 kg day^{-1} of concentrates. Slaughter at 500–600 kg gives carcasses of 260–330 kg. Steers are fed silage and 4 kg day^{-1} of concentrates to finish in early spring at 24 months, at a live weight of 620–680 kg and a carcass weight of 340–380 kg.

Bull Beef

In Europe, except the British Isles, most male beef cattle are bulls. From about 4 months they grow up to 8% faster than steers, giving perhaps 40 kg more carcass. Bulls kill out at about 57% (dressed weight as percentage of carcass), 2% more than comparable steers, with carcasses up to 15% heavier. About 74% of a bull's carcass is lean meat, compared to 66% for steers. Bulls have a heavier forequarter, but a higher yield of high-price cuts.

Most bull beef is from the dairy herd, being Holstein/Friesian dual-purpose and dairy beef crosses. Calves bought at 1–3 weeks of age are reared to 100–150 kg on 25–50 kg of milk replacer, concentrates, and roughage. Slaughter at 12 months requires a high-cereal or -fodder beet diet, giving a daily gain of 1.1–1.4 kg and a carcass weight of 180–220 kg. The meat is very pale. Slaughter at 18–21 months requires maize silage with 15–20% concentrates or beet pulp. Friesians reach 550 kg; dual-purpose and crosses may attain 600 kg.

In France, Spain, and Italy the suckler herd is an important source of bull beef. Veau de Lyons is Limousin, and at 12 months the slaughter weight is 450 kg; the meat is pale and not marbled. Slaughter at 18–21 months requires a diet like the dairy bull, but with more concentrates (25–30%). Carcass weights are 300–430 kg, depending on the region and breed.

Nearly all bulls are housed, usually loose in pens of 2–5 m^2 per bull with up to 25 per pen. Farmers raising bulls must insure safety, with secure housing and fencing, warning notices, and careful work practice.

Bovine Spongiform Encephalopathy

Bovine spongiform encephalopathy (BSE) is a progressive, fatal neurological disease. Since 1986 some 26 000 cases have been recorded in the UK, with sporadic cases in other countries. BSE presents, in adult dairy cows, as abnormalities of behavior and gait. The causal agent was in meat and bone meal in concentrates fed to calves. In 1988, feeding ruminant protein to ruminants was banned, and notification and compulsory slaughter were introduced. (*See* **Bovine Spongiform Encephalopathy (BSE)**.)

Meat Trade – Transport and Slaughter

The trade is closely controlled both nationally and internationally, e.g., by the EC. Feeds and therapeutics must not endanger consumers' health. Cattle handling must be humane, so animals must be led, not driven, and moved in production groups with minimal goading and noise. Journeys should be short and packing must allow fallen cattle to rise. A 12-m lorry will take 22 650-kg cattle.

Humane treatment improves meat quality and reduces cross-contamination; nervous overfrequent defecation increases *Salmonella* and other infections. Lairage at the meat plant must have drinking water and shelter. Groups should not be mixed as this causes fighting. Stock must not be fed for 24 h before slaughter.

Western slaughter is preceded by stunning with a blow or captive bolt. The unconscious animal is hoisted by a hind leg, over a 'bleeding trough' and stuck in the arteries of the throat. Delayed sticking allows blood pressure to rise; arteries in muscles burst so meat is blood-splashed and unsightly at sale. (*See* **Meat**: Slaughter.)

Jewish or Muslim ritual slaughter, kosher or halal, despatches the conscious animal with one cut across the throat; slaughtermen must be licensed by the religious authorities. Bleeding-out takes about 10 min. Blood supports microbial growth and its removal is important for increasing meat shelf-life.

The carcass, suspended by both hind legs, is dressed on the line. A moving chain carries it past successive work stations. Hooves and head are removed. The esophagus and rectum are tied and freed before the ventral abdominal wall is opened. The green offal – the alimentary tract – and the red offal – the heart, lungs, and liver – are removed on to conveyors. All parts are inspected by veterinarians. The carcass is flayed and split with a power saw into two sides. Trimming is to specifications agreed with the farmers' associations.

Sides are weighed 'hot' and graded for fatness and conformation (shape) by public inspectors. Payment

is generally on 'hot weight minus 2%' to accommodate evaporative weight loss in the chills. Sometimes grade will affect price.

Sides are washed and pass into the chill room about 1 h postmortem. Chilling is mandatory. Chilling rates are determined by carcass weight and fatness and by air speed and temperature. Faster cooling facilities throughput and reduces bacterial growth and evaporative weight loss, but is more expensive in equipment and energy. Cold toughening may result if muscle cools below 10 °C sooner than 10 h postmortem.

Cutting

EC regulations stipulate that, before cutting, sides must be chilled to below 7 °C. A 140-kg side of average fatness will achieve 7 °C in the center hip, in about 32 h under air of 0 °C at 1 m s^{-1}, but this rate could cause cold toughening in the striploin (longissimus dorsi, LD), so a slower chilling may be required.

Chilled beef sides are quartered according to local usage, often near the end of the rib cage, and go for shipping, to the boning hall or retail shops. The primal cuts of the side differ slightly by country, but are based on convenient anatomical divisions, eating quality and costing.

Figure 1 shows London and Home Counties cuts. Vacuum-packed, usually boneless, primals now predominate over quarters for distribution.

Beef differs in eating quality depending on the cut, the age of the animal, and pre- and postmortem handling. The relative price of sides and cuts depends chiefly on expected tenderness. Prime 2-year-old steer is more expensive than 7-year-old culled cow. Fillet (psoas major) is always tender, and is the most expensive; striploin and rump (gluteus medius) are slightly tougher, more unpredictable, and are cheaper in cost. Shin beef is cheapest of all. *B. indicus* meat is tougher than that from *B. taurus*, but breed differences are not large; reports of tougher bull meat are now attributed to faster cooling in the leaner sides.

Butchers, and customers, may identify different cuts, but once the beef is off the bone and trimmed of fat it is difficult to distinguish lean beef from, for example, adults of different ages or from fast- and slow-cooled sides. This has made beef marketing less transparent than that of other meats.

The trade has developed empirical techniques for improving quality. Prime beef is from 18–36 -months-old cattle. Aging, holding in chill for some days, effects some improvement in tenderness, but will not make cold-toughened beef as tender as slow-cooled beef.

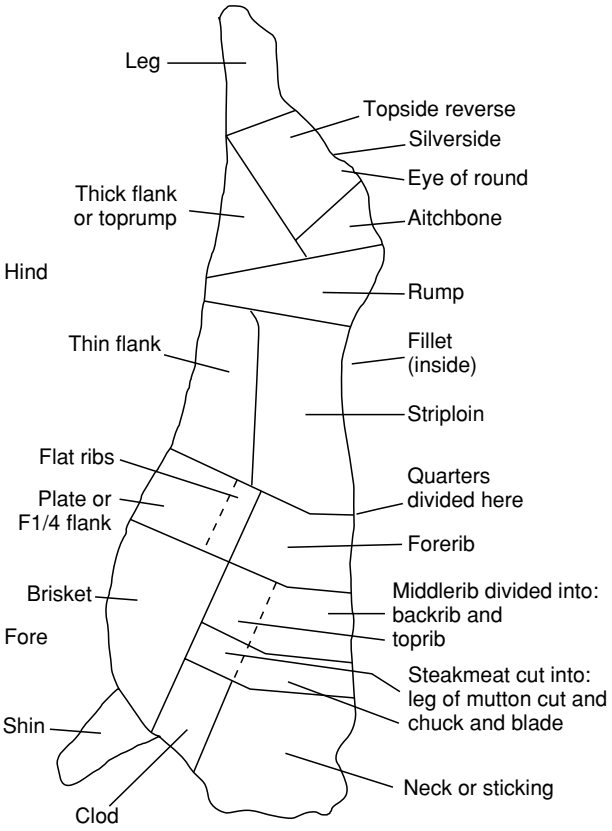

Figure 1 London and Home Counties primal cuts. Adapted from Gerrard F, Mallion FJ and Quin (eds) (1977) *The Complete Book of Meat*. London: Virtue.

Muscle biochemistry now provides explanations for much meat quality variation. In cattle, prolonged stress premortem depletes muscle glycogen reserves and postmortem production of lactic acid from glycogen is inadequate to bring the physiological pH of muscle from 7 to 5.4–5.6, the normal level 48 h after slaughter. Stressed cattle give meat of above pH 6.0 that is described as 'dark, firm, and dry' (DFD). Consumers react against the darker appearance compared to the customary bright cherry-red due to oxymyoglobin at pH 5.4–5.6; the higher pH facilitates microbial spoilage. (*See* **Meat**: Structure.)

Young bulls, and most cattle in the autumn, are more prone to stress and thus to produce DFD meat. Biopsies have shown that depleted muscle glycogen is not replaced in life for several days after the stress insult. Stressed cattle must be rested before slaughter. Humane handling will prevent most DFD meat.

Tenderness variation among muscles is partly due to differences in connective tissue collagen content. More collagen implies lower tenderness (Table 2(a)). Decreasing tenderness with age is due to increasing collagen molecular cross-linking. Solubility is an inverse measure of cross-linking and is less in older

Table 2 Collagen and tenderness

(a) Differences between muscles

Muscle	*Cut*	*Collagen (%)*	*Tenderness*
Psoas major	Fillet	2.24	6.7
Longissimus dorsi	Striploin	2.76	5.2
Gluteus medius	Rump	3.64	4.5
Semimembranosus	Topside	4.09	3.3
Semitendinosus	Eye of round	4.75	3.6
Biceps femoris	Silverside	5.07	2.8

Collagen is expressed as percent fat-free dry matter (Dransfield E (1977) Intramuscular composition and texture of beef muscles. *Journal of the Science of Food & Agriculture* 28: 833–842). Tenderness is on a linear scale: 0, extremely tough; 8, extremely tender (Joseph RL and Connolly J (1977) The effects of suspension method, chilling rates and post mortem ageing period on beef quality. *Journal of Food Technology* 12: 231–247).

(b) Collagen cross-linking and age

Extraction temperature of medium (°C)	*Animal age groups*			
	I (40–49 days)	*II (403–495 days)*	*III (5 years)*	*IV (10 years)*
60	544 ± 29	168 ± 10	82 ± 1	38 ± 1
70	863 ± 34	409 ± 26	171 ± 4	82 ± 1

Figures are average ± SE μg collagen extracted from samples into medium (Goll DE, Hoekstra WG and Bray W (1964) Age associated changes in bovine muscle connective tissue. II. Exposure to increasing temperature. *Journal of Food Science* 29: 615–628).

cattle. Table 2(b) shows that extraction, that is, solubility, of collagen falls significantly with increasing animal age.

Cold toughening seems to invoke two mechanisms. Early exposure to a temperature of about 10 °C causes the release of Ca^{2+} ions, which stimulate contraction in slack muscles like LD. As the muscle contracts into rigor, extra bonds are formed between the thick and thin filaments of the contractile myofibrils, and the strength and toughness of the meat are increased. This is cold shortening, and is confirmed by micrometry of the sarcomeres, units of the myofibrils.

Although ultrafast cooling may enhance tenderness, normal cold inhibition of protein-splitting enzymes during the very early period, 2–4 h postmortem, probably causes more tough beef in commerce than cold shortening. A near-physiological temperature should be maintained up to 4 h postmortem to maximize tenderness. Lower temperatures reduce tenderness *pro rata*. Subsequent aging at low temperature, and low pH, may not facilitate the splitting of particular protein links in the myofibrils which would be critical in providing reentrant cracks for the breaking of connective tissue during chewing. (*See* **Meat**: Preservation.)

Fillet is always consistently tender because it is low in collagen, it is stretched giving minimal thick–thin filament overlap and, being inside the rib cage under kidney fat, cools slowly.

A coherent explanation of beef tenderness is awaited; the synergy of temperature, pH, and Ca^{2+} concentration in controlling enzyme activity and shortening is complex, as is the interaction of connective tissue, myofibrils, and cooking.

Electrical stimulation (ES) of prerigor carcasses was patented 40 years ago to improve tenderness. ES causes muscular contractions, depleting the glycogen and other energy reserves in muscles, so preventing the cold shortening of slack muscles like LD. It may toughen muscles if the concomitant fast pH fall inactivates certain proteolytic enzymes. Its effect may be compounded by the tearing of opposing simultaneously contracting muscles. The New Zealand lamb industry and the North American beef industry use ES, but it is not widely used elsewhere.

Nutritional Value

Beef is central in most societies for celebrations and family meals, but has lost a little ground to white meats recently. Beef is an excellent food, supplying most nutritional requirements save fiber (Table 3); its vitamin B_{12} content promotes vitamin absorption from other sources. The three essential unsaturated fatty acids account for 3–6% of total fatty acid in lean beef. Trace elements (iodine, managanese, zinc, cobalt, selenium, nickel, chromium, molybdenum, fluorine, vanadium, silicon, arsenic) occur in beef so a normal diet will ensure an adequate supply. (*See*

Table 3 Contribution of 100 g of beef to recommended daily allowances (RDAs)

Nutrient	*US RDA*	*From beef*	*%RDA*
Energy	11.3 MJ	2.4 MJ	21.0
Protein	56 g	31.1 g	55.5
Calcium	800 mg	22.6 mg	2.8
Phosphorus	800 mg	312.8 mg	39.1
Iron	10 mg	4.7 mg	47.0
Magnesium	350 mg	31.7 mg	9.0
Vitamin A[a]	1000 μgRE	455 μg RE	45.5
Vitamin C	60 mg	1.16 mg	1.9
Thiamin	1.4 mg	0.50 mg	35.7
Riboflavin	1.6 mg	0.43 mg	26.9
Niacin	18 mg	7.95 mg	44.2
Vitamin B_6	2.2 mg	0.59 mg	26.8
Vitamin B_{12}	3.0 μg	5.23 μg	174.3
Folacin	400 μg	17.5 μg	4.4
Zinc	15 mg	7.1 mg	47.3
Copper	2.0–3.0 mg	0.21 mg	10.5

[a]1 retinol equivalent (RE) = 3.3 international units (IU) of vitamin A activity.

Meat: Nutritional Value.) Refer to individual nutrients.

The culinary uses of beef are numberless and it does not pall. Stock from beef and bones is the 'fond de cuisine.' The beefburger has been universally accepted by the world's youth. Charqui (biltong), sun-dried salted beef, provides protein and salt throughout the tropics. Salamis were developed to preserve beef, and other meats with salt and spices; now thousands of varieties are available. The 'roast beef of old England' still forms the centerpiece of state banquets. Beef is indeed the universal meat.

BEERS

Contents

History and Types

C W Bamforth, University of California, Davis, CA, USA

The Origins and History of Beer

We must look back to Babylon some 8000 years ago for the origins of beer. It is assumed that barley, which was beginning to be cultivated, was found to be both more nutritious and tasteful once it had been wetted and subsequently dried after sprouting, Furthermore the ensuing product, perhaps baked in the form of a bread, once more wetted and spontaneously fermented by adventitious yeasts, will have been particularly pleasurable. It was soon realized that the dough could be thinned by the plentiful addition of water and then strained to remove most of the solids prior to fermentation of the liquid component in earthen vats. Furthermore, the ancient brewers will have realized the merits of adding a proportion of the previous brew to 'kick-start' the fermentation. Addition of certain other plant materials, including mandrake, afforded flavors to complement the elements of the brew.

Beer soon became the staple drink of the Egyptian diet, as well as playing a key role in matters from currency to religious offering. It is claimed that the court of the Pharaoh Rameses included a brewery producing 10 000 hectoliters of beer each year.

Although brewing technology passed to the Greeks and Romans, beer was only consumed by their lower classes. In the warmer southern countries wine was the preferred beverage. The procession of beer-brewing technology took a more northerly route, with the Gauls, Germanic tribes, and Celts. In part this reflected their abilities to work with wood for the fashioning of vessels for brewing and storage. By the first century AD there is mention of Britons and Hiberni (Irish) making an alcoholic drink from barley.

Ale was a major beverage for the Danes and Anglo-Saxons and was regarded as the ideal drink for heroes. The Vikings drank heartily before setting sail next day, hence the origins of the phrase 'three sheets to the wind.' The word beer originates from the Anglo-Saxon *bjor*.

Right the way through and beyond the middle ages, much beer was brewed in the home, by the female of the household (the 'brewster'). However whenever history has seen the development of larger communities, it has been accompanied by the establishment of more substantial, commercial brewing operations. The development of new technologies also allows the scaling-up of brewing concerns, and so it was in the early AD centuries, with individuals learning to smelt and shape metal into vessels. Cleanable, flame-proof, heat-conducting copper brewhouse equipment emerged, and metal could also be used to hold together ever larger wooden fermenters, as well as barrels.

Through the ages some of the most substantial breweries have been located in ecclesiastical settings. Remnants today are the formidable Trappist beers of Belgium. The Domesday Book (1086) records that the brewery of St Paul's Cathedral was producing the equivalent of some 3150 hectoliters of ale. In every walk of life, ale was the principal beverage for all members of the family, young and old.

The roots of a truly major commercial brewing industry in the west were sown first in Bohemia and Bavaria. The importance of good malt to good beer was recognized, causing the development of specialist malthouses. Many of the European beers were flavored and preserved with proprietary mixtures of herbs and spices, including bog myrtle, coriander, cumin, and even strychnine. Such mixtures were known as gruit. Hops were first used in beer in Bavaria in the late eighth century, yet did not gain the ascendancy as the flavorant for several centuries in many countries, notably England. The term 'ale' was originally retained in that country for description of

products that did not contain hops, as opposed to beers, which did.

Until the sixteenth century ale (in later years incorporating hops) was the major beer style universally, such beers being produced in open vessels by yeasts that rose to the surface during fermentation (top fermentation). Bottom fermentation probably started in Bavarian monasteries in the early sixteenth century. A major factor was an edict of Prince Maximilian I in 1533 that largely precluded brewing in the summer months. The ale-style products from top fermentation had been brewed in warm conditions, but now bottom fermentation was performed in the winter, with the beer being stored ('lager' = 'store') until the subsequent autumn, when brewing could start again.

In Bavaria in 1516, Dukes Wilhelm IV and Ludwig X introduced the Reinheitsgebot to preclude the use of undesirable materials in brewing, a practice that had crept in due to shortages of barley and hops. The law has survived to this day and now extends throughout Germany for domestic production, restricting the raw materials of brewing to malt, hops, yeast, and water.

James I of England, whose exchequer took four pence for every quarter of malt, levied the first tax specifically on brewers in 1614.

Just 6 years later the first ales were landed in the New World with the Pilgrim Fathers, who actually put into Plymouth Rock because: 'We could no longer take time for further search or consideration, our victuals being much spent, especially our beer.'

In the late eighteenth century, with the Industrial Revolution, there was a decline in the proportion of beer brewed at home and a growth in brewing companies producing beer for consumption for a working population. The development of transportation systems enabled the increasingly growing brewing companies to distribute their products ever more widely. The railways and roads were fast becoming main arteries for beer distribution, but beer was also being shipped internationally, with products such as the India Pale Ale from England having a suitable long shelf-life, its high hopping acting as a preservative. Use of James Watt's steam engines (1765) within the brewery facilitated increased efficiencies and outputs. The development of artificial refrigeration by von Linde (1876) divorced the production of lager-style products from an association with natural ice such as was to be found in the winter months adjacent to the great lakes in North America, as well as allowing the shipping of beer ever greater distances in cold railcars.

