The determination of PAHs in food is complex, time-consuming, and requires experienced personnel. Nowadays, it is accepted that it has to be performed under a program of quality control/quality assurance, with the aim of providing fully reliable results.

PAH Selection

There is no standard list of PAHs to be determined and the selection performed by each investigator is commonly arbitrary, based on the available instrumentation and reference standards. Almost invariably, BaP has been determined in every investigation, due to its well-known carcinogenicity. Nowadays, special attention is generally given to the determination of other carcinogenic PAHs, especially in health-related studies. Also when other PAH concentrations are available, BaP is usually taken as a reference compound to compare the contamination and the toxicological potency of different food items. This is supported by the fact that BaP is by far the species of higher toxicological concern, due to the combination of its carcinogenic potency – relatively to the other PAHs – with its concentration levels.

Sample Preparation

Most foods are not homogeneous and must be carefully homogenized prior to analysis. Extraction and clean-up are crucial steps in the determination because of the very low amounts of PAHs and the need to separate them from substances which may interfere during analysis, especially the lipids. The general scheme shown in Figure 1 has been widely used, as such or with some modifications which were later introduced in its application to a wide range of foods and to total diet samples. Modifications to the scheme of Figure 1 most commonly involve the extraction and partitioning solvents (e.g., dimethyl sulfoxide replacing *N*,*N*-dimethylformamide), the chromatographic sorbent (e.g., XAD-2 resin combined with other sorbents or florisil or alumina combined with silica gel), and thin-layer chromatography as the clean-up step. The sonication extraction (e.g., of plants and smoked foods) has also been used efficiently; its advantages are the reduced time of extraction and possibly superior recovery efficiencies and reproducibilities, but the results depend on matrix, solvent, and experimental conditions. Conventional chromatographic columns are often substituted by prepacked commercial cartridges (solid-phase extraction), which give advantages in terms of time and solvents consumed, and of reproducibility performance.

Recently, supercritical fluid extraction (SFE: e.g., of smoked and broiled fish, and toast) and accelerated solvent extraction (ASE: e.g., of smoked meat) have gained attention as rapid alternatives to conventional liquid extraction.

Sample Analysis

Identification and quantification are performed by capillary gas chromatography (GC) or by high-performance liquid chromatography (HPLC). In GC analysis, the most widely used stationary phases are the methylpolysiloxanes, especially SE-54 (5% phenyl, 1% vinyl-substituted) and SE-52 (5% phenyl-substituted) or equivalent phases. A flame ionization detector is almost universally employed: it has an excellent response linearity and, coupled with cold on-column injections, gives an accurate and precise quantification; because of its nonselectivity, however, samples need to be highly purified. Mass-spectrometric detectors are powerful tools in identifying and confirming compounds, and have gained wide acceptance. In HPLC analysis, the most used packed material consists of silica particles chemically bonded to

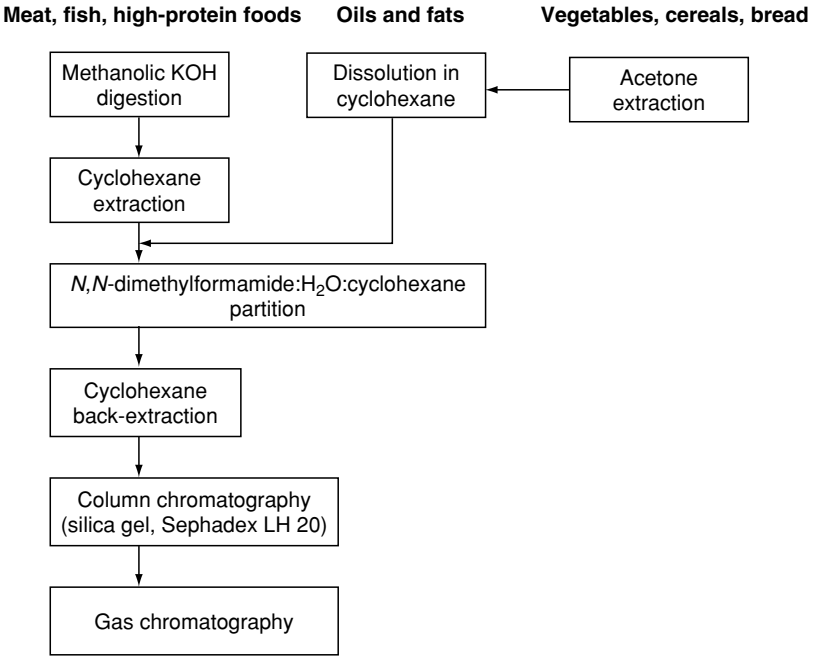

Figure 1 A classical general scheme for the determination of polycyclic aromatic hydrocarbons (PAHs) in food. Adapted from Grimmer G and Böhnke H (1979) Method 4 – Gas chromatographic profile analysis of polycyclic aromatic hydrocarbons in (I) high protein foods; (II) fats and vegetable oils; and (III) plants, soils and sewage sludge. In: Egan H, Castegnaro M, Kunte H, Bogovski P and Walker EA (eds) *Environmental Carcinogens: Selected Methods of Analysis*, vol. 3. *Analysis of Polycyclic Aromatic Hydrocarbons in Environmental Samples*, pp. 163–173. Lyon: International Agency for Research on Cancer.

linear C18 hydrocarbon chains. Ultraviolet (UV) and fluorescence detectors are used, usually arranged in series. The fluorescence detector is more sensitive, and its specificity allows for PAH determination in the presence of nonfluorescing interferences. For confirmation purposes, much information on the isomeric structure may be obtained from UV spectra acquired during the elution of chromatographic peaks by the UV diode-array detector.

Standard Methods

Standard methods for BaP in fats and oils have been prepared by International Standards Organization (ISO), American Oil Chemists' Society (AOCS), and IUPAC. General methods for PAHs in food have been published by IARC and Association of Official Analytical Chemists (AOAC).

Occurrence in Foods

Table 2 summarizes the levels of individual PAHs in various foods, as reported in the literature. The investigations for which the results are included in the table were selected on the basis of their representativeness of typical or (conversely) extreme situations, their recency (since the 1980s), and the wide spectrum of PAHs reported. While not exhaustive, the table aims to give general information on the contamination levels which may be found and to allow them to be compared in different foods. A number of investigations concerning only BaP determination are not included in the table but are discussed in the following sections.

Levels of individual PAHs generally range from below 1 $\mu g\,kg^{-1}$ to a few $\mu g\,kg^{-1}$. Occasionally, they are in the order of ten, and even hundreds of $\mu g\,kg^{-1}$.

The highest PAH levels were found in grilled food, smoked and broiled fish, mussels from polluted waters, and leafy vegetables grown in areas heavily exposed to air pollution. Shellfish such as crustaceans and bivalves do not metabolize PAHs appreciably and may accumulate high PAH amounts.

Food Smoking

There are considerable variations in the PAH contents of smoked foods, even within the same type of food. These are due to the variations in the smoke generation conditions, which include smoke production temperature, type and comminution of wood material, type of generators, time of smoking, and fat content of products. In general, the higher the smoking temperature, the more PAHs are formed.

High levels of individuals PAHs, and BaP in particular, were found in smoked fish (BaP, in the order of 10 $\mu g\,kg^{-1}$); this may be locally of major health concern for populations who consume large

quantities of these products. Considerable amounts of PAHs were found in home-smoked meat in Iceland, with most of BaP detected in the superficial layers of the meat, and in smoked cheese too. The highest BaP concentrations were found in samples of smoked cereals (up to 160 $\mu g\,kg^{-1}$) and smoked teas (up to 110 $\mu g\,kg^{-1}$).

Traditional smoking techniques, in which smoke from incomplete wood burning comes into direct contact with the product, can lead to extensive contamination with PAHs. Hence, smoke flavorings are used as an alternative. Current commercial smoking practices appear to be effective in controlling the deposition of PAHs. In a recent Spanish survey of commercial smoked products, BaP was found at low levels in almost all samples: up to 0.3 $\mu g\,kg^{-1}$ in meat products and up to 0.9 $\mu g\,kg^{-1}$ in cheese and in fish, with the exception of 2.5 $\mu g\,kg^{-1}$ in a sample of smoked sardine. The oil associated with the fish, if any, may be more contaminated than the fish itself, possibly due to the PAH leaching from the fish.

In a German survey conducted in the 1990s, PAH concentrations were compared between 27 smoked fishery products from traditional smoking kilns and 35 from modern smoking kilns with external smoke generation. The BaP levels from the modern kilns were one order of magnitude lower (on average, 0.1 $\mu g\,kg^{-1}$) than by the traditional systems (1.2 $\mu g\,kg^{-1}$).

Meat and Meat Products

The amount of PAHs formed during cooking depends markedly on the method of cooking and the conditions. In particular, PAH formation during charcoal grilling is dependent upon the fat content of the meat, the time of cooking, and the temperature.

This formation may be due to various causes: the incomplete combustion of charcoal, the transformation of some food components such as triglyceride and cholesterol, or – the most likely source of high PAH levels – the melted fat of the meat. Actually, during charcoal grilling at high temperatures, the fat drippings fall on the hot coals where they are pyrolyzed, producing PAHs which are then volatilized and deposited onto the meat surface.

An investigation of the effect of the method, including broiling on electric and gas heat, charcoal broiling, and broiling over charcoal with a no-drip pan, showed that PAH formation may be minimized by avoiding direct contact of the food with the cooking flame, cooking meat at lower temperatures for longer periods, and using meat with a low fat content.

The total concentration of six carcinogenic PAHs in a lamb sausage increased from 1.9 $\mu g\,kg^{-1}$ when grilled over charcoal under standard barbecue practices (distance between fire and meat 10 cm; temperature at the surface of the meat 200–250 °C) to 13.2 $\mu g\,kg^{-1}$ when heavily grilled for a prolonged time.

An experiment on PAH formation in duck meat during various processing methods showed the highest concentrations of carcinogenic PAHs were due to smoking (1 m distance between smoke generation source and meat), followed by charcoal grilling (1 m distance between charcoal and meat) and roasting (at 200 °C); no carcinogenic PAHs were detected in samples subjected to steaming or to flavoring by liquid smoke. The BaP concentration during smoking increased from 6.9 $\mu g\,kg^{-1}$ after 0.5 h to 13.9 $\mu g\,kg^{-1}$ after 3 h.

Fishes and Marine Products

Processing and cooking may increase PAH levels by the same routes described above for meats. The highest levels of BaP and other PAHs were generally found in smoked fishes, and especially in the smoked skin. In a study of commercial Baltic herrings, BaP was found at about 40 $\mu g\,kg^{-1}$ in a smoked specimen, but at a level one order of magnitude higher in a broiled one (about 400 $\mu g\,kg^{-1}$, which is the highest level of contamination reported). High concentrations are also found in marine products from contaminated sea.

Vegetables

The differences in PAH content may be due to variations in the ratio between the surface area and the weight, to location (rural or industrialized) or to growing season.

It is recognized that broad-leaved vegetables may have particularly high levels of PAHs, due to the deposition of airborne particulate matter. The importance of atmospheric pollution was shown by the high levels detected in lettuce grown close to a highway, with levels decreasing with distance from the road. The PAH profiles in lettuce were found to be similar to those in ambient air, confirming the deposition of airborne particles as the main source of contamination. In an investigation near a coking plant, PAH levels in vegetables with large, rough leaf surfaces (spinach and lettuce) were found to be 10 times higher than in other vegetables (carrots and beans), and this was likely due to deposition from ambient air.

The effect of washing vegetables on reducing PAH contamination due to vehicle exhaust appears controversial: in an investigation on kale, PAH content was not reduced other than at levels lower than about 10% (BaP, 10%). Conversely, in an experiment with lettuce, the higher-molecular PAHs were

considerably reduced (BaP, 67–95%). In no study, however, were lower-molecular PAHs significantly affected by washing.

In an experimental comparison of growth of terrestrial plants in a 'clean-air' chamber and in the open field, the contamination was shown to be due almost exclusively to airborne PAHs and not to synthesis by plants.

Cereals and Dried Foods

Growing crops (wheat, corn, oat, barley) in industrialized areas increases PAH levels in comparison to more remote areas. Grain samples from a heavily industrialized area contained 10 times more PAHs than samples from areas remote from industry. The growth of rye near a high-traffic highway resulted in PAH contamination, which decreased slightly 7–25 m away from the road.

Drying by combustion gases was also found to increase contamination by three- to 10-fold. In an experiment with wheat, drying over a light fuel oil flame increased the BaP deposition from six- to 130-fold depending on the degree of exposure.

Oils

The presence of PAHs in vegetable oils is due to contamination from technological processes (namely, smoke drying of oil seeds or contaminated extraction solvents) or to environmental contamination (e.g., traffic exhaust or industrial emissions).

BaP in olive oils is commonly within the 1 μg kg^{-1} level; higher levels may be present if the oils are from plants exposed to industrial emissions or if they are blended with previously contaminated vegetable oils.

The refining of olive oils (especially the deodorization step) has a marked reducing effect on the light PAHs but not on the heavy ones. The latter may be reduced by treatment with activated charcoal.

High PAH levels may be found in oil seeds. They are usually due to the process of direct drying the seeds, using wood or oil as a fuel. BaP at levels up to 25 μg kg^{-1} were found in corn oils. The PAH content of oil seeds is drastically reduced during refining, particularly by treatment with activated charcoal. This refining method is now widely used.

Dietary PAH Intake

Table 3 shows the dietary intake of PAHs, as estimated from different studies in three European countries. The intakes were calculated on the basis of food consumption surveys, except in one Dutch study where portions of a 24-h intake of food were provided by the participants and analyzed. There are numerous differences between the diets of northern and southern Europe and the criteria adopted in

the surveys are not homogeneous. Consequently, the intakes estimated in different studies cannot be directly compared and have to be considered as a rough estimate of the actual intakes. Notwithstanding these limitations, it is worth noticing that they are generally of the same order of magnitude and the differences are relatively small compared with the variation in cancer potency estimates.

The Contribution of the Different Food Groups

The contribution of different food groups to the total dietary intake of PAHs was estimated in the UK (Table 4).

The major contributors were the oil-and-fats group and the cereals group. The former has the highest individual PAH levels, but the latter, although never showing high individual PAH levels, is a major contributor due to its relative weight in the total diet. Although several studies indicated quite large amounts of PAHs in smoked meat and smoked fish, these products made a very small contribution to the pertinent food groups and these in turn were not major components of the diet. Consequently, at least in areas where eating barbecued food is an infrequent activity, this provides a very small part of the dietary intake of PAHs. The third major contributor was vegetables, and this was likely due to the atmospheric fallout of particle-bound PAHs.

These results were substantially confirmed in a subsequent study of the Dutch diet: cereal products were found to contribute most to the daily intake of PAHs (again attributed to the high consumption share), followed by sugar-and-sweets and by oils and fats. It was not possible to explain the surprisingly large share of the sugar-and-sweets group because none of the constituents (sugar, chocolate products, jellies, licorice) was suspicious with regard to high PAH levels. The relatively high contribution of the oils-and-fats group was at least partly attributed to the well-known elevated PAH concentrations possibly present in vegetable oils. Nuts, which were included in this group, contributed 6% to the total PAH intake, and this was most likely due to the roasted peanuts.

Cereals were also found to be the highest contributors in a Swedish study (where they were followed by vegetables, and by oils and fats), and in an Italian one.

A more accurate comparison of the results of all these studies is not possible due to the differences in the reporting criteria adopted.

Table 4 Contribution from individual food groups to the total UK dietary intake of polycyclic aromatic hydrocarbons (PAHs)

	% of total dietary intake	
	BaP	*Sum of six PAHs*[a]
Cereals	30	35
Meat	3	4
Fish	1	2
Oils and fats	50	34
Fruit, sugar and sweets	5	7
Vegetables	8	18
Beverages	0	0
Milk	2	1

PORK

R W Mandigo, University of Nebraska, Lincoln, NE, USA

Development of the Swine Industry

The earliest known records of swine domestication are from China and date to 4900 BC. Christopher Columbus brought the first pigs to the USA via the Canary Islands in 1493. The early colonists of the USA brought livestock with them from England throughout the 1600s. Gradually, as more grain was grown, larger herds of pigs developed and swine production became a true industry.

By the early 1800s, swine-slaughtering plants had emerged at several large population centers in the USA. The largest of these was at Cincinnati (also known as Porkopolis at that time) because of its prime location on the Ohio river. Early slaughtering plants were located near rivers for four reasons: rivers provided ice to keep the meat cold, transportation for products to be shipped, a source of water, and a place to deposit plant waste materials such as blood.

The advent of mechanical refrigeration led to industry expansion as pork could be processed year-round and kept fresh longer. Development of rail systems and the use of refrigerated rail carriages boosted industry growth as both livestock and meat could be more widely distributed. In the 1800s, pigs were often allowed to roam free in pastures and were fed garbage or what little grain was available. Today, most pigs are raised in large numbers in environmentally controlled buildings with a very specific diet designed to maximize growth.

The first slaughter operations were separate from packing operations. By the 1850s, the two had started to become integrated. Today, many plants have reverted back to specializing in either slaughter and fabrication or pork processing. This specialization has allowed modern-day slaughtering facilities to process around 1000 head per hour.

The pigs in the USA today are thought to have descended from two wild stocks, the European wild boar (*Sus scrofa*) and the East Indian pig (*Sus vittatus*). From these two genetic bases, modern pigs have been refined into several breeds which each have distinguishing characteristics. In addition to hair color and marking differences, breeds have been developed for specific purposes such as prolificacy, bacon production, ham production, and others.

In general, pigs have become leaner as the demand for lard has decreased and the demand for leaner meats has increased. The modern market pig is approximately 71.5% carcass while the remaining 28.5% is mostly byproducts used in the medical and animal feed industries.

Slaughter, Fabrication, and Processing

Procurement

Although pigs of all sizes can be slaughtered, most swine-slaughtering plants have equipment designed to handle pigs marketed at about 105 kg. Swine producers can sell their pigs to slaughter plants in various ways. Pigs can be marketed at a central location such as an auction or a packer buying station or they can be purchased from the farm by a packer buyer. The latter method is the most popular today. A new way to market pigs that has some popularity is contract producing for a specific packer.

After pigs arrive at the slaughtering plant, they are slaughtered within 2–3 h of arrival. If a substantial delay is expected, then they will usually be held in pens for 12–24 h. It is important to allow pigs time to become acquainted with their environment as high-stress conditions can cause undesirable changes in muscle color and juiciness. In pigs with a certain genetic make-up, severe stress can cause the meat to be pale and watery (known as pale, soft, and exudative, PSE). Long-term stress, on the other hand, can lead to a condition where the muscle is dark and very dry-appearing (known as dark, firm, and dry, DFD). The physiological basis for these conditions is an abnormal muscle pH change between the time of death and the completion of rigor mortis. Therefore, it is necessary to minimize stress by proper handling of pigs prior to slaughter. Feed is usually kept from the animals during this period to decrease stomach fill. This improves percentage of carcass dressing, aids evisceration during slaughter, helps minimize contamination, and improves color. (*See* **Meat**: Slaughter.)

Slaughter

All meat sold interstate in the USA must be inspected by the US Department of Agriculture, Food Safety and Inspection Service (USDA-FSIS). Inspection begins *antemortem* and continues throughout the entire slaughter, fabrication, and processing system. This helps ensure the wholesomeness of meat products offered to the consumer. If the meat will be sold intrastate only, some states allow inspection by state-employed inspectors. This inspection, by law, must be equal to federal inspection. Similar inspection regimes apply in Europe and other developed regions of the world.

At the time of slaughter, pigs are herded into a chute where they are stunned to render them unconscious. Stunning can be accomplished by one of several methods, but is mandatory to comply with the US Humane Slaughter Act of 1958. If stunning is not performed correctly, the incidence of poor-meat-quality problems could increase. An example of this is a condition referred to as blood splashing. Blood splashing occurs when small capillaries in muscle tissue burst during stunning, leaving spots of blood in the muscle. The most common method of stunning is accomplished using an electrical current. Other methods include a blow from a captive bolt to the head, moving pigs through a carbon dioxide gas chamber to cause suffocation, or cardiac arrest stunning. The goal of stunning is to render the animals unconscious while allowing the heart to continue to beat and pump blood out of the body.

After stunning, the pig is immediately shackled, hoisted by the hind leg, and the jugular vein is severed with a knife to allow blood to exit the body. Bleeding will remove around 50% of the blood in the body. Much of the remaining blood is removed with the organs during evisceration.

Pigs can either be skinned or they can be scalded and dehaired. To dehair carcasses, the pig is put in a scalding vat of hot water (60 °C) with lye to loosen the hair follicles. The pig is removed from the scalding tank and dehaired mechanically and/or by hand using blades to scrape away the hair. Whole skins from skinned pigs can be saved and made into pigskin for use in garments and for gelatin production.

After dehairing or skinning, the abdominal and thoracic cavities are opened and the internal organs removed. Certain organs are washed, inspected, and saved as edible byproducts. These include the liver, heart, tongue, and brain. Other organs may also be saved as inedible byproducts, and will be discussed later in this article.

The carcass is washed, weighed, and placed in a cooler for chilling. The cooler temperature is maintained at about −2 to 5 °C so that internal areas of the carcass will be adequately chilled in 24 h. While in the cooler, most of the remaining stored energy in the muscle will be depleted and the carcass will undergo

rigor mortis. Some carcasses are processed before they go through rigor mortis. This is called hot boning. Although fabrication is more difficult, the cuts can be chilled faster than whole carcasses, so product that has been hot-boned can be moved through the system faster.

Fabrication

Pig carcasses are fabricated into wholesale cuts, using knives, saws, and other mechanical equipment. The wholesale cuts include the ham, loin, Boston shoulder, picnic shoulder, belly, and spare ribs. The wholesale cuts may be shipped fresh to further processors, food service operations, or to the retail market. Some plants will continue to fabricate the wholesale cuts into retail cuts and trimmings and sell these items. Many plants that slaughter will carry out further processing such as curing and smoking bellies and hams in the same plant. (*See* **Curing**.)

Processing

Further processing of pork can involve many different processes. Processing encompasses many steps, including particle size reduction, the addition of nonmeat ingredients, cooking, smoking, and a variety of packaging procedures. Patties can be made by grinding pork trimmings, with a specified fat level, with salt and other seasonings. Restructured products often have salt and phosphates added to flaked or chunked meat. These ingredients are then mixed and formed into steaks, chops, or roasts. Sausage is another type of further processed meat. Sausages can be cured, smoked, dried, or cooked. Some sausages are coarsely ground while others are finely chopped, forming what is sometimes called an emulsion or batter. Bratwurst, frankfurters, and bologna are sausages that typically contain pork. (*See* **Meat**: Sausages and Comminuted Products.)

The hams and bellies from pork carcasses are usually cured and smoked. The curing may be done by packing in a dry cure or, more commonly, by pumping or injecting a solution containing the cured ingredients into the meat. The curing solution may contain any or all of the following ingredients: water, salt, sugar, phosphate, nitrite, erythorbate, or spices and seasonings. Water is used to add moisture to the product as well as acting as the solvent in a curing solution. Salt solubilizes proteins in meat so the meat particles bind together better. Salt also adds flavor and, at high levels, retards microbial spoilage. Sugar can be used for flavor, to promote browning, and to act as a food source for desirable bacteria in some fermented meat products. Phosphates are added to help retain water in the product and to prevent oxidative rancidity from occurring. Nitrite is the curing agent. Nitrite binds to meat pigments and causes the meat to develop a stable pink color. It also lends flavor, acts as an antimicrobial agent, and helps to prevent oxidative rancidity. Erythorbate is used to speed up the curing process, which is economically important to pork processors. Spices and seasonings are added to develop flavors unique to a particular product. (*See* **Smoked Foods**: Principles.)