The ability to regulate the process was, by now, manifest. In 1762 Michael Combrune had employed a thermometer to enable the checking and regulation of temperatures in the mash tun and fermenter. Prior practice was to dip the thumb into the brew to ensure that the wort wasn't too hot for the yeast – the 'rule of thumb.' Another Englishman, John Richardson, further facilitated enhanced process control with the construction in 1784 of the first brewer's saccharometer. Other significant technological developments included Pasteur's understanding (1860) of the natural spoilage of foodstuffs by microorganisms and the role of heat in countering this, as well as the development of bottle-closing technology, the crown cork. This was invented in Baltimore by William Painter, a man of British descent who accordingly took out his first patent on closures in London in 1885 and who, by 1891, had arrived at the familiar crimped metal device. Accordingly, beer for domestic consumption, as opposed to draught beer for retail in pubs and bars, could now reach a vast hinterland. The appearance of beer had been revolutionized by Enzinger's (1879) introduction of filtration while the consistency of beer was dramatically enhanced by Hansen's realization in 1883 of the importance of using isolated, pure yeast strains for fermentation of individual beers. The advent of cylindroconical vessels through the patents of Nathan filed between 1899 and 1905 allowed the large-scale fermentation of beer. The first cans suitable for filling with beer were produced by the American Can Company in 1934, and the initial company to go ahead with a canned product was Krueger's of Newark with its cream ale, in January 1935.

Other key developments in the evolution of a refined brewing process were the establishment of breeding programs for the key raw materials barley and hops. The first named barley variety came in 1823 in the UK through the skill of Chevalier, and it was duly named for him. The first established hop-breeding program was also in the UK, with Howard at Wye, commencing in 1904. By the 1950s for barley and 1970s for hops the most significant advances in how to process them had been put in place. Thus the importance of steeping barley intermittently with air rests between water soaks had led directly to a halving of total malting time and huge enhancement of output and efficiency. For hops, the establishment of pellet technology and, later, extraction of the key principles using liquid carbon dioxide allowed enhanced utilization of resins and oils and flexibility of product design.

Styles of Beer

One of the most fundamental approaches to classifying beers is based on whether they are produced by

'top fermentation' or 'bottom fermentation,' which basically refers to whether the yeast congregates at the top of the vessel or sinks to the base. With modern cylindroconical fermenters and their high hydrostatic pressures there tends to be less of a distinction.

Top fermentation, with its vastly older pedigree, tends to be performed at relatively warm temperatures (15–25 °C), under which conditions yeast tends to produce higher levels of flavor volatiles such as esters, affording fruity characteristics. Bottom-fermentation beers are produced at much lower temperatures (say 6–15 °C) and frequently possess significant sulfury notes.

Top-Fermentation Beers

Ales Perhaps the major product in the genre is the English pale ale, which is referred to as bitter when dispensed on tap (draught). Alcohol content will be in the range 3–7.5% by volume (ABV). Classically it is produced from well-modified malt, kilned to a relatively high-temperature regime to impart a copper color. The products are relatively malty, especially in the case of Scotch ales, which may be sweeter and darker than their English counterparts. After fermentation ales are traditionally primed with extra sugars, 'dry-hopped' with a handful of cones and dosed with isinglass finings prior to racking in casks. Residual yeast uses the sugars to introduce natural carbonation (albeit at a low level of perhaps 2.5 g l^{-1} CO_2), prior to being sedimented along with other insolubles by the finings. The product is not pasteurized and is distributed for retail in pubs, whether by gravity dispense or hand-pumping via a beer engine. Because of the skill needed to deal with cask ales (if infections and clarity problems are to be avoided), it has become increasingly common for such ales to be conditioned in the brewery and pasteurized prior to packaging in keg (for draught dispense) or bottle or can. Such products have a carbon dioxide similar to that of other beers sold from kegs or small packs, between 4.5 g l^{-1} for large packs and up to 6 g l^{-1} for small packs. Lower carbonation products in both keg and small packs have become increasingly prevalent over the past decade. They incorporate nitrogen gas, which enhances foam stability and also affords a smooth texture to the product. Because of the greatly reduced tendency for foam to form at the lower carbonation levels, it is common to use nucleation devices called 'widgets' in cans and even bottles containing beer of this type.

Mild ale, a style which is in decline and largely perceived as old-fashioned, is a sweeter, darker product, the color being either due to caramel or in part to a low proportion of heavily kilned malt, though not so much as to impart burnt flavors. It tends to have a lower alcohol content (less than 3.5% ABV) and when bottled may be referred to as brown ale. Traditional terms in Scotland have been heavy, for their stronger bitters, and light, for the milds.

Barley wines are fermented at very high gravities (the higher the specific gravity, the greater the content of sugars available for fermentation), which is an additional factor impacting on the very high ester/fruity character and, of course, accounting for a very high alcohol content of up to 10% ABV. They are usually sold in smaller volumes, in bottles called nips.

Porter In early eighteenth-century London there were three main categories of beer: ale, which was strong, the weaker beer, and two-penny, a better quality of beer. There were brown, pale, and amber versions of each. People tended to ask for 'half and half' – equal measures of ale and beer – or 'two-thirds' – (three threads): ale, beer and 'tuppenny' in equal measure. One far-sighted brewer in 1722 conceived of a product based on the second of these but with the three styles premixed in the brewery, and as a consequence saving the landlord's time. Because most of the customers wanting their beer in a hurry were porters in the local markets, it became known as porter. There are few, if any, genuine porters to be had these days. They are traditionally very dark, due to the use of roasted barley, and not overwhelmingly strong (about 5% ABV).

Stout A close relative of porter, stout originated in Ireland, of course, with intense color and burnt, smoky flavors due to the use of roasted barley adjuncts and high bitterness. These robust flavor characters have been tempered for many years now by the use of nitrogen gas, which 'smoothes' the palate as well as affording the rich, white, and creamy foam. Alcohol content may be between 4 and 7%, with up to 10% in imperial stouts. Sweet stouts are a British variant, of lower alcohol content (up to 4% ABV), with less roast character (often due to the use of caramel and less roast barley as colorant).

Belgium top-fermentation beers There is a greater diversity of beer styles in Belgium than any other country. Trappist beers are relatively dark, intensely bitter, acidic products of up to 12.5% ABV, with clear fruity notes. The Lambic and Gueuze products possess a diversity of complex flavor characteristics, imparted through the agency of the metabolic activities of a more complex microflora than brewing yeast alone. They tend to be quite sour (low pH) and are frequently not clear. Various flavorants may be added

to certain Belgian beers, including cherries (Kriek) or raspberries (Framboise).

German ales Alt from the German means 'old,' is brewed 'in the old way' from a grist of barley and (to a lesser extent) wheat malts. It is a dark-copper color, relatively bitter, and approximately 5% ABV. Kolsch, from Cologne, is a much lighter beer, of similar alcohol content. The darker malts used in the production of alt are replaced by a less intensely kilned malt, called Vienna malt.

German wheat beers Weizenbier is made from a grist comprising at least 50% wheat malt. The products are relatively highly carbonated, affording a refreshing character alongside the fruity and phenolic (clove-like) characters. Kristallweizen denotes that the beers have been filtered to remove yeast, whereas Hefeweizens are cloudy due to yeast, which is traditionally employed to carbonate the bottled product through 'natural conditioning.' The products are relatively lightly colored (straw-like) and have alcohol contents of 5–6% ABV. Weissbier ('white beer') is much weaker (e.g., 2.8% ABV), and made from a grist of less than 50% wheat malt, with the addition of lactic acid bacteria to generate a low pH of 3.2–3.4. Accordingly such beers are quite sour, and may be taken with raspberry or sweet woodruff syrups.

Bottom-fermentation beers

The classic style originated in mid nineteenth-century Bohemia, in the Pilsen city brewhouse. It is quite a malty brew (the malt traditionally being relatively undermodified), typically with 4.8–5.1% ABV and a pale gold color. Particularly prized is the late hop character, afforded by retaining a proportion of the hops for addition late in the kettle boil to ensure that the desired fraction of essential oils presents.

All too often the term *lager* is used synonymously with pilsner (pils). Lager as a term is really an umbrella description for all relatively pale brews, fermented and dispensed at low temperatures.

The greatest breadth of styles of this type of product is to be found in Germany. To many the distinction between some of the styles is subtle and, for those seeking to replicate them internationally, may own as much to marketing as to major differences in brewing practice.

Export is a little stronger than Pilsner (5.5% ABV) and darker, though somewhat less bitter.

Bock is a stronger beer (6–8% ABV) with sulfury and malty flavors and colors ranging from straw to dark brown. The related Doppelbock may contain up to 12% ABV.

Marzen ('March beer') was historically brewed to a high strength (up to 6.5% ABV) with pale and dark versions. It has 'middle-of-the-road' characters, with some toasted notes.

Helles (4.5–5.5% ABV) is pale amber, very malty, with a low bitterness and hop character.

Dunkel has a similar alcohol content but is copper-brown, whilst Schwarzbier is black, dry, and between 3.8 and 5% ABV.

Malt liquor is a term used to describe alcoholic products (6–7.5% ABV) which are very pale, very lightly hopped and quite malty and sweet, and originating in the USA.

The other lager-style product indigenous to the USA is steam beer. The origins of this product can be traced to the California gold rush and a demand for light and refreshing drinks despite the unavailability of ice for cold storage and conditioning. Bottom yeasts were used at warmer fermentation temperatures in shallow vessels into which the 'steaming' wort was introduced to cool.

Other classifications of beer

There is considerable blurring of the boundaries that divide the classic beer styles. For example, products both light and dark have been developed with all manner of additional flavors, such as citrus character, cf. the traditional mixers of ale with lemonade (shandy) or lager with a splash of lime or lemon (lager top). Flavors as diverse as oyster, chocolate, coriander, and chilli have been used. Black lagers have been developed, as indeed have colorless ones. There is probably no limit to the ingenuity of new product development teams, although most of these products tend to be quite short-lived as brands.

Ice beers The original provenance of this style stems from the trick (mostly in Canada) of concentrating beer by placing it on the window sill in the heart of winter, under which conditions water freezes out first, leaving a more alcoholic and warming solution behind. In fact, the freeze concentration technique used in the manufacture of such beers in the brewery produces ice in only sparing amounts, but there is a loss of some of the tannin materials, which may make these products slightly less astringent than the norm.

Dry beers These are lagers with a relatively low proportion of residual sugars making for a low sweetness. They are related to the light beers, the most rapidly growing genre. Standard beers contain a proportion of carbohydrate surviving the fermentation process, whereas a light beer has most or all of this sugar converted. These beers therefore have fewer

calories, provided that the extra alcohol is diluted to the level found in 'normal' beers. They are produced using a more convoluted mashing procedure to allow as much starch conversion as possible, followed by the use of malt extracts (or microbial enzymes if the brewer is content to use additives) in the fermenter.

Draft beers The term 'draft' ('draught') is nowadays used not only to describe large pack dispense (keg, cask) but also nonpasteurized beers in small pack.

Non- and low-alcohol beers There are many definitions worldwide about what constitutes low-alcohol products. Perhaps the most stringent is in the UK, where non- and low-alcohol beers contain less than 0.05% or 1.2% ABV respectively. They are produced either by removing the alcohol from a full-strength brew, by techniques such as vacuum distillation or reverse osmosis, or by restricting the ability of yeast to ferment wort, either by making a wort containing very low levels of fermentable sugars or by ensuring that the contact between yeast and wort is at a very low temperature and for a relatively brief time.

Raw Materials

P Hughes, Heineken Technical Services, Zoeterwoude, The Netherlands

Background

The production of beer has a long history, dating back to the Sumerians and the Egyptians. A unique beverage, the quality of beer is substantially dependent on the identity and quality of its raw materials. The major raw materials of beer are cereals and hops. Both have a number of roles in beer production and final beer quality, but the cereals principally provide sugars and amino acids for fermentation. Hops are used to provide a unique flavor and to stabilize the beer foam. Both can be processed for optimal and more flexible usage for beer production. Here, aspects of hops, and cereals as they pertain to the brewing industry, are described. For clarity, brewing specific terms are defined in **Table 1**.

Hops

The cultivated hop (*Humulus lupulus* L.) was originally added to beers during their production for flavor and to extend the beer shelf-life. Historically, herbs have also been used, but today, essentially only the hop is used commercially. Hops are cultivated solely for beer production and grow almost exclusively in the temperate regions of the world, between the latitudes of 35 and 55°, both north and south of the equator. Owing to continuing improvements in the utilization of hops and the gradual reduction of beer bitterness levels, the global production of hops is currently decreasing (**Table 2**), whereas beer production is increasing on a world-wide basis.

The hop plant is a hardy, climbing, herbaceous perennial plant. The rootstock stays in the ground from year to year. The vines that grow from the rootstock are not self-supporting, and the provision of a support structure or wirework is a significant capital investment when setting up a hop garden. Traditionally, hop plants attained heights in the region of 5 m, but the recent development of commercial dwarf varieties (*c*. 2.5 m in height) allows more cost-effective supporting structures such as hedges to be used.

Hops for Beer Production

The brewing value of the hop is embodied in its cones. These are structures that bear small, physically robust yellow lupulin glands. It is these glands that contain the hop essential oil and the hop acids that are responsible for hoppy and bitter flavors, respectively. Traditionally, cones were added to the wort boil, during which time extraction and chemical conversion of the appropriate brewing value occurs. However, neither the extraction nor chemical conversion is particularly efficient during a typical beer production process, and an industry has grown up, whereby hop cones are processed to enhance efficiency, or utilization, of this raw material. Today, around 85% of all hop products used are either extracts (45%) or pelleted hops (40%). The remainder is made up of reduced extracts and the unprocessed hop cones themselves (**Table 3**). These various products are used at a number of stages during beer production (**Figure 1**).

Hop Pests and Diseases

These are numerous and can have widespread effects on the resulting crop. The sensitivity of hops to various pests and diseases is in some cases dependent on

Table 1 Definitions of common malting and brewing terms

Term	*Definition*
Boiling	Operation that follows lautering. The sweet wort is boiled to ensure its sterilization. α-Acids added with hops or hop products are partially isomerized here, and there is also substantial development of solids that are later removed. Yeast is added to the cooled product to begin fermentation.
Fermentation	Yeast added to the cooled boiled wort uses the sugars, free amino acids and residual lipid present to grow and generate ethanol.
Lautering	A common process in many breweries. The mash is allowed to run through a coarse slotted plate. Insoluble husk material settles on to this plate and creates an effective filter bed.
Malting	Process of partial germination to convert barley (or, less commonly, wheat) into malt.
Modification	In terms of malt, this indicates the degree of biopolymer degradation in the grain.
Pasteurization	Commonly applied operation that neutralizes any residual bacteria in the final product by controlled heating. Some companies prefer to sterile filter their product.
Run-off	Refers to the gravitational separation of malt extract (wort) from residual solids, usually during the lautering operation. This can be seriously hampered by a number of wort constituents, such as β-glucan gums.
Trub	Solids formed during wort boiling and subsequent cooling. Mainly composed of protein–polyphenol complexes.
Utilization	Traditionally refers to the ratio of the moles of bitter iso-α-acids recovered in the final beer to moles of α-acids added to the wort boil. Now often modified to include efficiency of isomerized hop product dosing.
Wort (sweet)	The liquid that recovered, for instance after lautering. The term 'sweet' refers to the high levels of fermentable sugars that are released during the mashing operation. The addition of hops at wort boiling gives a bitter wort.
Whirlpool	A common device in breweries for effective solids removal from hot boiled wort. Wort is passed into the whirlpool vessel tangentially, and the solids present accumulate at the center and deposit as a cone at the base of the vessel.

Table 2 Global production of hops

Country	*Global production (percentage of global production)*	
	By area (hectares)	*By mass (tonnes)*
Germany	18 600 (31.5)	29 290 (30.3)
USA	14 630 (24.8)	30 650 (31.7)
Czech Republic	6 110 (10.4)	4 890 (5.1)
China	4 930 (8.4)	13 000 (13.5)
Poland	2 250 (3.8)	3 060 (3.2)
England	1 980 (3.4)	2 800 (2.9)
Slovenia	1 620 (2.7)	1 760 (1.8)
Russia	1 520 (2.6)	820 (0.8)
Total	59 020 (100)	96 610 (100)

Table 3 Distribution of global hop sales

Hop product class	*Proportion of total sales (%)*	*Comments*
Cones	7	Traditional. Use declining
Bittering pellets	19	Enhanced control of bitterness
Aroma pellets	22	Enhanced control of hoppy aroma
Extracts	44	Highly concentrated aroma/ bitter products
Reduced extracts	8	Chemically modified by selective reduction

variety, so that breeding programs, such as those at the Hop Research Unit at Wye College, specifically test for resistance to a range of challenges as part of its selection criteria. For instance, resistance to verticillium wilt, endemic in some parts of the UK, is essential here for acceptance to the grower.

The Hop Market

Hop producers rely almost solely on brewers to purchase their product. In previous years, the susceptibility of the hop crop to a range of pests and diseases has affected their market price. This resulted in the practice of the forward contract, whereby a grower or merchant would undertake to supply certain quantities of hops or hop products to a buyer for a given period. Hops that were not put aside for forward contracts were sold on the spot market. At the end of the 1990s, the hop industry suffered from overproduction, so hops and hop products were available for unprecedented low prices on the spot market, and forward contracts became unpopular. Many growers, particularly in Europe, ceased growing what became an uneconomical crop. The cost of the infrastructure to grow hops and the need for two to three seasons before a high-quality crop can be expected mean that there will be an inertia for farmers to turn back to hops. At the beginning of the new millennium, the reductions in acreage worldwide have begun to redress the supply and demand balance.

Impact on Beer Production and Quality

The use of hops in brewing is famous for the provision of bitterness in the final beer. However, they have a number of other effects on the final beer quality and on the production process itself.

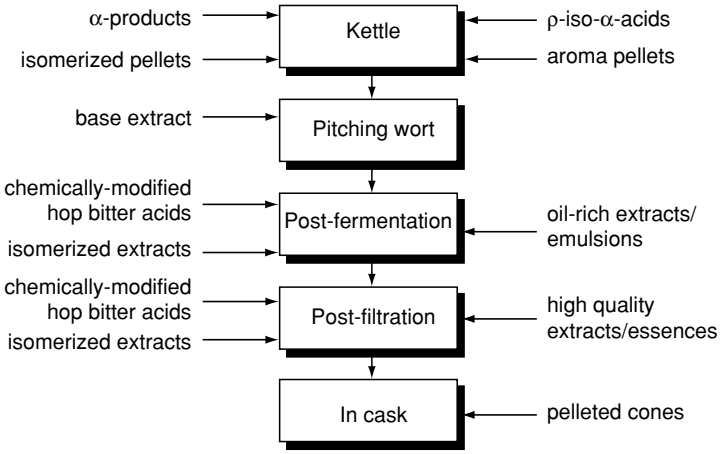

Figure 1 Points-of-addition of hops and hop products during beer production. Generally, the boiling stage is mandatory if isomerization of the α-acids is necessary.