Some sausages are cured and may also contain acidulants, starter cultures, or extenders. Acidulants and starter cultures of bacteria can be used to lower the pH of products in order to develop certain flavors and protect the product from spoilage. Nonmeat extenders, such as soya proteins or nonfat dry milk, may be used as inexpensive protein sources.

The US Department of Agriculture (USDA) has regulations regarding the composition of processed meat products and the proper use of some ingredients used in processing. Hams must be labeled according to the amount of protein they contain on a fat-free basis. The amount of phosphates, nitrites, erythorbate, and nonmeat ingredients added are also limited. These regulations, and similar ones in other countries, are designed to provide consumers with high-quality, safe meat products.

Pork is also regulated by the USDA in an attempt to control the disease trichinosis. Trichinosis is caused by the organism *Trichinella spiralis* and can be transmitted from pig to humans by ingestion of infected muscle tissue. Simply put, the regulation states that pork for use in products that are not fully cooked in the home must be certified as 'trichina-free.' Pork may become certified trichina-free by being subjected to specific heat or freezing to kill the organism. (*See* **Zoonoses**.)

Chemical Composition

Fresh pork muscle is 70–75% water, and the protein content ranges from 18 to 22%. There are three main types of protein in the pig: myofibrillar (skeletal), stromal (connective tissue), and sarcoplasmic (pigments). Lipid or fat is another major constituent of fresh pork. It makes up between 5 and 7% of the muscle tissue. Lipids include phospholipids and triacylglycerols (also known as triglycerides). The carbohydrate content of meat is negligible, generally less than 1%. Vitamin and mineral content of fresh pork is usually about 1–2%. (*See* **Fats**: Classification; **Meat**: Structure; Nutritional Value; **Protein**: Chemistry.)

Different cuts in the carcass will have different compositions. This is largely due to the varying fat

Table 1 Composition of various raw pork cuts ($g\,kg^{-1}$ raw meat)

	Moisture	*Fat*	*Protein*	*Ash*
Ham slice	730	55	205	10
Bacon	370	530	95	5
Loin chop	710	70	210	10
Spare ribs	575	245	170	10

level in different areas of the carcass. Table 1 contains some example cuts and their typical raw composition.

Nutrient Value and Dietary Significance of Pork

Pork supplies many nutrients essential for maintenance and growth.

As with other meat, pork is an excellent source of protein. A single 85-g serving of pork contributes 41% of the daily protein requirement for a normal adult male. Not only does pork contain a large amount of protein, this protein is of good quality. (*See* **Protein**: Requirements.)

Pork also contains lipids and fats. About 34% of pork fatty acids are saturated and 66% are unsaturated. Cholesterol is another lipid found in pork. Cholesterol is found in cell membranes in the animal body and is synthesized in the liver of humans and animals. Consumption of animal products, therefore, provides a dietary source of cholesterol which can be used in the body. Cholesterol, like saturated fats, has been associated with increased risk of developing heart disease. The relationship is not well understood, but the American Heart Association recommends keeping dietary intake of cholesterol to less than $300\,mg\,day^{-1}$. One 85-g serving of pork provides about 79 mg of cholesterol or about 26% of the recommended 300 mg. (*See* **Cholesterol**: Role of Cholesterol in Heart Disease; **Fatty Acids**: Properties.)

Pork is an excellent food source for several vitamins and minerals. It supplies large amounts of thiamin, vitamin B_{12}, niacin, riboflavin, and zinc. Pork is also a good source of vitamin B_6, phosphorus, and iron. Dietary iron can be classified into two types, heme and nonheme. Heme iron, which is the major type found in pork, is absorbed more easily and better utilized by the body. Iron is a component of the molecule hemoglobin, which is the major carrier of oxygen in our blood stream. Intake of heme iron is especially important in warding off anemia, which may result from a low level of hemoglobin in the blood. Refer to individual vitamins and minerals.

Pork, when consumed in moderation, is an excellent source of many important dietary nutrients.

Microbiological and Other Hazards

Muscle is essentially sterile prior to death. However, meat destined for human consumption is cross-contaminated with microorganisms by equipment and handling at the time of slaughter and processing. Just as pork is an excellent source of nutrients for our bodies, muscle or meat is also an excellent growth medium for microorganisms. Controlling the growth of microorganisms on pork by acidifying, curing, salting, modified-atmosphere packaging, drying, cooking, or refrigerating is essential. (*See* **Meat**: Preservation.)

Food poisoning can result from consuming pork that has been mishandled, allowing certain microorganisms to grow. Causative organisms of food poisoning may include *Staphylococcus aureus, Bacillus cereus, Salmonella* spp., *Listeria monocytogenes, Yersinia enterocolitica, Clostridium botulinum, C. perfringens*, and *Campylobacter fetus* ssp. *jejuni*. Food poisoning is quite common and, in its mildest forms, is often mistaken for influenza because the symptoms are very similar. Generally, foodborne illnesses are relatively short-lived and more uncomfortable than harmful. However, food poisoning can be a very serious matter. It can be debilitating or even fatal for those with poor immunological defenses such as infants or the elderly. Like other microorganisms, pathogens which cause food poisoning are well controlled by heat, refrigeration, chemicals, or other means mentioned earlier. However, undercooking, improper cooling, or recontamination of cooked food by raw food are common ways that pathogens appear in the food supply. (*See* ***Bacillus***: Food Poisoning; ***Campylobacter***: Properties and Occurrence ***Clostridium***: Food Poisoning by *Clostridium perfringens*; Botulism; ***Listeria***: Properties and Occurrence; ***Staphylococcus***: Food Poisoning.)

Of particular concern in pork is the parasitic nematode *T. spiralis*. This organism forms a cyst in porcine muscle. The organism can be transmitted to humans who consume the contaminated pork, but is readily destroyed by heating the muscle to 62 °C. Processing plants that sell pork which is not likely to be cooked again are required to heat or freeze the meat to certify that it is trichina-free.

Pork-slaughtering and processing plants have rigid sanitation programs that allow production of safe food. Good sanitation at the plant and proper handling throughout the food chain help keep microbial growth under control. Plants producing pork must keep processing temperatures below 10 °C or stop production and sanitize the equipment every 8 h. Most plants keep their working temperature low enough to require cleaning and sanitizing only once every 24 h. Cleaning and sanitizing are not the same

thing, but they are most effective when carried out together. Generally speaking, a plant is cleaned with soap and water to remove residual meat particles. Then the soap is rinsed off and sanitizer is applied to kill microorganisms that survived the cleaning. Common sanitizers used can be chlorine, ammonia, or iodine-based. (*See* **Sanitization**.)

A great deal of effort is spent to clean and sanitize the plant thoroughly, as well as educate employees about the importance of good hygiene in reducing food contamination. Microbiological status of the processing area is monitored daily. In addition, the plant must pass a sanitation inspection by a USDA inspector before the day's production can begin.

Despite all the in-plant efforts to control microorganisms, pork can still be contaminated or growth of microorganisms already present can occur as a result of product abuse in the warehouse, on the delivery truck, in the retail outlet, or in the home. Perishable foods should always be frozen or refrigerated at temperatures below 4 °C. Once cooked, pork should be kept above 60 °C or quickly cooled to under 4 °C. Many microorganisms grow rapidly in the temperature range 4–60 °C. Two very common mishandling problems that occur in the home are failing to refrigerate leftovers promptly and recontaminating cooked product by using the same utensils used with the raw product.

To minimize microbiological hazards and maximize eating quality, the recommendations in Table 2 have been devised as maximum limits for storage of pork. Molds and yeasts are of little concern in fresh pork because the high water activity allows bacteria to dominate. In dried pork items such as pepperoni, molds may grow on the surface. However, mold growth is retarded by a potassium sorbate dip applied by the manufacturer or by vacuum packaging. (*See* **Spoilage**: Bacterial Spoilage; Molds in Spoilage; Yeasts in Spoilage; **Water Activity**: Effect on Food Stability.)

Very few other hazards exist with the consumption of pork. Muscle from pigs is regularly monitored for drug and pesticide residues by the USDA. Incidences of contaminated meat have been isolated and total far less than 1% of the pork supply.

Table 2 Pork storage recommendations[a]

	Refrigerator (2–4 °C)	*Freezer (−18 °C)*
Fresh pork	4 days[b]	3–6 months[c]
Cured pork	7 days	2 months

[a]Packaging and handling prior to the consumer will greatly impact shelf-life of pork.
[b]Ground meat, 2 days.
[c]Ground meat, 1–2 months.

Food Uses and Products

Pork is a very versatile food that can be prepared in many ways. Popular entrée items include pork roast, ham steaks, barbecued spare ribs, and grilled pork chops. Pork is also a common component of many foods such as bacon on pizza or ham dices in a chef's salad.

Pork trimmings can be ground and made into patties or sausages of all types, including frankfurters, pepperoni, and Italian sausage.

Waste or Byproduct Utilization

People in the swine industry say that no part of the pig is wasted. This statement is not far from the truth. The major waste product from the live pig is manure, which is a good nitrogenous fertilizer.

Waste products from swine slaughter and processing are perhaps better referred to as byproducts because they are seldom wasted. Blood, bones, and inedible viscera from pig slaughter are usually dried and ground for use in animal feeds. Gelatin is made from collagenous proteins found in pig skin. Industrial lubricants, plastics, and rubber are made from fat trimmed off pig carcasses. Pig skin fabric can be produced from cured pork skins. Even the pig's hair is sometimes used for brushes or insulation.

Perhaps the most important byproducts of swine slaughter and processing are those used in medicine. Hormones such as pig insulin or heparin can be prepared for human use. Heart valves from pigs have been used to replace damaged or diseased human heart valves and are often used in heart disease research. Skin grafts from pig skin have been successfully used on human burn victims. These are only a few examples of many medicinal uses of byproducts from the swine industry.

PORT

Contents

The Product and its Manufacture

E Cristovam, University of Adelaide, Adelaide, Australia
A Paterson, University of Strathclyde, Glasgow, UK

Background

Ports are fortified wines based upon a long tradition with expert blending employed for style, create defined characters and produce the quality factor that makes port highly prized. Production methods differ from table wines primarily in that the fermentation – in some case still from spontaneous endogeneous microfloora of the must – takes place only during the 2–3 days of maceration. During this period, there is extraction of soluble compounds responsible for characteristic color and flavor characters of ports. Addition of brandy terminates the fermentation, leaving a young wine with high amounts of residual sugars. Such fortified wines have been produced in Portugal since the seventeenth century. Originally exported to Britain, since the 1960s France has been the largest importer. Many port houses are still British-owned and blenders follow house styles, believed to yield wines suited to British markets. Port is also used in elegant cocktails and receptions ('Porto de honra'). Three major product styles are recognized – Portuguese, English, and French – based on house cultures. Ports have many myths and traditions associated with Christmas, gout, the British upper classes, and formal dinner parties. Consumer rituals abound, Port should be passed to the left from the host, and ladies should not touch a Port bottle. These wines are established products with an image of luxury, with seasonal peaks in demand dominated by that from the older generation and males. Port wine is a key product for a national economy of Portugal and a symbolic asset representing the country world-wide: unfortunately, demand is decreasing, probably as a result of social and lifestyle changes. However, port is now drunk on formal occasions, and such changes may enhance the demand for higher-quality wines.

History and Origin

The designation 'port' in wines appeared during the second half of the seventeenth century when this fortified product increased in popularity in Britain, replacing Bordeaux wines in English trade. This was enhanced by the Methuen Treaty between England and Portugal in 1703, guaranteeing preferential customs tariffs for port wines to balance similar tariffs for imports of British textiles by Portugal.

At that time such wines, from the Douro in Northern Portugal, were red, dry, and coarse, with an alcohol content of 12–13%. Subsequently, brandy was added to stabilize wines, to reduce spoilage during the long sea journey around Western Europe. However, this fortification practice became central to the production process – removing excess acidity,

rounding the flavor character and creating a characteristic set of attributes that became unique to port wine. In 1756, the Marquis of Pombal set legal boundaries for the Douro Valley vineyards, annual production quotas, and strict rules for cultivation, transportation, and prices. Even a tasting was required before wine was sold. The aim was to safeguard port wine's authenticity, and effectively, a new product was created. In 1921, a further addition was made to the definition of port wines in that these must be *lodged* in the country for a given period before being deemed fit for export.

In the 1860s, phylloxera destroyed most vineyards in the demarcated region. This forced a restructuring of viticulture and winemaking techniques. At the same time, imitations of port started to appear from France and Spain. At the beginning of the twentieth century, in order to counteract such fraud and maintain quality, regulations were imposed for the production, sale, and export of Ports. Denomination of origin was reserved for fortified wines from the Douro region, in Northeast Portugal, with a minimum of 16.5% alcohol. Distillation of Douro wines was prohibited, and fortifying spirit had to be obtained from other regions.

In 1926, a bonded area was created in Gaia – Vila Nova de Gaia – a city opposing Porto on the Douro river mouth (Figure 1). Gaia became part of the demarcated region, and here, port trade companies were forced to build lodges to age wines. Now, shipments can be made from both Gaia and the demarcated Douro region. Lodges maturing in the Douro produce wines with characteristic baked flavor notes through the high temperatures experienced upriver.

By the 1930s, exports were at a peak, but prices soon fell as quality was neglected, and production exceeded market demands. To counter this, legislation was introduced to control the two facets of the port industry – production and trade. In 1932, winegrowers were organized into guilds, now Casa do Douro (CD), responsible for monitoring vineyards, wine quality, and grape brandy production. A year later, a guild of port wine shippers was established, and the Instituto do Vinho do Porto (IVP) was formed to coordinate activities. The IVP regulates the description of ports with respect to dates and indication of age, controls the seal of guarantee, and still coordinates Casa do Douro activities.

Prior to entering or leaving Gaia, all ports are submitted to a chamber of tasters, constituted by experienced specialists. This is overseen by a consultative committee of tasters from individual port firms, chosen on the basis of reputation and expertise, but confirmed and formally appointed by the Ministry of Economy. This gives expert tasting opinions and has the final decision.

In theory, any must produced within the Douro demarcated region can be used for port. However, the IVP sets limits to annual quantities of wine to be 'beneficiado' (improved or benefited). Growers must apply to the CD for the right to produce within this allowance. Applications must list the name of the

Figure 1 (see color plate 122) Vila Nova de Gaia; bonded area in Portugal.

petitioner, the municipality and parish of each property, property names, number of vines over 4 years old, estimated production, and amount of wine to be used for port. Applications are checked against a register that makes reference to a classification system. Class A vineyards are, on average, granted a *benefit* of 600 l per thousand vines and Class E 400 l per thousand vines. Production is quantified in *pipes* – the volume of a traditional 550-l oak cask. Allowances are varied according to vineyard classification, total allowance for the year, and prospects for wine production in that year.

Today, port is a product that requires careful quality management strategies. To protect the industry, there is an upper limit on the number of vintages that can be declared and maxima to the fractions of wine in houses that can be traded in any year.

Production Area

The boundaries of the demarcated Douro region – the oldest in the world – have remained largely unchanged since 1756 (although revised in 1907, with minor alterations in 1921). This region consists of four districts: Vila Real, Bragança, Viseu, and Guarda covering *c*. 250 000 acres, with three subregions: Baixo Corgo, Alto Corgo, and Douro Superior (**Figure 2**), each with individual characters. Vines cover approximately 15% of the region, with the Baixo Corgo dominating. Small vineyards can be found throughout the region, with the larger vineyards mostly located in the Douro Superior. Before planting on the steep mountainous slopes, terraces must be formed. This was done in the past with hammers and dynamite but is now done with bulldozers when possible. Grape production is difficult because of the nature of the soil, schistose with granite in certain areas, and narrow terraces. The climate is harsh with frosty winters, hot (> 37 °C) dry summers, and in certain areas wet springs.

Grape Varieties

Only approximately 10 500 hectares (26 000 acres) are authorized for vineyards that can be used for port production. Most vine varieties are regional, grafted on to rootstock types chosen for grape variety and soil compatibility. The rootstocks used are Rupestris du Lot, Berlandier hybrids, either Riparia strains (420-A, SO4, 161/49) or the Rupestris varieties (R.99 and R.110).

The varied microclimates in the Douro region have resulted in 48 grape varieties being used in port production. However, there has been a rationalization to increase quality and optimize vine planting and grape production. Currently, an official EC recommendation quotes 29 varieties for port: 15 red and 14 white. Desirable red grape varieties produce tannic, intensely colored wines. Until recently, one of the most popular was *Tinta Francisca*, derived from Pinot Noir. Other important varieties are *Touriga Nacional*, *Tinta Roriz* (*Tempranillo* in Spain), *Touriga Francesa*, *Tinta Barroca*, and *Tinto Cão*. The dominant white grape varieties are *Malvasia Fina*, *Viosinho*, *Donzelinho*, and *Gouveio*.

Of the Douro red grapes, *Touriga Nacional* is considered to produce the finest and most complex wine, although the yield is low. It is also a vigorous and adaptable variety, growing in a wide range of conditions. Wines from *Touriga Nacional* have an aroma character suggesting red fruit, often with floral notes, notably of violets. Flavors are complex, elegant, balanced, and rich in nonaggressive tannins, and finishes are long and smooth.

Another red grape, *Tinta Roriz*, grows best on fertile soils, producing large, tight clusters of thick-skinned grapes of a high quality. Wines, less colored than those from *Touriga Nacional*, also have rich aroma characters dominated by red berries, with strong herbal overtones. Flavor characters are strong and astringent from harsh tannins, and lengthy fruity finishes contribute structure in blending.

The most fragrant wines are from *Touriga Francesa*. This variety is adaptable but requires a warm growing season to completely ripen grapes. Strong floral characters, notably of rose, dominate the aroma notes. Flavor, with fruity and floral attributes and earthy overtones, is thought to be well balanced with a long, concentrated finish. These wines contribute aroma and structure to products in blending.

Tinta Barroca is a high-yielding variety with large, loose clusters of thin-skinned, oversized berries. Wines are soft, fragrant, and delicate with a lingering red fruit aftertaste, but are often lacking in complexity and light in color. These wines contribute little to blend structure. *Tinto Cão* produces a smaller grape than other varieties.

A central problem in the Douro is finding a balance between the desirable character attributes in varietal grapes and production yield. The overall must color

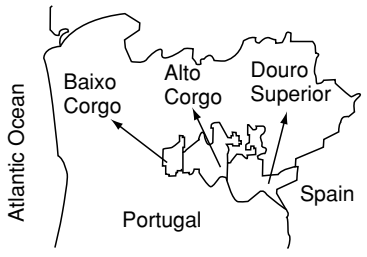

Figure 2 Região Demarcada do Douro.

in young port wines, central to production, is influenced more by cultivar than by season.

Production Method

Harvesting of port grapes is difficult. Grapes are picked entirely by hand, between 15 September and 15 October depending on the weather and region, in vineyards that slope at an average of 45°. After grape destemming, traditionally grape treading was carried out to extract must in a 'lagar' (a large open, shallow stone tank). However, this quaint procedure has generally been replaced by more readily controlled and standardized practices. Currently, most port is produced in closed fermentation tanks often equipped to turn over the wine automatically. Alternatives include open tanks, in which must is pumped around, and concrete or stainless steel tanks, fitted with mechanical stirrers. Grapes are generally broken in centrifugal crushers with pumps. In certain production sites, for total or partial removal of skins, crushed grapes fall into a blender that shreds skins completely. The fermenting must is run off when most sugars have been converted into alcohol after 2–3 days of fermentation. After separation from solids, fermentation is inhibited by *aguardente* (grape brandy) addition. Wine officially becomes port at 19–20% (abv).

Brandy fortification, in addition to quenching the spontaneous fermentation, contributes specific sensory attributes to wine, improves chemical stability, and controls the final sweetness intensity. The sweetness in ports comes only from unfermented sugars. Fermentation must therefore be terminated when the residual wine sugars contribute to the desired sweetness. The quality of brandy added to the fermenting must is also a key factor in determining the chemical composition and final flavor character potential of quality ports.

The nascent port wines are stored in tanks, vats, or casks. It is not clear whether container capacity influences final wine character, but container material certainly does. More important seems to be the storage site, i.e. whether upriver at Douro or by the sea at Gaia – concrete tanks with a tartaric acid coating or stainless steel are often used. Once transported to Gaia, wines must be submitted to the IVP tasters for classification. Group 1 wines are considered 'of immaculate quality, carrying special privileges'. Group 2 wines have slight imperfections but are fit for usage. The final Group, 3, is for wines rejected either by tasters or by analysts.

Traditional Vintage

The traditional process, predominant until 1960, consisted of handpicking of grapes by groups of workers with transport in large baskets either on the shoulders or by cart. At the winery, workers crushed grapes barefoot in the *lagar*, marching back and forth in a line, until the juice floated on top of a pulpy residue. This initiated the fermentation with must darkening as the color was extracted from skins. To maintain the fermentation, paddles stirred the must, and when sufficient sugar was converted to alcohol, the liquid was run off into wooden vats and 110 l of *Aguardente* added for each 440 l of wine.

The nascent port was held in 'toneis' and tasted regularly until it was ready to be transported by expert boatmen down the river Douro in 'barcos rabelos,' in the spring following the harvest, or vintage. Gaia was originally chosen as the bonded area because port pipes could be easily off-loaded from riverboats to lodges and transferred to seagoing vessels.

Modern Vintage

With decreased manpower through migration, major changes have been, and are, taking place in port production. The vinification process, blending policies, maturation practices, and transport to lodges in Vila Nova de Gaia have changed considerably.

The widespread introduction of electricity in the early 1960s led to the replacement of human contributions with the autovinification process. Such mechanization led to establishment of wine centers at larger *quintas*. The result was that farmers sold more grapes, and wine production was centralized to facilitate improved quality control. Closed autovinification plants and open tanks came into use, but certain producers still believe that open-tank fermentations with automatic paddles optimize the color extractions from must.

Since the 1970s, production has moved from individual *quintas* to wineries with a greater plant capacity: currently, both fermentation and storage tanks are considerably larger. By the 1980s, over 80% of port was produced in wineries, with cooperatives producing approximately 40%.

Grapes arrive by lorry in open steel containers and are weighed, tipped into reception tanks, and immediately carried by screw feeders into a crushing and stemming machine. This is typically an upright cylinder, approximately 1 m in diameter, which centrifugally removes stalks to an extent depending on the tannin requirement. The must is pumped into square concrete or triangular stainless steel tanks, autovinification vats, an autovinificator cylinder is clamped on, and a water escape valve is filled. Provided that the temperature is *c.* 16 °C, the must starts fermenting almost immediately. Fermentations last 2–3 days, with sugar contents assessed continuously from

specific gravity. The total sweetness of the port is derived from the original grape sugars.

Young ports stay in wooden vats or cement holding tanks in the Douro until they are ready for transport to Gaia in the spring by the road tankers. The narrow and winding roads of the Douro retain some of the hazards of bygone eras.

White port production uses white grapes, often with limited maceration, and wines are aged under oxidizing conditions. Grape skins acquire a golden-brown hue at harvest, and in order to produce a light gold, rather than a yellow–white, port, it is necessary to minimize skin contact during fermentation. Consequently grape skins are removed after crushing, and the maceration time is also kept to a minimum. Oxidation is not encouraged if complex floral aroma notes and pale yellow color are desired in the final wine.