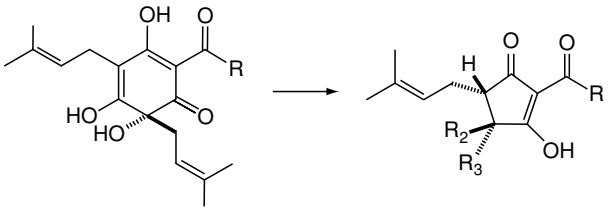

Figure 2 Isomerization of α-acids to the bitter iso-α-acids. The mechanism of the reaction is unclear, but the result is a ring contraction and the production of *cis*- and *trans*-isomers. R represents isopropyl, isobutyl, or *sec*-butyl substituents. R_2 and R_3 are either hydroxyl or 4-methylpen-3-enoyl, depending on whether a *cis*- or *trans* isomer is formed.

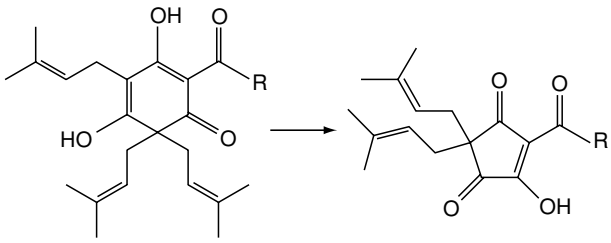

Figure 3 Degradation of hop β-acids to bitter hulupones. This reaction is far from quantitative, although it is believed by some to impart a good-quality bitterness to the final product. See Figure 2 for the definition of R.

Bitterness Most, if not all, of the bitterness of beer is due to the presence of the iso-α-acids. These are a mixture of six major components, which are three stereoisomeric pairs of compounds derived from each of the three hop α-acids (Figure 2). These α-acids are isomerized to the iso-α-acids during the wort boiling stage, although in practice, the final utilization is around 30–40%. In contrast, isomerization by hop processing gives yields in excess of 90%. There are probably minor differences in the bitterness of the individual compounds. Nevertheless, whilst hops come in a wide range of varieties, current thinking is that variety has little effect on bitterness intensity or quality. High-α-acid hop varieties have become a lucrative breeding target, because of the generally favorable yields of α-acids per hectare. Today, α-acids are considered a commodity on the hop market. There are some who consider the cohumulone content of the α-acids to have a poorer-quality bitterness, but to date, this has not been conclusively demonstrated.

Hops also contain the β-acids. Although these do not undergo isomerization in the sense of α-acids, they do form bitter degradation products – the hulupones – when present during wort boiling (Figure 3). In practice, this contribution to bitterness is usually minor.

Hoppy flavor Hop cones have a characteristic aroma, which is particularly evident when hops are rubbed between the hands. This is due to the presence of over 300 volatile compounds in the essential oil of hops. In addition to volatility, some hop oil compounds are chemically reactive, so that after wort boiling, very little of the original hop aroma compounds remain, with some being lost completely. Nevertheless, what is left, subject to the impact of fermentation, stays in the beer to give a unique flavor. Beers vary substantially in the intensity and quality of their hoppy flavor. The intensity is dependent on the brewing practice and dosing level, whereas the quality is mostly dependent on the varieties used

Table 4 Common hop varieties widely available to brewers, in decreasing order of tonnage (these varieties account for > 60% of all hops produced in 2000)

Hop variety	*Growing areas*[a]
Qingdao Flower	China
Nugget	USA, Germany, Spain
Perle	Germany, (USA)

(Table 4). Hops with perceived high-quality aromas can command a premium price in the marketplace. This is in contrast to hops sold for bitterness, where trading is often carried out on a kilogram α-acid basis.

Foam The chemical structure of the iso-α-acids is conducive to beer foam stabilization. Beer foam is predominantly made up of malt-derived polypeptides, and the iso-α-acids can cross-link these polypeptides to provide a more stable foam structure. Furthermore, the foam that adheres to the inside of a beer glass during consumption – the lacing or cling – is reliant on the presence of iso-α-acids in beer.

Antibacterial potency The initial reason for adding hops to beer – to stabilize it against flavor deterioration – is well founded. At levels found in beers and at the pH of beer (*c*. 3.9–4.5), the iso-α-acids effectively kill many Gram-positive bacteria. This bacteriostatic effect is aided by the presence of ethanol. Given the global trends for increased beer pH and decreased bitterness of beer, there is a school of thought that considers that this mode of beer protection could be compromised. In any case, other measures, such as good brewery hygiene, sterile filtration, and pasteurization also help to insure that beer is not affected by microbial action.

Hops and Beer Production

The traditional use of hop cones themselves meant that a significant quantity of leaf material needed to be removed from the wort after the boiling stage. This was done with a hop back, a specifically designed sieve to clarify the wort. The widespread use of pellets and extracts means that, today, the hop back is absent from many modern breweries. Alternative clarification procedures were therefore required, particularly for the remains of pellet powder. Based on an initial discovery by Einstein, the whirlpool was developed. This is a vessel whereby the wort, after boiling, is pumped in tangentially. The circular motion of the liquid results in the deposition of solids (trub) in the center of the vessel, where it sinks to the bottom. This development signified the beginning of hop-pellet penetration into the brewing industry.

The presence of polyphenols in hops also assists in the precipitation of excess polypeptides extracted from the malt. If this precipitation is limited, there is an increased risk of the final beer producing a haze during its shelf-life. These polyphenols are also attracting interest because of their antioxidant properties, although, as yet, the complexity of these components in hops means that few specific details on their properties are known.

Quality-control Aspects of Hops

Hops and hop products purchased principally for bittering the final beer are assayed for α-acids. Today, this is commonly achieved by high-performance liquid chromatography (HPLC), although traditionally, this was carried out using spectrophotometry or the measurement of the so-called lead conductance value. For aroma attributes, judgements are primarily on the basis of the name of the variety: there is no specific test available for predicting hop aroma performance. The time-honored approach of rating hops according to their visual characteristics and the aroma released on rubbing hop cones in the hands is still very much in use.

Hops and hop products should be stored cold (but above 0 °C), and, where possible, sealed packages should not be breached until the contents are required. Both aroma and bittering components of hops are sensitive to heat and oxidation, although there is some varietal dependence of the rate of hop degradation during storage. (*See* **Chromatography**: High-performance Liquid Chromatography.)

Cereals

Cereals form the basis of beer. Although quantites vary, for a typical beer, some 200 g of cereals per liter of beer are used during production. Cereals provide the carbohydrates and amino acids necessary for the yeast to grow, generate ethanol and carbon dioxide, and produce key flavors in the final beer. Malted wheat and rye are used in some German beers, and malted sorghum is used in some African beers. Raw cereals, in the form of flour or grits, and cooked cereals, generally as flakes or torrified (syn. torrefied)

are still widely used as adjuncts to form part of the grist. Today, most brewing malt (with the exception of some specialist beers made from wheat malt) is made from barley, since it has been recognized that in certain essential properties, barley is superior to many other cereals. In any case, with the exception of the Japanese happoshu beer brands, which may use as little as 25% malt in the grist, barley malt makes up at least 40% of the total grist. Nevertheless, perhaps with the exception of the Japanese brewing industry, the proportion of extract derived from malt remained essentially constant over much of the twentieth century.

Malted barley, as well as adjuncts and syrups, are usually assessed for extract yield. This is the quantity of sugars released per unit mass of malt, adjunct, or syrup. This extract yield relates directly to the quantities required and therefore the impact on cost. Extract yield, though, is measured by density and reflects the total sugar content. However, a proportion of the sugar content is nonfermentable, and this is assessed by a further measurement – that of fermentability. This is determined by carrying out a test fermentation and measuring the maximum amount of extract consumed. Again, this is done by density measurements. The remaining sugars are termed dextrins. Whilst they may not contribute directly to the yield of ethanol, dextrins may have a subtle role to play in the sensory qualities of the final beer. Two other common measurements are the total nitrogen content, a measure of protein content, and, in malt, *S*-methylmethionine. The significance of the latter is that it is readily degraded to yield dimethyl sulfide, a distinctive sulfur compound, with an aroma reminiscent of sweetcorn. At the correct levels, it is a key flavor impact component of many beers, particularly lager-style beers. For pale malts, the levels of enzyme activity – especially α- and β-amylase, are important parameters for satisfactory performance of the malt in the brewery. Typical analytical data for various cereals and their products are given in Table 5. (*See* **Cereals**: Contribution to the Diet.)

Barley

The most popular cereal is barley that has been malted. Its use has several advantages: it has a suitable level of protein (8–12% dry weight) and low levels of lipids, it develops high levels of amylolytic enzymes during germination, and it has a husk that assists in the separation of insoluble material from the required extract.

Barley is essentially a temperate plant that is nevertheless distributed widely in both tropical and subtropical zones. The main commercial growing areas of barley are in the grassland belt, across the northern hemisphere from the northern USA and Canada, across northern Europe into Asia and North Africa, where it probably originated. Again, in the southern hemisphere, barley is grown commercially in South America, on the fertile uplands of South Africa and in Australia and New Zealand. (*See* **Barley**.)

Barley malting The malting of barley has several purposes. Firstly, the development of amylolytic enzymes is essential for the subsequent brewing operation, as these are required for the formation of fermentable sugars from the malt starch. This diastatic power is more than enough for conventional brewing, so this can be diluted to some extent with nondiastatic materials, such as syrups and speciality malts. Secondly, on a practical level, it is desirable to reduce or eliminate the β-glucans present in barley. These form gels that substantially slow down or even stop the separation of the sweet wort from the residual solid material. Thirdly, there needs to be enough free amino acids released, either during malting or in the mashing stage of beer production, to support the yeast growth required during the early stages of fermentation. Finally, in terms of flavor, 'grainy' or 'green' flavors should be eliminated, to be replaced by desirable 'malty' flavors. Other aspects are assuming importance, namely the reduction in levels of agrochemical residues during malting, which in turn means lower levels finding their way into the final

Table 5 Typical malt specifications

Parameter	*Level*	*Applicability*
Malt		
Moisture (%, w/w)	5	To ensure storage stability
Hot water extract (l °kg^{-1})	310	Indicates the amount of soluble extract available
Color (°EBC)	3	Has a large impact on final beer color
S-Methylmethionine (mg kg^{-1})	4.5	Indicative of likely dimethyl sulfide levels in final beer
Total nitrogen content (%, w/w)	< 1.65	Ratio with soluble nitrogen gives an indication of the degree of malting (modification)
Total soluble nitrogen (%, w/w)	0.70	Indicates the amount of soluble nitrogen (protein)
Free amino nitrogen (mg l^{-1})	140	Indicates the degree of proteolysis during malting

beer. This also applies to the presence of barley microflora, which can be accompanied by a range of mycotoxins.

The malting process involves several stages. The malt, once produced, is considered to be relatively stable if the grain moisture levels are below about 12% (w/w), and can be stored under appropriate conditions for many months. Low atmospheric moisture and attention to possible fungal growth are essential during prolonged storage. The final malt color will depend on the kilning regime used to dry the malt so that it is stable during storage. Thus, so-called lager malts are dried at temperatures well below 100 °C, whereas an ale malt is dried at around 100 °C. These higher temperatures stimulate nonenzymic browning reactions between sugars and free amino compounds, thus resulting in a darker color and, generally, a higher degree of flavor. Crucially, though, both still retain enzyme activity essential for the mashing operation. The degree of enzyme development is termed 'modification' and has an impact on how the malt is used in the brewery.

Brewing with malt The early stages of beer production have been tailored to the properties of malt. Thus, to effect recovery of as much brewing value as possible from the malt, it must be ground, and the enzymes generated during malting need to be activated (Table 6). There are some variations on the milling and mashing operations, but essentially, milled malt is blended with water in a specific ratio, typically 1:3 (w/w).

Specialty malts Some beers are brewed with relatively low concentrations of specialty malts. Generally, these retain little enzymic activity, but are used because of the specific flavor or color attributes that they confer on the final beer (Table 7). Whilst not a malt, roasted barley may also be considered, together with specialty malts, as it is used for similar reasons. Many darker beers contain small percentages of specialty malts as part of the grist.

Adjuncts

This is a term reserved for nonbarley malt derived cereal substitutes in beer production. Whilst barley malt is best tailored to the requirements of brewing, there are good reasons for partial substitution of barley malt for other cereals. These include flavor modification, increasing brewery capacity, potentially favorable costs (malting barley often commands a premium price), enhancing the stability of the final product with respect to haze formation, and as a point of beer brand differentiation (e.g., oatmeal stouts, wheat beers). The lack of diastatic power in adjuncts is not usually a serious issue as good-quality malt is characterized by having amylolytic activity surplus to requirements. As a rule of thumb, there is little need to be concerned about the final diastatic power if the level of diastatic malt in the grist is at 70% or higher.

Adjuncts come in a variety of forms. Some of these forms generally require a specific brewery plant, the installation of which implies a future commitment to the chosen adjuncts. A brewer therefore needs to be

Table 7 Typical color and flavor descriptor attributes of specialty malts

Specialty malt	*Color*	*Typical flavor characteristics*
Pale malt	4.5–4.8	Biscuit-like
Caramalt	25–35	Sweet, nuitty, cereal, toffee
Crystal	100–300	Malty, toffee, caramel
Amber	40–60	Nutty, caramel, fruity
Chocolate	900–1200	Mocha, treacle, chocolate
Black	1250–1500	Smoky, coffee
Roasted barley[a]	1000–1550	Burnt, smoky

[a]Not strictly a malt, but included here for completeness.

Table 6 Some enzyme activities present in milled malted barley during mashing

Type	*Enzyme*	*Activity*
Amylases	α-Amylase	An endoenzyme, mainly responsible for the breakdown of high-molecular-weight starch
	β-Amylase	An exoenzyme that releases maltose
	Limit dextrinase	Breaks down branch points of starch
	α-Glucosidase	An exoenzyme that releases glucose
Proteases	Endopeptidases	A sulfydryl protease of general activity
	Exopeptidases	Important for free amino nitrogen generation
	Aminopeptidases	Exopeptidase that attacks the amino end of protein
	Carboxypeptidases	Most important proteases, attacking the carboxyl end of protein
Other carbohydrases	β-Glucan solubilase	Releases β-glucan from cell walls
	Endo-β-glucanases	Break down potentially troublesome β-glucans
	Pentosanases (xylanase)	Degrade pentosans
	Xylosidase	Breaks down xylan polymers

sure that the source of required adjunct is and will be available at the required quality for the foreseeable future.

Raw cereal grains In principle, suitably milled barley, wheat, rye, and *Triticale* grains can be used during mashing without prior treatment. Of these, most interest has focused on the use of whole barley. Careful milling of the cleaned barley, preferably retaining the husk as intact as possible, provides a suitable grist addition. Hammer milling of raw cereal grains is generally avoided, as problems with β-glucan extraction and subsequent run-off difficulties can occur. If the proportion of raw barley in the mash is high, enzyme supplementation is highly desirable to degrade the proteins and carbohydrates present. As a total replacement for malt, raw barley is financially attractive, although a balanced mixture of enzymes is essential to give the required extract for subsequent fermentation.

Cooked intact cereal grains Roasted barley, torrefied or micronized barley, and wheat grains contain no active enzymes. However, their preheating results in partly precooked starch and a disrupted grain structure. Such products are readily milled and easily handled, giving extracts generally higher than those for raw cereals. The heat also partly degrades β-glucans, so that the resulting worts from torrefied grains are less viscous than those from raw materials.

Grits Grits may be defined as uncooked, nearly pure fragments of starchy endosperm from cereal grains. If they are used directly in the brewery, they must be cooked or flaked (see below). The removal of other parts of the grain reduces the levels of lipid, ash, and fiber. Rice grits, or broken rice, are often a byproduct of debranning and milling rice for human consumption. Nowadays, milling efficiency has improved such that less of this byproduct is produced. Rice grits are generally low in lipid and fiber but must be cooked well if adequate extract is to be recovered. There are substantial differences in the suitability of various rice cultivars for beer production, but rice is considered to be flavor-neutral and is therefore a popular adjunct.

Maize grits are the most common adjunct used in the USA. They can be prepared in a number of ways, but in any case, the aim is to remove the outer layers and the lipid-rich germ. The resulting grits are rich in starch and contain much less lipid than their parent grain. They are popular, as, after cooking, they yield a good extract during mashing.

For use in the brewery, all grits must be cooked to disrupt them and gelatinize the starch. They are then usually mixed with conventional barley malt mash to complete the starch conversion. The grits are mixed with a small proportion of highly diastatic malt or with microbial amylase and then heated. Temperatures may be raised to boiling or cooking can be carried out under pressure to effect gelatinization. The swollen and gelatinized starch is partly degraded or liquefied before the heat inactivates the amylase activity. Consequently, viscosity neither increases to unmanageable levels nor sets to a gel on cooling. This is important from a practical point of view, as it can be pumped and does not burn on to the heating surfaces. Such burning can lead to problems such as flavor pick-up, color generation, and deteriorating heat-transfer characteristics.

Flaked cereals These are produced either by cooking whole grains with steam or by micronization. In both cases, the heated grain is passed through feed rolls to flaking rolls, typically held at 85 °C. For the more traditional steam process, the flakes are dried prior to packaging. The flakes may also be lightly crushed, as the flakes themselves have a low bulk density. Because the starch is already gelatinized, the flakes do not need cooking and can be added directly to the mash. Flakes also produce relatively little soluble nitrogen, so they can be used as a wort nitrogen diluent.

A range of cereals are flaked. Whilst flaked rice is popular because of its good extract yield and neutral flavor and color, it is not used for economic reasons. Flaked maize grits and flaked whole wheat grains and barley grains are currently in use.

Flours In principle, both wheat and barley can be hammer-milled in the brewery to produce coarse flours. These are suitable for addition directly into the mash. Nevertheless, flour milling is a rather specialist process, and in practice, the brewer buys flour from certain suppliers.

Syrups Sucrose, and its hydrolysis product, inverted sugar, are used by some brewers during beer production. Produced either from sugar cane or sugar beet, the range of products available is large, in terms of color, mineral content, and residual syrup present. They can be supplied for the special flavors that they can confer. These can include descriptors such as burnt, raw sugar, and bland.

Syrups and sugars from the partial or essentially complete hydrolysis of refined maize starch, unlike beet or cane syrups, contain no significant quantites of nitrogenous components or other yeast nutrients. Thus, like sucrose syrups, they are wort extenders rather than wort replacers. Their production requires

two hydrolytic stages. The first is the solubilization of starch slurry to form dextrins. Here, the starch is completely solubilized, so much so that it does not form gels or retrograde (precipitate) on cooling. In the second stage, the dextrins of the first stage are converted into the desired spectrum of sugars. Dilute mineral acid and enzymes can be used in both stages to accurately control the desired result. (*See* **Syrups**.)

Malt extracts and wort-replacement syrups Malt extracts are essentially sweet wort (i.e., unhopped), from which the water has been removed under reduced pressure. Although the extracts may be either diastatic or nondiastatic, the former are rarely, if ever, used. Malt extracts are an expensive source of extract, because the malt itself is relatively expensive, as are the operations for water removal.

Summary

The hop- and beer-production industries are, for the foreseeable future, inextricably linked, as there is no viable alternative to hops that brewers can employ and few, if any, other outlets for hops other than brewing. Like hops, cereals are essential to beer, and indeed, the two have been intimately linked ever since beer was first produced. Specific barley varieties are bred and tested for their performance in all aspects of agronomic, malting, and brewing characteristics.

Wort Production

M Ortega-Heras and M L González-Sanjosé, University of Burgos, Burgos, Spain

Background

One of the most common and simple definitions of beer is: 'beer is the drink resulting from the fermentation by means of selected yeast of the wort, which is obtained from malted barley, alone or mixed with other starch sources, and it is flavored by boiling with hop flowers.'

Brewing process can be divided into three phases: malting, wort production and fermentation, and maturation. Starting with the malting process, this includes different phases, such as steeping, germination, drying, and toasting. In this way, barley is transformed into malt.

During these phases, barley undergoes the following changes:

1. Steeping: The barley grain is humidified in large tanks of water into which air is bubbled to prevent anaerobic conditions developing. The temperature is also controlled. When this phase ends, the barley grain has a humidity of between 42 and 46%.
2. Germination of the grain: This involves partial development of the embrion, activating several endogenous enzymatic systems, such as the α- and β-amylases and the proteases, which are capable of hydrolyzing the starch and proteins, respectively. This germinated barley is known as 'green malt.'
3. Drying and toasting: In this phase, the grain is dried, the embrion is destroyed, and the enzymatic activity is stopped to avoid using up the reverse substances. In this way, the malt is obtained.

The aroma and taste of the toasted grain are formed simultaneously by Maillard reactions. The beer color is lighter or darker depending on the toasting of the malt.

The second phase includes different processes that convert malt into wort. Wort is a liquid extract containing fermentable sugars (sweet wort), amino acids, vitamins, and other compounds, and it is the principal substrate in which beer is obtained by fermentation.

Before fermentation, the wort is boiled with hop flowers to flavor it (sweet hopped wort).

The third phase is associated with wort fermentation and maturation, a process in which yeast transforms the wort into beer, by consuming sugars and releasing ethanol and CO_2. This phase ends with the filtration process, to produce a clear beer, and then bottling.

Nowadays, only some breweries have their own malt factory, and most of them have to buy the malt, as well as several other raw materials. In such cases, the first stage of the brewing process is wort production.

Wort Production

During this phase, malt and other starch sources (adjuncts) undergo different processes, in which the main aim is to obtain a fermentable extract, the wort.

Adjuncts are used in order to reduce the quantity of malt used, since malt is more expensive than these products, and so the use of adjuncts in relatively large amounts (20–30%) significantly reduces the cost of the brewing process. The most common adjuncts are rice, corn, wheat, or even sugars, syrups, and liquid starches, etc.

It is important to note that some legislation, especially European legislation, does not permit the addition of exogenous enzymes during the brewing process. Therefore, the use of malt is essential in order to obtain a fermentable extract, because when the exogenous enzymes cannot be used, malt is the only source of enzymatic activities, as will be shown later.

However, some special beers, such as wheat beers or sorghum beers (very common in African countries) are produced without the use of malt. In these cases, cereals are previously malted in a process similar to that for barley, or exogenous enzymes are usually added during mashing. The most recent adjuncts described are 'chufa nuts' or sedge tubers, which, after commercial enzymatic treatment, produce a wort comparable with sorghum wort, which may even have a better filterability, probably because of its higher fiber content.

In most of the cases adjuncts arrive at the brewery in a ready-to-use state, usually in the form of flour or other similar product, or may even be pretreated by different processes such as micronization, extrusion, etc. In this way, they can be used without reducing their particle size, and pretreatment gelatinizes the starch, so that their transformation into a liquid fermentable extract is easier.

Recently, a study on the use of nonmalted barley has been published, in which barley was gelatinized by cooking and thus was able to replace up to 10% of the malt, and extruded barley substituted up to 50% of the malt. However, barley treated previously with commercial enzymes did not yield satisfactory results.

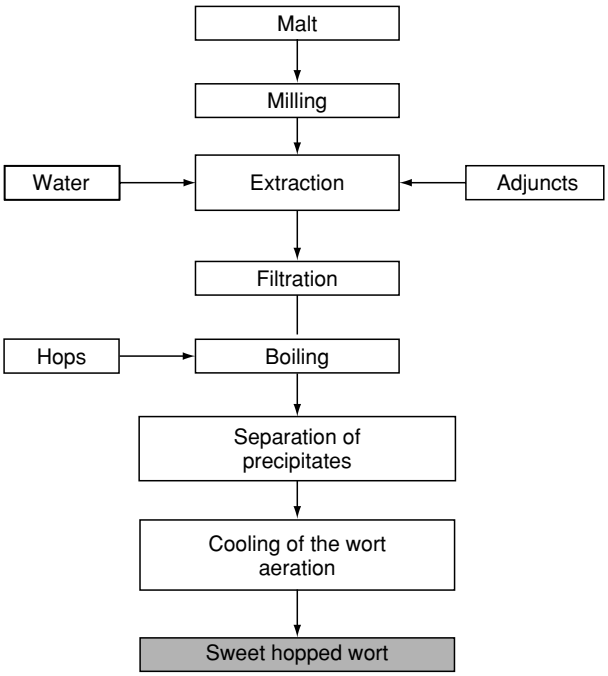

Figure 1 Process of wort production.

The process to convert malt into wort comprises several stages as can be seen in Figure 1.

Malt Milling

Malt or other malted cereals (e.g. sorghum) arrive at the brewery as a complete kernel, so the first process is malt milling, which is carried out in order to reduce the size of the particles, thus facilitating extraction and transformation of the desired compounds.

This process involves separating the endosperm from the husk and reducing the particle size to yield thick seeds, fine seeds, and mainly flour. However, it is important that the husk remains as intact as possible, so as to act as a natural filter during the filtration process.

The most commonly used milling system is the roller mill, generally consisting of three pairs of rollers. Placed between the rollers these are a series of sieves that separate the grist fraction by size. The final product of the milling process can be classified as follows:

1. Husks: These are the largest particles and consist of the outer case of the barley grain. They contribute very little to the wort.

2. Thick particles: These contain the least modified endosperm. They account for 20–25% by weight of the milled malt and yield 10–12% of the soluble extract.
3. Fine particles or flour: These contain the most modified endosperm. They account for 50–60% by weight of the milled malt and yield 89–90% of the final extract.

The milling system must be adjusted in order to improve the production of fine particles, without fractionating the husk. In this sense, malt is sometimes steam-treated to increase the moisture of the husk, which remain then more elastic and is more difficult to fragment.

The next process is mashing, in which the liquid extract is obtained.

Mashing

Once the malt has been milled, it is mixed with water to form the 'mash.' The mash is heated under controlled conditions, and then important transformations of the malt components are carried out by the action of endogenous malt enzymes.

After the hydration process, the enzyme activity that was latent in the dry malt is renewed. Enzymes work best under the following conditions: abundant water (high water activity), high-surface-area particles (allowing better access to their substrates, i.e. starch, proteins, lipids, etc.), and optimum temperatures, which are reached in subsequent stages.

A recent study has shown that during mashing, it is very important to control the oxygen availability, since some of the enzymatic systems that could be activated during this step are oxygen-dependent. Furthermore, the presence of oxygen determines the development of nonenzymatic oxidation, which can be very important in the formation of undesirable products such as aldehydes formed from unsaturated fatty acids or the formation of brown pigments.

The mashing phase is usually carried out in a single vessel, lasts between 4 and 6 h, and is often carried out in accordance with a particular temperature profile, since each type of enzyme has its optimum working temperature:

1. 35–50 °C: Dominated by the action of proteases and phosphatases. Proteins are hydrolyzed, and amino acids and other nitrogen compounds are released.
2. 50–65 °C: Dominated by the action of the β-amylases, which convert starch into maltose and limiting dextrines.
3. 65–75 °C: α-Amylase activity is dominant. Starch hydrolysis continues, and its saccharification is completed.
4. > 75 °C: All enzymes in the mixture are rendered inactive.

The exogenous enzymes can be added sequentially at each stage or at the beginning as a complex mixture that usually contents proteases and amylases.

Different breweries apply different extraction methods. The three most commonly used methods are described below.

Infusion Mashing

This is the traditional method employed in the manufacture of English 'ale.' The method uses a single vessel, and mashing is carried out at a single temperature, known as the conversion temperature, usually within 62–67 °C. This extraction method requires well-modified or broken-down malts. It is not suitable for use with additional starch sources that require prior gelatinization.

Decoction Mashing

This is the traditional method for making 'lager' beer. The equipment used for this type of process include a mash tun, a mash cooker, and a filter vat.

In this process, part of the mash is pumped into a second vessel, heated to boiling temperature, and re-added to the main mash. In mixing the two parts, the whole mash reached the different expected temperatures. This method is especially suitable for use with malts that have not been broken down to any large degree or are only slightly modified.

The traditional system uses three decoctions (the Pilsen method), in which the temperature is raised in three steps (34–40 °C, 50–65 °C, 75 °C). This system has been replaced by a double and finally a single decoction, since malts used nowadays are more modified.

This decoction procedure can also be applied to adjuncts in which the starch usually has a gelatinization temperature higher than that of the malt starch.

Double Mashing

This is the traditional method used in the USA. The adjuncts, which represent 30–50% of the total extract required and 10% of the malt or an external source of α-amylase, are heated in a mash cooker to 70 °C and maintained at this temperature for a specified period of time.

The temperature is then raised to the boiling point and maintained for 20 min under these conditions. After a while, the part that is removed and boiled off is pumped into the mash tun, which has been

kept at 35–40 °C. The temperature of the mixture is controlled by the speed of pumping.

Recent studies have focused on the use of different exogenous enzymatic systems in order to improve the quality of the wort during mashing, such as studies in the use of a new purine-nucleosidase to reduce the levels of purine nucleosides of worts and the use of proteinases to stabilize the foam.

Moreover, several studies on the thermostability of endogenous enzymes of different varieties of barley, an important factor for the malting and mashing process, are being carried out, in order to determine the best varieties for the brewing process. It is interesting to note that some breweries usually add some selected *Lactobacillus* spp. to increase the acidity of the mash and wort.

After mashing, all desired compounds are extracted and transformed into their respective byproducts, thus yielding a fermentable extract. However, this extract is cloudy, with a large amount of solids in suspension, so filtration is required to separate the liquid from the solid particles.

Filtration

In this phase, the insoluble part of the mixture, the spent grain, is separated from the liquid part, the 'sweet wort'.

Filtration is usually carried out using a lauter tun or by a mash filter (filter press). The lauter tun is a vessel with a flat, perforated bottom. First, the husk rapidly forms a filter cake on the bottom, which contains a natural filter through which the wort can be filtered. This filter yields wort of an excellent quality, but the filtration time is long, and it presents several problems in terms of removal of the spent grain. There is a special type of lauter tun, the strainmaster, which has a different bottom with slotted triangular pipes instead of a perforated bottom. In this way, the filtration area is larger, and the run-off is quicker. The quality of the wort is also good, but the filter cake retains a large amount of liquid, and discharge is not easy.

Several hollow frames and plates, separated by filter cloths, form the mash filter or filter press. In a similar way to the lauter tun, when wort crosses the filter, husk is retained on the frames forming the filter cake. The wort obtained with this type of filtration system is not as clear as that obtained using the lauter tun, and the wort also has higher levels of lipids. However, it is a more rapid process, and it is easier to automate. Usually, mash filtration is carried out to a high temperature in order to improve the filtration process and reduce the duration. This step is very important in the brewery; it could be considered one of the limiting steps. Brewers and related commercial industries have spent much time researching how to develop fast filtration systems that do not result in any losses of the wort quality. Some of the first studied systems were high-pressure mash systems, but the filter in these types of system had several technical shortcomings and did not meet the requirements. Later, a membrane mash filter was developed. This system yields wort of a good quality, and enables good separation of the solid part, even when a fine grist is used. Membranes can be inflated with compressed air to remove more of the liquid remaining in the filter cake, thus improving the extraction yield. This system can be easily automated. In the early 1990s, different breweries installed this type of filter. Another system developed at the beginning of the 1990s was the 2001 filter. This is an automatic system equipped with polypropylene plates and a frame filter, and comprising the following stages: filling, filtration, precompression, sparging, compression, and spent-grain removal. The advantages of this filter include: production of a clear wort with a low fatty acid content, reduced volume of sparging liquor, production of a dryer spent grain, reduced O_2 uptake, zero heat radiation and waste water, high efficiency (12 brews per day), simplified milling technology, flexible load (70–110% normal capacity), and flexibility with regard to raw material and mashing procedures.

The final product of this step is more or less a 'clean' liquid extract called a 'sweet wort.'

Wort Boiling and Addition of Hop

Wort boiling is carried out for different reasons, which can be summarized in terms of the main effects and secondary effects that are very important for the final characteristic of the final beer, such as stabilization, improve flavor, modify color, etc.

The main effects are: to render enzymes inactive, once starch, proteins, and other constituents have been transformed (hydrolyzed), and to sterilize the wort, converting it into a sterile medium for the subsequent fermentation.

Some of the most important secondary effects are:

- Coagulation of the remaining proteins (hot break), which is very important in preventing cloudiness in the beer;
- Precipitation of calcium phosphate, which causes a fall in pH.
- Extraction and transformation of important compounds as boiling is carried out in the presence of hop. Therefore, during this process, humulones and lupulones are extracted, and then, after heat

treatment, they are isomerized to give the typical bitter taste of beer. In addition, the isoacids formed help to stabilize the foam.
- Removal of volatile products (e.g., undesirable flavor compounds such as sulfated compounds) and some of the essential oils extracted from the hop.
- Partial caramelization of the wort sugars and the formation of Maillard reactions products, improving the flavor, and slightly changing the color. Some of these products (e.g., melanoidins) induce changes in the surface tension and also help stabilize the foam.
- Partial oxidation of phenols and their condensation with proteins. Therefore, they can be removed more easily from the medium, the beer is more stable, and cloudiness is reduced.
- Evaporation of water and wort concentration.

Boiling is traditionally carried out in boiling vessels, where hop is added as hop flowers, pellets, or even hop extracts. In the manufacture of 'ale,' the hops are usually added in the initial stages of boiling, as formation of foam can be controlled during the process. In 'lager' production, the hop is usually added manually and at different times during the boiling process, thus imparting a hop aroma. Different types of vessel are used in the wort boiling process. The most common types are as follows.

Traditional Boiling Vessels

Open-top vessels, in which the process takes places at atmospheric pressure. Traditionally, boiling vessels were made of copper and had an external heat source. Modern vessels have an internal heat source and are made of stainless steel, which is a low heat conductor, thus minimizing heat loss. However, some authors claim that the traditional copper vessel seems to impart a special flavor characteristic to the wort.

In traditional systems, the boiling process lasts between 1 and 2 h. In order to reduce the energy needs for this process, several heat systems have been developed. The use of an external heat exchanger, or calandria, requires a shorter boiling time, because, in this system, the wort circulates through the heat exchanger and reaches higher temperatures (106–110 °C).

Other systems have focused on recycling the vapor formed. Mechanical vapor-compression systems have been used as external boiling systems.

Continuous High-temperature Systems

Focusing on energy reduction, these systems consist of several consecutive heat exchangers, in which the wort temperature is increased to approximately 140 °C and held for 3–5 min. The pressure is then reduced using two expansion vessels, and the vapors are finally recycled to heat the heat exchanger. In this way, the brewing process time is reduced, and less energy is consumed, so the final costs can be reduced considerably. Several different systems, with diverse designs, have been patented in recent years. Some authors have indicated that there are remarkable differences between the sensorial characteristics of the worts produced by both methods.

The final product from the boiling step is called 'sweet hopped wort,' which must be filtered before fermentation in order to eliminate all the precipitates formed during boiling (hot precipitates).

Separation of Hot Precipitates (Filtration)

The first point to note is that after the boiling process, all operations must be carried out under sterile conditions in order to avoid any recontamination of the wort.

Hot precipitates, together with hop flowers if they have been used, must be removed from the medium. In these cases, the hop flowers form a filter bed or cake through which the wort is filtered. When pellets or extracts are used, wort is usually clarified by the addition of a clarifying agent, such as bentonite or, even better, silica gel, before it is pumped into the filtration systems. The types of equipment employed in this filtration process include the so-called windmill, Whirlpool, centrifuge, or hot settling tank.

Different modifications of the filter systems have been developed in recent years, with the main aim to improve the filtration process by reducing the operation time and increasing the cleanness of the sweet hopped wort.

After hot filtration, the clean wort must be cooled in order to reduce the temperature and to allow the addition of yeast, and must be aired to promote the growth of the yeast, so that the wort will be in the best condition for the next step: fermentation.

Cooling and Aeration of the Sweet Hopped Wort

There are several systems of cooling and aeration used in beer manufacture. These include:

1. *Flat recipients*: In this traditional system, the wort was loaded on to the recipients to a height of 25 cm. Cooling was achieved by evaporation of the water through ventilation holes through which air flowing over the wort could enter. These containers also allowed aeration of the wort and decanting of hot and cold precipitates. The air used would be

passed through aseptic filters that were free of undesirable microorganisms.

2. *Refrigeration by means of plate or tubular heat exchangers*: The cooling agent used is usually cold water, or refrigerated glycolate, alcohol or brine. Air is introduced, in the form of sterile air or oxygen, usually between the two sections of the plate heat exchanger, when the wort enters the final stage of cooling. The fall in temperature leads to the formation of new precipitates, which are eliminated by sedimentation, although some breweries do this by filtration or centrifugation of the wort, or even by flotation separation, which is more effective than sedimentation when the particle size is very small. Furthermore, studies carried out in 2000, showed that flotation techniques minimize wort losses. Cross-flow, micro- and ultrafiltration have also been described as interesting techniques by which to eliminate the wort cold break precipitates.

The aeration is usually controlled by specific mechanisms based on concurrent flow of the liquid and gas, and on the residence time of the liquid in the treatment unit.

The final product is a clean, cold, and aired sweet hopped wort, ready to be transformed into beer after its fermentation by the action of selected yeast.

Special Wort

Several patents have been developed in recent years for the production of 'special wort,' such as 'concentrate wort,' which can be used as a raw material in small breweries or in home installations common in some countries such as the UK.

In addition, special wort with lower levels of fermentable sugars is used in the brewing process for low-alcohol beers. Limiting the action of amylases, especially β-amylase, reduces the production of fermentable sugars. This can be achieved with a high-temperature mashing process, in which β-amylase is thermal destroyed by heat. This wort has a high level of dextrin. Low-gravity wort is also employed in low-alcohol beer manufacture. This type of wort is obtained by low-gravity brewing or, more usually, by diluting normal wort.