Maturation and Blending

Young ports are stored in vats or casks made of oak or mahogany in the Douro. During the first winter, wine is racked (pumped off) from the lees into fresh casks. The first tasting in November uses a classification based on sensory attributes. The finest wines, produced in an exceptional grape quality year, are usually set aside with a view to *declaring a vintage*; most are used for blending. Vintages represent highpoints in port wine quality. During the initial 2 years, wines are racked frequently with aeration as often and vigorously as required for the attributes considered desirable after aging, as determined by the winemaker. Winter conditions help precipitate colored matter together with yeast and potassium salts of tartaric acid. Young ports are then observed to 'close up' or show a color intensification. Ports are transported to Gaia for classification in early spring.

Port was traditionally stored in lodges or cellars in Gaia but can now be retained in the Douro. Ruby wines, matured in the Douro, are subjected to its climatic extremes and are considered to lose vigor and freshness. A common view is that older tawny ports should mature in the Douro, and younger ruby ports in Gaia, where temperature and humidity are less variable.

On arrival at Gaia, casks are stored by vineyard and vintage in the cellars of individual port houses. Large cylindrical stainless steel vats and lined concrete are often used for the temporary storage of wines on arrival, but maturation, for at least 2 and usually for 3–40 years or longer, is in wood. Cellar-masters decide between the 550-l 'pipas' (pipes or oak casks), and larger casks (25 000–35 000 l) or vats (550 000 to 750 000 l) (Figure 3).

Figure 3 Wooden casks and vats used for wine maturation.

On arrival in Gaia, a second tasting takes place: wines are classified, and the first *lotas* (blends) are married in large vats fitted with stirrers or pumping. This is on the basis of decisions on the potential of each wine and amalgamating similar wines. There is then separation of the top-quality wines i.e. those to be used when declaring a vintage. Such wines are kept separate for two winters and a summer, and if they do not develop to predefined standards, a vintage will not be declared that year, and the wines will be used for blending.

The purpose of blending is to obtain specific final sets of sensory attributes, port types, and styles. Consequently, young port is always stored in well-seasoned vats or pipes to retain the fresh aroma characters and deep red color with purple hues. As production is based on traditions, wooded ports are created to ensure continuity of style; new blends contain a percentage of previous wines. Previously, individual pipes were blended, but currently, concrete or large wood vats are filled from maturation casks.

Ports are blended from wines varying in age and character. Cellar-masters choose young wines on the basis of fruit flavor notes and color, and older wines for body and 'smoothness.' The objective is a character and quality typical of the style of that port house.

Regulations stipulate aging of ports at least 3 years in cask or bottle prior to release.

Aging

Port wine storage leads to varied changes in the wine character and composition. The type and capacity of containers are selected for the character evolution required, but those from grapes also contribute. Ports are aged under oxidizing conditions except for vintage and late bottled vintage (LBV) products. Young ports are blue–purple in color – gradually turning red, then tawny and progressively paler with age, eventually achieving amber and golden tones (Figure 4). The aging method varies. All red ports are aged for at least 2 years in oak casks and continue maturation either in casks (ruby, tawny, aged tawnies) or in bottles (vintage, LBV). Ruby ports retain an intense dark red color with the sensory characteristics of young wines.

Red ports are aged in wooden vats and pipes, stacked four high to minimize evaporation. With white ports, in order to avoid color gain through prolonged wood maturation, concrete vats are used.

With labor costs increasing, larger vats (5–400 pipes in capacity) are used more often for aging wines. The rate of maturation is inversely related to volume. As a consequence, wines are selected early according to style requirements and then stored in appropriately sized containers. Traditional lodges in the Douro exhibit wine liquid temperature changes of up to 20 °C. The atmosphere is also dry, leading to faster evaporation and maturation rates and baked or maderized flavor notes. In Gaia, the relative humidity is constant (approximately 54%), evaporation lower, and temperature fluctuations under normal storage conditions limited to 14–16 °C. Maturation is slower, producing fresher wines than the Douro.

Wood

Although the character of the grape variety is central to wine flavor development, wood has been considered to play important roles in port maturation. Staves are from local and imported oak (including some used for Scotch whisky casks), chestnut, and Brazilian mahogany. Dried fruits and spicy aroma notes, and smooth mouthfeel (texture) characters, attributed to lengthy wood maturations, characterize premium tawny ports. Traditional guidelines for production include the use of small oak pipes with frequent racking to induce sufficient aeration. Contact between the wood surfaces and the wine, regular racking, and oxygen migration through the staves have been reported to be important variables in port maturation.

Unlike table wines, port is aged in a varied range of container sizes. Wood is often reused many times, depending on the style and cellar practice. New wood is rarely used and, if required, is seasoned thoroughly with a second pressing wine, table wine, and/or young red port before deployment. Consequently, some experts believe that little woody character should be detectable in ports, through the use of extractive-depleted staves, except in the older tawnies matured in the Douro.

LBV ports are stored in large vats, and tawny ports are stored in pipes. Frequent racking with aeration of wines influences maturation. Wood aging of such wines is believed to be primarily an oxidative process with limited parallel extraction of nonflavonoid phenolics from stave lignins and tannin degradations.

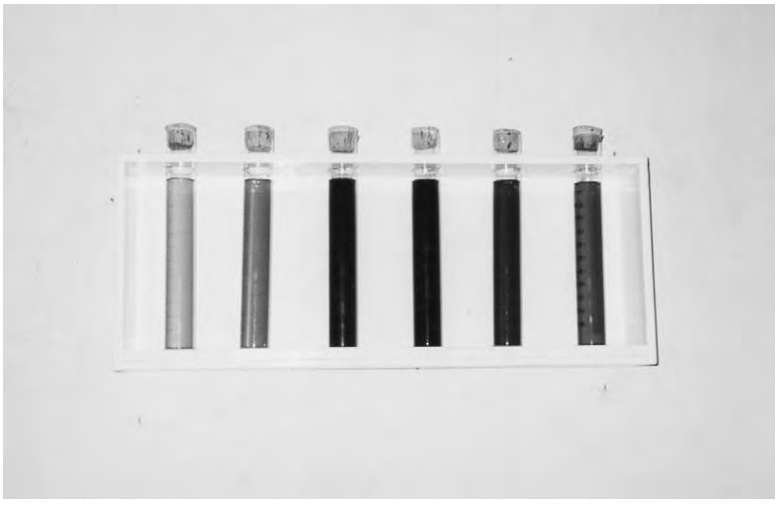

Figure 4 (see color plate 123) Samples of different types of port, showing the range of colors.

Wine maturation is thought to occur mainly from evaporation and oxidation.

Fining and Stabilizing

Fining, traditional for clarifying wines, removes a certain amount of color and tannins to produce softer and 'older' wines. Port is usually filtered: modern methods have replaced the cloth bag method of separating wine from lees. Modern filters consist of a series of woven nylon pads that allow lees to circulate until the pads are evenly coated with solid material. The resulting solid cake then acts as a filter that introduces clarity in the wine. Bentonite may be used with white wines to remove protein.

Refrigeration is now used to stabilize wines: chilling precipitates unstable coloring matter and the potassium salts of tartaric acid. Chilled wine is passed through a vessel that encourages deposition of potassium hydrate tartrate. Chilling is followed by further filtration (continuous refrigeration). There may be wine retention in an insulated tank for up to a week before filtering (Gasquet process). Finally, the clarified product is passed through a plate heat exchanger separated by thin stainless steel plates from incoming wine at ambient temperature.

Refrigeration and sulfur dioxide addition, prior to bottling, allow wines to remain bright in bottle for up to 18 months under normal storage conditions. Brief pasteurization may also be used after cold treatments. In addition, Kieselguhr with pad filtration may be a final processing after fining or refrigeration.

Bottling

In earlier years port was shipped in pipes to England for transfer to squat and bulbous bottles, designed for transporting wine from cask to table. Oxidation was a problem, since stored on their side such bottles did not allow cork contact. In 1775, bottles with longer bodies and shorter necks, were introduced to allow better storage. This change initiated the development of bottle aged vintage ports.

By the 1930s, bottling had become more centralized as suppliers, instead of merchants, could now bottle under customs and excise supervision. Duty was not payable until port was declared from bond. In the 1970s, more shippers began bottling under their own labels instead of shipping in bulk. The result was that it became possible to develop the international brands that currently dominate the consumer's attention.

Port Styles

The IVP governs how producers may use labels to describe port wines. There are four major premium categories of port: vintage, LBV, quinta, and aged tawny (Figure 5).

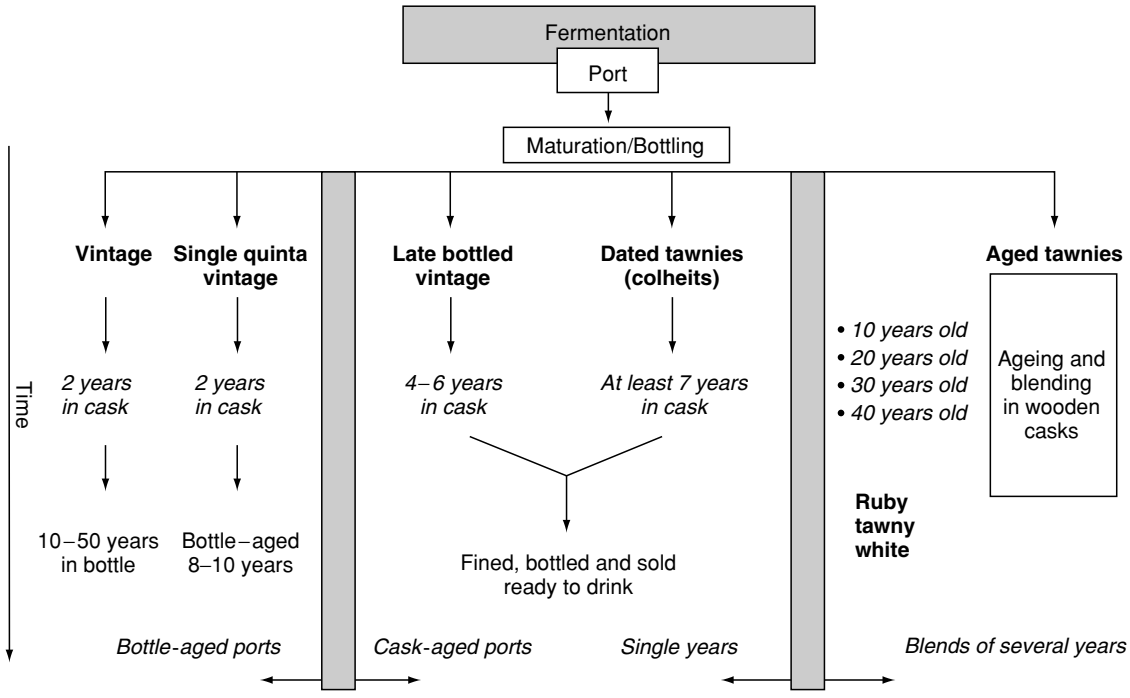

Figure 5 Processes involved in the different types of port production.

Vintage ports are wines of a single harvest, produced in a specifically recognized year, and have sensory characters regarded as exceptional. Such port wines spend 2–3 years in wooden casks or vats prior to bottling. The IVP has rights to descriptions of vintage and corresponding dates. Subsequently, maturation reactions occur in the bottle for 10–20 years and in some cases up to 50 years, with little possibility of oxidation. Such ports are never fined or filtered; the wines generate precipitates, or 'throw a crust,' and require decanting prior to consumption.

LBV ports are wines of a single harvest, aged in wood for 4–6 years. Bottling is between 1 July of the fourth year and 31 December of the sixth year. Bottle maturation reactions may continue for 5 years or more with continuing improvements. Traditional, now rare, LBVs are not fined or filtered, and throw a crust with improvements on bottle aging. However, modern LBVs are treated to remove solids.

Quinta are wines that come from grapes from a single property, named on the label. Such ports are made only in years not deemed good enough to declare a vintage. Single Quinta vintage ports have been available for some time, but currently, the market is expanding to include this designation for both ruby and tawny ports.

Aged tawnies are typically matured for 10, 20, 30, or 40 years, the average of ports blended. Old tawnies have a characteristic gold color. *Dated tawnies* are wines from single harvests, matured in oak casks for at least 7 years with the harvest and bottling date specified on the labels. A special reserve tawny contains wines that have spent 3–4 years in the cask prior to blending.

Wines Matured in Wood

Wood-matured ports, such as tawnies, are treated to encourage color lightening. Blend components are racked at least once a year to remove deposits and ensure oxygen dissolution. During the initial years of aging, container size is thought to be of little importance. Frequent use of wooden containers of considerable size such as 650-l oak casks, or vats, for short periods, stainless steel or tartaric acid-lined tanks.

Racking and the resulting wine aeration lead to oxidation, essential for the maturation of these port wines. During racking, more alcohol may be added, or maturing wine may be 'refreshed' by adding small quantities of younger wine. On creation of the blend, to assist maturation, wines are usually transferred to smaller vats or casks. When the desired degree of maturity has been reached, the final standard blends, with sensory attributes specific to each company, are prepared for bottling and export. As noted previously, no port may be sold for consumption in Portugal or abroad until it is at least 3 years old.

Wines Matured in Bottle

Vintage and LBV ports, bottled after only a few years in casks, have sensory attributes that are more dependent on must characters than on wine treatment. Vintage ports are racked infrequently to prevent excessive aeration, using smaller casks that are considered to provide a more controlled and uniform aeration. Bottles are stored in dark cellars of constant temperature with controlled ventilation and humidity. Color loss occurs slowly compared with wooded wines, and bottled ports retain their characteristic fruitiness, retaining a full flavor and purple–red colors for many years.

Composition and Analysis

E Cristovam, University of Adelaide, Adelaide, Australia
A Paterson, University of Strathclyde, Scotland, UK

Introduction

The demarcated Douro region – established in 1756 – consists of three subregions: Baixo Corgo, Alto Corgo, and Douro Superior (**Figure 1**), each with individual characters. Vines cover approximately 15% of this steep mountainous region, with the Baixo Corgo dominating. Small vineyards can be found throughout the region, with the larger mostly located in the Douro Superior. Vineyards producing grapes for port wines are graded on a point system, biased towards environment – *c*. 75% for vine productivity, altitude, soil, locality, and vine training, 14% from grape cultivars and degree of site slope, and >10% from local features. Grape varieties favored (around 7% points) include Tinta Francisca, Tinta Cão, Touriga Nacional, and Mourisco. Low-scoring musts are utilized in table wines.

Oxidative Aging – Tawny Ports

Tawny ports, matured from 10 to 40 years and particularly important, have maturations dominated by oxidative aging in wooden casks allowing oxygen migration, supplemented by oxygenation during frequent initial rackings. Small 'pipes,' as opposed to large vats, insure high cask surface area-to-volume ratios.

Reactions between wine congeners, together with cask-derived components, are important. Congener oxidations facilitate flavor evolution to characteristic mellowness with dried fruits, caramel, and vanilla notes. Most obvious, and dominating, are relationships between aging and color, with oxidations of red and purple anthocyanins, and losses as insoluble precipitates that include tannins. Tawny ports have yellow, amber, and tawny hues at intensities related to maturation period and cask choice, at rates dependent on original varietal choice and wine composition.

Reactions between acetaldehyde, anthocyanins and catechins yield reddish-blue condensation pigments that darken ports, 'closing up,' over the initial 6 months. Progressive lightening follows, with hue changes and gradual browning from competing aldehyde-induced reactions and direct condensations of anthocyanins with phenolics (**Figure 2**). Less is known about wood contributions to tawny ports spending over 50 years in old and recycled casks than character in red table wines. For tawny ports, color loss is essential and style-defining; in red wines it is detrimental to quality. (*See* **Antioxidants**: Natural Antioxidants.)

Nonoxidative Aging – Vintage Ports

Vintage ports age in bottles for up to 30 years. Initial oxygen, absorbed during bottling, is slowly reduced by reactions with anthocyanins and other wine components. Color is lost more slowly than in cask

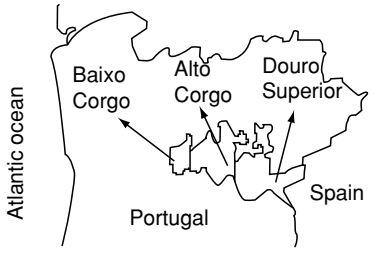

Figure 1 Região Demarcada do Douro – demarcated Douro region.

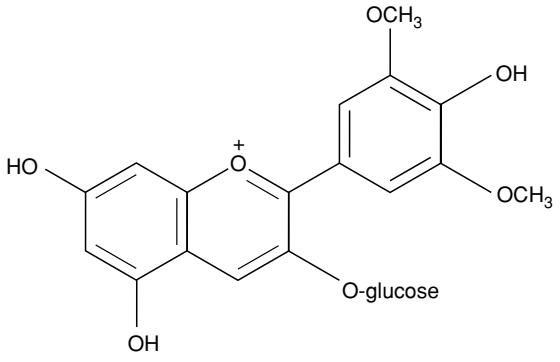

Figure 2 Oxidation/polymerization of phenolic components in ports.

maturations and the initially full-bodied wines retain flavor intensity, fruity characters, purple-red coloration, and freshness of youth for many years. Limited oxidation reduces aldehyde formation, precipitation of insoluble phenolic products, and leucoanthocyanins loss, yielding more condensed products.

Vintage ports show direct relationships between age and volatile acidity, and contents of ethyl acetate, pentyl alcohols, and sodium. This is from either maturation or modern wine-making strategies, including reductions in air contact of grapes; introduction of coating equipment; decanting without aeration; replacement of sodium metabisulfite by SO_2; and quality control in fortifying grape spirit. Clear aging effects include decreases in tartaric acid through deposition of potassium hydrogen tartrate, in citric acid content and total acidity, and increases in glycerol content and changes in alcohols.

Oxidative Reactions

Formation of Esters

In acidic, high-ethanol port wines, esterifications, slow in table wines, proceed at rates influenced by temperature and pH (pH 3.5–4.0), yielding ethyl esters of organic acids – lactic, succinic, malic and tartaric acids. Nonvolatile phenolics influence ester solubilities in the aqueous ethanol, removing such aroma-active congeners from head spaces, influencing perceived character.

Esters of higher (*iso*amyl, hexyl and 2-phenylethyl) alcohols show inverse maturation relationships through hydrolyses with equilibria functions of initial concentrations, those of parent acids and storage temperature. In aging, ethanol and acetaldehyde oxidations yield acetic acid, influencing pH, ester equilibria, and forming ethyl acetate. Such ester formation appears central to desirable flavor changes in fortified wines. (*See* **Oxidation of Food Components**.)

Formation of Carbonyl Compounds: Aldehydes, Acetals

In maturations, important aldehydes are converted to alcohols or combine with sulfur dioxide. Acetaldehyde is most abundant, but other aldehydes are derived from carbohydrate (furfural, 5-methylfurfural, and 5-hydroxymethylfurfural) or lignin degradations (vanillin, syringaldehyde, coniferaldehyde, and sinapaldehyde, cinnamaldehyde). Residual carbohydrates (approximately $100\,g\,l^{-1}$) in port contribute to such reactions.

Furfural, acetaldehyde, and other higher aldehyde contents can be directly related to maturation period, especially at higher temperatures. Woody flavor characters have been linked to aldehyde polymerization.

In acidic wines, acetals are principally formed from reactions between monohydric alcohols, and aldehyde carbonyl groups, notably of acetaldehyde. Oxidations yield flavor-active aldehydes, notably benzaldehydes, also contributing to acetal formation.

Other Reactions

Phenols derived from wood maturations include guaiacol, phenol, *m*-cresol, eugenol, 4-vinylphenol, and 4-vinylguaiacol. Lactones include β-methyl-γ-octactone. Wood-extracted aldehydes include vanillin, syringaldehyde, coniferaldehyde, and sinapaldehyde.

Classic Enological Analyses

Port Acidity

Total titratable acidity values of port wines at pH 7.0 range from 5.86 to $3.45\,g\,l^{-1}$ as tartaric acid. Older wines have increased volatile and total acidities through acetic acid formation. In young ports, total acidity is reduced by tartrate precipitation.

Volatile Acidity

Determined by official Office International de la Vigne et du Vin (OIV) methods, volatile acidity is dominated by acetic acid (around 90%) but propionic, formic, and butyric acids also contribute. Such acids are from yeast and lactic acid bacterial fermentations and wood maturation reactions. Port wines generally have volatile acidity values $< 0.35\,g\,l^{-1}$ acetic acid, although $1.02\,g\,l^{-1}$ was recorded for a 40-year-old tawny and a 1960 Colheita tawny.

Organic acids

Grapes contribute tartaric and malic acids to wines. Tartaric acid concentration varies during grape ripening, and is more related to climatic conditions than varietal character. Tartrate precipitation during maturation decreases wine contents to 0.445–$1.688\,g\,l^{-1}$, independent of age or wine type.

In contrast, malic acid contents, more dependent on grape variety than climate, fall during ripening. Contents are lower in younger port wines, than older, possibly through later picking in recent vintages.

Lactic acid, formed by strain-dependent anaerobic yeast metabolism, is present in port wines in the range $0.3–1.68\,g\,l^{-1}$, independent of wine age.

Type differentiation was achieved on the basis of contents of citric acid and alcoholic strength (Table 1) in 21 red and four white ports, and six Spanish

port-style wines. Australian port-style wines have higher ethanol contents. (*See* **Acids**: Natural Acids and Acidulants.)

Alcoholic Strength

Alcoholic strength (% v/v ethanol) in red ports ranges between 19 and 22%, with white ports as low as 16.5% (light, dry white port). Spirit contributes about 20% initial volume to port wines; subsequent alcoholic strength adjustments dilute wine congeners, and increase precipitation of tartrates and extraction of wood substances. Alcoholic strength changes with water and ethanol evaporation through staves; it is dependent on storage conditions and wine sugar content.

Sulfur Dioxide

Total SO_2 is from summations of iodometric titrations of free and bound components in acid conditions after a standard pretreatment by the Portuguese official method (Portaria 985/82 and pr NP-2220). Values between 9 mg l^{-1} (Colheita tawny, cask wine) and 99 mg l^{-1} (10-year-old tawny, commercial wine) have been reported. In vinifications, SO_2 is added for microbial stability and antioxidant properties. Free SO_2 rapidly binds to ethanol but also hydrogen peroxide, produced during phenol oxidations, reducing further oxidation.

Reducing Sugars and Glycerol

Must origin and quality, shipper requirements, and house style, all influence residual sugar content, typically 80–120 g l^{-1} from the Lane-Eynon method.

Certain sweet red wine musts – geropigas – can be 150 g l^{-1} residual sugar; drier, more fermented musts have 20–50 g l^{-1}. White geropigas are made for blending or specialty products; dry white aperitif ports contain < 50 g l^{-1} sugar. Glucose and fructose concentrations range from 161 g l^{-1} (Colheita tawny, cask wine) to 63 g l^{-1} (30-year-old tawny, commercial wine). Fructose at 60–70 g l^{-1} is more abundant than glucose (40–50 g l^{-1}).

Typical must specific gravities are 1090–1100 for red and 1085–1095 for white ports; fermentations are terminated around 1045. In Australian port-style wines, specific gravities (20/20 °C) of 1036 and 1080 make these even sweeter than the sweetest port wines (Table 2).

The IVP (Instituto do Vinho do Porto) recognizes classes of port wines, varying in sugar content (Table 3).

Glycerol, the second most abundant alcohol, contents are from 3 to 8 g l^{-1}. Glycerol acetals are found as in other aged fortified wines, and *trans* 5 hydroxymethyl-2-methyl-1, 3-dioxolane in port.