Biochemistry of Fermentation

G G Stewart, Heriot-Watt University, Riccarton, Edinburgh, UK

Introduction

The characteristic flavor and aroma of any beer are, in large part, determined by the yeast strain and the fermentation conditions. Thus, proprietary strains belonging to individual brewing companies are usually (but not always) jealously guarded and conserved. In Germany, most of the beer is produced with only four lager strains, and approximately 65% of the beer is produced with one strain.

The Fermentation Process

The genus *Saccharomyces* has many species that are generally regarded as safe and produce the two important primary metabolites – ethanol and carbon dioxide (CO_2). Lager and ale, the two main types of beer, are fermented with strains of *Saccharomyces uvarum (carlsbergensis)* and *Saccharomyces cerevisiae*, respectively. The scientific literature increasingly refers to them as *Saccharomyces cerevisiae* (ale type) and *Saccharomyces cerevisiae* (lager type).

Traditionally, lager is produced by 'bottom-fermenting yeasts' at 7–15 °C, which, at the end of primary fermentation, flocculate and collect on the bottom of the fermenter. 'Top-fermenting yeasts,' used for the production of ale, ferment at temperatures between 18 and 22 °C. At the end of fermentation, the culture forms into loose clumps of cells that are adsorbed on to CO_2 bubbles and are carried to the surface of the wort. Consequently, top yeasts are

collected (skimmed) for reuse from the surface of the fermenting wort, whereas bottom yeasts are collected (cropped) from the bottom of the fermenter. The difference between lager and ales on the basis of bottom and top cropping has become less distinct with the advent of cylindroconical fermenters, where the yeast sediments to the base of the vessel, and centrifuges, where the yeast remains in suspension throughout the fermentation.

There is a plethora of literature describing the genetics and biochemistry of *Saccharomyces cerevisiae* laboratory strains, but there is a lack of knowledge regarding the genetics and biochemistry of industrial *Saccharomyces* strains. The haploid strain that the molecular biologist employs in the university laboratory as the organism of choice is usually totally unsuitable for use in breweries. Brewing yeasts and many other industrial yeasts have been selected over time for those characteristics that render them unamenable to easy genetic manipulation in the laboratory. They are usually polyploid or aneuploid, lack a mating-type characteristic, and sporulate poorly, if at all, and the spores that do form are usually not in fours, exhibiting a poor spore viability and rendering tetrad analysis difficult.

The objectives of wort fermentation are to consistently metabolise wort constituents into ethanol and other fermentation products in order to produce beer with a satisfactory quality and stability. Another objective is to produce yeast crops that can be confidently repitched into subsequent brews. During the brewing process, overall yeast performance is controlled by a plethora of factors. These factors include:

- the yeast strains employed and their condition at pitching and throughout fermentation;
- the concentration and category of assimilable nitrogen;
- the concentration of ions;
- the fermentation temperature;
- the pitching (inoculation) rate;
- the tolerance of yeast cells to stress factors such as osmotic pressure and ethanol;
- the wort gravity;
- the oxygen level at pitching;
- the wort sugar spectrum; and
- yeast flocculation characteristics.

These factors influence yeast performance either individually or in combination with others and also together permit the definition of the requirements of an acceptable brewer's yeast strain.

> In order to achieve a beer of high quality, it is axiomatic that not only must the yeast be effective in removing the required nutrients from the growth/fermentation medium (wort), able to tolerate the prevailing environmental conditions (for example, ethanol tolerance) and impart the desired flavour to the beer, but the microorganisms themselves must be effectively removed from the wort by flocculation, centrifugation and/or filtration after they have fulfilled their metabolic role.

It is worth noting that brewing is the only major alcoholic beverage process that recycles its yeast. It is therefore important to jealously protect the quality of the cropped yeast because it will be used to pitch a later fermentation and therefore will have a profound effect on the quality of the beer resulting from it.

Over the years, considerable effort has been devoted in many research laboratories to the study of the biochemistry and genetics of brewer's yeast (and industrial yeast strains in general). The objectives of these studies have been twofold:

- to learn more about the biochemical and genetic makeup of brewing yeast strains; and
- to improve the overall performance of such strains, with particular emphasis being placed on broader substrate utilization capabilities, increased ethanol production, and improved tolerance to environmental conditions such as temperature, high osmotic pressure and ethanol, and finally, to understand the mechanism(s) of flocculation.

When yeast is pitched into wort, it is introduced into an extremely complex environment due to the fact that wort is a medium consisting of simple sugars, dextrins, amino acids, peptides, proteins, vitamins, ions, nucleic acids, and other constituents too numerous to mention. One of the major advances in brewing science during the past 30 years or so has been the elucidation of the mechanisms by which the yeast cell, under normal circumstances, utilizes in a very orderly manner the plethora of wort nutrients.

Pathway and Regulation of Fermentation

Wort contains the sugars sucrose, fructose, glucose, maltose, and maltotriose, together with dextrin material. In the normal situation, brewing yeast strains (ale and lager strains) are capable of utilizing sucrose, glucose, fructose, maltose, and maltotriose in this approximate sequence (or priority), although some degree of overlap does occur. The majority of brewing strains leave the maltotetraose and other dextrins unfermented, but *Saccharomyces diastaticus* is able to utilize dextrin material as a result of the secretion of the extracellular enzyme glucoamylase. The initial step in the utilization of any sugar by yeast is usually either its passage intact across the cell membrane or its hydrolysis outside the cell membrane, followed by

entry into the cell by some or all of the hydrolysis products. Maltose and maltotriose are examples of sugars that pass intact across the cell membrane, whereas sucrose (and dextrin with *Saccharomyces diastaticus*) is hydrolyzed by an extracellular enzyme, and the hydrolysis products are taken up into the cell. Maltose and maltotriose are the major sugars in brewer's wort, and as a consequence, a brewer's yeast's ability to use these two sugars is vital and depends upon the correct genetic complement. Brewers' yeast may possess independent uptake mechanisms (maltose and maltotriose permease) to transport the two sugars across the cell membrane into the cell. Once inside the cell, both sugars are hydrolyzed to glucose units by the α-glucosidase system. It is important to reemphasize that the transport, hydrolysis, and fermentation of maltose are particularly important in brewing, since maltose usually accounts for 50–60% of the fermentable sugar in wort. Maltose fermentation in *Saccharomyces* yeasts requires at least one of five unlinked (each independent) MAL (maltose) loci each consisting of three genes encoding the structural gene for α-glucosidase (maltase) (MAL S), maltose permease (MAL T) and an activator (MAL R) whose product coordinately regulates the expression of the α-glucosidase and permease genes. The expression of MAL S and MAL T is regulated by maltose induction and glucose repression. When glucose concentrations are high (greater than 1% (w/v)), the MAL genes are repressed, and only when 40–50% of the glucose has been taken up by yeast from the wort will the uptake of maltose and maltotriose commence. Thus, the presence of glucose in the fermenting wort exerts a major repressing influence on wort fermentation rate. Using the glucose analog 2-deoxy-glucose (2-DOG), which is not metabolized by *Saccharomyces* strains, spontaneous variants of brewing strains have been selected in which the maltose uptake is not repressed by glucose, and as a consequence, these variants (called derepressed) have increased wort fermentation rates. Once the sugars are inside the cell, they are converted via the glycolytic pathway into pyruvate. To date, only derepressed ale strains have been isolated. Repressed lager strains have not been found.

Active yeast growth involves the uptake of nitrogen, mainly in the form of amino acids, for the synthesis of proteins and other nitrogenous compounds of the cell. Later in the fermentation, as yeast multiplication stops, nitrogen uptake slows down or ceases. In wort, the main nitrogen source for synthesis of proteins, nucleic acids and other nitrogenous cell components is the variety of amino acids formed from the proteolysis of barley proteins. Brewer's wort contains 19 amino acids, and, as with wort sugars, the assimilation of amino acids is ordered. Four groups of amino acids have been identified on the basis of assimilation patterns (Table 1). Those in group A are utilized immediately following yeast pitching, whereas those in group B are assimilated more slowly. Utilization of group C amino acids commences when group A types are fully assimilated. Proline, the most plentiful amino acid in wort and the sole group D amino acid, is utilized poorly or not at all. Proline is usually still present in beer at 200–300 $mg\,l^{-1}$. However, under aerobic conditions, proline is assimilated after exhaustion of the other amino acids, since its uptake requires the presence of mitrochondrial oxidase.

The regulation of amino acid uptake by brewers' and related yeast strains is complex, involving carriers specific to certain amino acids and a general amino acid permease of broad substrate specificity. The utilization pattern of wort nitrogen is due to a combination of the range of permeases present, their specificity, and feedback inhibition effects resulting from the composition of the yeast intracellular amino acids.

The metabolism of assimilated amino nitrogen is dependent on the phase of the fermentation and on the total quantity provided in the wort. The majority of amino nitrogen is ultimately utilized in protein synthesis and, as such, is vital for yeast growth. It would appear that amino acids are not usually incorporated directly into proteins but are involved in transamination reactions, a significant proportion of the amino acid skeletons of yeast protein being derived via the catabolism of wort sugars. This explains why the total amino content of wort is important in determining the extent of yeast growth, the amino acid spectrum being somewhat secondary. However, the amino acid spectrum of wort does influence beer flavor.

The yeast assimilates the wort amino acids, a transaminase system removes the amino group, and the

Table 1 Classification of amino acids according to their spread of absorption from wort by a brewing yeast strain

(A) Fast absorption	*(B) Intermediate absorption*	*(C) Slow absorption*	*(D) Little or no absorption*

Arginine			

carbon skeleton is anabolized, creating an intracellular oxo-acid pool. The oxo-acid pool generated by the transaminases and anabolic reactions is a precursor of aldehydes and higher alcohols that contribute to beer flavor. Thus, the formation of higher alcohols (i.e., higher in number of carbon atoms than ethanol) is tied in with nitrogen metabolism.

The main nitrogen composition of wort has far-reaching effects on fermentation performance and on beer flavor. Where malt is used as the principal source of extract, the quantity and composition of amino acids are such that these problems are not encountered. However, care must be exercised when using adjuncts, many of which are relatively deficient in amino nitrogen.

Wort fermentation in beer production is largely anaerobic, but when the yeast is first pitched into wort, some oxygen must be made available to the yeast. Indeed, it is now evident that this is the only point in the brewing process where oxygen is beneficial. Oxygen must be excluded as far as possible from all other parts of the process, because it will have a negative effect on beer quality. Specifically, it will promote beer flavor instability. The widespread adoption of high-gravity brewing procedures has increased our awareness of the importance of oxygen during wort fermentation and has stimulated basic and applied research on the mechanisms of oxygen interactions during cell growth and the application of this knowledge in the process.

Oxygen has a profound influence on the activity of yeasts and particularly on yeast growth. Certain yeast enzymes only react with oxygen, and this cannot be replaced by other hydrogen acceptors. This applies to the oxygenases involved in the synthesis of unsaturated fatty acids and sterols, which are vital components of cell membranes. Quantitative studies on the effect of aeration on yeast growth and fermentation have been given little serious consideration until the last 25 years. The traditional concept of beer fermentation was that growth occurred prior to the fermentation of most wort sugars and that fermentation was carried out by nongrowing, stationary phase cells. It is now known that yeast growth, sugar utilization, and ethanol production are coupled phenomena. For example, the rate of fermentation by growing, exponential phase cells of an ale yeast strain is 33-fold higher than that of nongrowing cells.

For a brewery fermentation to proceed rapidly, there must be sufficient amounts of yeast synthesized. Inadequate growth of a brewer's yeast culture will result in poor attenuation, altered beer flavor, inconsistent fermentation times, and recovered pitching yeasts, which are undesirable for subsequent fermentations. Trace amounts of oxygen have profound stimulatory effects on yeast fermentation and particularly on yeast growth. Pasteur demonstrated that oxygen was necessary for normal yeast reproduction, although excessive wort aeration caused undesirable flavor effects on the finished beer. Oxygen requirements were confirmed by such early notable brewing researchers as Adrian Brown, Horace Brown, and Frans Windisch. Windisch concluded that overvigorous aeration of fermenting worts led to yeast 'weakness,' illustrated by increasingly sluggish fermentations characterized by longer lag phases, a slower specific rate of fermentation, and/or residual sugar remaining in the final beer. The critical importance of oxygen was confirmed when, in 1954, it was shown that, under anaerobic conditions, *Saccharomyces* yeast strains require both preformed sterols and unsaturated fatty acids as growth factors. These two lipids are both found in membranes and are critical for membrane function and integrity. Both of these lipid classes require molecular oxygen for their biosynthesis.

Lipids in beer quantitatively form an almost negligible component, but can influence a beer's organoleptic and physiochemical properties. Malt is the main source of unsaturated fatty acids in wort. Wort concentrations of these acids are suboptimal and can be growth-limiting. During fermentation, yeast can take up free fatty acids from wort, most of which are incorporated as structural lipids.

Yeast cultures synthesize fatty acids throughout fermentation, but the ratio of the acids varies with time. Unsaturated fatty acid (for example, palmitoleic (C16:1) and oleic (C18:1) acids) synthesis only occurs in the presence of dissolved oxygen. Oxygen is present in aerated/oxygenated pitched wort for a relatively short period (3–9 h), and during this period, there is a large increase in the percentage of unsaturated fatty acids. When oxygen is depleted, there is an increase in the production of short-chain fatty acids (C6–C12).

The sterol component of brewing yeast ranges from 0.05 to 0.45% of the cellular dry weight (depending on the prevailing environmental conditions) and accounts for less than 10% of the total cell lipid. Ergosterol is the major sterol in brewing-yeast strains and can account for over 90% of the total sterol. The biosynthetic pathway for sterol formation is complex. The important fact for this chapter is that the precursor sequences can be synthesized anaerobically, but the final reaction that produces ergosterol requires molecular oxygen. The major function of sterols in yeast is to contribute to the structure and dynamic state of the membranes. The primary role is to modulate membrane fluidity under fluctuating environmental conditions. For example, ergosterol confers

increased resistance to ethanol and multiple freeze–thaw effects. A decrease in the ergosterol level of membranes has been directly related to a reduction in cell viability in the presence of ethanol.

Pitching yeasts are propagated under weakly aerated conditions or recovered from previous fermentations. In both cases, the cells are lipid-depleted, and to promote normal growth and attenuation, either preformed lipids must be added to the wort or oxygen must be made available for their synthesis. In commercial brewing, only the second alternative is feasible. Wort is cooled and aerated/oxygenated to 8–16 $mg\,l^{-1}$ dissolved oxygen. Within a few hours of pitching, most of this oxygen is removed from the wort. During this time, there is intensive synthesis of lipid (sterol and fatty acid) and a decrease in cellular glycogen. In practice, sterol synthesis by brewing yeasts in the presence of oxygen appears to be of greater significance than unsaturated fatty acid synthesis. This may be due to the contribution of wort to the fatty acid pool. Wort does not contribute exogenous sterol to the fermentation.

Although ethanol is the major excretion product synthesized by yeast during wort fermentation, this primary alcohol has little impact on the flavor of the final beer. It is the type and concentration of the many other yeast excretion products formed during wort fermentation that primarily determine the flavor of the beer. The formation of these excretion products depends on the overall metabolic balance of the yeast culture, and there are many factors that can alter this balance and, consequently, beer flavor. Yeast strain, fermentation temperature, adjunct type and level, fermenter design, wort pH, buffering capacity, wort gravity, etc., are all influencing factors.

Flavor Formation

Some volatiles are of great importance and contribute significantly to beer flavor, whereas others are important in building background flavor. The following groups of substances are found in beer: organic and fatty acids, alcohols, esters, carbonyls, sulfur compounds, amines, phenols, and a number of miscellaneous compounds. In flavor terms, the higher alcohols (also called fusel oils) that occur in beer and many spirits are: *n*-propanol, isobutanol, 2-methyl-1-butanol, and 3-methyl-1-butanol. However, more than 40 other alcohols have been identified. Regulation of the biosynthesis of higher alcohols is complex, since they may be produced as byproducts of amino acid catabolism or via pyruvate derived from carbohydrate metabolism.

Esters are important flavor components that impart flowery and fruit-like flavors and aromas to beers, wines, and spirits. Their presence is desirable at appropriate organoleptic concentrations, but failure to properly control fermentation can result in unacceptable beer ester levels. Organolepiticaly important esters include ethyl acetate, isoamyl acetate, isobutyl acetate, ethyl caproate, and 2-phenylethyl acetate. In total, over 90 distinct esters have been detected in beer.

Some 200 carbonyl compounds are reported to contribute to the flavor of beer and other alcoholic beverages. Those influencing beer flavor, produced as a result of yeast metabolism during fermentation, are various aldehydes and vicinal diketones, notably diacetyl. Also, carbonyl compounds exert a significant influence on the flavor stability of beer. Excessive concentrations of carbonyl compounds are known to cause stale flavor in beer. The effects of aldehydes on flavor stability are reported as grassy notes (propanol, 2-methyl butanol pentanol) and a papery taste (*trans*-2-nonenal, furfural).

Quantitatively, acetaldehyde is the most important aldehyde. This is produced via the decarboxylation of pyruvate and is an intermediate in the formation of ethanol. It may be present in beer at concentrations above its flavor threshold (approx. 10 $mg\,l^{-1}$), at which it imparts an undesirable 'grassy' or 'green apple' character. Acetaldehyde accumulates during the period of active growth. Levels usually decline in the stationary phases of growth late in fermentation. As with higher alcohols and esters, the extent of acetaldehyde accumulation is determined by the yeast strain and the fermentation conditions. Although the yeast strain is of primary importance, elevated wort oxygen concentration, pitching rate, and temperature all favor acetaldehyde accumulation. In addition, the premature separation of yeast from fermented wort does not allow the reutilization of excreted acetaldehyde associated with the later stages of fermentation.

Other important flavor-active carbonyls, whose presence in beer is determined in the fermentation stage, are the vicinal diketones, diacetyl (2,3-butanedione) and 2,3-pentanedione. Both compounds impart a 'butterscotch' flavor and aroma to beer. Quantitatively, diacetyl is the most important, since its flavor threshold is approx. 0.1 $mg\,l^{-1}$ and is 10-fold lower than that of 2,3-pentanedione. The organoleptic properties of vicinal diketones contribute to the overall palate and aroma of some ales, but in most lagers, they impart an undesirable character. A critical aspect of the management of larger fermentations and subsequent maturation is to ensure that the mature beer contains concentrations of vicinal diketones lower than their flavor threshold.

Diacetyl and 2,3-pentanediones arise in beer as byproducts of the pathways leading to the formation of valine and isoleucine. The α-acetohydroxy acids, which are intermediates in these biosyntheses, are in part excreted into the fermenting wort. Here, they undergo spontaneous oxidative decarboxylation, giving rise to vicinal diketones. Further metabolism is dependent on yeast dehydrogenases. Diacetyl is reduced to acetoin and, ultimately, 2,3-butanediol, and 2,3-pentanedione to its corresponding diol. The flavor threshold concentrations of these diols are relatively high, and therefore the final reductive stages of vicinal diketone metabolism are critical in order to obtain a beer with acceptable organoleptic properties.

The diacetyl concentration peak occurs towards the end of the period of active growth. The reduction of diacetyl takes place in the later stages of fermentation when active growth has ceased. In terms of practical fermentation management, the need to achieve a desired diacetyl specification may be the factor that determines when the beer may be moved to the conditioning phase, filtered or centrifuged (depending on the processing procedures). Thus, diacetyl metabolism is an important determinant of overall vessel residence time, which clearly affects the efficiency of plant utilization.

Sulfur compounds make a significant contribution to the flavor of beer. Although small amounts of sulfur compounds can be acceptable or even desirable in beer, in excess, they give rise to unpleasant off-flavors, and special measures such as purging with CO_2 or prolonged maturation times are necessary to remove them. Many of the sulfur compounds present in beer are not directly associated with fermentation but are derived from the raw materials employed. However, the concentrations of hydrogen sulfide (rotten egg aroma) and sulfur dioxide (burnt match aroma) are dependent on yeast activity. Failure to manage fermentation properly can result in unacceptably high levels of these compounds occurring in the finished beer.

The concentration of hydrogen sulfide and sulfur dioxide formed during fermentation are primarily determined by the yeast strain used, although the wort composition and the fermentation conditions are major factors, particularly where levels are abnormally high. Both compounds arise as byproducts of the synthesis of the sulfur-containing amino acids cysteine and methionine from sulfate. Their synthesis is influenced by wort composition in that the yeast will preferentially assimilate sulfur-containing amino acids. It is only when wort is depleted in such amino acids that the biosynthetic route comes into operation.

Flocculation

The flocculation property or, conversely, lack of flocculation of a particular yeast culture is one of the major factors when considering important characteristics during brewing and other ethanol fermentations. Unfortunately, some degree of confusion has arisen by the use of the term flocculation in the scientific literature to describe different phenomena in yeast cell behavior. Specifically, flocculation, as it applies to brewer's yeast is ' the phenomenon wherein yeast cells adhere in clumps and either sediment from the medium in which they are suspended or rise to the medium's surface.' This definition excludes other forms of aggregation, particularly that of 'clumpy-growth' and 'chain formation.' This nonsegregation of daughter and mother cells during growth has sometimes erroneously been referred to as flocculation. The term 'nonflocculation' therefore applies to the lack of cell aggregation and, consequently, a much slower separation of (dispersed) yeast cells from the liquid medium. Flocculation usually occurs in the absence of cell division, but not always, during late logarithmic and stationery growth phase and only under rather circumscribed environmental conditions involving specific yeast cell surface components (proteins and carbohydrate components) and an interaction of calcium ions. Although yeast separation often occurs by sedimentation, it may also be by flotation because of cell aggregates entrapping bubbles of CO_2 as in the case of 'top-cropping' ale brewing yeast strains.

Individual strains of brewer's yeast differ considerably in flocculating power. At one extreme, there are highly nonflocculent, often referred to as powdery, strains. At the other extreme, there are flocculent strains. The latter tend to separate early from suspension in fermenting wort, giving an underattenuated, sweeter, and less fully fermented beer. Beers of this nature, because of the presence of fermentable sugars, are liable to biological instability. By contrast, poorly flocculent (nonflocculent or powdery) yeasts produce a dry, fully fermented, more biologically stable beer in which clarification is slow, leading to filtration difficulties and the possible acquisition of yeasty off-flavors. The disadvantages presented by the two types of yeast strain are especially relevant to more traditional fermentation systems where the fermentation process is dependent upon the sedimentation characteristics of the yeast.

Contemporary brewing technology has largely reversed this situation where yeast sedimentation characteristics are now fitted into the fermenter design. The efficiency, economy, and speed of batch fermentations have been improved by the use of

cylindroconical fermentation vessels and centrifuges (which are often, but not always, employed in tandem). There is no doubt that differences in the flocculation characteristics of various yeast cultures are primarily a manifestation of the culture's cell wall structure. Several mechanisms for flocculation have been proposed. One hypothesis is that anionic groups of cell wall components are linked by Ca^{2+} ions. In all likelihood, these anionic groups are proteins. Another hypothesis implicates mannoproteins specific to flocculent cultures acting in a lectin-like manner to cross-link cells; here, Ca^{2+} ions act as ligands to promote flocculence by conformational changes. Most people working in the field agree that the latter hypothesis is the most credible. In addition to flocculation, there is the phenomenon of coflocculation. Coflocculation is defined as the phenomenon where two strains are nonflocculent alone, but flocculent when mixed together. To date, coflocculation has only been observed with ale strains, and there are no reports of coflocculation between two lager strains of yeast. There is a third flocculation reaction that has been described where the yeast strain has the ability to aggregate and cosediment with contaminating bacteria in the culture. Again, this phenomenon appears to be confined to ale yeast strains, and cosedimentation of lager yeast with bacteria has not been observed.

As described above, flocculation requires the presence of surface protein and mannan receptors. If these are not available or are masked, blocked, inhibited, or denatured, flocculation cannot occur. The onset of flocculation is an aspect of the subject where there is great commercial interest but about which relatively little is known. As previously discussed, the ideal brewing strain remains in suspension as fermenting single cells until the end of fermentation when the sugars in the wort are depleted, and only then does it rapidly flocculate out of suspension. What signals the onset of activation or relief from inhibition? This is still an unanswered question that is currently being studied by a number of research laboratories.

Yeast flocculation is genetically controlled, and research on this aspect of the phenomenon dates from the early 1950s. However, because of the polyploid/aneuploid nature of brewing yeast strains, most, but not all, of the research on flocculation genetics has been conducted on haploid/diploid genetically defined laboratory strains. Numerous genes have been reported to directly influence the flocculent phenotype in *Saccharomyces* spp. Four dominant flocculation genes have been identified: *FLO1* (whose alleles are *FLO2*, *FLO4*, *FLO8*), *FLO5*, *FLO9*, and *FLO10*, as well as semidominant gene, *flo3*, and two recessive genes, *flo6* and *flo7*. In addition, mutations in several genes, including the regulatory genes, *TUP1* and *SSN6*, have been found to cause flocculation or 'flaky' growth in nonflocculent strains. In total, at least 33 genes have been reported to be involved in flocculation or cell aggregation. Although the role of many of these genes is far from understood, *FLO1* and other FLO genes have been successfully cloned into brewing strains and the flocculation phenotype expressed.

Chemistry of Brewing

C W Bamforth, University of California, Davis, CA, USA

Introduction

The word 'brewing' is used in at least two contexts in beer making. Strictly speaking, the most accurate usage of the term is to describe the process by which is produced the feedstock, wort, that will be fed to the yeast. Thus it is customary for those within the industry to talk of 'brewing and fermentation.' Frequently, however, the word brewing is used to describe the entirety of the operation by which malted barley (and other sources of sugar) and hops are converted to beer. For the purposes of a description of the chemistry of brewing I am taking the latter definition, but we must not ignore the prior process of malting (the controlled germination of barley) because the conversion of barley into wort involves this stage also. It is very difficult to divorce a discussion of the mashing stage of brewing from malting, for in reality they are but successive stages in the enzymic conversion of barley into wort. **Figure 1** summarizes the structure of barley and the distribution of the key polymers within the starchy endosperm, whilst **Table 1** summarizes the key process stages of malting and brewing. I will approach this somewhat complex

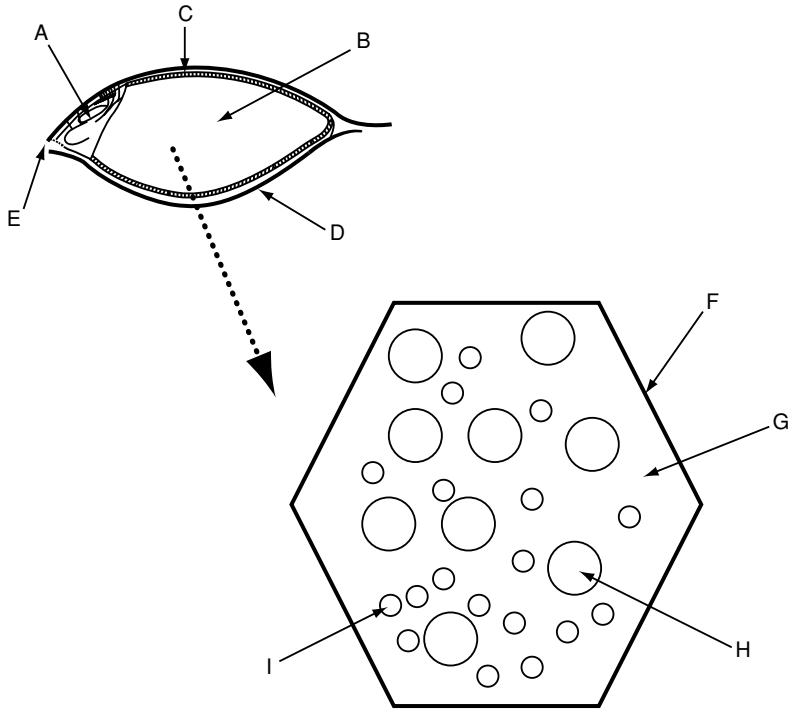

Figure 1 The structure of barley and of one of the cells of the starchy endosperm. A, embryo; B, starchy endosperm; C, aleurone; D, hull; E, micropyle; F, cell wall (75% β-glucan; 20% arabinoxylan; 5% protein; traces ferulic and acetic acids); G, protein; H, large starch granule; I, small starch granule.

issue by focusing on the chemistry of the finished product and highlighting how the balance of components in beer is determined by the various stages occurring in the maltings and brewery.

The Chemistry of Beer

The properties of beer result from the presence of a diversity of chemical compounds, some large (macromolecules) and some small. For the majority of beers these materials are derived in their entirety from the raw materials or are generated through the metabolism of brewing yeast, *Saccharomyces cerevisiae*. Most brewers are reluctant to introduce additives at any stage of the process and will also place stringent specifications on the water, grist, and hop materials in respect of what may or may not be used in the processes of their suppliers. Some brewers will use propylene glycol alginate to protect foam on the product from the deleterious impact of lipophilic materials entering the beer at point of sale, for example, fats from food or detergent in inadequately rinsed glasses. Sulfur dioxide or ascorbic acid is sometimes (but increasingly sparingly) employed to protect beer from staling. (*See* **Yeasts**.)

Ethanol

The equation at the heart of the production of all alcoholic beverages is:

$$C_6H_{12}O_6 \xrightarrow{\text{Yeast}} 2C_2H_5OH + 2CO_2$$

In the case of the majority of beers the sugar is derived during mashing of malted barley. In fact, most of the sugar derived in conventional mashing operations is maltose, with lesser quantities of glucose, maltotriose, sucrose, fructose, and dextrins.

The majority of beers worldwide contain between 3.5 and 5.5% alcohol by volume (ABV).

Ethanol impacts on the quality of beer in several ways. It contributes directly to flavor, with a recognizable warming characteristic absent from nonalcoholic or low-alcohol products. It also affects the contribution to aroma of other volatiles by influencing their partitioning between the beer and its head space.

Ethanol lowers surface tension, thereby promoting bubble formation. Conversely, it competes with other surface-active molecules for sites in the bubble wall, leading to a lessening of foam stability. (*See* **Alcohol**: Properties and Determination.)

Table 1 The key events in malting and brewing

Process stage	*Treatments*	*Events*
Steeping of barley	Water added, separated by air rests, to raise water content of embryo and endosperm (target in whole grain is usually 44–46%); takes up to 48 h at 14–18 °C	Water enters through micropyle. Distribution through embryo, aleurone, and starchy endosperm critical to enable modification. Synthesis of hormones (including gibberellins) by embryo, hydration of substrate (starchy endosperm)
Germination of barley	Controlled sprouting (modification) of grain – typically 4–5 days at 16–20 °C	Synthesis of enzymes by aleurone (triggered by hormones) and migration into starchy endosperm; sequential degradation of cell walls, some protein, small starch granules, and pitting of large granules
Kilning	Heating of grain via increasing temperature regime (50–220 °C) for desired properties: enzyme survival, removal of moisture for stabilization, removal of raw flavors, development of malty flavors and color	Enzyme survival greater with low-temperature start to kilning and lower final curing temperature. Increased heating of malts of increased modification (i.e., higher sugar and amino acid levels) gives increasingly complex flavors and colors via Maillard reactions
Malt storage	3–4 weeks' ambient storage, otherwise wort separation problems occur later	Unknown
Mashing	Extraction of milled malt at temperatures between 40 and 75 °C; typically < 1–2 h. Separation of wort from spent grains by lautering or mash filtration with sparging to recover extract fully. Spent grains go to cattle feed	Enzymolysis continued, especially of starch after gelatinization at > 62 °C
Use of adjuncts	Solid adjuncts used in brewhouse, taking advantage of malt enzymes; rice and corn need 'cooking' at up to 100 °C, < 1 h (liquid sugars are products of acid and enzyme action in sugar factory and added at boiling stage)	Cereals with higher starch gelatinization temperatures than for barley need precooking before combining with main mash
Boiling	1–2 h at 100 °C, before clarification (< 1 h) and cooling	To sterilize, extract hops, concentrate, and kill all residual enzymes. Precipitation of insoluble materials as trub, enhancing final product stability
Fermentation	Wort pitched with yeast and fermented for 3–14 days at 6–25 °C	Fermentation of glucose, maltose, sucrose, maltotriose to alcohol; enzymic production of various flavorsome compounds (alcohols, esters, fatty acids, sulfur-containing compounds, etc.) Synthesis and removal of diacetyl as an offshoot of amino acid production
Cold conditioning and filtration	− 1 °C for ≥ 3 days; possibly stabilization (silica hydrogels, tannic acid or papain to remove protein; PVPP to bind polyphenol); then filtration	Precipitation, sedimentation, and removal of solids

PVPP, polyvinylpolypyrrolidone.

Carbon Dioxide

A typical brewery fermentation will produce some 150 g CO_2 per hectoliter for every degree Plato (1 degree Plato is basically equivalent to a 1% sugar solution). Most of this CO_2 sweeps out and is lost during fermentation. Many packaged beers will contain 500–550 g $CO_2\,hl^{-1}$ and extra gas needs to be introduced to the product prior to packaging. At 1 atm pressure (as CO_2) and 0 °C, a beer will dissolve no more than 200 g hl^{-1} CO_2. Achievement of the very high levels of CO_2 demands the pressurizing of beer. None the less, when a beer container is opened, the gas usually stays in solution: the beer is 'supersaturated' with CO_2. When fobbing occurs spontaneously when a can or bottle is dispensed, it is called 'gushing.' In the absence of agitation as a cause, the most likely reason for the phenomenon is the presence of low-molecular-weight, highly hydrophobic peptides contributed by infection of barley, notably from *Fusarium*.

CO_2 affords the 'sparkle' to beer, through its reaction with the pain receptor mechanism of the trigeminal nerve. Apart from this influence on mouth feel, CO_2 establishes the extent of foam formation during

dispense and of course impacts heavily the delivery of volatiles into the head space of beers and therefore the aroma.

Other Gases in Beer

Oxygen has major negative effects on beer via its oxidation of various components, leading to cardboard and other stale notes and to the formation of haze. Brewers therefore strive to minimize the oxygen level in beer (preferably to $0.1\,mg\,l^{-1}$ or ideally even less) by avoiding ingress into the product downstream of the fermenter (yeast is a powerful oxygen scavenger and many brewers feel that it is only after the removal of yeast that oxygen is a concern).

The stale papery notes are due to a series of unsaturated carbonyl compounds, which are usually held to include *trans*-2-nonenal, though this has been no means fully substantiated. Several components of beer can degrade to such carbonyl substances during oxidation, including the 'higher' alcohols, the iso-α-acids, and the unsaturated fatty acids.

Nitrogen has long been introduced to beer to promote foam stability. The foams produced on beers containing N_2 tend to have populations of much smaller bubbles. These foams are more resistant to collapse and the beer displays a much smoother mouth feel. Typical levels of N_2 are $20–50\,mg\,l^{-1}$ which are three orders of magnitude lower than those of CO_2.

Water

The vast majority of beers contain between 90 and 95% water: apart from ethanol and carbon dioxide, the remaining constituents usually amount to less than 1% of the product. The water used for brewing must have no taints or hazardous components and water is often treated coming into the brewery to adsorb any contaminants by charcoal filtration and ultrafiltration. The ionic composition of water is also significant (although the grist also contributes salts). High levels of calcium, e.g., $200–350\,mg\,l^{-1}$, are claimed to be desirable in the production of ales. Much lower levels of calcium are traditionally associated with the brewing of lagers, for example, the water in pilsen (the home of the classic lager-style) contains less than $10\,mg\,l^{-1}$ calcium. A scientific justification for this is not entirely proven, but may relate to the role of calcium in promoting the surface behavior of the top-fermenting ale yeasts (calcium promotes the flocculation of yeast). Brewers may add salts or remove them (e.g., by reverse osmosis) to adjust the ionic composition of the product.

Two key impacts of calcium are on pH and the levels of oxalic acid surviving into beer. Calcium reacts with phosphate to lower the pH to the appropriate level for mashing:

$$3Ca^{2+} + 2HPO_4^{2-} \rightarrow Ca_3(PO_4)_2 + 2H^+$$

By precipitating out malt-derived oxalic acid in the brewhouse, calcium eliminates a material that, if surviving into beer, causes problems such as haze, gushing, and the blocking of dispense pipes.

Carbohydrates

Although most of the sugars found in wort are converted to ethanol by yeast, those containing four or more glucoses (i.e., maltotetraose and bigger, and known as dextrins) are not fermented. In order to sweeten the finished beer, some brewers may contrive to leave a proportion of fermentable sugar unconverted, or may add 'priming' sugar.

Most of the starch survives malting, because it is relatively resistant to enzymatic hydrolysis when in the form of large granules. When starch is gelatinized by heating, however, its constituents (amylose and amylopectin) become accessible. Mashing, therefore, incorporates a stage, typically at around 65 °C, to allow for the gelatinization of malt starch. The starch in some other cereals has higher gelatinization temperatures, e.g., rice and corn starches gelatinize over the range 70–80 °C and so are cooked separately from the main mash and then mixed with the malt mash to be degraded by the amylases from malt. (*See* **Carbohydrates**: Classification and Properties.)

Starch hydrolysis starts with α-amylase, a highly heat-resistant enzyme abundantly present in malt. It is endo-acting, catalyzing the hydrolysis of α-1→4 bonds within the starch, releasing dextrins. From amylose the enzyme release linear dextrins, and from amylopectin it produces dextrins with side chains. (*See* **Starch**: Structure, Properties, and Determination.)

β-Amylase is an exoenzyme, which removes maltose units from the nonreducing ends of starch and dextrin molecules. This enzyme has sufficient stability at 65 °C to achieve most of the conversion of starch and dextrins of which it is capable but if mashing is carried out at somewhat higher temperatures, e.g., 72 °C, then β-amylase is rapidly inactivated and the ensuing wort contains a high dextrin level and low content of fermentable sugars. Such high-temperature mashing can be used in the production of low-fermentability worts which will give low-alcohol beers.