Dry Extract, and Folin-Ciocalteu Index

Dry extract values are determined indirectly as density of the residue without alcohol, following replacement of alcohol with an equivalent volume of water in the Portuguese norm (Portaria 985/82 and pr NP-2222) and OIV methods. Values in Colheita tawnies range from 120 to 188 g l^{-1}. Maturation changes include: alcohol and water evaporations; extractive increases; and precipitation of salts,

phenolic compounds, proteins, polysaccharides, and other components.

The Folin-Ciocalteu index, from European Economic Community (EEC) recommended method (EEC no. 2676/90), expresses wine total phenols (anthocyanins, tannins, flavones, flavonols, catechins, cinnamic acids, and related compounds).

Tannins and Phenolic Compounds

Tannin levels in ports have been reported to between 400 and 600 mg l^{-1}.

Color in ports, principally from soluble grape-skin anthocyanins (Figure 3), is from malvidin (3-glucoside, 3-*p*-coumarylglucoside, and 3-acetylglucoside, in decreasing order). Varietal differences in such compounds are important. Aldehyde-bridged polymers of anthocyanins and other phenolics dominate over direct condensation of anthocyanins with phenolics, through free aldehyde contents (50–100 mg l^{-1}) of young ports. With aging, anthocyanins rapidly disappear, replaced by polymers of progressively decreasing absorbance, at rates depending on racking and cask choice. Prolonged oxygen diffusion yields wine of tawny coloration influenced by wood extractives and composition.

Wine aeration during filling and racking seems more important for color changes than subsequent oxygen diffusion from studies of varietal port wines aged in miniature recycled-stave casks. The reduced soluble extracts, including ellagic tannins, of recycled wood suggest limited contribution to wine changes, dominated by an evolution in phenolic components. Port maturations are likely primarily driven by oxidation, influenced by grape varietal differences, with inert but permeable casks making little direct contribution. (*See* **Tannins and Polyphenols**.)

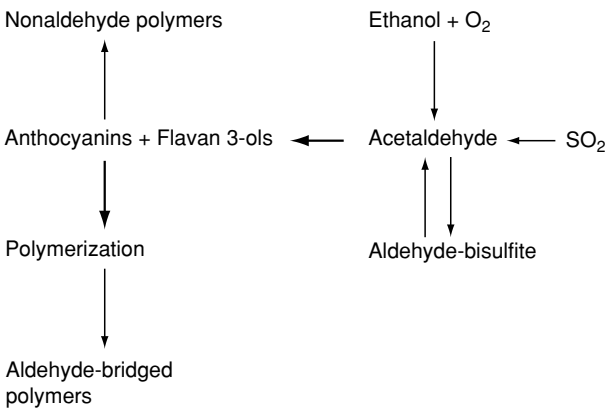

Figure 3 Structure of malvidin 3-glucoside, an anthocyanin occurring in grapes used for port wine production.

Color Measurements

Spectrophotometric measurements at $A_{520\,nm}$ and $A_{420\,nm}$, yield tint ($A_{420\,nm}/A_{520\,nm}$), and color density ($A_{520\,nm} + A_{420\,nm}$) values and at natural pH specify redness and brownness in color, respectively. CIELAB (Commission Internationale de l'Èclairage) 76 L*a*b values (hue, angle, and chroma), are high L* for lightness and low for darkness; a* measures redness and b* brownness. Total pigments and total phenols can also be determined.

Metal Ions

Trace metal contents differentiate between Portuguese ports and similar styles in wine from Spain. Rubidium and manganese contents (Table 4) mirror soil differences, although rubidium varies with maceration intensity, as can lithium, and manganese from vineyard treatments. Iron and aluminum concentrations in Spanish wines may also reflect soil differences.

Volatile Compounds in Port

Thirty-five volatile aroma components were quantified in 20-year and 100-year Australian port-style wines with higher ethyl lactate (110–370 mg l^{-1}) and diethyl succinate (61–130 mg l^{-1}) than in younger wines. Only the former contributes to aroma. *Trans*-β-methyl-γ-octalactone (oak lactone) contents were 0.8–2.2 mg l^{-1}.

Furfural, 2-acetylfuran, 5-methyl furfural, ethyl lavulinate, ethyl furoate, and 5-ethoxymethyl furfural are derived from carbohydrate degradation, heating, and prolonged storage. The older wine had more volatile components from wood and carbohydrate degradation.

Table 4 Metal ions in red and white ports and Spanish port-style wines

	Portuguese red ports	*Portuguese white ports*	*Spanish port-styles*
Rb (mg l^{-1})	0.66–1.43	NA	0.00–0.44
Mn (mg l^{-1})	0.77–1.32	NA	0.20–0.58

Fe (mg l^{-1})	1.0–3.4	NA	3.6–7.4
Li (μg l^{-1})	17–54	31–37	45–64

NA, not analysed.

In two commercial Portuguese ports, a ruby (young wines retaining an intense dark-red color) and a tawny, 141 volatile flavor components were identified: 81 esters, 14 alcohols, 9 dioxolanes, 6 hydrocarbons, 5 acids, 5 carbonyls, 4 nitrogen components, 3 hydroxy carbonyls, 2 phenols, 2 alkoxyalcohols, 2 alkoxyphenols, 2 halogen compounds, 2 lactones, 2 other oxygen heterocyclics, 1 sulfur component, and 1 diol.

Alcohols were most abundant, followed by esters, dominated by ethyl esters and lower-molecular-weight acetates, the latter increasing with maturation. The tawny port was rich in flavor-active succinates (approximately 100 $\mu g\,g^{-1}$) from slow esterification and *trans*-esterification reactions at wine pH and maturation stave contact. Ethyl lactate was present at 15 and 30 $\mu g\,g^{-1}$ in ruby and tawny ports, respectively, and together with diethyl malate and succinate may indicate age, as can acidic degradation of fructose to 5-hydroxymethylfurfural. Other furan derivatives contribute baked and caramelized flavor notes to older wines. The flavor contribution of β-methyl-γ-octactone, important in oak-aging, is unclear in port wines, as are relationships between maturation and concentration of vitispirane (abundant in the ruby; traces in the tawny).

Reserva ports (single harvest without blending), matured in wood under oxidative aging, show maturation increases in diethyl succinate, ethyl acetate, ethanal, octanal, glyoxal, and methyl glyoxal (Table 5) and also benzaldehyde (oxidation of the alcohol), *trans*-2-octenal, 2-decanone, and 2-tridecanone, but inverse relationships for acetoin and methanol.

Differentiation of red ports (21) from similar Spanish wine (6) on the basis of volatiles concentrations are shown in Table 6.

Characteristic port volatile components are esters and alcohols, the former dominated by ethyl esters, acetates, and succinates. Older tawny ports are rich in, and age-differentiated by, contents of 2-propenoic acid, diethyl succinate, butanedioic acid, oak lactone, ethyl dodecanoate, *iso*amylbutyrate, 1-butanol, decanoic acid, and ethyl lactate, amongst other components. Vintage ports have been differentiated from late-bottled vintage (wines of a single harvest, aged in wood for 4–6 years) from 3-butanoic acid contents.

Table 5 Concentration of volatile compounds in two Portuguese Reserva ports

	Reserva ports	
	1968	*1991*
Glyoxal ($\mu g\,l^{-1}$)	1302.9	669.7

Other esters ($mg\,l^{-1}$)	0.53–1.30	0.22–0.53

Flavor in Port Wines

Port wine flavors originate in the volatile and nonvolatile components in grapes, from fermentation or maturation. Although ports have traditionally been vinified using endogenous microflora, including a range of yeasts and bacteria, there have been moves towards encouragement of yeast mono- or at least mixed cultures, for example *Saccharomyces cerevisiae* UCD 522. Butanol, isobutanol, and 1-hexanol originate from yeast fermentation of carbohydrate and amino acid sources; hexyl acetate and 2-phenethyl acetate are also fermentation products. Ethyl lactate and diethyl succinate, resulting from esterification reactions, increase in the wines due to storage and long maturations. Oxidation reactions originate mainly from benzaldehyde and ethyl-2-phenylacetate, while 2-phenethanol and oak lactone result from wood extraction.

Few published studies describe flavor components, as opposed to volatiles. Young ports have notably astringent flavor characters through high contents of total and individual phenols with a *harshness* mellowed by wood maturations. Older ports have 'softer' characters with increased flavor complexity.

Flavor characters evolve through oxidation and polymerization of solution nonvolatile phenolic

Table 7 Variables used to model vintage age prediction

Variable	*Code*

Tone (H*), chroma (C*), clarity (L*), and saturation (S) are four CieLab parameters.

compounds, changing partitioning of aroma-active components between wine head spaces and liquid. The products of oxidations of congeners and ethanol, depolymerizations and extraction of wood components all influence partitioning. Grape varietal character is central to flavor development, but wood aging provides oxidative processes and nonflavonoid phenolics from lignin and tannin degradations determining final character.

Relating key sensory attributes to concentrations of volatile flavor components would assist understanding of port wine character. Partial least-squares (PLS) regression has facilitated modeling relationships between compositional factors and age in vintage ports. Certain variables (A-I, Table 7) showed a low modeling power (32–49%) in predicting age, while others (J–S) contributed greatly (above 70%). Wine aging is generally understood as polyphenol evolution, using Sudraud, Garoglio, and other indices including color evolution. The importance of carbonyl compounds in vintage port wine aroma has also been recognized.

In further PLS modeling of ports, clear relationships between sensory data and concentrations of head space components, and between sensory and nonvolatile component data, support hypotheses that changes in nonvolatile phenolics influence the perception of flavor character through changing head space congener concentrations. Relationships were also established between such components and total maturation age, through oxidation and polymerization of wine compounds. Prediction of intensity of certain flavor notes has also been possible from solution concentrations of congeners, notably for caramel and smooth characters. (*See* **Flavor (Flavour) Compounds:** Structures and Characteristics; **Sensory Evaluation:** Aroma.)

Port and Replica Wines Production

With the success of the Portuguese product, there have been a number of attempts to produce similar wines, including Starboard, in other countries, notably Australia, California, and South Africa. In 2001 port sales were healthy, suggesting a good future. However, non-Portuguese producers have been required, with changes in international trading, to stop the use of the port descriptor in the labeling of their fortified wines and future exports look problematic.

Properties and Determination

M A Amaro López and R Moreno Rojas, University of Córdoba, Córdoba, Spain

Background

Potassium is a light, soft metal and a strong reducing agent, discovered by Davy in 1807 in caustic potassium (KOH). It is widely distributed in minerals such as sylvin (KCl), carnallite ($KMgCl_3$ or $MgCL_2{\cdot}KCl$), langbeinite ($K_2Mg_2(SO_4)_3$) or polyhalite ($K_2Ca_2Mg_2(SO_4)_4{\cdot}2H_2O$). Potassium is a very abundant metal and is the seventh most abundant element in the earth's crust (2.59% corresponds to potassium in the combined form). Sea water contains 380 p.p.m. of potassium, making this mineral the sixth most abundant in solution.

Potassium is used extensively, mainly in the form of potassium salts, in various fields such as medicine (iodide as a disinfectant), photographic processing (carbonate), explosives (chlorate and nitrate as powder), defreezing agents, poisons (potassium cyanide), metallurgy and basic chemistry (hydroxide in, for example, strong bases, oil sweetening, CO_2 absorbent, chromate and dichromates as oxidants, carbonate in glass industry), fertilizers (nitrate, carbonate, chloride, bromide, sulfate), detergents and soaps (hydroxide and carbonate), coolants in nuclear reactors (NaK alloy), etc.

Potassium (atomic number = 19) forms part of the group of alkali metals classified between sodium (atomic number = 11) and rubidium (atomic number = 37). It has an atomic weight of 39.098, oxidation state 1 and an electronic orbital structure of [Ar] $4s^1$. This electronic configuration (one electron in the 4s orbital) enables potassium to ionize easily to the cation K^+ owing to the loss of its most external electron. It does not appear as a native metal in nature. Potassium exists in nature in three isotopes: ^{39}K (93.26%), ^{40}K (0.0117%) and ^{41}K (6.73%). ^{40}K is radioactive and responsible for most of the naturally occurring internal radioactivity in the body. This property enables researchers to monitor total body potassium values as a function of age and disease.

The behavior of potassium in its metallic form is very similar to that of sodium, with which it is closely related, both being alkali metals essential for life owing to their involvement in cellular physiological development and the regulation of body fluids, together with

chlorine, thus explaining why it is common for both alkali metals to appear in the form of their corresponding chloride salts. Given this relationship with cellular liquids, potassium, sodium, and chlorine are also known as electrolytes (ions with greater proportions in the composition of organic fluids).

The K^+ ion is the main intracellular cation, with an approximate $[K^+]$ of $5.6\,g l^{-1}$ in cellular fluids, approximately 30 times more concentrated than in plasma or interstitial liquid ($0.15–0.20\,g l^{-1}$). Its high intracellular concentration is regulated by the cell membrane through the sodium–potassium pump. The intracellular K^+ regulates the catalytic action of numerous enzymes, through the attachment of the cation to active locations with negative charges of the enzymatic proteins, modifying the conformation of the molecule and its activity, as well as participating in cellular division processes.

The small percentage of extracellular potassium (2% of body potassium) is of great physiological importance, since it is a critical determinant of neuromuscular excitability (nervous impulse and contraction of bone muscles). At the cellular membrane level, the transport and permeability of energy-dependent potassium, with simultaneous excretion of sodium linked to the Na/K enzyme ATPase, is essential for generating the potentials of membranes required for the proper functioning of nervous and muscular cells. It also helps to maintain the acid–base equilibrium and blood pressure.

Homeostasis of potassium is still the subject of research, although it is known that 90% of dietetic potassium is absorbed in the small intestine and that body potassium (1.6–2 g per kilogram of body weight) is regulated by renal glomerular filtration and tubular secretion, potassium being lost on a daily basis through urine, gastrointestinal secretions (ileum and colon) and, to a lesser degree, sweat. Provided that renal function is normal, it is practically impossible to reach an excessive level of potassium with normal dietary intake, since the kidney is capable of excreting more potassium than it can filter. (*See* **Potassium**: Physiology; **Sodium**: Physiology.)

The effect of potassium on blood pressure has been discussed in recent reports on metaanalysis; these have confirmed that increases in doses of potassium from 60 to 80 mmol per day (2.3–3.1 g per day) may prompt a decrease of 4 mmHg in systolic blood pressure and possibly reduce the number of deaths related to high blood pressure by 25%.

The use of potassium chloride salts as substitutes for sodium chloride, in individuals in whom the intake of sodium is restricted because of problems relating to hypertension, is a questionable alternative, since cardiac arrythmias have been reported in association with the excessive intake of salt substitutes containing potassium chloride. In this connection, hyperkalemia is recommended in healthy individuals for intakes exceeding 17.5 g per day (acute toxicity limit), highly unlikely in normal diets, and certain risks for individuals with renal dysfunctions not detected with intakes of potassium exceeding 5.9 g per day (safest maximum dose). Cardiovascular or neuromuscular complications arising from situations of hypo- and hyperkalemias are resolved favorably by correcting the plasmatic potassium levels. (*See* **Hypertension**: Hypertension and Diet.)

The mean potassium intake in Western populations ranges between 1.6–5.9 g per day and the required dietary intakes of this are met without any problem, thanks to the ubiquitous presence of potassium in both vegetable- and animal-based foods. The Scientific Committee for Food of the European Community recognizes that the Minimum Recommended Intake of potassium is 1600 mg d^{-1}, and the Reference Intake for the population 3100 g d^{-1}.

Analysis of Potassium

Potassium can be analyzed using a number of different methods, although many of these are not commonly used for routine analysis of potassium in food and biological samples. In the case of potassium, there has been a shift from the old gravimetric methods, based on the precipitation of potassium using chloroplatinate or tetraphenylboron, to the spectroscopic methods, mainly flame emission and flame absorbance spectroscopy and which, according to the scientific community, are the most commonly used.

However, there are other techniques for analyzing potassium that are not as 'popular' as those mentioned above, and equally applicable to other mineral elements. These include selective electrodes, nuclear magnetic resonance spectroscopy, X-ray analysis, helium glow photometry, inductively coupled plasma optical emission, inductively coupled plasma atomic fluorescence, ion-scattering spectrometry, and other methods. Another procedure can be used – namely, radioactive dilution of potassium isotopes – when determining both potassium content and its distribution in extra- and intracellular compartments.

Emission and absorbance spectrometry have been the most widely used techniques for analyzing trace elements in biological and food samples. Their widespread use is justified by their analytical specificity, good detection limits, excellent accuracy, and relatively low cost. Both techniques are based on energy modifications of the electronic orbital structure of the atoms of mineral elements in response to certain

stimuli (flame emission spectrometry and incidence of a beam of light of specific wavelength for absorption). (*See* **Sodium**: Properties and Determination.)

The determination of potassium by spectroscopy requires a stage of preparation of samples for analysis that entails the drying, grinding, and destruction of the organic matter of the sample. There are two alternatives for destroying the organic matter of biological and food samples, both with different variants: wet oxidation and dry ashing. Both techniques yield reasonably comparable results, and it is often the analyst who decides on which technique to employ. (*See* **Cadmium**: Properties and Determination; **Spectroscopy**: Atomic Emission and Absorption.)

Flame Emission Spectroscopy

The determination of potassium in biological and food samples, as in the case of sodium, may be performed using flame photometers and atomic absorption spectrophotometers (with the option of working in emission conditions). A specific wavelength of 766.5 nm is used in order to determine potassium, and the detector is adjusted to the response given to the pattern of greatest concentration used. Efforts must be made to avoid possible interference problems owing to the matrix characteristics of the sample in flame emission photometry; this can be achieved by separating the element from the object of study, eliminating the ions responsible for the interferences, or using a compensatory technique. For this purpose, recommended practice for correcting interferences includes the addition of lithium (as an internal standard) both to the samples and to the standards. It is important to obtain a suitable calibration curve, either linear by diluting the samples, or by logarithmic adjustment between emission values and potassium concentration. (*See* **Sodium**: Properties and Determination.)

Flame Absorption Spectroscopy

The determination of potassium using an atomic absorption spectrophotometer requires a light source (wavelength for $K = 766.5$ nm) and an atomization source (flame). For the light source, arc discharge lamps may be used for K, although hollow cathodes are preferred. Standard working conditions for analyzing potassium by atomic absorption spectroscopy are listed in Table 1.

Comparing flame emission photometry and atomic absorption spectroscopy, the detection limits for potassium ($\mu g\,ml^{-1}$) are 0.0005 and 0.005, respectively. Using an atomic absorption spectrophotometer, the accuracy and precision of potassium analysis by flame emission can be obtained (Table 2).

Table 1 Standard conditions for potassium analysis by atomic absorption spectrometry

Spectrometers setting	*Potassium*
Wavelength/slit (nm)	766.5/0.2
Nebulizer	Spoiler
Oxidant	Air
Fuel	C_2H_2
Flame condition	Oxidizing
Optimum concentration range in solution ($\mu g\,ml^{-1}$)	1–10
Detection limit ($\mu g\,ml^{-1}$)	0.005
Sensitivity 1% absorption ($\mu g\,ml^{-1}$)	0.05
Interferences	Ionization

Table 3 shows a series of official methods for determining potassium, based on flame emission and absorption spectrophotometry.

Inductively Coupled Plasma-atomic Emission Spectrometry (ICP-AES)

There are numerous references to the use of this powerful technique in multielement analysis by emission spectroscopy. ICP-AES enables samples with a high degree of variability and minimum interferences to be used. Samples can be prepared by either wet oxidation or dry ashing, and a wide range of concentrations can be used without the need to dilute or concentrate the sample. Also, many of the other mineral elements can be quantified, thus reducing analysis time. These advantages, together with the high speed and excellent instrument stability, make ICP-AES highly attractive.

For potassium determined by ICP-AES in plant tissues, a solution detection limit of 0.06 ($\mu g\,ml^{-1}$) and a sample detection limit of 2.0 ($\mu g\,g^{-1}$, based on a 2-g sample diluted to 50 ml) are recommended. There is also an AOAC Official Method (984.27) for the determination of potassium in infant formula by means of ICP-AES, which recommends the following ICP emission spectrometer operating parameters for potassium; wavelength (nm) = 766.5, no background correction and low standard = 0 and high standard = 200 ($\mu g\,ml^{-1}$). The AOAC also recommends an Official Method (985.01) for the analysis of potassium in plants and pet foods by ICP spectroscopy.

Potassium-selective Electrodes

Potassium-selective electrodes have developed from the first ion-selective glass electrodes, with little ion selectivity, to potassium-selective electrodes based on valinomycin, a highly specific neutral carrier compound for analyzing potassium, to potassium-sensitive electrodes with ion-exchange compounds dissolved in organic solvents that are not very specific

because of significant interference induced by the presence of sodium and other cations in organic solutions. Ion-exchange electrodes have faster response times than those of organic solvent solution membranes of valinomycin, although the latter show fewer interferences from other ions. However, neither type of electrode is effective in organic solvents. Furthermore, electrodes measure ion activity and therefore do not detect ions linked to other molecules or potassium that is not in solution.

Ion-selective electrodes are also incorporated into gasometric equipment for measuring electrolytes (Na, K, Cl, and ionized Ca), in oxygenation, ventilation, basic-acidic state, and electrolytic metabolism of patients with respiratory problems. In this context, it is useful to quantify the exchange of gases and electrolytes through cellular membranes; for this purpose, the so-called *anion gap* is calculated, which interrelates with sodium (*anion gap Na*), potassium (*anion gap K*), bicarbonate, and chlorine. This parameter provides information on electrolytic alterations and the presence of toxins in blood, and also helps to control quality in laboratories by interrelating informed values (in normal individuals, not very high values).

Some developments in the field of potassium-selective electrodes have focused on the appearance of novel potassium-selective valinomycins in the development of ion-selective sensors based on new technologies and on the combination of these ion-selective electrodes with other analytical methodologies, as shown in Table 4.

Nuclear Magnetic Resonance (NMR)

NMR is used to study the relationship between metabolism and function in living systems as simple as cells in culture and as complex as human subjects (e.g., the effect of temperature on the sodium/potassium pump in red blood cells). As a noninvasive, nondestructive spectroscopic technique, NMR offers a powerful approach to the study of ion balance in intact biological systems. The aims are to validate new NMR methods, to elucidate tissue-specific mechanisms, and to draw conclusions with respect to basic concepts and design in tissue metabolism and function.

The possibility of determining potassium by NMR is due, on the one hand, to the relatively high concentrations of the cation in cellular tissue and, on the other hand, to the natural abundance of ^{39}K nuclide (NMR sensitivity is about 2000 times less than that of one hydrogen atom) and the short longitudinal relaxation time. The concentrations of intracellular and extracellular potassium in tissues may be quantified by applying impermeable cell-membrane chemical shift reagents.

However, this quantification by NMR measurement depends on the NMR invisibility of the potassium actually present, in accordance with other techniques. Several previous studies have shown that only approximately 20% of cardiac intracellular potassium is visible with current NMR techniques. This NMR sensitivity of potassium (about 60%) represents a serious obstacle to its proper quantification in biological tissues. (*See* **Spectroscopy**: Nuclear Magnetic Resonance.)

A study of factors affecting ^{39}K NMR detectability in rat thigh muscle showed that the signal may be substantially higher (up to 100% of total tissue potassium) than values previously reported of around 40%, these signals presenting two superimposed components – one broad and one narrow – and involving improvements in spectral parameters (signal-to-noise ratio and baseline roll), together with computer simulations of spectra that enable a spectrum quality with a major effect on the amount of signal detected, largely owing to the loss of detectability of the broad signal component.

Biological and biochemical cellular research in connection with the quantification of ions in intracellular and extracellular compartments, transport and ionic metabolism at the level of different cells and biological tissues, are based on the use of ^{39}K NMR spectroscopy, together with ^{23}Na and ^{31}P NMR studies.

Proper ion equilibrium between intra- and extracellular compartments is required for normal physiological function. Conversely, alterations in membrane ion transport occur in numerous pathological states. By introducing an anionic paramagnetic shift reagent into the medium, NMR signals of intra- and extracellular Na^+ and K^+ can be resolved, enabling ion transport processes to be studied by NMR. Unfortunately, rare NMR active nuclides that are isotopes of the 100% naturally abundant $^{23}Na^+$ and $^{39}K^+$ are not available for tracer kinetic studies of Na^+ and K^+ transport. However, Cs is a biologically active analog of K^+, and the 100% naturally abundant NMR active $^{133}Cs^+$ nuclide can be employed to examine K^+ transport. Other studies have shown the potential of ^{39}K NMR as a useful tool in the study of protein–cation interactions and the binding of K^+ to double-helical DNA.

X-ray Analysis

X-ray analysis is another nondestructive, noninvasive, *in-vivo* technique for determining mineral elements – including potassium – in foods and biological samples. X-ray analysis is based on bombarding a small area of the powdered sample with high-energy X-rays, measuring the Kα line of the element using one of several different detectors according to the wavelength of the emitted radiation. The limitations of this technique are related to scope, in terms of detected elements and their concentration range. X-ray analysis is combined with the use of an electronic microscope for quantifying and locating the mineral element in the sample, even at the subnuclear compartmental level. Another limitation of the X-ray

technique relates to the complexity of the sample preparation process for electronic microscopy.

The bibliography describes different X-ray analysis techniques for measuring potassium in food and biological samples, as indicated in Table 5.

X-ray fluorescence (XRF) can be successfully used for the qualitative and quantitative elemental analysis of various agricultural products. Its simplicity, high throughput and automation possibilities make it useful for screening large numbers of samples. The K content of tea samples has been determined by XRF analysis (an uncommon method for mineral analysis in food), and the findings have been compared with the results obtained using atomic emission techniques, with the conclusion that the XRF system can be used effectively for quantitative analysis of the K content of tea samples.

The methods for preparing the specimens of liquid media of the organism and XRF analysis are simple and fast, entail no disintegration of the sample, and allow measurements of elements at sigma $1 = 0.02$ at concentrations of $12\,\mu g\,ml^{-1}$ to be obtained. The method is preferable and promising for several basic elements (P, S, Cl, K, Ca), which are difficult to measure using other methods.

The use of total reflection X-ray fluorescence analysis (TXRF) in life sciences is considered a powerful analytical tool for simultaneous multielement determination. TXRF is basically an energy-dispersive technique, with the sample being excited in total reflection geometry. This technique only requires minute samples with simple preparation and involves a large dynamic measuring scale. Simultaneous detection of almost all chemical elements and lower limits of detection are achievable in optimized excitation conditions. The preferred sample types are aqueous and acidic solutions, particularly samples digested with HNO_3. Special preparation techniques are required for solids and other samples.

Table 5 X-ray techniques for potassium analysis in food and biological samples

Samples	*X-ray analysis*
Meat and meat products	X-ray fluorescent analysis
Serum and peripheral blood cells	
Fresh green tea, black tea, and tea residue	
Leaves of lettuce	Electron microprobe X-ray analysis
Walls of the mosaic virus-infected wheat leaf cells	Energy-dispersive X-ray analysis
Perisperm tissues of seeds	
Cancerous and normal tissues	Total reflection X-ray fluorescence analysis
In vegetable foodstuffs and their respective cell fractions	
Cancerous breast tissue	
Human brains	Proton-induced X-ray emission analysis
Human atherosclerotic artery wall	

The application of the proton-induced X-ray-emission (PIXE) method has enabled us to determine not only the concentrations of elemental composition, including K, but also their localization in different artery-wall regions. Furthermore, the usefulness of the micro-PIXE method for studying biomedical materials has also been considered.

Radioactive Isotopes

The dilution of radioactive isotopes of potassium is applied to establish the concentration and distribution of the amounts of potassium in the different sample compartments. The dilution of radioactive isotopes enables the volumes of the organic tissue compartments to be determined. The differences in potassium concentrations between the extra- and intracellular spaces may be studied by diluting the radioactive isotopes of potassium.

For this purpose, it is important to take into account that animal and plant tissues present different potassium compartments in which the ion is accumulated, and this conditions the radioactive isotope dilution process. In animal tissue, three cellular compartments (plasma + extracellular fluid, cells, and spaces where ions are closely fixed or form complexes) are described, whereas in plant tissue, only two spaces (cytoplasm and vacuoles) must be considered, since the extracellular space is small in size. This compartmental distribution conditions the process of radioactive isotope dilution.

In animal tissue, the method involves incorporating a known amount of the tracer isotope of potassium into the extracellular compartment and monitoring the changes in plasma isotope concentration until equilibrium is reached with all the compartments. This entails estimating the distribution of potassium (1) in extracellular fluid, using tracer polymers (inulin or polyethylene glycols) that cannot penetrate cell membranes, (2) in cellular volume, by subtracting the extracellular volume from the total distribution space (determined using labeled water, tritiated or deuterated), and (3) in the space where the ion is strongly fixed or forms complexes (this is calculated by subtracting the amount of extracellular potassium + cellular potassium from the amount of potassium isotope injected).

In plant tissue, the dilution of radioactive isotopes of potassium presents limitations owing to the difficulty involved in terms of separating vacuolar volume and cytoplasmic volume. For this reason, more appropriate methods than radioactive dilution methods have been

developed for determining cytoplasmic and vacuolar potassium concentrations, namely ion-selective microelectrodes or X-ray microprobe analysis.

Introduction

Potassium is the most abundant intracellular cation in the human body and plays an important role in a variety of cell functions. This review summarizes the main aspects of potassium physiology and nutrition, including absorption, transport, distribution, storage, and excretion, as well as homeostatic mechanisms of K balance.

Role in the Body

Potassium is essential for the muscular, cardiovascular, nervous, endocrine, respiratory, digestive, and renal systems. Cell metabolism depends on the maintenance of a high intracellular K^+ concentration. Many of the body functions of potassium are due to its ionic character: it generates gradients of concentration, potential, and pressure. Potassium is the predominant osmotically active species inside the cell. Together with other ions such as sodium and chloride, which are characteristic of the extracellular fluid, potassium determines osmolarity and plays a major role in the distribution of fluids inside and outside the cell and hence in the maintenance of cellular volume. In addition, potassium participates in the regulation of the acid–base balance and is involved in cellular growth and division, energy transduction, glycogenesis, protein synthesis, hormone secretion, etc. Consequently, its deficiency causes growth retardation, with a pronounced decrease in circulating levels of growth hormone and somatomedin C and inhibition of protein synthesis.

Cell excitability and muscle contraction depend on potassium. The transmembrane electrical potential is determined by the ratio of the intracellular to extracellular potassium and sodium concentrations, in particular that of potassium. Differences in K^+ and Na^+ concentrations across cell membranes are maintained by the specific permeability to each of these ions and by K^+/Na^+-ATPase activity (K^+/Na^+-pump). Thus, K^+ is critical for the excitability of nerve and muscle cells.

During vigorous exercise, potassium is released from muscle cells, leading to an increase in extracellular potassium concentrations which facilitates ongoing muscle contraction and induces vasodilatation, increasing local blood flow. However, liberation of potassium also leads to muscular fatigue. Training reduces the exercise-induced rise in plasma K^+ concentration and also increases the total activity of Na-K pumps in muscle. The potassium internal balance helps to delay the onset of fatigue during exercise and to restore homeostasis during recovery.

Potassium can be defined as a cardioprotector nutrient. It acts directly on the heart, regulating its mechanical and electrical properties. Epidemiological data suggest that potassium intake and blood pressure are inversely correlated. The greatest hypotensive

effect of potassium occurs in hypertensive patients and in subjects with a high sodium intake. The mechanisms involved include: enhancing natriuresis, baroreflex sensitivity, direct vasodilatation, catecholaminergic functions, improvement of glucose tolerance, and effects on the central nervous and the renin–angiotensin–aldosterone systems.

Potassium also protects against stroke, which is the third leading cause of death worldwide (after coronary artery disease and cancer). This electrolyte may decrease ischemic as well as hemorrhagic stroke risk through its effect on blood pressure on one hand, and by inhibiting the formation of free radicals at the endothelial cell level, thus affecting vasomotion, on the other hand. Moreover, potassium inhibits the proliferation of smooth muscle cells, platelet aggregation, and arterial thrombosis. Potassium may also prevent the death of cerebellar neurons.

Interrelationships exist between potassium and other nutrients. Potassium and sodium are strongly metabolically interrelated, principally due to K^+/Na^+-ATPase. This enzyme also provides the driving force for the transport of other solutes, such as amino acids, phosphate, vitamins, and glucose. Potassium depletion, which is more intense if there is a simultaneous excess of sodium, enhances urinary loss of calcium. This interaction may have adverse effects on bone and blood pressure.

Requirements and Daily Intakes

To date, no recommended potassium intake has been unanimously established. The UK report on dietary reference values established a reference nutrient intake of 3500 mg day^{-1} for adults. Lower amounts were recommended for infants (mg day^{-1}): 800 and 850, 0–3 months and 4–6 months, respectively; 700, 7–12 months; 800, 1–3 years; 1100, 4–6 years; 2000, 7–10 years; and 3100, 11–14 years of age. No specific levels were recommended during pregnancy, lactation, or for the elderly. The Nutrition Working Group of the European International Life Sciences Institute (ILSI) suggested a higher recommended daily intake (3900 mg). This recommendation was aimed at promoting a potassium intake similar to that of sodium, in molar terms, i.e., an intake of 100 mmol day^{-1} of each cation (2300 mg and 3900 mg for Na and K, respectively). However, more recently a Na:K ratio below 1 (1600 mg and 3500 mg for Na and K, respectively) has been recommended to prevent hypertension, stroke, and cardiovascular disease.

During exercise potassium needs may be increased owing to higher losses in sweat, especially in hot climates and in unaccustomed individuals. These needs should be satisfied by eating food rich in potassium and exceptionally by potassium supplements.

Published values of nutrient consumption demonstrate that in some populations, sodium intake is higher than recommended, while potassium intake should increase. In the UK, the 1991 report of the National Food Survey Committee showed that the average sodium intake was 170% of the reference intake, while that of potassium was 80% of the reference value. In Spain, data from the same year revealed that the estimated potassium intake was satisfactory but that of sodium was 140% above the reference value.

Potassium is ubiquitous in all kinds of food, but the best sources are vegetables and fruits because they combine a high potassium content with low sodium concentration (Table 1). Potassium is an essential element of all forms of life, whereas sodium and

Various		
Chocolate	300	11
Tomato ketchup	590	1120

chlorine are essential for animals but not for many plants. Meat and fish contain important amounts of potassium because they are highly cellular tissues, but they also contain large amounts of sodium chloride, due to the extracellular fluid present in animal food. Raw foods are preferable to processed ones because during food preparation salt is usually added to enhance flavor and retard bacterial growth (e.g., bread, bacon, tomato ketchup, and cookies). Potassium salts, however, are not palatable and are not added to food during processing.

Legumes represent a good source of potassium because they provide at least 1 g potassium per 100 g portion and very little sodium. Dried fruits, for example, apricots, figs, and prunes, should also be mentioned, since they often exceed 0.5 and even 1 g potassium per 100 g portion. Nuts such as pistachios and almonds contain a considerable quantity of potassium, but the addition of salt during roasting upsets the ideal sodium-to-potassium ratio normally present in these foods. Bananas are known to be one of the fruits richest in potassium, together with coconuts, melons, avocados, and kiwi fruit. Milk is the largest dietary source of potassium for infants.

All these data should be considered, taking into account the amount of each food item consumed. For example, a ration of legumes is approximately 80 g while those of meat and milk can easily reach 200 g. Although cereals are low in potassium, they account for almost 75% of potassium ingestion in western diets. There is a wide range of potassium intake by western populations (1560–5850 mg). It is higher in vegetarians and people who consume more food from plant than animal sources. The Mediterranean diet provides a mean daily intake of potassium equivalent to the recommended value (3500 mg).

Although thermal treatments have no effect on dietary potassium, during processes such as boiling, soaking, or canning it can be reduced as a result of leaching, particularly if food is to be cut into pieces and the liquid is not consumed.

In order to protect against hypertension and stroke, except in clinical hypokalemia, potassium from good dietary sources should be encouraged rather than potassium from supplements, because such supplements may have severe adverse effects. Fruits and vegetables also contain magnesium and fiber which seem to have protective effects.

Absorption

Normal subjects absorb about 90% of ingested potassium in the intestinal tract. The net absorption is the difference between fluxes from lumen to blood and from blood to lumen. In the human small intestine, K^+ permeability is high and potassium absorption is carried out across the epithelium of duodenum, jejunum, and ileum by passive mechanisms in response to electrochemical gradients and solvent drag. In the proximal small bowel K^+ is concentrated through the absorption of water, providing a driving force for the movement of this cation across the intestinal mucosa, preferably through the tight junctions between enterocytes. Duodenum and jejunum absorb this ion even more rapidly than water. Indeed, shortly after a meal, the K^+ concentration [K^+] in jejunum rapidly reaches plasma levels. In the ileum, the transepithelial electrical potential difference strongly influences its movement. There is no evidence of active potassium absorption in the small intestine, but the existence of an apical membrane H^+/K^+-ATPase could suggest active K^+ transport.

In the colon K^+ may be secreted or absorbed in response to variations in potassium status: net secretion occurs when the luminal concentration is less than 20–25 mmol l^{-1}, while net K^+ absorption takes place when levels are above 25 mmol l^{-1}. There are two mechanisms for K^+ secretion; the major mechanism involves potential-dependent, passive flux, mostly via the tight union, or by facilitated transcellular diffusion. The second is an active serosa-to-mucosa secretory mechanism in the proximal and distal colon which is the result of uptake across the basolateral membrane mediated by Na^+/K^+-ATPase and Na^+-K^+-Cl^- cotransport and movement across the apical membrane through potassium channels. Active K^+ absorption also occurs in the distal colon, in which the K^+ uptake appears to be an exchange for H^+ across the apical membrane. This process is energized by adenosine triphosphatases (ATPases) located in that membrane. Passive potassium absorption may also take place in the proximal colon.

Bioavailability

The availability of dietary potassium is high because potassium salts are entirely soluble and few dietary factors modify its digestive utilization. Olive oil favors potassium uptake, while some fibers and certain ion exchange resins may decrease K^+ absorption.

Physiological status also affects the nutritive utilization of potassium. Infants absorb a greater proportion of salts than adults. This may be due to the increased permeability of the immature small intestinal epithelium of newborns, and especially to a higher activity of the K^+-absorptive pumps in the colonic apical membrane, while K^+-secreting channels are less relevant. During the second half of pregnancy, fecal potassium decreases. Urinary K^+ output increases in parallel with Na^+ retention; nevertheless,

enough potassium is retained to cover gestational needs. Glomerular filtration rates fall with age, accompanied by limitations of K^+ secretion and Na^+ conservation. Many drugs used in the elderly alter potassium homeostasis.

Transport

Potassium, being an electrolyte, is transported mainly under ionic form in the body fluids. Intracellular potassium concentration is 110–160 mmol l^{-1} of cells while plasma concentration averages 4–5 mmol l^{-1}, of which only 10–20% is bound to proteins.

Figure 1 schematically illustrates the intracellular and paracellular mechanisms of potassium transport. Different potassium transport mechanisms can operate simultaneously. They are usually interrelated and are also linked to other ion transport systems. Each name, except the last one, corresponds to an entire family of transporters.

Na^+/K^+-ATPase activity is responsible for the maintenance of the extra- and intracellular Na^+ and K^+ concentrations against electrochemical gradients. This ATPase is found in the plasma membrane of virtually all animal cells and represents an enormous metabolic energy cost which increases the entropy of the system. It is a carrier protein that pumps $2K^+$ in and $3Na^+$ out of the cell during each cycle of conformational changes driven by adenosine triphosphate (ATP) hydrolysis. This process is electrogenic, meaning that one net positive charge is removed from the cell every pump cycle. Many hormones and various neurotransmitters can modulate K^+/Na^+-ATPase activity.

Another active K^+ transport is controlled by the H^+/K^+-ATPase which ejects H^+ in exchange for K^+. This pump has an important role in some gastrointestinal cells and in the renal tubules.

Other potassium transport systems are driven by the force of ion gradients. The free energy gained during the movement of an inorganic ion down an electrochemical gradient (sum of the concentration gradient and the electrical potential difference) is used as the driving force to pump other solutes against their electrochemical gradient. Thus, the carrier protein acts as a coupled transporter and electroneutrality is maintained. Cotransport depends on ATP only indirectly. Various Na^+-K^+-Cl^- cotransporters, which carry $1Na^+$, $1K^+$ and $2Cl^-$ inside the cell, have been identified in salivary glands, gastrointestinal tract, and renal tubules. The K^+-Cl^- cotransporter, related to the former ones, plays an important role in erythrocytic volume. The first cotransport mediates K^+ influx while the second mediates efflux.

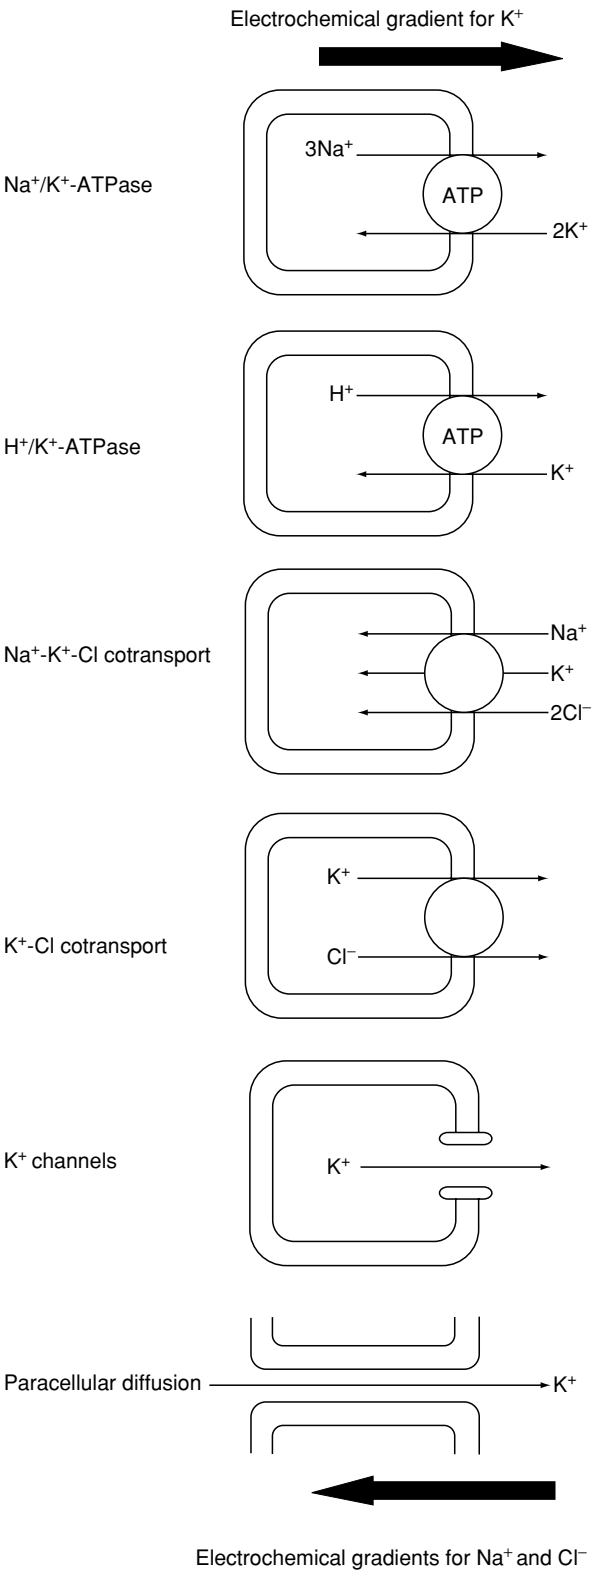

Figure 1 Potassium transport via intracellular and paracellular pathways. ATP, adenosine triphosphate.

Passive transport of K^+ occurs via intracellular and paracellular pathways. The intracellular mechanism involves K^+ channels, which are pores in the plasma membrane made by a specific protein. Channels have 'gates' which open and close in response to specific stimuli: voltage, stretch, ATP, Ca^{2+}, hormones, neurotransmitters, etc. Various stimuli sometimes act together on a channel. K^+ channels exhibit great diversity and participate in many cell functions.

Distribution and Storage

Body potassium concentration is 45–55 mmol kg^{-1} of body weight, thus a 70-kg adult man contains approximately 135 g potassium. Women contain 35–40 mmol kg^{-1} of body weight, and during childhood and in the elderly, body potassium concentration is also lower than that for young men. These differences are due to the lower muscle mass in these groups. Almost 98% of the potassium in the body is inside the cells, making it the major intracellular cation. More than 95% of total potassium is exchangeable.

Total potassium is an index of lean body mass because potassium is only present in the fat-free compartments of the body. It can be measured with K^{40}, a natural isotope present as a small fraction of the total potassium, which emits γ-rays and can be detected by a sensitive whole-body counter, although other isotopes and other techniques that are not based on total potassium are also available.

Studies of body composition in healthy humans have demonstrated that the total body potassium/total body nitrogen ratio is constant. However, in chronic protein-energy malnutrition this ratio can decrease owing to the reduction of muscle proteins and loss of intracellular potassium. The cellular exchange of sodium and potassium is altered, leading to potassium loss and increased intracellular sodium and water. In contrast, exercise and training increase total lean body mass, thereby causing a rise in potassium body content. Increase in muscular mass is only possible if proteins, as well as potassium, phosphorus and magnesium, which are the main intracellular elements, are present in the diet in adequate amounts.

In the extracellular fluid (ECF) an increases of potassium equivalent to 1% of total body potassium may double the concentration of potassium in plasma, resulting in muscle hypopolarization. However, if such an increase is stored in the cells, only minor intracellular changes would result, with little change to the potassium concentration difference across the cell membranes. To accomplish this buffer function, the major reservoir of potassium is the muscle, followed by the liver and erythrocytes, although each cell possesses the capacity for accumulating potassium.

Excretion

About 90% of daily potassium intake is excreted in the urine and 10% in the stool, although this last percentage can be somewhat higher in cases of diarrhea. When dietary potassium is severely restricted, its fecal loss decreases to approximately 3.5 mmol day^{-1}. This presumably represents obligatory potassium losses related to K^+ digestive secretions (salivary, gastric, biliary, and pancreatic), cell desquamation, and mucus secretion. Potassium concentration in sweat is about 10 mmol l^{-1}, so loss through perspiration is small, provided that the climate and exercise conditions are not extreme.

Renal Potassium Handling

The kidney plays the main role in potassium excretion. Renal potassium excretion shows a circadian rhythm, characterized by peak output during the subject's activity.

K^+ is freely filtered by the glomerulus. Usually, urinary potassium excretion is 5–15% of the amount filtered, which indicates the existence of tubular potassium reabsorption. The renal tubules are capable of reabsorbing and secreting potassium in response to various stimuli.