β-Amylase cannot pass the α1→6 branch points in the dextrins formed from amylopectin. Limit dextrinase carries out this function but is generally present in fairly low concentrations because it is developed

very late during barley germination and because it is inactivated by association with another protein. Furthermore, limit dextrinase is relatively heat-labile. It is because of the limited action of limit dextrinase that 20–25% of the starch remains as dextrins in most conventionally mashed beers.

In so-called 'light' or 'lite' beers all of the starch is converted to ethanol. One way of achieving this is to add heat-stable glucoamylase or pullulanase from microbial sources to the mash or to the fermenter, although those brewers seeking to avoid any additions may modify their brewhouse and fermenter operations so as to take maximum opportunity of endogenous enzymes.

The major component of the barley cell walls is a linear β-glucan comprising approximately 67% β1→4 links with 33% β1→3 bonds that are for the most part every third or fourth linkage. The key enzyme hydrolyzing this molecule is an extremely heat-sensitive endo-β-glucanase, which is destroyed within 5 min of mashing at 65 °C. Accordingly, one of the main purposes of malting is to remove the cell walls, in large part through the action of this enzyme. In practice some cell wall material (at the distal end of the barley) will survive and if it is not properly degraded it can afford increased viscosity to the wort and cause sluggish wort separation in the brewhouse and retarded beer filtration. Some brewers mash-in at low temperatures such as 40–50 °C to allow β-glucanase to act, before raising the temperature to that needed for starch gelatinization. Alternatively, heat-stable β-glucanases from bacteria (e.g., *Bacillus subtilis*) or fungi (e.g., *Trichoderma, Penicillium*) may be used.

Proteins, Polypeptides, and Amino Acids

Amphipathic polypeptides in beer stabilize the bubbles in foam. Their hydrophobic regions 'drive' them into the surfaces produced during foaming and are largely responsible for their interaction with other hydrophobic molecules, notably the iso-α-acids. The matrix formed counters the force of surface tension that seeks to minimize increased surface area generated in foaming. Some of the protein in beer can react with polyphenols to form hazes.

There is no advantage in having significant levels of residual amino acids in beer; rather they are a risk in so far as they represent assimilable nitrogen sources for spoilage microorganisms. However, it is important that wort contains the correct balance of amino acids to support yeast growth and fermentation. Sufficient proteolysis must occur during malting and mashing to yield these amino acids and to remove haze-potentiating proteins, whilst leaving ample foam-positive polypeptide. (*See* **Protein**: Chemistry.)

The native proteins of barley undergo considerable degradation and denaturation in malting and brewing. During germination of barley, endoproteinases develop and attack the heart of substrate proteins to release polypeptides and peptides. An exoacting enzyme, carboxypeptidase, acts during malting and mashing by splitting off amino acids successively from the carboxyl-terminus of the peptides produced by the endoproteinases.

Lipids

Barley comprises some 3% by weight lipid, most of it in the embryo and aleurone. Very little survives into beer, because it is removed by adsorption on insoluble matrices (e.g., spent grain, trub) during the process. Lipids are severely detrimental to beer foam, disrupting the network of proteins and iso-α-acids in the bubble wall. As observed earlier, the unsaturated fatty acid component of lipids is suspected to be at least one precursor of the stale flavors (e.g., 'cardboard') that develop in beer. (*See* **Fats**: Classification.)

Flavors from Hops

Hops afford the bitterness (from the hop resins) and aroma (from the essential oils) to beer.

The most important resins are the α-acids (Figure 2), accounting for 2–15% of the dry weight of the hop,

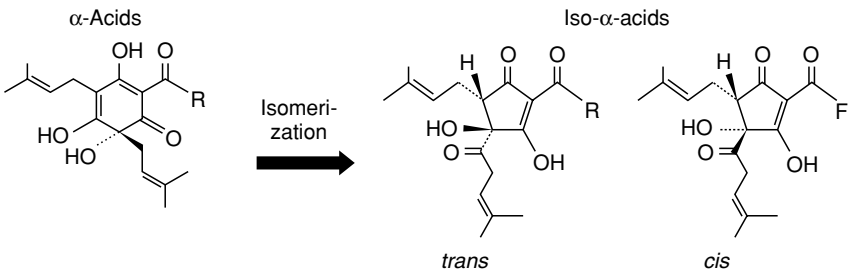

Figure 2 The isomerization of α-acids. R = $-CH_2CH(CH_3)_2$ in humulone and isohumulone. R = $-CH(CH_3)_2$ in cohumulone and isocohumulone. R = $-CH(CH_3)CH_2CH_3$ in adhumulone and isoadhumulone.

depending on variety and environment. The more α-acids, the greater the bitterness potential.

There are three different α-acids in hops, differing in side-chain structure. The α-acids are isomerized to form the more soluble and bitter iso-α-acids during wort boiling (Figure 2). Each iso-α-acid has two isomers, *cis* and *trans*, with differing orientation of the side chains. The six iso-α-acids have a range of bitterness intensities and it is generally held that the hops should have a relatively low level of cohumulone.

Apart from their impact on bitterness and foam, the iso-α-acids have strong antimicrobial properties and inhibit many Gram-positive bacteria.

Hops comprise 0.03–3% w/w essential oil, comprising a complex mixture of more than 300 compounds (Figure 3). The components are very volatile and tend to be lost during wort boiling. To ensure hoppiness in beer it is necessary to add a proportion of the hops late in the boil (late hopping, associated with lager-style products) or to the finished beer (dry hopping, associated with some ales).

Hops are either used in a traditional way as whole cones, though increasingly after hammer milling and extrusion into pellets, in which form they are more stable and more efficiently utilized, or after extraction by liquid carbon dioxide and isomerization by weak alkalis. The latter products can be added to beer downstream, greatly increasing the efficiency of bitterness utilization and flexibility of product formulation. The oils in such extracts may be separated from the resins and also added to beer to provide hoppy aroma.

In some preparations the iso-α-acids are reduced, using hydrogen gas in the presence of a palladium catalyst. Such reduction prevents the formation of the skunk-flavored 3-methyl-2-butene-1-thiol from the side chains when the bitter compounds are exposed to light. The reduced preparations can be used in the production of beers for packaging into green and clear glass bottles, which are particularly prone to light damage.

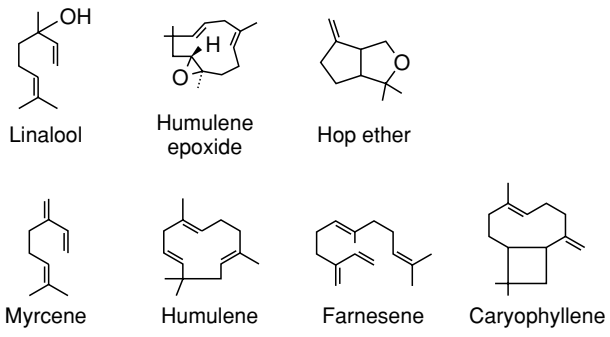

Figure 3 Some components of the essential oil fraction in hops.

Phenolic Materials

The simplest phenolic acid in beer is ferulic acid, a molecule found associated with the arabinoxylan component of the starchy endosperm cell walls. It may have antioxidant properties both for the beer and for the drinker's body. When decarboxylated, by an enzyme present in the yeast strains used to make wheat-based beers though not barley-based ones, 4-vinylguaiacol is produced, which has a distinct clove-like character.

Certain flavanoids, including catechin and quercetin, derive from the outer layers of malt and from hops. They, too, may have antioxidant properties, but when oxidized they polymerize, to produce tannoids that cross-link through the proline groups in certain beer polypeptides to form the insoluble complexes responsible for haze. Haze formation is lessened by reducing oxygen ingress and by reducing the levels of haze-forming polypeptides and phenolics. Silica hydrogels, tannic acid, and the proteinase papain have been used to attend to the former, while polyphenols can be removed using polyvinylpolypyrollidone (PVPP). Vigorous wort boiling and chilling of beer to as low a temperature as possible without freezing (−1 °C) are both important stages in the colloidal stabilization of beer.

The level of tannic materials in beer is probably too low to have any significant impact on astringency. (*See* **Tannins and Polyphenols**.)

Other Flavor Components of Beer

The four main flavor features detected by the tongue are bitterness, sweetness, sourness, and saltiness. The nose detects the other characteristic aromas of beer and this is a balance between positive and negative notes, each of which may be due to more than a single compound from different chemical classes. Although some of these substances originate in the malt and hops, many are products of yeast metabolism.

Esters Esters afford a fruity character to beer: two of the most important components are ethyl acetate and iso-amyl acetate. Esters are formed from their equivalent alcohols when the acetate group is available by not being needed for the synthesis of key components (lipids) of the yeast membranes. Therefore, factors that promote cell production lower ester production, and vice versa. Ester levels in beer are impacted, *inter alia*, by the ratio of carbon to nitrogen in the wort and by the amount of oxygen available to the yeast. The yeast strain is very

important; some strains inherently produce much higher ester levels.

Alcohols The alcohols are the immediate precursors of the esters. As the esters are substantially more flavor-active, it is important to regulate the levels of the higher alcohols if ester levels are also to be controlled.

The higher alcohols (i.e., those larger than ethanol) are produced by transformation of amino acids, so the levels of amino acids in wort have a major impact: the more amino acids available to the yeast, the greater the production of higher alcohols. However, *Saccharomyces* will also produce higher alcohols as an offshoot of the metabolic pathways responsible for amino acid elaboration, pathways that are particularly significant when the amount of assailable nitrogen in the wort is low. Hence higher alcohol production is increased when both too much and too little amino nitrogen is available to the yeast. Ale strains produce more higher alcohols than do lager strains. Conditions favoring increased yeast growth (e.g., excessive availability of oxygen) promote higher alcohol formation.

Sourness This is due to the organic acids, such as acetic, lactic, and succinic, produced by yeast during fermentation. It is the H^+ ion produced by their dissociation that causes sourness. Higher levels of the acids are produced in vigorous fermentations.

Vicinal diketones The vicinal diketones (VDKs), diacetyl and pentanedione, afford highly undesirable butterscotch and honey characters respectively to beer. These substances are offshoots of the pathways by which yeast produces certain amino acids. Precursors leak from the yeast and decompose spontaneously to form VDKs. Yeast, however, can reassimilate the VDK, provided the cells are healthy and remain in contact with the beer. Brewers may allow a temperature rise of 2–3 °C at the end of fermentation to speed up the removal of VDK. Additionally, a proportion of freshly fermenting wort is introduced to the beer as an inoculum of healthy yeast (a practice called krausening). Alternatively a bacterial enzyme (acetolactate decarboxylase) can be added to a fermentation; this enzyme converts acetolactate to acetoin, thereby avoiding the much more flavor-active diacetyl.

Persistently high VDK levels may be a symptom of infection by *Pediococcus* or *Lactobacillus* bacteria.

Sulfur compounds In the right levels and proportions, the sulfur compounds play a substantial role in determining the character of diverse beers. Some ales display a distinct hydrogen sulfide character when first dispensed, albeit one which subsides to reveal the dry hop character. Lagers often have a more complex sulfury character, which for many includes dimethyl sulfide (DMS), with its cooked corn/parsnip note. DMS is the best understood of all the sulfur compounds in terms of its production route.

All of the DMS ultimately originates from a precursor, *S*-methylmethionine (SMM), which develops in the barley embryo during germination. SMM is heatlabile, breaking down rapidly at temperatures above about 80 °C in malting and brewing. Accordingly, SMM is at a lower level in the more highly kilned ale malts and, therefore, there tends to be less DMS in ales. SMM is extracted into wort during mashing and is broken down during boiling and in the whirlpool. In a vigorous boil most of the SMM is converted to DMS and lost by volatilization. In the whirlpool the temperature is still hot enough to degrade SMM, but conditions are nonturbulent and the DMS tends to linger. Brewers aiming for a finite level of DMS in their beer specify a target level of SMM in the malt and will adjust the boil and whirlpool stages so as to deliver a certain level of DMS in the pitching wort. In fermentation a great deal of DMS is swept away with the CO_2, hence the level of DMS targeted in the wort is higher than that specified for the beer. Some of the DMS produced during malt kilning is oxidized to dimethyl sulfoxide (DMSO). This is not volatile but is water-soluble and enters wort, to be reduced by yeast to DMS. Hence the level of DMS in the finished beer is a function of how much DMS is present in pitching wort, how much is volatilized, and how much is replenished via the reduction of DMSO.

There is no simple relationship between the level of DMS in beer and the perception of its flavor. This is because phenylethanol and phenylethylacetate interfere with the perception of DMS. There must be many other antagonisms of this type contributing to the complexity of beer flavor, but they have not been studied.

Hydrogen sulfide (H_2S) is produced by yeast via the breakdown of cysteine or glutathione, or by the reduction of sulfate and sulfite. A vigorous fermentation purges H_2S and factors that hinder fermentation (such as a lack of zinc or vitamins) will increase H_2S levels in beer.

Malty notes As well as being the source of the DMS character in beer, malt contributes in other ways to flavor. Malty character is in part due to isovaleraldehyde, produced by the reaction of leucine with reductones in the malt. The toffee and caramel

Table 2 Order-of-magnitude composition of a typical pilsner beer

Component	*Typical level (mg l^{-1})*

Essential oils from hops	< 1
Dimethyl sulfide	0.06
Total organic sulfur compounds	< 1

character from crystal malts and the roasted, coffee-like notes in darker malts are due to complex components derived from amino acids and sugars when they cross-react during kilning. Of equal importance during kilning is the disappearance of grassy and beany notes, due *inter alia* to *cis*-3-hexen-1-ol, *trans*-2-hexenal, *trans*-2-*cis*-6-nonadienal, and 1-hexanol.

The cross-linking of sugars and amino acids induced by heating in kilning and wort boiling leads to the formation of melanoidins via the Maillard reaction. The melanoidins are responsible for imparting color to beer: darker beers are produced from grists incorporating malts and other adjuncts that have been kilned to more intense regimes. Polyphenol oxidation, occurring during wort production, can make a significant contribution to color in some of the paler beers.

Miscellaneous Acetaldehyde, which is converted to ethanol in actively fermenting yeast, imparts an undesirable 'green apples' character to beer. High levels of acetaldehyde are due to premature separation of yeast before fermentation is complete, poor yeast quality, or infection by the bacterium *Zymomonas*.

The short-chain fatty acids, with their rancid notes, are offshoots in the synthesis of membrane lipids by yeast. When yeast needs fewer lipids (when it needs to grow less), these compounds accumulate.

Table 2 offers a summary of the approximate chemical composition of a pilsner-type beer.

Microbreweries

A Nothaft, BrewTech Serviços Ltd, Jacarepaguá-Rio de Janeiro, Brazil

Background

Although the term 'microbrewery' strongly suggests a small-scale beer production plant, which is usually true, the microbrewery activity is actually what makes the difference in comparison with a large-scale beer factory. A microbrewery is a driving force in different marketplaces to reintroduce or, even more often, to develop many different types of beer with varying flavors. Tradition and diversity are key words when describing specialty beers, which once was defined by Charlie Papazian with the following statement.

> Beer is an expression of the human endeavor of living. We use science as a tool to create it, but its essence is and always will be a form of art expressing the variety of the world's lifestyles. The diversity of the world's food, beverages (other than beer), art, religion, music, clothes offer a great deal of varietal choice and contribute to the quality of life. Beer belongs to this list. The variety of specialty beers currently produced by small breweries and brewpubs create the opportunity for the beer industry to join global trends in offering diversity while also enhancing the image of beer.

History

After World War II, the scenario in the brewing industry world-wide began to change with the formation of large national breweries that, through the acquisition of regional breweries and the consolidation of the production sites as well as the product lines, strongly influenced the marketplace. In England, this consolidation happened during the 1960s and 1970s when six national operating breweries were formed as a result of the concentration of the production that changed the industry and the way in which beer was marketed.

In 1971, four men, Jim Makin, Bill Mellor, Michael Hardmann, and Graham Lees, unhappy with the changes in the beer industry, especially with the fact that they could no longer drink beers with traditional flavor, decided to create a movement aimed at changing this tendency. Initially, an association, named 'The Campaign for the Revitalization of Ale,' shortly after renamed 'Campaign for Real Ale' (CAMRA) set the starting conditions for the microbreweries on the way we know them today.

In the late 1970s, interest in cask ales was regained, and national breweries started to produce different brands, encouraging regional brewers to maintain efforts in producing the traditional beers. These changes and the response from the consumers were the catalyst for a wave of microbreweries in the early 1980s.

The success of CAMRA in England was a starting point for similar international activities. Soon after, CAMRA Canada was created, and the English CAMRA become one of the members of the European Beer Consumer's Union acting in the European Parliament.

In Canada, where beer production was extremely consolidated and the industry had to deal with strong legal restrictions for production and commercialization, the major activity of the organization was to legalize home brewing and the brewpubs.

In the USA, the driving organization was the American Home Brewer's Association, active since the early 1980s, providing information and promoting beer culture. This organization evolved to the Association of Brewers, which is an educational and trade association, still loyal to the initial motivation of promoting beer culture, through their publications, technical discussions on forums, conferences, and expositions, as well as beer festivals such as The Great American Beer Festival and, more recently, the World Beer Cup.

Table 1 Major beer types and styles

Type	*Style*
Ale	Belgian Witbier; German Weissbier; Dunkel-weizen; Weizenbock; Berliner Weisse; lambic; Gueuze; Faro; Kriek; Framboise
	Sweet Stout; Oatmeal Stout; Dry Stout; Imperial Stout Porter
	Pale Mild; Dark Mild; Bitter; Best Bitter; Strong Bitter; Brown Ale; Old Ale; Irish Red Ale; Scotch Ale; Belgian Brown; Pale Ale; India Pale Ale; Belgian Ales; Saisons; Trappisten; Altbier; Kölsch; American Ale; Cream Ale; Barley Wine
Lager	Pilsener; Dortmunder; Export; Strong Lagers; American Malt Liquor
	Vienna; Märzen; Oktoberfest; Amber; Red Lager
	Munich Pale; Munich Dark; Dark Bock; Pale Bock; Double Bock
Special	Fruit Beers
	Chilli Beers
	Honey Beers
	Spiced Ales
	Smoke Beers
	Stone Beers
	California Common

Beer Styles

Diversity is the driving force for microbreweries, and many different types of beer have been offered to the public. Some would certainly have disappeared if microbrewery activity did not exist, being found only in history books. Additionally, the segment is constantly introducing new styles of beers reflecting the evolution of the market and technology.

Usually, beers are divided into ales and lager, distinguished by the fact that ales have a fruity aroma and flavor, and lagers are smoother and crisper. Also, some beers are made using specific techniques and ingredients, rendering their classification as 'specialty' beers, and they can be either ales or lagers.

Table 1 lists the major types of beer; note that they may have additional differentiations depending on local conditions in different marketplaces around the world.

Microbrewery Operation

The size of the microbrewery plant size varies according to the type of beer being produced, as detailed in Table 2. Differences in plant size also entail different methods of processing and quality control. In larger plants, the same standards as those in major breweries apply. Measurements to insure that potential processing deviations can be identified and corrected before they can affect the quality of the final product are mandatory.