Proximal tubule The proximal tubule is responsible for the reabsorption of approximately 60% of previously filtered potassium. Solvent drag and diffusion have been proposed as the major driving forces of this process, and K^+ is reabsorbed largely via the paracellular pathway. However, some observations suggest participation of a transcellular route of potassium reabsorption by an active mechanism. The fractional rates of K^+ reabsorption are similar to those of sodium and water along the proximal tubule and changes in fluid and potassium transport are closely coupled.

In this region the basolateral K^+ channels have higher conductance than the apical ones, and this is essential to maintain a negative intracellular potential and hence promote reabsorption of positively charged carriers (Na^+-glucose cotransport, etc.)

Loop of Henle The concentration of K^+ increases as the filtrate passes through the loop of Henle, where permeability for potassium is very high. At the end of the descending limb the amount of K^+ present usually exceeds that of the glomerular filtrate. There is a net passive secretory entry of potassium into the proximal straight tubule and the descending thin limb of Henle, which arises from reabsorption in the collecting tubule and partly in the ascending limb. These pathways of K^+ transport constitute potassium recycling in the renal medulla.

In the thick ascending limb potassium is mainly reabsorbed. The mechanism of active transport includes apical uptake by Na^+/K^+-Cl^- cotransport and passive paracellular exit across the basolateral membrane by diffusion. Driven by transepithelial potential difference, reabsorption also occurs through the paracellular pathway.

The role of this limb in potassium secretion has also been recognized. The K^+ secretion through apical K^+ channels is important for net Na^+ and Cl^- reabsorption through Na^+ /K^+-Cl^- cotransport, since luminal Na^+ and Cl^- concentrations are higher than luminal K^+ levels.

Distal tubule and collecting duct These tubules are the major determinants of urinary K^+, since they are able either to reabsorb or secrete potassium at rates which depend on K^+ intake and other factors.

Potassium secretion occurs in 'principal cells' by active uptake across the basolateral membrane by Na^+/K^+-ATPase and passive diffusion into the lumen across the apical membrane by K^+ channels or using a K^+-Cl^- cotransport (Figure 2). K^+ transport follows this route towards the lumen thanks to a favorable electrochemical gradient and the greater K^+ permeability of the apical membrane in comparison with the basolateral one. High Na^+ concentration in the lumen favors K^+ secretion, as the entrance of Na^+ into the cell generates a potential difference that tends to make the interior positive, so K^+ diffuses in the opposite direction. Simultaneously, the enhanced delivery of Na^+ into principal cells facilitates the action of Na^+/K^+-ATPase, and the accelerated potassium uptake favors its secretion towards the lumen.

Potassium reabsorption mechanisms have been detected in the intercalated cells of the distal tubule and collecting duct. It appears that there is a component of potassium reabsorption even during net secretion. Several isoforms of H^+/K^+-ATPases are able to reabsorb K^+ in exchange for H^+. The Na^+-K^+-Cl^- contransport may also introduce K^+ into the cell while the basolateral K^+ channels enable potassium to pass from the cell into the interstitial space. Proton secretion by H^+/K^+-ATPase, together with that by H^+-ATPase, contributes to urine acidification. These enzymes participate in the acid–base balance and potassium status.

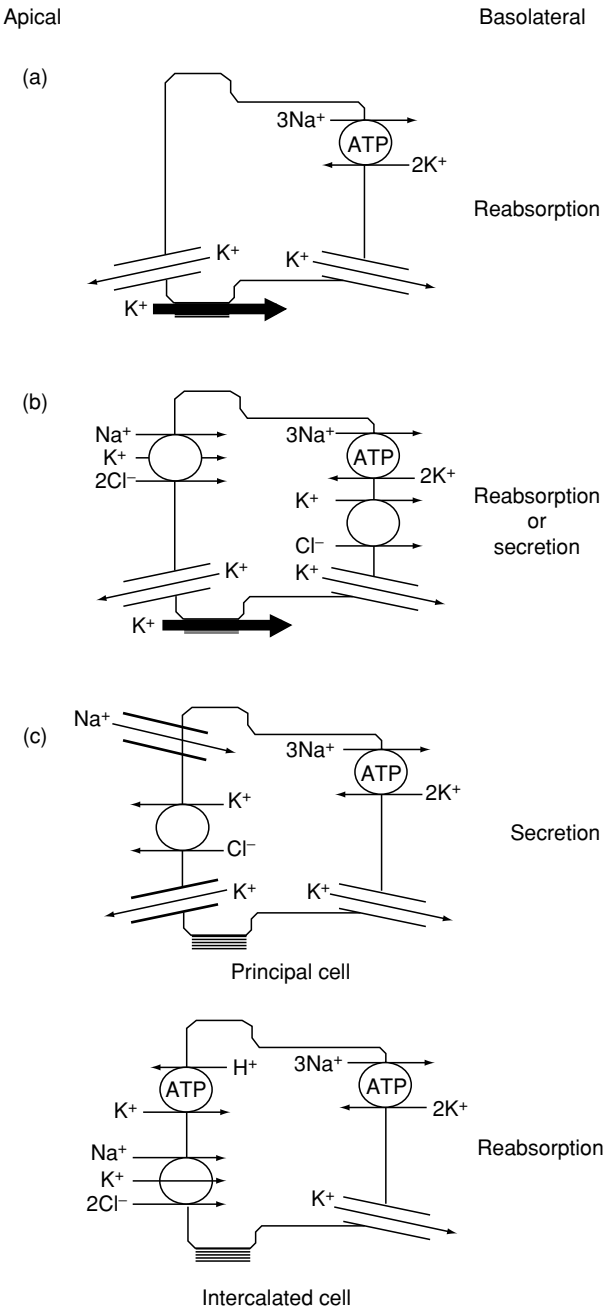

Figure 2 Principal mechanisms of potassium transport in the major tubular segments of the nephron: (a) proximal tubule; (b) thick ascending limb; (c) distal tubule and collecting duct. ATP, adenosine triphosphate.

Potassium Balance and Homeostasis

Intra- and extracellular potassium concentrations must be maintained within narrow limits, despite wide fluctuations in dietary intake. This is achieved, on the one hand, by 'internal balance': distribution of K^+ between the intracellular fluid and ECF carried out mainly by Na^+ K^+-ATPase, and on the other hand, by 'external balance': maintenance of the amount of K^+ in the body through equilibrium between K^+ intake and excretion, which is achieved principally in the kidney but also in the intestine. After a meal, the absorbed K^+ rapidly enters the ECF. The subsequent rise in plasma [K^+] is attenuated by a rapid cellular K^+ uptake (which occurs within minutes). To maintain external K^+ balance, all

of the K^+ absorbed in excess must be excreted slowly by the kidneys.

Potassium Homeostasis

To maintain the equilibrium previously described, several factors which act at different levels contribute to potassium homeostasis (Figure 3).

Internal balance A rise in plasma [K^+], especially with hyperkalemia, and the hormones insulin, epinephrine (adrenaline: by activating β_2-receptors), and aldosterone promote K^+ uptake by muscle, livers, bone, and red blood cells. In contrast, a decrease in plasma [K^+], such as with hypokalemia, and stimulation of α-adrenergic receptors induce K^+ transport from cells to the ECF. Moreover, hyperkalemia stimulates insulin, aldosterone, and epinephrine secretions, while hypokalemia has the opposite effect. These are the major physiological factors involved in internal K^+ balance homeostasis.

Furthermore, other factors which are not normal homeostatic mechanisms influence K^+ movements across the plasma membrane: metabolic acidosis promotes exit of K^+ from cells, whereas metabolic alkalosis favors its uptake. Increased osmolality of the ECF enhances K^+ release by cells. Cell lysis (severe trauma, burns, etc.) induces K^+ release and may produce hyperkalemia. During intense exercise, K^+ is also released from skeletal muscle cells.

External balance There are two hypotheses concerning the homeostatic mechanisms which regulate external K^+ balance:

1. The first involves a peripheral mechanism without central nervous system (CNS) intervention. In this case [K^+] would stimulate urinary K^+ excretion and aldosterone secretion directly.
2. The second attributes K^+ regulation to a reflex mechanism initiated by K^+ receptors in portal vein and liver stimulated by high [K^+]. Afferent fibers would transmit signals to CNS – 'K control center' – and efferent limbs, mediated by several hormones and other factors, would modulate urinary K^+ excretion in response.

In any case, plasma [K^+] and aldosterone are the major physiological regulators of K^+ excretion. High [K^+] increases aldosterone secretion and both act synergistically, stimulating K^+ elimination by the intestine (particularly increasing colonic secretion) and, above all, by the kidney (promoting secretion in the distal tubule and collecting duct). Renal secretion is due to stimulation of the Na^+/K^+-ATPase pump, increased permeability of the apical membrane to K^+, and greater K^+ uptake across the basolateral membrane. Hypokalemia decreases K^+ secretion by antagonist action. Under repletion conditions, potassium transported by Na^+/K^+-ATPase and H^+/K^+-ATPase recycles back into the lumen through K channels; however, when potassium levels are low, little potassium is wasted through luminal channels and passage of K through basolateral channels predominates.

Aldosterone secretion is favored by angiotensin II. On the other hand, aldosterone stimulates Na^+ and

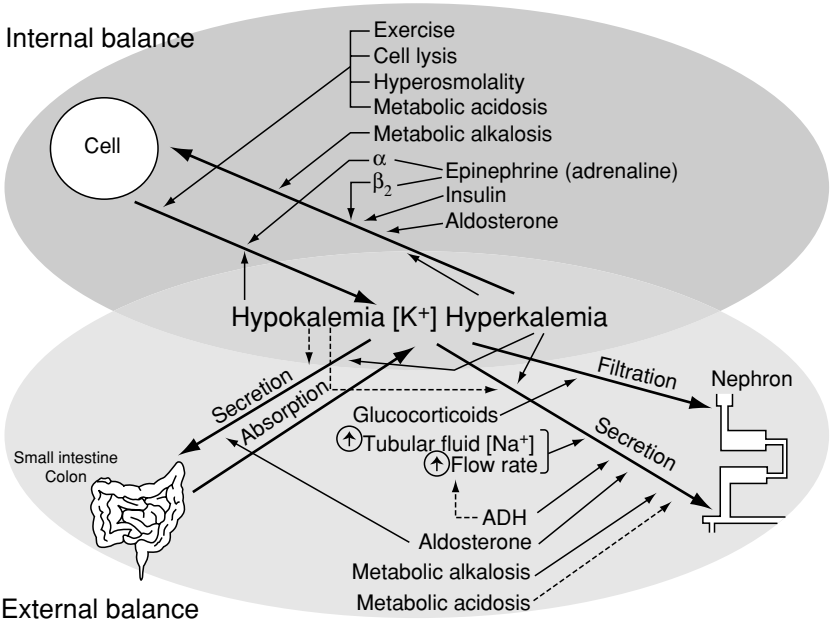

Figure 3 Potassium homeostasis. ADH, antidiuretic hormone. Continuous arrow, increase; dashed arrow, decrease.

water reabsorption and consequently decreases tubular flow at first. However, flux is restored in time, permitting aldosterone to increase K^+ renal excretion.

Antidiuretic hormone (ADH) increases K^+ secretion in the apical membrane of the principal cells in exchange for Na^+ absorption. However, because ADH also decreases tubular flow, changes in ADH levels do not substantially alter urinary K. K^+ secretion rises along the distal tubule in a flow-dependent manner and it is influenced by dietary potassium intake. This means that diuretics may enhance urinary K^+ excretion. However, K^+ excretion and distal flow rate are not completely coupled and, the K^+ balance is maintained through compensatory mechanisms when necessary.

Physiological [Na^+] does not alter K^+ secretion but high [Na^+] in tubular fluid increases K^+ secretion, whereas a fall in concentration has the opposite effect. Acid–base balance is another factor that modulates K^+ secretion: alkalosis increases secretion, whereas acidosis decreases it. Glucocorticoids are kaliuretic, but their effects appear to be a consequence of an increase in the glomerular filtration rate.

K^+ itself exerts a feedback regulation over most of its own control factors. Together, all these mechanisms allow the human body to maintain normal plasma [K^+]. However, the equilibrium can sometimes be altered, causing either hyperkalemia (extracellular [K^+] over $5.5\,mmol\,l^{-1}$) or hypokalemia (extracellular [K^+] below $3.5\,mmol\,l^{-1}$).

Hyperkalemia may be the consequence of a K^+ shift from cells to ECF or the effect of excessive K^+ retention. The first signs are flaccid paralysis, natriuresis, and other minor effects. The most important consequences are ventricular fibrillation and cardiac arrest. Hyperkalemia may be:

- Without potassium excess: caused by K^+ shift from cells (acute acidosis, hyperosmolality, insulin deficiency, β-adrenergic blockers, vigorous exercise, etc.)
- With potassium excess: impaired renal excretion (renal failure, aldosterone deficiency, primary tubule dysfunction). Inappropriately high oral or parenteral K^+ administration.

Hypokalemia may be the result of either intracellular shift or K^+ depletion, or both. Among its clinical sequelae are hyperpolarization of membrane, which affects nerves and muscle activity, and produces renal, cardiac, and metabolic alterations. The hypokalemia may be caused by:

- Intracellular shift: alkalosis, insulin excess, familial periodic paralysis, catecholamine increase, intoxications, etc.
- Extrarenal causes: insufficient K^+ intake, diarrhea, vomiting, skin loss, etc.
- Excessive renal losses: renal tubular acidosis, hypermineralocorticoidism, syndrome of choride depletion, diuretic condition.

POTATOES AND RELATED CROPS

Contents

The Root Crop and its Uses

M V Rama and P Narasimham, Formerly of Central Food Technological Research Institute, Mysore, India

Introduction

The potato (Irish potato, white potato, *Solanum tuberosum* L.) is of ancient origin. It has originated and was first domesticated in South America, even before the appearance of maize. It was initially introduced to Spain and the UK, and gradually to parts of Asia and North America. It has spread around the world over the past 400 years, and gained recognition as an inexpensive and nutritive food in the eighteenth century. It is now among the 10 major food crops of the world and grown in over 140 countries. This article reviews the geographical distribution, varieties, commercial importance, morphology, and anatomy of the tuber, chemical composition, nutritive value, and postharvest handling and storage of potatoes.

Geographical Distribution

The potato (*S. tuberosum* L.) belongs to the Solanaceae family and is largely grown in cool regions where the mean temperature during the growing season does not exceed 18 °C. World production of potato accounts for 47% from 37% acreage of total root and tuber crops. It is the fourth most important food crop in the world, next to wheat, maize, and rice in global tonnage (Table 1). The principal producers are the European and Asian countries, North America, and the Andean countries of Latin America (Table 2). Production shows a yearly increase in both the developing and developed countries, more significantly in the former. Russia, China, USA, Poland, India, Germany, UK, France, Turkey, and Canada are some of the highest potato-producing countries of the world (Table 3). The USA and Canada together account for 8% of the world production from 4% of acreage.

Commercial Varieties and Transgenic Potatoes

There are more than 150 wild species of potato found in Central America, Mexico, and the USA. *S. tuberosum* L. (tetraploid) represents the cultivated species and there are seven other cultivated species, including *S. ajanhuiri, S. goniocalys, S. phureja, S. stenotomum* (diploids), *S.* × *juzepczukii, S.* × *chaucha* (triploids), *S.* × *curtilobum* (pentaploid), which are grown in different parts of Peru, Bolivia, Ecuador, and Venezuela. Many improved local varieties have been developed and introduced in several countries and these may show increased yield, disease resistance, better tuber shape, texture, and quality for processing as well as flavor.

In recent years, attempts have also been made worldwide to generate transgenic potato plants and assess the impact of transgenic expressions on diverse parameters such as yield, quality, carbohydrate metabolism, stress physiology, and pest and disease resistance. The outcome of the transgenic approach is promising and already insect- and herbicide-resistant potato plants are in commercial use.

Commercial Importance

The potato is grown as an early or late crop for seed or ware purpose. Even in comparatively harsher climates, it produces more dry matter (DM) and protein per hectare than major cereal crops of the world. It is a major food crop in the temperate zone and is either a staple food or merely a vegetable in tropical and subtropical countries. Tubers are consumed in various forms after cooking or processing. In the UK, USA, and India 65–90% of the production is consumed as food, and a small quantity is used for industrial purposes. In The Netherlands, a large percentage is used for starch production. Starch, alcohol, glucose, and dextrin are the industrial products of potato. World production of potato starch is about 2×10^6 t. Potatoes are generally boiled, cooked in oil, or baked. Dehydrated, frozen, and canned products are also popular. In the USA, 50% of the potato crop is consumed in processed form; the most relished is potato chips. Varieties with high DM content are preferred for potato chips. Frozen products include hash browns (patties), French fries, croquettes (puffs), and mashed potato, while dehydrated products include granules, flakes, diced chunks, and julienne strips. The common canned products are new potatoes, hash, stew, and soups. Papa seca and chuno are the traditional dried potatoes, which form a vital part of the diet in the highland areas of Peru and Bolivia. Dough-like sliceable, storage-stable potato products have also been developed. (*See* **Starch**: Sources and Processing.)

The waste water collected from peeling, cutting, and blanching in the processing industries has been used to recover highly nutritive protein of 80–85% purity. The use of this recovered protein of high biological value is limited as human food, due to the presence of antinutritional factors, but the residual water can be used in preparing a growth medium for single-cell protein production. Potato peel itself is superior to wheat bran, containing high amounts of

Table 4 Advantages of using true potato seeds (TPS) for potato production

Parameters	*Advantages*
Seed rate	25 g of TPS against 2 t seed tubers per hectare
Profit	Planting material cost is very low; saves cost on transport, cold storage, and needs less storage room
Productivity	More productive due to higher yield and more dry matter
Technical feasibility	Can be effectively used in different agroclimatic zones
Less risky/environment-friendly	Built in broad-based resistance to late blight: reduced usage of pesticides

Adapted from Upadhya MD (1994) True potato seed: propagule for potato production for the 21st century. In: Shekhawat GS, Khurana P, Pandey SK and Chandla VK (eds), *Potato: Present and Future*, pp. 15–22. Shimla, India: Indian Potato Association.

minerals and fiber. The water extract of the peel is a nonmutagenic antioxidant with potential antimicrobial activity. Snakin-1 (SN-1), a peptide isolated from the potato tuber, is shown to be active against potato bacterial and fungal pathogens. Further, potato plant having tuber as the sink for carbon and nitrogen is said to serve as a model species for various experiments involving bacteria-mediated gene transfer systems. (*See* **Alkaloids**: Properties and Determination.)

Tuber is also used for propagation. Tuber seed is the costliest input, accounting for nearly 40% of the cost in potato production; the availability of an adequate quantity of virus-free seed stock is still a constraint for increased production, especially in developing countries. Hence, in recent years commercial crops are being raised using true potato seed (TPS), which has several advantages over traditional tuber seeds (Table 4). However, usage of TPS is still limited in developed countries, due to erratic germination and low yield. A host of hybrid TPS families with desirable attributes has been developed by the International Potato Research Center (CIP), Peru, and Central Potato Research Institute (CPRI), India, using *S. andigena* and *S. tuberosum* as parental lines.

Morphology and Physiology of the Tuber

The potato is an underground, modified, fleshy stem, with a shortened axis, developing from the subapical region of a diageotrophic rhizome or lateral shoot. The tuber end that is attached to the rhizome is called the stem end or heel end, and the other end is the bud end or rose end. There are as many as 20 eyes in the axils of leaf scars (eye brows) arranged spirally around a tuber. Each eye has one main bud and several small lateral buds. Physiologically, the youngest bud is the last formed apical bud (Figure 1a). Tubers sprout after completing the inherent dormancy period, which lasts from 6 to 16 weeks after harvest, depending upon the variety. Tubers exhibit apical dominance. Studies have shown that the balance between the two hormones, abscisic acid (ABA) and gibberellic acid (GA_3), in the tubers determines the extent of the dormancy period. Dormancy breaking is also related to protein degradation and mobilization of nitrogen reserves for sprout formation. Morphological characters of the tuber such as shape (round, oval, or elongated), size (small, medium, or big), skin color (light yellow to black or purple), and depth of eye (deep or shallow) determine its acceptability for various end uses.

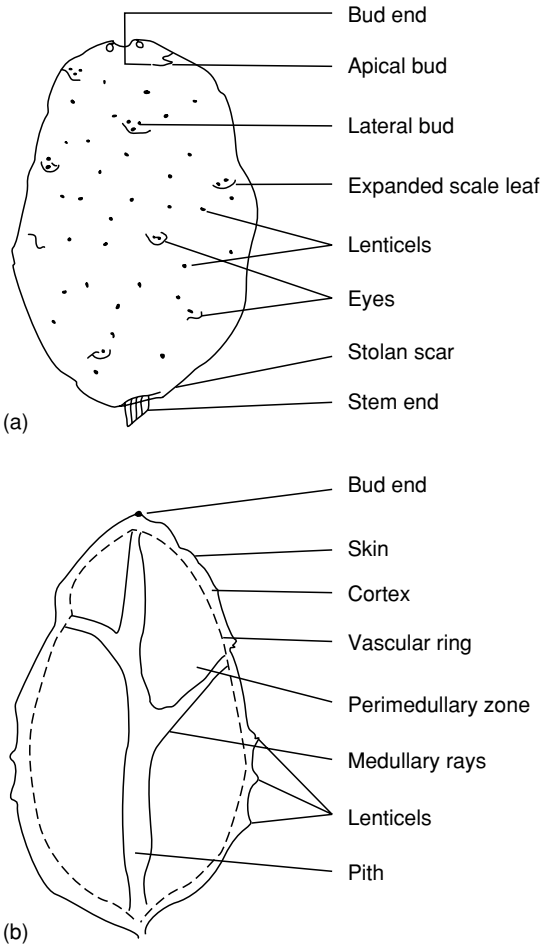

Figure 1 A potato tuber: (a) morphological details; (b) longitudinal section.

Anatomy of the Tuber

The potato tuber is protected by the outermost skin or periderm, consisting of six to 10 layers of suberized cells. Skin color depends on the anthocyanin concentration in the periderm and peripheral cortex. The active periderm of a young tuber can be easily removed, and tuber enlargement is associated with sloughing off the periderm, which is then replaced by a new 'cork' layer, formed from beneath. Similarly, wound healing takes place in damaged tuber tissue by the formation of a wound periderm, which is more impervious than normal skin. A number of lenticels are found in the periderm, and these pores also facilitate the exchange of gases and the entry of pathogens. Inside the periderm is the parenchymatous cortex (0.3–1.0 cm thick) in which food material is stored in the form of starch granules. Cortex (potato flesh) may be white or various shades of yellow depending upon the variety. Yellow-fleshed varieties are sometimes highly prized. The parenchymatous perimedullary zone is seen between the vascular ring and the medullary ray (Figure 1b). Xylem is visible as a ring, while phloem forms many bundles in the cortex and perimedullary zones. Medullary rays run from the stem end to the eyes. The pith present at the center of the tuber is translucent, as it has less starch.

Chemical Composition

The chemical composition of potato varies with variety, soil type, cultural practice, maturity stage, disease, and storage conditions. The distribution of DM and chemical compounds (Figure 2) is extremely heterogeneous within a tuber. The data in Tables 5 and 6 shows potato to be a good source of carbohydrates, vitamins, and minerals. The small fraction of protein present in the tuber consists of many essential amino acids.

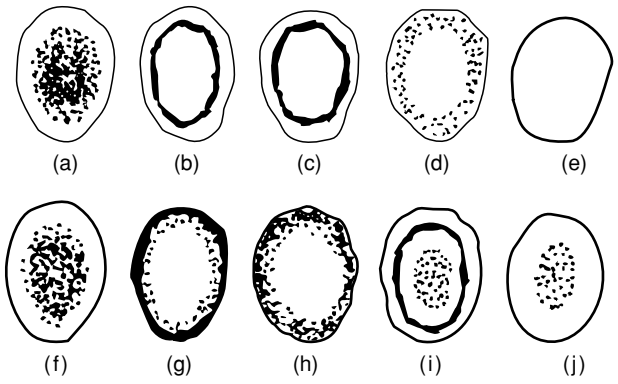

Figure 2 Pattern of distribution of chemical compounds (shaded areas) within a potato tuber. (a) Starch; (b) sugars; (c) proteins and amino acids; (d) fat; (e) crude fiber; (f) vitamins; (g) minerals; (h) organic acids; (i) phenol compounds; (j) alkaloids. Starch, being the major carbohydrate (16–20% on a fresh-weight basis or fwb), constitutes 60–80% of the dry matter, and it is composed of amylose and amylopectin in a 3:1 ratio. Potato starch gelatinizes above 70 °C. The total sugar content ranges from 0.1% to 0.7% (fwb), and this is chiefly associated with maturity, senescence, and sprouting. The major sugars of potato are glucose, fructose, and sucrose. Trace amounts of melibiose, raffinose, stachyose, glycerol, galactinol, and glucosyl have also been identified. Tubers containing more than 2% (fwb) reducing sugars give dark-colored chips owing to Maillard reactions and are not suitable for processing. In mature stored tubers, starch and sugars exist in a state of dynamic equilibrium. The nonstarchy polysaccharides, such as cellulose, hemicellusose, and pectic substances, constitute about 1.2% (fwb) and are present in the cell walls and middle lamellae. They contribute to the final texture of cooked potato, and act as a source of dietary fiber. (*See* **Browning**: Nonenzymatic; **Carbohydrates**: Requirements and Dietary Importance; Classification and Properties; **Starch**: Structure, Properties, and Determination.)

Proteins and Amino acids

Potato is considered to be low in protein (2% fwb), but is rich in lysine compared to cereal proteins, while the concentration of sulfur amino acids is less than in cereals. The protein is concentrated more in the cortex and pith. The levels of proteins such as albumin, globulin, prolamine, and glutelin are 48.9%, 25.9%, 4.3%, and 8.3% of total protein respectively. Nearly 75% of the nonprotein nitrogen (NPN) occurs as free amino acids and amides. Two-thirds of the NPN fraction is composed of free amino acids and 21 of the amino acids have been identified. The essential amino acids and their concentrations are given in Table 6. Sprouting, storage, diseases, and fertilizer applications influence the concentration of free amino acids in the tuber. Amides like glutamine and asparagine occur in almost equal amounts. (*See* **Protein**: Chemistry; Requirements.)

Vitamins and Minerals

Potato contains substantial quantities of vitamins B and C (Table 5). Vitamin C is present in both oxidized and reduced forms. Freshly harvested tubers may contain 20 mg of ascorbic acid per 100 g; losses of vitamin C occur during long-term storage (40–60%), cooking, and processing (20%). Ascorbic acid content of potato is higher than that of several other vegetables like carrots, pumpkins, onions, and green beans. The vitamin B group comprises thiamin, riboflavin, nicotinic acid, and pyridoxine; folic acid along with pantothenic acid is also present in potato. The ash content is about 1% (fwb), which is equivalent to 4–6% of the DM content. Fat-soluble vitamins occur in traces or are absent. This necessitates supplementation of other food sources rich in vitamin A in a potato diet. The major elements present are phosphorus, potassium, magnesium, sodium, and calcium, with wide ranges in their amounts. Potato is a poor source of calcium and sodium. A small percentage of phosphorus (25%) occurs as insoluble phytic acid. Others, such as boron, copper, zinc, iodine, aluminum, arsenic, nickel, and molybdenum, are found in trace amounts. (Refer to individual minerals and vitamins.)

Lipids and Organic Acids

Approximately 0.1% (fwb) lipid is found in potato; it is concentrated in the periderm. Linoleic, linolenic, and palmitic acids are the major fatty acids. A number of organic acids are present in potato in varying quantities; they contribute to the flavor and buffering of the potato sap. The major organic acids are citric, oxalic, fumaric, and malic acids. Other than phytic acid, nicotinic and chlorogenic acids have also been reported. Chlorogenic acid reacts with ferric iron, forming a complex, which causes darkening after cooking. Enzymatic browning in cut and homogenized potato tissue is caused by the oxidation of tyrosine. Both enzymatic and nonenzymatic browning can be inhibited by treatments with sulfur dioxide and sulfites. Other phenolic compounds found in potato are polyphenols, flavones, anthocyanins, and tannins. Phenols are again associated with after-cooking discoloration of tubers, particularly at the stem end. Tannins being localized in the periderm impart tan coloration to the skin. (*See* **Acids**: Natural Acids and Acidulants; **Fats**: Classification; **Fatty Acids**: Properties; **Phenolic Compounds**; **Tannins and Polyphenols**.)

Enzymes and Pigments

The enzymes reported in potato include amylase, glyoxalase, phosphorylase, tyrosinase, peroxidase, catalase, aldehydrase, phosphatase, sistoamylase, and zymohexase. The phosphorylase and amylase systems form sugars at low temperatures. The probable role of D-enzyme (EC 2.4.1.25; 4-alpha-glucanotransferase) in starch metabolism has been suggested. Transgenic potato plants with reduced D-enzyme activity have been obtained. Polyphenol oxidase, peroxidase, and catalase enzymes involved in the oxidation of phenols bring about browning of the freshly cut surface of the potato. The yellow color of potato flesh is attributable to carotenoids such as α-carotene, auroxanthin,

violaxanthin, lutein, isolutein, and neo-β-carotene. Flavonols, flavones, flavin, and neoxanthin are also found in small quantities. Red-skinned potatoes have anthocyanin in the periderm and outer cortical cells. Chlorophyl is present in tubers exposed to light, and these green potatoes lose their market value. (*See* **Carotenoids**: Occurrence, Properties, and Determination; **Chlorophyl**; **Colorants (Colourants)**: Properties and Determination of Natural Pigments; **Enzymes**: Functions and Characteristics.)

Antinutritional Factors

The glycoalkaloids, proteinase inhibitors, and the lectins are the major antinutritional factors present in the tubers. The synthesis of toxic glycoalkaloids such as α-solanine and α-chaconine, which are believed to be a part of a disease-resistance mechanism, takes place in damaged and light-exposed tubers; a normal tuber contains an insignificant amount (5–10 mg $100\,g^{-1}$) of these alkaloids. They are recognized as natural products with insect deterrent and antifungal activity, concentrated more in the peel, sprouts, and around the eyes, and absent in the pith. Tubers develop bitterness and off-flavors when the alkaloid content is 25–80 mg $100\,g^{-1}$, and consumption of tubers with more than 20 mg of glycoalkaloid causes fatal illness. It can be eliminated to an extent of 60%, by peeling the tuber, while its accumulation can be controlled by waxing, oil and water dipping, and storing in the dark. The nutritional significance of two other toxic substances, proteinase inhibitors and lectins, has not been much studied, but they are reported to be heat-labile. (*See* **Alkaloids**: Toxicology.)

Nutritive Value

Potato is one of the richest sources of energy and has a greater capacity to supply energy than any other food crop. In some developing countries, potato is considered merely a vegetable rather than a staple food because of the belief that excessive consumption causes flatulence in humans. Experiments have shown that cooked potato starch is easily digestible, and hence forms a valuable food, even for infants. Potato has a slightly lower energy content (335 kJ $100\,g^{-1}$) than other roots, tubers, cereals, and legumes (Table 7), but this is advantageous in overcoming the problem of obesity in the developed world. On the other hand, large quantities of potato have to be consumed in developing countries to meet their populations' daily energy needs. It has been calculated that 100 g of potato can supply 5–7% of the daily energy and 10–12% of the daily protein need of children aged 1–5 years.

Potato protein has a biological value equal to that of soya bean protein and the ratio of total essential amino acids to total amino acids is so balanced that it can meet the needs of infants and small children. It has been calculated that 100 g of potato can supply 3–6% of proteins, the recommended daily allowance (RDA) for adults (depending upon sex and body weight), and one medium-sized potato provides 15 mg of vitamin C, which is about 20% of the recommended allowance (75 mg) per person per day. Eating the tuber with the skin on increases the dietary fiber intake. It is also a most valuable food for those who suffer from excess acidity of the stomach as it has an alkaline reaction. Potato fat is too low to have any nutritional significance, but it does contribute towards palatability. The tuber also provides most of the trace elements needed to maintain good health, and although potato is not a primary source of iron, 100 g of cooked potato can supply between 6% and 12% of the daily iron requirement of children or adult men. About 7% of the US RDA of phosphorus for both children and adults is available from 100 g potato. A low percent of phytic acid present in potato tuber, compared to other staple cereals and vegetables, is an advantage as it allows greater availability of free calcium, iron, zinc, and phosphorus for absorption by the human intestine. (*See* **Amino Acids**: Metabolism; **Ascorbic Acid**: Physiology; **Dietary Fiber**: Physiological Effects; **Energy**: Measurement of Food Energy; **Iron**: Physiology; **Protein**: Quality.)

Handling and Storage

In most countries, potatoes are only harvested at certain times of the year, and harvested tubers must be stored for at least a few months. Harvesting and subsequent processes such as assembling, grading, bagging, transport, and marketing, may cause damage to the tubers; such tubers lose water quickly and are highly susceptible to microbial spoilage. Bruising also causes a physiological disorder called black spot which is as the result of oxidative biochemical reactions involving chlorogenic acid, polypohenol oxidase, amino acids, and tyrosine, resulting in melanin formation (enzymatic browning); bruised black-spotted tubers have less market value and shorter shelf-life. Degree of dormancy, rate of tuber respiration, chemical composition, and ability of wound healing influence the spread of disease-causing organisms through the tuber tissue. Thus curing, a process which promotes wound healing, is necessary before potato storage. Complete curing takes 3–6 days at 20 °C and 85–90% relative humidity (RH), but is faster at higher temperature. The physiological disorders, diseases, and pests of the tubers in the field and in storage are listed in Table 8.

Good storage conditions should prevent excessive sprouting, root development, moisture loss, sugar accumulation, greening, and temperature damage. The postharvest losses in potatoes are estimated to vary from 5 to 40%. For short periods, the tubers can be stored in clamps, in specially designed simple sheds, pits, cellars, or buildings with controlled temperature and humidity. Modern potato storages are equipped with computer-based control systems to monitor and maintain optimum levels of temperature and humidity with air envelop facilities. Long-term storage without sprouting and minimum loss of moisture is possible at 4–5 °C, but temperatures below 6 °C lead to the formation of reducing sugars, and this is not a desirable feature for industrial processing. Tubers can be reconditioned by transfer to a higher temperature, but the sweetness developed by long-term, low-temperature storage (senescent sweetening) cannot be eliminated completely; nearly 30% of the starch is lost as sugars, reducing tuber quality, particularly for processing.

The freezing of tubers takes place at − 1 °C to − 2 °C, and frozen tubers soon become soft and unusable. Potato stores are artificially heated using oil or gas heaters when the outside air temperature is lower than the required temperature. On the other hand, when potatoes are stored above 30 °C, accumulation of carbon dioxide leads to death of cells, causing black heart. In temperate regions, where the ambient temperature falls below 4 °C, potatoes are cooled with outside air. In the tropics and subtropics, refrigeration is used. The recommended temperatures for tubers to be used for different purposes are as follows:

- Seed potato 2–4 °C
- Fresh consumption 4–5 °C
- Chipping 7–10 °C
- French frying 5–8 °C
- Granulation 5–7 °C

(*See* **Storage Stability**: Mechanisms of Degradation.)

Sprouting increases weight loss, softens the tuber, and favors accumulation of glycoalkaloids, thus decreasing marketability and nutritive value. Apart from low-temperature storage, other methods of achieving sprout inhibition include the use of maleic hydrazide (MH), isopropyl-*N*-phenylcarbamate (IPC) and isopropyl-N-(3-chlorophenyl)-carbamate (CIPC), tetrachloronitrobenzene (TCNB), naphthalene acetic acid (NAA), methyl ester of naphthalene acetic acid (MENA), and irradiation. Time, method of application, and concentration of the chemical are important factors, as treatment may have adverse effects such as

inhibition of wound healing, increasing the reducing sugar content, and the problem of toxic residues. TCNB, CIPC, and IPC treatments are to be coupled with cold storage, as they are ineffective at tropical ambient temperatures (> 20 °C). The sodium salt of NAA (1000 p.p.m.) is an effective and economical postharvest sprout-retardant for storing potatoes under tropical ambient conditions (Table 9).

Several naturally occurring volatile and aromatic compounds have proved to be potent sprout inhibitors, but their acceptability for commercial application needs further investigation. Ware potatoes (those potatoes intended for human consumption in contrast to seed potatoes) can be kept sprout-free for a long time by irradiation, but its economic feasibility remains to be ascertained. Irradiated tubers need to be stored below 20 °C, and irradiation often lead to increased *Fusarium* attack and discoloration after cooking. Controlled-atmosphere (CA) storage of potatoes with as low as 5% carbon-dioxide concentration causes black heart and low oxygen concentrations inhibit wound healing; therefore CA storage appears not to be beneficial. Sprout inhibition beyond 3 months at tropical temperatures (22–35 °C) is possible by periodical vapor heat treatment at 60 °C, RH 95% for 60 min (Table 9). This method is superior to manual desprouting, and avoids the use of toxic chemicals. Hot-water dip treatment at 57.5 °C for 20 or 30 min prior to storage at 18 °C enhances storability, by inhibiting sprouting and spoilage by *Fusarium* and *Erwinia*. (*See* **Irradiation of Foods: Applications.**)

Evaporative cooling systems can be used effectively in tropical conditions to store potatoes. The containers needed for this storage can be fabricated locally using brick, sand, bamboo, and metal sheets; it is a cheaper method of storing potatoes, with reduced water loss, at farm level (Table 10). These containers maintain a high RH (85–95%) in the atmosphere and the tuber temperature, which is close to the wet bulb temperature, is the lowest possible for evaporative cooling. Seed potatoes are often exposed to natural or artificial light during storage, as light retards physiological aging, inhibits sprout growth, and increases resistance to fungal infections. On the other hand, exposure of ware potatoes to light should be avoided, as it leads to the formation of the toxic α-solanine and green pigment, chlorophyl; the market value of green potatoes is also low.

Avoiding damage to potatoes and dry, cool storage are necessary to prevent bacterial and fungal attack. Benzimidazole compounds are used to combat fungal diseases. Efficient ventilation in any store is necessary to eliminate excess moisture, which otherwise may enhance rotting. (*See* **Fungicides; Spoilage:** Bacterial Spoilage.)

Fruits of the Solanaceae

M V Rama and P Narasimham, Formerly of Central Food Technological Research Institute, Mysore, India

Background

The family Solanaceae includes about 75 genera and 2000 species of herbs, shrubs, and small trees distributed in the tropical and temperate regions of the world. Important vegetable crops such as tomato, brinjal, pepper, tree tomato, and husk tomato are included in this family. Potato and tobacco are also from this family. This article reviews the geographical distribution, morphology, anatomy, chemical composition, nutritive value, and uses of some solanaceous fruits.

Geographical Distribution, Morphology, and Anatomy

The important fruits of the family solanaceae are shown in **Table 1**. Tomato (*Lycopersicon esculentum*) is the most popular and widely cultivated vegetable and has been consumed by the inhabitants of Central and South America since prehistoric times. It is considered to be a native of the Peruvian and Mexican regions. It is an indispensable fruit today, grown all over the world (outdoors in temperate regions and in green houses in the colder regions), and constitutes about 15% of the world total vegetable production (**Table 2**). World production of tomato for processing is over 20 million tonnes, and in the USA, it ranks second to potato in dollar value, among all the other vegetables grown. Major tomato-producing countries

Table 1 Some important solanaceous fruits

Scientific name	*Common name*
Lycopersicon esculentum	Tomato
L. pimpinellifolium	Redcurrant or grape tomato
Solanum melongena	Eggplant, brinjal, berenjana, aubergine, guinea squash
S. macrocarpon	African eggplant
S. nigrum	Garden huckleberry, wonderberry
S. muricatum	Pepino, melon pear
S. quitoense	Naranjillo, lulo
S. gilo	Jilo
Capsicum annuam	Bell pepper, sweet pepper
C. frutescens	Pimiento, chili, aji, hot pepper, bird chili
Physalis peruviana	Cape gooseberry, uchida
P. ixocarpa	Tomatillo, ground cherry
P. purinosa	Husk tomato
Cyphomandra betacea	Tree tomato, tamarillo

Table 2 World production of major solanaceous fruits (× 1000 tonnes)

Regions	*Tomato*	*Eggplant*	*Capsicum*
World	91 663	21 165	18 024
Africa	10 799	799	2 078
Asia	41 246	19 543	10 715
Europe	19 789	709	2 705

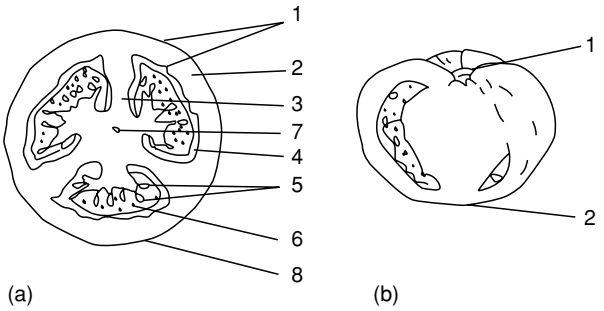

Figure 2 Structure of the tomato fruit: (a) transverse section; (b) longitudinal section. (a) 1, pericarp; 2, outer wall; 3, radial wall; 4, locule; 5, seeds; 6, gel; 7, axile fleshy core; 8, skin. (b) 1, stem scar; 2, blossom end scar.

are China, USA, Spain, Italy, Turkey, and Russia. The fruit is normally round, lobed or pear-shaped, and the diameter ranges from 1 to 12 cm. New cultivars with differently shaped fruits have been developed to suit mechanical harvesting and handling systems (Figure 1). It is a two- to many-loculed berry with a fleshy placenta and many small, kidney-shaped seeds, covered with short, stiff hairs and a jelly-like parenchyma (Figure 2). The tough skin or pericarp thickness varies with the cultivar.

The genus *Lycopersicon* includes red-fruited edible species with carotenoid pigmentation (subgenus *Eulycopersicon*), and green-fruited species with anthocyanin pigmentation (subgenus *Eriopersicon*). *Lycopersicon esculentum* and *L. pimpinellifolium* are red-fruited cultivars, while *L. pissisi, L. peruvianum, L. hirsutum, L. glandulosum*, and *L. cheesmanii* are green-fruited. Varieties evolved on pure-line selection, hybridization, and genetic engineering techniques for market and processing needs are also cultivated in many countries. The Flavr-savr™ is currently a genetically engineered approved tomato variety in the US market. Cultivars suited for home, market, shipping, and processing are listed in Table 3.

The edible *Physalis* species are grown widely in the warmer parts of the world. The fruit of *Physalis purinosa* (husk tomato) is round, yellowish, and acidic-sweet. *Physalis peruviana* (cape gooseberry) is a native of the Andes, and grows from Venezuela to Chile; the fruit is a spherical or ellipsoidal, smooth berry, measuring about 4 cm long and 3 cm wide. The skin color is greenish yellow. *Physalis ixocarpa* (tomatillo or ground cherry) is of Mexican origin; the fruit is a round, green or purplish berry, with a high ascorbic acid content.

Cyphomandra betacea (tree tomato or tamarillo) is a native of Peru and is also grown in India, Sri Lanka, and New Zealand. The fruit is greenish or purple in the early stages and turns reddish at maturity. It has a musky acid taste and tomato-like flavor. The fruit rind is rough with a disagreeable flavor. Several species in the genus *Solanum* are prominent vegetable crops. *Solanum melongena* (eggplant or aubergine) is a popular and staple vegetable crop in Asia, accounting for 92% of the total world production; in Africa

Adapted from Madhavi DL and Salunke DK (1998) Tomato In: Salunkhe DK and Kadam SS (eds), pp. *Handbook of Vegetable Science and Technology – Production, Composition, Storage and Processing*, pp. 171–201. New York: Marcel Dekker.

and Europe, its production is 3.7 and 3.3%, respectively (Table 2). The leading country of its cultivation is China, followed by India, Turkey, Japan, Indonesia, and Philippines. It is an extensively grown perennial crop in the tropics and an annual in the temperate zones. The fruit can be round, globose, long, or pear-shaped. Most cultivars have purple to blackish skin, while some have a white–green or mottled green skin, with white flesh; in the white–green types, the mature fruit has yellow skin. There are regional preferences for the color and shape of the fruit; purple, large, more or less round fruits are preferred in North America. Wild eggplants with spiny and bitter fruits are found in India; of the several improved Indian cultivars, black beauty, long black, round purple, Pusa purple long, Pusa purple round, Pusa purple cluster, long purple and hybrids such as Vijay, S-1, S-4, S-5, and S-8 are popular. *Solanum melongena* has three main varieties; see Table 4.

The African eggplant (*S. macrocarpon*) is a perennial crop grown in the Ivory Coast. The fruit resembles the eggplant. Garden huckleberry (*S. nigrum*) is native to North America and has a wide distribution in temperate and tropical regions; the fruit is a berry about 6 mm in diameter, the color being green when unripe and red, yellow, or black when ripe. Jilo (*S. jilo*) is a major crop of Nigeria and a minor crop in Central and Southern Brazil. Immature green fruits with a spherical to oval shape (of 4 cm in diameter and 6 cm long) are harvested, and on ripening, the fruit develops an organish red color.

Naranjillo or Lulo (*S. quitoense*) is native to Ecuador and is cultivated in Ecuador, Peru, Colombia, and some Central American countries. The fruit is spherical, 3–5 cm in diameter, and with a yellow, rough skin when ripe. The pulp containing many white seeds is green and acidic in taste.

Pepino or melon pear (*S. muricatum*) is an ancient cultivated crop of the Andes, chiefly grown along the central coast of Peru and at elevations of 1000–3000 m from Colombia to Bolivia. It is also cultivated to a limited extent in northern Argentina, Chile, New Zealand, and Australia. The fruit is long, ovoid, or ellipsoidal, and the color varies from light green to pale yellow.

Capsicum (hot, chili, bell, or sweet pepper) is the second most important fruit of the Solanaceae, grown as a vegetable and condiment crop in tropical and subtropical regions of the world. The world production of this pepper is shown in Table 2. There are five major recognized cultivated species of *Capsicum* (Table 5) and seven botanical varieties of *C. annuum* (Table 6). The important species are *Capsicum annuam* (annual with flowers borne singly in leaf axils) and *C. frutescens* (perennial with flower clusters in leaf axils). The bell pepper or sweet pepper (*C. annuum*), which is either mildly pungent or nonpungent, has a thick pericarp and is used in flavoring vegetable preparations. The highly pungent fruit of *C. frutescens* has a thin, smooth pericarp and is used as a condiment. Paprika is a nonpungent type of pepper with a thick pericarp, selectively bred for color and flavor.