In microbreweries, where usually just a small number of tanks are in use at a given time, and the products are in different stages of process, a completely different approach for quality control is necessary. The brewer has to focus on all precautions necessary during the process to guarantee that the product meets the desired standards. This is a relevant difference between microbreweries and large-scale production.

Looking further at the personal skills needed to manage the different types of breweries, people involved with microbreweries are usually individuals

Table 2 Characteristics of microbreweries

Brewpub	Most of the production is dedicated for in-house sales
Microbrewery	Produces for external sales in a reduced geographical area
Regional brewery	Produces for external sales in a larger geographical area
Contract brewing	The company develops the product formula, merchandising and sales, and production is hired from a third party company

Figure 1 (see color plate 8) View of the brewhouse in a microbrewery.

Table 3 Recommended tasks for quality control in a microbrewery

Process step	*Minimal level of control*
Raw materials	
Water	Sensorial evaluation before every use and periodical external evaluation
Malt	Sensorial evaluation, malt analysis from the supplier, and periodical external evaluation
Adjuncts	Sensorial evaluation (hot water extract) and supplier analysis
Wort production	
Raw material addition	Weigh control
Malt grist	Visual evaluation and periodical external evaluation
Water addition	Volume control
Saccharification	Iodine test
Evaporation rate	Calculation
Production yield	Calculation
pH	Determination
Break formation	Visual evaluation
Bitterness	Sensory evaluation and periodical external evaluation
Color	Visual evaluation and periodical external evaluation
Wort clarity	Visual evaluation
Wort cooling/aeration	
Cooling temperature	Temperature control during the whole process
Process time	Record time needed to cool
Oxygen intake	Visual evaluation of the wort after the oxygen intake
Terminal load on wort	Total time the wort was kept over 85 °C, measured from the filling of the kettle to the final of the wort cooling
Yeast dosing	
Yeast control	Check flavor and appearance of the yeast, frequent renewal, and periodical microbiological control
Yeast storage	Control how long yeast was stored between brews
Dosing volume	Weight of yeast added to fermentation
Wort clarity	Visual evaluation
Fermentation/aging	
Extract reduction	Record the extract reduction against the fermentation time
pH	Check the pH on the end of fermentation and aging
Time/temperature/pressure	Record the process parameters
Diacetyl	Sensorial evaluation at the end of fermentation and aging
Cells in suspension	Visual evaluation at the end of fermentation and aging
Oxygen intake	Preventive operational procedures
Filtration/packaging	
Appearance	Visual evaluation of the brightness of the beer
Carbonation	Sensory evaluation and periodical external evaluation
Foaming	Visual evaluation and periodical external evaluation
Alcohol/extract	Control with a saccharometer; although the analysis is not correct, it gives indications about fluctuations. Periodical external evaluation
pH	Control of the final product. Deviations are strong indicators of microbiological contamination
Bitterness	Sensory evaluation and periodical external evaluation
Diacetyl	Sensory evaluation and periodical external evaluation
Oxidation	Sensory evaluation and periodical external evaluation

who constantly like to face new challenges. They are involved in the operation in all different aspects, often being involved at different stages, from providing the resources for brewing to sales or technical support in the marketplace, and are often keen to play an active part in developing a new beer formulation.

This does not mean that they are better brewers than those running large breweries. Large brewery professionals gain their motivation by managing such a complex structure involved in the beer production.

A plant showing the brewing house of a microbrewery is presented in Figure 1.

Quality Control

The construction of a laboratory with sufficient capacity to run all necessary analyses to control all phases of the process can easily double the cost of the investment made in a microbrewery, and, as discussed previously, this will not insure the quality of the final product. This means that strict control of the process, by recording and evaluating processing data and also by sensory evaluation of all process steps, will contribute effectively to a successful quality control.

Table 3 lists the recommended control tasks for the operation of a small-scale microbrewery.

Perspectives

Microbrewing has become a reality in most countries, mainly due to the diversity of products offered to consumers in general and to beer lovers in particular. It has become a well-established segment of the brewing industry in Europe, North America, Asia, and Oceania. However, in South America and Africa, this tendency has not yet achieved the same degree of development. Clearly, there is potential for growth, and it is anticipated that the formation of many new microbreweries around the world will introduce a variety of products and flavors to beer consumers.

BEHAVIORAL (BEHAVIOURAL) EFFECTS OF DIET

D A Booth, University of Birmingham, Edgbaston, Birmingham, UK

Nutritional Effects on Behavior

Behavior other than eating and drinking can be influenced by physiological effects of the constituents of foods and beverages. Indeed, consumers' attributions of effects on their subjective feelings or objective performance appear to be among the major determinants of the acceptance or refusal of certain items of the diet. This aspect of the many relationships among food, nutrition, and behavior is the topic of this article.

Scientific Study of Effects of Diet on Behavior

The possible influences of diet on behavior have attracted a considerable amount of public and professional attention in recent years, and yet reliable scientific information on such effects remains very limited.

This is partly because studies claiming positive findings are often open to serious criticism of their design and also of the theory behind them. Even arguably supportable findings have frequently failed to be substantiated after some years, at least on the scale initially claimed. A field that acquires a dubious reputation, or at best an air of scientific intractability, will naturally have difficulty attracting much good research. Nevertheless, definite scientific progress could be made by close collaboration among social cognitive psychologists, applied nutritionists, and food technologists.

The measurement of behavioral performance or experiences is not the real difficulty in studying dietary effects on behavior, despite a widespread misconception to the contrary. Even the answers to questions about personal viewpoints, which seem such 'soft' data to biologists and chemists, can be shown, by the well-established criteria of multivariate psychometrics, to reflect underlying determinants. Such adequately scaled instruments provide valid and reliable expressions of differences in emotional state and in judgments of one's own ability. Sound measurements of intellectual performance, such as ability to concentrate or remember, or indeed physical performance, such as athletic endurance, can be constructed by cognitive or exercise scientists at least as easily as self-ascription scales such as mood or ability.

The greatest difficulties arise in the design and interpretation of investigations of real-life psychological phenomena and, indeed, in measuring the composition of the everyday diet as well. As in any other area of science, effective research requires a good theoretical grasp of the mechanisms involved and hence of the methods for obtaining evidence of their operation. There are no standardized tests for

effects of diet on behavior and there never will be, any more than there can be standardized tests for dietary effects on children's growth or for consumer perception of food quality.

Hence what follows is an impressionistic sketch of the theoretical issues of how diet might affect behavior, with brief comments on the current state of evidence for the mechanisms involved. Detailed reviews referring to original studies are included in the Further Reading section.

Long-Term Effects of Diet on Behavior

There are broadly speaking two ways in which constituents of the diet could have long-term psychological effects. They may affect the general physical growth or deterioration of the nervous system. Alternatively, diet might permanently affect the functioning of the brain, via short-term effects on changes within specific neural connections that have long-term psychological consequences.

Brain Development

The nerve cells in the human brain have virtually all been formed prior to birth. Considerable elaboration of interneuronal connections occurs postnatally, however. Maternal nutrition might therefore affect the fetus or the breast-fed infant. Nevertheless, the brain is very effective at extracting essential nutrients from the blood supply and is not susceptible to overdevelopment. Hence there is reason to think that only metabolic disorder or extreme deficiency in the diet is liable to prejudice development of the brain.

In the rare inherited metabolic disorders, the accumulation of unusual catabolites damages the brain unless prevented by dietary or genetic engineering. As well as neurological disorders, more or less severe learning difficulties (mental handicaps) can result. (*See* **Inborn Errors of Metabolism**: Overview.)

Possibilities under study include psychological sequelae of neurological defects, prematurity or very low birth weight, to which maternal deficiency (such as in folic acid) might contribute. There is concern that some fatty acids in breast milk may be needed in infant milk formulae, at least in premature babies, in order for the brain to develop to full intellectual potential.

Energy–protein deficiency early in childhood is associated with slow intellectual development. It is difficult to disentangle effects of malnutrition and disease on brain growth from functional handicaps arising from effects of economic and social disadvantage. Nutritional supplementation and psychosocial stimulation exert separate effects. In addition, school failure in low-income areas is associated with missing breakfast. However, regular provision of supplements or breakfasts can be an important environmental change, aside from its physiological effects. (*See* **Breakfast and Performance**; **Protein**: Deficiency.)

Brain Damage

Nutritional factors have repeatedly been proposed for schizophrenic and other psychiatrically diagnosed disorders. None has yet been substantiated, however, when subjected to controlled investigation. Thiamin deficiency produces neurological symptoms, and lack of this and other B vitamins is generally considered to contribute to some encephalopathies that involve several memory defects. Therapeutic effects of supplementation remain to be established. (*See* **Thiamin**: Physiology.)

Toxic contaminants of the diet may damage the brain, with psychological sequelae. Nevertheless, no long-term psychological effect of the present dietary levels of residues, heavy metals, etc., has been established to date. Ingestion of flakes of paint or contaminated dust can contribute to an accumulation of lead in the brain but this generally results from hands or objects being brought to the mouth, not from dietary consumption. (*See* **Heavy Metal Toxicology**.)

Short-Term Mediation of Long-Term Effects

Long-term psychological effects of dietary constituents on children, such as those on intelligence quotient (IQ), personality, or behavior disorders, are likely to be mediated by acute psychological effects of the daily diet. For example, if school performance were permanently improved by regular provision of breakfast, it could be because each meal facilitated learning that morning.

Additives and hyperactivity Feingold's initial hypothesis that intolerances to food additives such as colorings cause widespread behavioral problems in children was narrowed at an early stage to tartrazine and salicylates. Much subsequent investigation has established the very low incidences of food intolerances and the infrequency and transience of proven allergenic reactions to food proteins in young children. Moreover, recent work has shown no systematic behavioral effect when a toxicological sensitivity has been provoked. (*See* **Food Additives**: Safety; **Food Intolerance**: Types; Food Allergies; Lactose Intolerance.)

Vitamins and IQ Several recent reports have provided data interpreted as supporting the hypothesis that supplementation with one or more unspecified vitamins and/or minerals prevents a supposed slowing of the normal rise in nonverbal intelligence test

scores (IQ) in schoolchildren whose diets are alleged to be deficient in those micronutrients.

As yet, however, there is no satisfactory evidence that those whose IQ scores appear to respond to supplements are deficient in micronutrients, because the only relevant dietary data are the children's dietary records and these are likely to be confounded by factors that influence scores in IQ tests. Furthermore, children who are estimated to be consuming less than recommended levels of a micronutrient generally appear also to have inadequate energy intakes. The accuracy of these records is therefore suspect. Alternatively, these children may be chronically hungry or reacting to other sorts of deprivation. This might account at least in part for the fidgetiness and apparent lack of attention that have been reported in children having the poorer dietary records, which in turn could make for poor learning and hence slowed development of performance in some IQ tests. (*See* **Energy**: Measurement of Food Energy.)

Another (not incompatible) hypothesis is that the high sugar intake of some children might have acute sedative effects. This could result in difficulty in thinking clearly, so that the child becomes restless when faced with an intellectual challenge. (*See* **Sucrose**: Dietary Importance.)

No biochemically sound mechanism has yet been proposed by which moderate vitamin or mineral deficiency could affect nonverbal learning. Theory is hardly feasible in any case because, although some speculations have been offered, the neural bases of individual differences in human intelligence are as yet unknown.

Short-Term Effects of Diet on Behavior

The acute effects on behavior of a constituent of a drink or even of the composition of a meal are both theoretically and methodologically much more accessible than chronic dietary effects. Even so, they pose formidable multidisciplinary challenges to investigators, in design and analysis of characteristics of the diets, the consumers and the situations to be observed.

Design of Investigations

The foods When the issue is physiological effects in the brain, the postingestional effects of the diet must be distinguished from its sensory effects. This is crucial in principle because a flavor or texture may suggest effects to the consumer (e.g., filling, nutritious, junk food, luxury) that could confuse the search for physiologically mediated effects. The distinction has become demonstrably necessary in some cases, such as reduction of distress – just the taste of sugar can quieten a baby and raise the pain threshold. Hence differences in dose of the hypothesized active constituent must not be detectable to the subject. If the agent cannot be swallowed in a capsule, demonstration of effective sensory matching or masking is necessary. (*See* **Sensory Evaluation**: Sensory Characteristics of Human Foods.)

For major constituents of the diet, the technological requirements to design unambiguous research protocols may be so unusual and difficult as to be impossible at reasonable expense. Experimental cognitive psychology can provide a way round by measurements that pick out the effects of sensorily triggered expectations, but this demands sophisticated design and analysis (and a modicum of good luck).

The eaters Individuals may vary from one another physiologically in susceptibility to a dietary factor. They will certainly differ in prior experiences with foods and drinks containing the component(s) of interest.

Where the psychological effect being studied is known to the public, and especially if it is commonly sought or avoided, the effectiveness of a study is likely to depend on designing and analyzing it around the participants' uses of items and the occasions when they are consumed. This will not only help to accommodate differences in both physiology and experience; it can also enable differences to be exploited. For example, disguised variations of a constituent, around the level at which an individual normally consumes it with the expectation of a relevant psychological effect, are likely to be a more sensitive design than the same levels imposed on everyone tested, without regard to their normal expectations.

The test tasks and situations A psychological effect may be wanted only in certain situations by a given consumer. Indeed, the effect may only occur in specific circumstances. That can be because the effect is part of conventional behavior and experience in those circumstances or because the user personally discovered something, when the conditions were right, that the item could do for mood or performance. It may well be crucial, therefore, that the setting investigated and the state of mind of the research participant are suited to the mood or performance under study and that the behavioral tests measure those particular benefits that each participant obtains during normal use of the dietary item.

Alcohol

Alcoholic beverages have been an important part of the diet in many cultures from time immemorial. The

alcohol content is widely regarded as a source of good cheer on social occasions and soothing or even emotionally anesthetic at times of distress. However, incapacitating effects of alcohol are also well known, as is the risk of problems from its continuous heavy use. (*See* **Alcohol**: Metabolism, Beneficial Effects, and Toxicology.)

Neurophysiological evidence suggests that ethanol has psychoactive effects by acting on the γ-aminobutyric acid (GABA) receptor system at inhibitory synapses throughout the nervous system. Such neural inhibition is critical to the precision of information processing. Thus the postingestional psychological effects of ethanol are likely to be protean. It may be that all forms of fine control, including precise physical movements (walking down a straight line), vigilance against subtle dangers (crossing in front of approaching traffic), and self-critical social performance (ethical inhibitions and fears for self-esteem), are rendered less competent.

However, ethanol has been regarded in animal pharmacology as specifically anxiety-reducing at subsedative doses. The benzodiazepines (such as Valium), that also act on the GABA system, are used as antianxiety agents, as well as muscle relaxants and sedatives. Thus the neural actions of ethanol may be more effective at reducing tensions than at incapacitating generally.

Many of the effects of common levels of consumption of alcoholic beverages on mood and social behavior appear to have at least as much to do with the drinking situation as with neural actions of ethanol. Merriment and perhaps sexual predation are what is expected at parties; personal aggressiveness and vandalism became a norm for soccer fans, and gloom is natural for the lone(ly) drinker. All these effects have been seen in experimental studies, but there tend to be large 'placebo' or expectancy effects too. It seems that ethanol contributes some disinhibition or incapacitation but a participative spirit achieves the rest.

The behavioral effects of ethanol in the diet are therefore complex to investigate. The sensory qualities of ethanol and the aftereffects of its ingestion on bodily sensations and mental and physical abilities are well known to experienced drinkers. This weakens the interpretations of sophisticated experiments on the behavioral effects of ethanol (as also for other familiar substances).

One example is the so-called 'balanced placebo' design. This has four conditions, two drinks with ethanol and two without, where one of each pair is stated by the investigator to contain alcohol and the other is said not to. The presence and absence of alcohol are supposed to be masked but, when the sensory disguise is checked, it is often found to have been ineffective. Furthermore, characteristic effects of ethanol are liable to be noticed some minutes after ingestion of the ethanol-spiked drink that was alleged to be an alcohol-free drink. This is likely to provoke an emotional reaction and to change the strategy in the task set by the experimenter. An experienced user not feeling the usual effects when the drink was falsely said to contain alcohol is also likely to react to that disparity but in a different way, perhaps more disappointed than angry. Thus the effects on behavior of stated and actual alcohol contents cannot be separated out by analysis of this two-by-two design on an additive model: it is not balanced and placebo control is impracticable (as generally for familiar psychoactive substances). Detailed evidence is needed on the cognitive processes after drinking more or less alcohol with the normal approximate knowledge of amount.

Traditional dose–response studies of behavioral effects of alcohol are subject to similar problems, even when the variations in alcohol content are not detected during consumption and aftereffects are hard to distinguish, e.g., within the lower range of doses. Sensitive tests of psychomotor performance can show deficits at low doses that are proportionate to those at higher doses, thus justifying an argument for a zero blood alcohol limit on drivers. However, the consumer of a known amount of alcohol before driving or working may pay closer attention to the task and put extra effort into control and decision. In some circumstances, such an effort can overcompensate for the detrimental effect of ethanol, associating a low dose with objectively improved performance. Of course, such an effect should not be confused with the personal belief that a little alcohol has improved one's performance, since that is liable to be an illusion fostered by ethanol's disruption of self-critical abilities. Nevertheless, this phenomenon does illustrate how actively people use the effects of food and drink; they are not just affected passively or automatically.

Caffeine

Caffeine is thought to be able to act as a mild alerting agent by blocking synaptic receptors for endogenous adenosine, which is sedative. However, the experimental literature on human behavior has been confused by the use of large doses relative to those obtained through normal coffee, tea, and cola drinking, by differences between people in responsiveness to caffeine, and in the benefits to performance or mood habitually obtained from such drinks, and by unrealistic tests for such benefits. (*See* **Caffeine**.)

In a study using normal doses, quite strong and consistent effects of caffeine (at a dose as low as

32 mg) were shown on tests of mental concentration (attentive and integrative thinking), effects which the participants themselves noticed in ratings of their state. Furthermore, in another study the participants rated themselves also to be more cheerful and less anxious, perhaps because they felt that they were doing better at the cognitive tests. Such conscious benefits may mediate some of the attractions of caffeinated drinks, over and above cultural norms and advertisers' implications.

A remaining weakness in even these studies is a lack of dose–response relationships. As recognized by physiologists, engineers, and others, if an effect does not become stronger with increasing strength of an influence, that is a sign we are not looking at the actual mechanism. Grouped designs may sample a wide range of personal dose optima, depending on the benefits habitually gained from the use of caffeine in particular contexts by different individuals. Hence studies of behavioral effects of caffeine (and of other dietary constituents) should investigate individuals' habitual uses at doses ranging around that which is usual for each person in that situation.

Blood Glucose and Behavior

Hypoglycemia has been blamed for aggressiveness in members of societies subsisting on low energy intakes and for restlessness and poor attention in children consuming large amounts of sucrose. However, such claims are not well supported by measurements of blood glucose levels. Hypoglycemia is in fact quite rare, in contrast to the prevalences claimed for such problematic behavior. (*See* **Hypoglycemia (Hypoglycaemia)**.)