China, Korea, Indonesia, Sri Lanka, Pakistan, Japan, Mexico, Ethiopia, Spain, Italy, and Hungary are some of the principal chili-producing countries. The world demand for chilies is increasing. The main exporters of chili are India, China, Indonesia, Hungary, Singapore, Malaysia, Mexico, and Japan. The bell pepper, *C. annuum* var. *grossum* (syn. Simla

Table 4 Common cultivated varieties of *Solanum melongena* and their fruit characteristics

Variety	*Fruit characteristics*
Var. *esculentum* (Wees)	Large, pendent, ovoid, oblong berries, 5–30 cm long, shiny
Var. *depressum* (Baily)	Small, pear-shaped fruits, purple in color, 10–13 cm long
Var. *serpentium* (Deeft)	Slender, greatly elongated, 30 cm long, 2–5 cm in diameter, end-curled

Table 6 Botanical varieties of *C. annuum* and their fruit characters

Variety	*Common names*	*Fruit characteristics*
Var. *abbreviatum*, Fingerh	Wrinkled peppers	Ovate wrinkled fruits, about 5 cm long or less
Var. *accuminatum*, Fingerh		Linear, oblong, pungent, pointed fruits about 9 cm long
Var. *cerasiformae* (Miller) Irish	Cherry peppers	Globose, pungent fruits red, yellow, or purple in color, with firm flesh and 1.2–2.5 cm in diameter
Var. *conoides* (Miller)	Cone peppers (Tabasco type)	Erect, conical, pungent fruit, about 3 cm long
Var. *fasciculatum* (Stuart) Irish	Cluster peppers	Clustered, erect, slender, very pungent fruits, about 7.5 cm long
Var. *grossum* (L.) Sendt.	Sweet peppers, paprika	Large inflated fruit with a basal depression, red or yellow thick flesh with mild pungency
Var. *longum* (DC) Sendt.	Long peppers	Mostly dropping fruits with tapering apex

Adapted from Rajput JC and Parulekar YR (1998) Capsicum In: Salunkhe DK and Kadam SS (eds) *Handbook of Vegetable Science and Technology – Production, Composition, Storage and Processing*, pp. 203–224. New York: Marcel Dekker.

mirch, sweet pepper, bullnose capsicum) is cultivated widely in India, Central and South America, Bolivia, Peru, Costa Rica, Mexico, Hong Kong, and almost all European countries. Based on characteristics such as fruit size, color, texture, flavor, pungency, and uses, a 13-group classification has been proposed for cultivars of this species (Table 7).

The *Capsicum* fruit is a pod-like berry with a short, thick peduncle, developing from a bi-carpellary ovary with axile placentation. Many seeds are present in the cavity between the placenta and fruit wall. The unripe fruit is commonly green, but fruits with cream, greenish yellow, orange, purple, and purplish black colors also exist. Ripe fruits are usually red, but sometimes yellow or orange.

Chemical Composition and Nutritive Value

There is considerable variation in the chemical composition of the fruits of this family (Tables 8 and 9). The stage of maturity, cultivar, environmental, and cultural practices influences the chemical composition.

Tomato

Glucose and fructose are the principle sugars in tomato (representing more than 60% of the solids) with small amounts of sucrose. Ripe fruits also contain raffinose; the glucose concentration increases with ripening. Tomato being a climacteric fruit, ripening is associated with increase in respiration and ethylene production: these in turn are integrated with the disappearance of starch, degradation of chlorophyll, synthesis of lycopene, flavor components, and polygalacturonase. The pectic constituents mainly control the texture and firmness of the fruit. In the ripening process, the predominant protopectin in the green fruit decreases, and the pectin increases, making the fruit soft. The protein content is about 1.0% in ripe fruit, and all the essential amino acids except tryptophan are present; other amino acids identified are tyrosine, aspartic acid, glutamic acid, serine, glysine, α-aminobutyric acid, and pipecolic acid; glutamic and aspartic acids occur in greater concentrations.

Citric acid is the principle organic acid of tomato which gives the fruit its typical taste. Along with a

Table 7 Bell pepper groups, fruit character, and uses

Group	*Cultivars*	*Uses*	*Fruit characteristics*
Bell	California wonder Yellow wonder	Fresh market, salads, pitza, meatloaf, and canning	Large, nonpungent with thick flesh (7–12 cm × 5–10 cm)
Pimento	Pimento select	Fresh market, salads, soups, processed meat, and canning	Large, nonpungent, thick-walled (5–10 cm × 5–7 cm)
Squash or cheese	Cheese, antibois and gambo	Processing, canning, freezing, pickling, salad, and culinary purposes	Small to large, thick-walled, nonpungent, green or yellow to red (2.5–5 cm × 5–10 cm)
Ancho	Mild California, big jam, New Mexican chili	Dried, powdered, and culinary purposes	Large, heartshaped, thin walled, less pungent fruits (10–12 cm × 5–7 cm)
Anahein chili	California chili, paprika	Sauces and canning, processed into powder dehydrated pods	Slender, medium-thick flesh, medium to dark green color turning red, sweet to moderate pungency (12–15 cm × 2–3 cm)
Cayenne		For market, pickling, dry powder, sauces culinary purposes	Irregular, wrinkled, highly pungent fruits turning green to red (12–22 × 1.5–6 cm)
Cuben		Fresh market, salads, pickling, and frying	Long, thin walled, irregular fruits of mild pungency, turning yellowish green to red (10–20 cm × 1.5–5 cm)
Jalapeno	Jalapeno	Fresh green pods, dried powder, canning, and sauces	Elongated, round, cylindrical shape, highly pungent, thin-walled, red at maturity (5–7 cm × 2–5 cm)
Small hot	Red chili, sontaka	Dried powder and sauces	Slender, medium- to thick-walled, highly pungent, turning red (4–7 cm × 1–2 cm)
Cherry	Red cherry, large Red cherry, small	Pickling	Small, spherical, pungent fruit turning red (2–5 cm in diameter)
Short wax	Floraljam, caloro, cascabella	Pickle, cooking, sauce, and processing	Medium- to thick-walled, tapering, turning yellow to orange red (5–7 cm × 2–5 cm)
Long wax	Hungarian yellow wax, sweet banana	Fresh market, pickle, sauce, and canning	Pointed or blunt fruits turn yellow to red (8–12 cm × 1–4 cm)
Tabasco	Green leaf Tabasco, Tabasco	Vinegar, sauce, and pickles	Slender, highly pungent fruits, turning yellow to red (2–5 cm × 0.5 cm)

Adapted from Rajput JC and Parulekar YR (1998) Capsicum In: Salunkhe DK and Kadam SS (eds) *Handbook of Vegetable Science and Technology – Production, Composition, Storage and Processing*, pp. 203–224. New York: Marcel Dekker.

small amount of malic acid, traces of acetic, formic, lactic, and succinic acids have also been detected. The lipid fraction of the tomatoes is composed of triglycerides, sterols, sterol esters, free fatty acids, and hydrocarbons. The phenolics reported are caffeic, ferulic, chlorogenic, and *p*-coumaric acids. The chief coloring materials of tomato at the mature green stage are chlorophyll a and b, while at the ripe stage, carotene and lycopene contents dominate, contributing 7 and 87%, respectively. The final color of tomato depends upon the ratio of the carotene and lycopene. The various volatile compounds in ripe fruit are alcohols, aldehydes, carbonyls, and sulfur compounds, contributing to the flavor quality.

Tomato is regarded as an essential protective food. It is a rich source of ascorbic acid: On a fresh-weight basis, the vitamin C content averages about 25 mg per 100 g, varying with the variety, maturity, and season.

Table 8 Macronutrient content (per 100-g edible portion) of some solanaceous fruits

Crop	Energy (J)	Water (g)	Protein (g)	Fat (g)	Carbohydrates (g)

Research has shown that the inclusion of tomato in the diet can prevent deficiencies of vitamins and minerals. One medium-size, raw tomato provides 47% of the B vitamin, 33% of vitamin A, and 1% of the energy of the daily dietary requirement of an average person. The mineral content varies between 0.3 and 0.6%; apart from calcium, potassium, magnesium and iron, the tomato contains zinc, boron, iodine, cobalt, and aluminum in trace amounts.

The tomato contains a glycoalkaloid, tomatine, and traces of solanine. Narcotine is present in unripe fruit. The tomatine content is lowest in the pink stage of ripeness and increases slightly in the fully ripe tomato.

Brinjal or Eggplant

This contains about 4% carbohydrate, composed of sucrose, glucose, and fructose. Brinjal protein has a high biological value and contains amino acids such as arginine, histidine, lysine, tryptophan, leucine, isoleucine, and valine, although the protein is relatively poor in lysine and tryptophan, isoleucine, and methionine. Brinjal contains a higher percentage of vitamins than many other vegetables. However, it is not a rich source of vitamin B_2. The physical characteristics such as the shape, color, and presence of spines on the calyx have also been found to influence the composition; hence the green, white, and purple varieties are often compared for chemical composition. Dark-purple-skinned varieties contain more vitamins than those with white skins. The white cultivar contains twice as much crude fiber as the purple and green cultivars. The amino acid content is higher in purple cultivars and lowest in the white. Purple cultivars are poor in potassium and chloride content, while green cultivars are rich in these minerals. The polyphenol oxidase activity is highest in the purple type, thus making the fruit turn dark faster when cut surfaces are exposed to air. Variations in the activities of other enzymes have been observed in differently

colored fruits. The main pigment of the fruit is an anthocyanine, nasunin; lycopene and lycoxanthin are also present. The seed oil is reported to be rich in linoleic acid.

The fruit peel contains a bitter principle, solasonine. The phenolic compounds present in the fruit are chlorogenic acid, neochlorogenic acid, scopoletin, and caffeic acid; a trace amount of hydrocyanic acid is also present. Higher concentrations of glycoalkaloids (20 mg per 100 g fresh weight) result in a bitter taste and off-flavor.

Pepper

Pepper is a good source of vitamins A and C, and is superior to tomato and eggplant in this respect. The vitamin C content varies with the variety and maturity stage (160–210 mg in green chilies and 113–160 mg in red ripe fruits). The pungent principle of chili is capsaicin (a crystalline, colorless compound), which is concentrated more in the placenta (90%) that connects the seeds with pericarp. A highly irritating vapor is liberated on heating capsaicin. Yellow chilies are more suitable for capsaicin extraction. An African chili variety, 'Mombusa,' is known for its high capsaicin content. The green fruits contain chlorophyll a and b. The coloring matter of ripe fruit includes capsanthin, capsorubin, zeacanthin, cryptoxanthin, and α- and β-carotene.

Other Solanaceous Fruits

Husk tomato, tomatillo, and cape gooseberry are also important sources of vitamins and minerals (Table 9). Tree tomato contains substantial amounts of carbohydrates and minerals. It is rich in vitamin C and is also a good source of provitamin A.

Handling and Storage

Tomato

Tomato fruits are harvested at different stages of maturity (Table 10), depending upon the use, and are often harvested at the mature green stage for the market and ripened either in transit or during storage. For canning or juice extraction, the fruit is harvested at the ripe stage. The postharvest losses in tomato may range from 5 to 50%; the highest loss is attributable to mechanical damage, and other causes may be physiological disorder, diseases, and heat and chilling injury.

Packing-house operations include cleaning, grading, waxing, wrapping, and packing. Fruits are transported to the market in bamboo baskets, corrugated board cartons, or wooden boxes. In general, the optimum storage temperature and relative humidity (RH) for tomato storage is 12 °C and 86–95%. However, depending upon the stage of fruit maturity at harvest, storage conditions vary. Mature green tomatoes can be stored at 13–18 °C and 85–90% RH for 3–4 weeks as the fruits ripen at this temperature without chilling injury. Holding them below 10 °C for more than 24 h should be avoided to overcome the symptoms of chilling injury. However, storing green fruits above 18 °C results in early ripening, which leads to rapid deterioration in the quality of the fruits, while at about 30 °C, the red pigment formation is hindered, and the ripe fruit develops an orange to yellow color. Fruits at the breaker stage are less sensitive to chilling injury than immature green fruits. Ripe tomatoes can be preserved for 7–10 days at 3–5 °C and 85–90% RH. Fully ripened fruits are held between 1.7 and 4.4 °C until they are ready for use. Prolonged storage of fully ripe tomato causes softening and loss of color of the fruits.

Controlled-atmosphere and hypobaric storage can also prolong the shelf-life of the tomato. The packaging of tomatoes in polyethylene bags provides a modified atmosphere, which extends the shelf-life. Postharvest treatment with gibberellic acid markedly retards ripening, while 2,4-dichlorophenoxyacetic acid, naphthalene acetic acid, and ethylene hasten ripening, and this facilitates the marketing of mature green tomatoes. Ethephon, an ethylene-releasing compound, has been used commercially to accelerate

Table 10 Maturity stages of tomato

Stage	*Characteristics*
Immature green	Seeds and jelly-like substance surrounding the seeds not yet formed
Mature green	Fully grown fruit shows a brownish ring on the stem scar, and blossom end turns yellowish green; seeds are surrounded by a jelly-like substance
Turning (breaker stage)	One-quarter of the surface at blossom end appears pink
Pink	Three-quarters of the surface appears pink
Hard ripe	Nearly all red or pink, but flesh is firm
Over-ripe	Fully red and soft

Adapted from Gould WA (1992) *Tomato Production, Processing and Technology*, 3rd edn. Baltimore, MD: CTI.

ripening. Chemicals such as captan, dithane, and thiram have the greatest potential as fungicidal treatments on tomatoes.

Brinjal

Brinjal is a heavy vegetable and requires care in handling, even though it is not as perishable like the tomato. The fruit becomes edible from the time it attains one-third or the full growth size. Over-mature fruits are dull, seedy, and fibrous, sometimes tasting bitter. After harvest, the graded fruits are packed in special crates or bushel baskets. In tropical countries, chilling injury and certain pests and diseases cause high losses of eggplants. Temperatures below 10 °C cause chilling injury, the symptoms of which are pitting, surface bronzing, and browning of the seeds and pulp. Fruit rot and anthracnose caused by *Phomopsis parasitica* and *Gleosporium melongense*, respectively, are the most serious postharvest diseases. Hot water (50 °C) and a low concentration of dithiocarbamate provide good disease control. The fruit can be stored successfully for 2–3 weeks at 10.0–12.8 °C and 92% RH. Controlled-atmosphere storage has not been found to be beneficial in extending the storage life of the eggplant. Small fruits are not well suited for long-term storage, and chilling injury is more common in tender fruits. Prepackaging of brinjal in adequately ventilated polyethylene bags (100-gauge) increases the shelf-life, and treating brinjal with a fungicidal wax emulsion extends the shelf-life by 30–40%.

Pepper

Chili, used as a raw vegetable, is harvested green, but for processing, only red ripe chilies are harvested. The important postharvest losses in chili are weight loss, chilling injury, and microbial spoilage. At the recommended storage conditions of 7.2 °C and 85–90% RH, green peppers can be stored for 2–3 weeks, and ripe peppers at 5.6–7.2 °C and 90–95% RH can be stored for about 2 weeks. Storage in paper bags rather than in polyethylene bags can prolong the shelf-life of hot peppers. Bell peppers are harvested when they attain their full size and are still green. Storage below 7 °C results in chilling injury and, subsequently, *Alternaria* rot. Controlled-atmosphere storage at various temperatures has been recommended to extend the shelf-life of bell peppers, while hypobaric storage is not beneficial as it greatly increases the weight loss. Fruits are commonly wax-coated to reduce the moisture loss before shipment. Ripe fruit can be preserved at room temperature (20 °C) for only a week, but for 12–14 weeks at 3–4 °C after dipping in hot water at 50 °C for 10 min. A common storage disease is bacterial decay by *Erwinia carotovora*.

Uses of Solanaceous Fruits

Fresh, ripe tomato fruits are refreshing and appetizing, and are consumed raw in salads or after cooking. Unripe fruits are usually cooked and eaten. Large quantities are processed in southern European countries and in California. Tomatoes can be processed into juice, purée, paste, ketchup, sauce, soup, and powder. Special varieties have been evolved to meet these processing requirements. The tomato cultivars for juice should have a bright color, rich flavor, and high total acidity. They should also be juicy and not meaty. Tomatine, a glycoalkaloid present in the fruit, yields, on hydrolysis, tomatidine, which can be transformed into hormones such as progesterone and testosterone. The oil of tomato seeds is used in the soap and paint industry. The pressed cake can be used as a feed for livestock or a fertilizer. Tomato also has several medicinal applications and is used in the preparation of traditional medicine in Japan, Greece, and Peru. The hot water extract of dried fruits has been used in the treatment of ulcer wounds and burns, and tomato has been reported to reduce the risk of prostrate and digestive tract cancers.

Brinjal is valued more as a vegetable during the autumn when other vegetables are scarce. It is a fairly good source of calcium, iron, phosphorus, and vitamin B. Sun-dried or hot-air-dried eggplant powder with good organoleptic and nutritive qualities has been prepared. Treatment with brinjal is recommended in liver complaints. It has been reported to stimulate the intrahepatic metabolism of cholesterol and produce a marked drop in blood cholesterol level.

The garden huckleberry (*S. nigrum*) leaf has great medicinal value. The tender leaves are boiled like spinach and eaten in many parts of India. Ripe fruits are used as a substitute for raisins in plum puddings. The berry is considered to possess tonic, diuretic, and cathartic properties, and is useful in the treatment of heart disease. The berries also find use as a domestic remedy for fever, diarrhea, ulcers, and eye problems.

Peppers are used green, or after ripening, in a great variety of ways. Chilies, when taken with food, stimulate the taste buds and increase the flow of saliva. The commercial red pepper(s) consists of the fruits of a small, pungent variety, which is dried and ground to a fine powder. Dry chili powder and green chilies are commonly used in various culinary preparations and in the preparation of sauces, soup, ketchup, and salads. Pepper sauce, prepared in a variety of ways, consists of the fruit of pungent varieties preserved in brine or strong vinegar. Both red and

green bell peppers are sold frozen and are also canned, along with other vegetables. Tabasco sauce is prepared from the juice of a pungent variety, expressed by applying pressure. Paprika, a Hungarian condiment, is made from fruit ground after removing the seeds. Pepper is used in pickles of various kinds. The sweet varieties are stuffed and baked. *Capsicum* preparations are used as a counterirritant in neuralgia and rheumatic disorders. Green chilies are a good source of L-asparaginase, which has an antitumor effect and is used in the treatment of acute lymphocytic leukemia.

The oleoresins have varying color properties and pungency, are prepared from the dried fruits of *Capsicum*, and are used in the pharmaceutical, food, and cosmetic industries. The three types of oleoresins are oleoresin capsicum, oleoresin red pepper, and oleoresin paprika; oleoresin capsicum is used in making pain-balms and vaporubs. The nonpungent type of oleoresin is chiefly used as a coloring agent, while the pungent type is used for flavoring and coloring snack foods. Chili seed cake, a byproduct of seed oil, has a protein content of 27–29% and can be used as a fertilizer or as an animal feed. Chili color is a new product, which can replace artificial food colors.

The melon pear fruit is cooked and eaten when immature, while the mature fruit has a fleshy pulp with an aroma and flavor similar to those the cucumber. Lulo is cultivated mainly for the juice, especially in Ecuador, Peru, Columbia, and some Central American countries. The young shoots of jilo are finely chopped and used in soups in Nigeria. Tomatillo can be used to make chili sauce and is used for dressing meats in Mexico. The ground cherry, which is acidic-sweet, is used for preserves and sometimes for sauces, and the Cape gooseberry is eaten raw or preserved as a pickle.

Processing Potato Tubers

M G Lindhauer, N U Haase and B Putz, Federal Centre for Cereal, Potato and Lipid Research, Detmold, Germany

Background

The convenience aspect of processed potatoes (*Solanum tuberosum* ssp. *tuberosum* L.) has become of significant importance in the total use of potatoes by humans. Especially in some industrialized countries, the percentage of potato products in relation to total use of potatoes as foodstuff has reached a value of up to 65% (e.g., in the USA). To get an overview, the main directions of potato processing are discussed in this article.

Raw Material for Processing

Potato processing requires special quality profiles of the raw material. Therefore, the number of varieties suitable for processing is limited. Plant breeders make a great effort to select new varieties with better agronomical behavior and with higher internal quality. Today, only a few varieties with a known processing quality are grown worldwide.

Several specific aspects must be observed:

- The oxidative potential of the harvested tubers should be low to prevent discoloration during the first processing steps.
- Key constituents like protein, minerals, and vitamins should be high because of inevitable losses during processing. Also the total content of solids should be high to make processing more worthwhile, by achieving an higher input-to-output ratio.

Typical nutrient contents of selected potato products are listed in Table 1.

Storage Aspects

Storage has to provide high-quality potato tubers to the processing plant for several months. Good storage management should prevent excessive loss of moisture, development of rot, and excessive sprout growth. Also the loss of potato constituents (e.g., ascorbic acid) should be low. Finally, the accumulation of reducing sugars must be controlled to prevent dark-colored products.

After harvest, potatoes pass through a period of several months without any sprouting. The following sprout growth is little or absent at temperatures below 5 °C. However, reducing sugars accumulate in excessive quantities, resulting in undesirable dark-brown colored products. Therefore, potatoes for processing are stored at 8–10 °C. At that temperature sprouting must be controlled. Experiments have been conducted with gamma-irradiation of tubers or treatment of vines with maleic hydrazide. Also several chemical compounds are known to inhibit sprouting (e.g., ethylene, volatile monoterpenes, ethanol, abscisic acid, and naphthalene), but in practice isopropyl-*N*-(3-chlorophenyl) carbamate (CIPC) is preferred. To prevent the use of antisprouting agents, potato breeders have created cold storable varieties without cold sweetening to avoid the problem described.

Immature tubers with considerable amounts of free sugars will not reduce that level during storage. Also storehouses with little gas exchange capacity lead to high contents of reducing sugars inside tubers. This is because of the increasing carbon dioxide concentration in the storage atmosphere. An increase of carbon dioxide towards 0.5% in the atmosphere already shows a significant deterioration of baking color. Depending on the geographical region, storehouse equipment must include a mechanical ventilation and cooler. The relative humidity should be 90% minimum.

Potato Processing for Food

A schematic overview of several processing techniques is given in Figure 1.

Common Techniques

Washing Washing systems remove dirt and attached soil from the tubers. Stones can be removed through stone catchers or through exploitation of the different specific density in comparison to tubers. Often the washing water is taken from the overflow of waste water decanters within processing.

Peeling With few exceptions, all tubers are peeled before processing. Abrasive and steam peelers are common, while in the past lye (caustic) peelers were also used. Because of concern about environmental effects, the importance of that type of peeler has decreased. In abrasive peelers, designed with carborund layers or knives or combinations thereof, the amount of peeling waste can be up to 60% of tuber weight, if the tuber shape is irregular or deep potato eyes exist. Most single cells are disrupted and oxidative enzymatic discoloration must be avoided (often by additives, such as sulfur). Steam peelers remove much less of the tuber cortex. Most of the tissue with high nutritive value achieves further processing.

Table 1 Typical nutrient concentrations of processed potatoes

	Per 100 g edible material					
	Energy (kJ) (kcal)	*Main constituents*				
		Protein (g)	*Fat (g)*	*Carbohydrates (g)*	*Potassium (mg)*	*Ascorbic acid (mg)*
Cooked potatoes	298 (71)	2.0	traces	14.8	443	14
Potato chips (crisps)	2241 (536)	5.5	39.4	40.6	1000	8
French fries	1215 (290)	4.2	14.5	35.7	926	28
Mashed potatoes	314 (75)	2.0	1.9	12.2	259	9

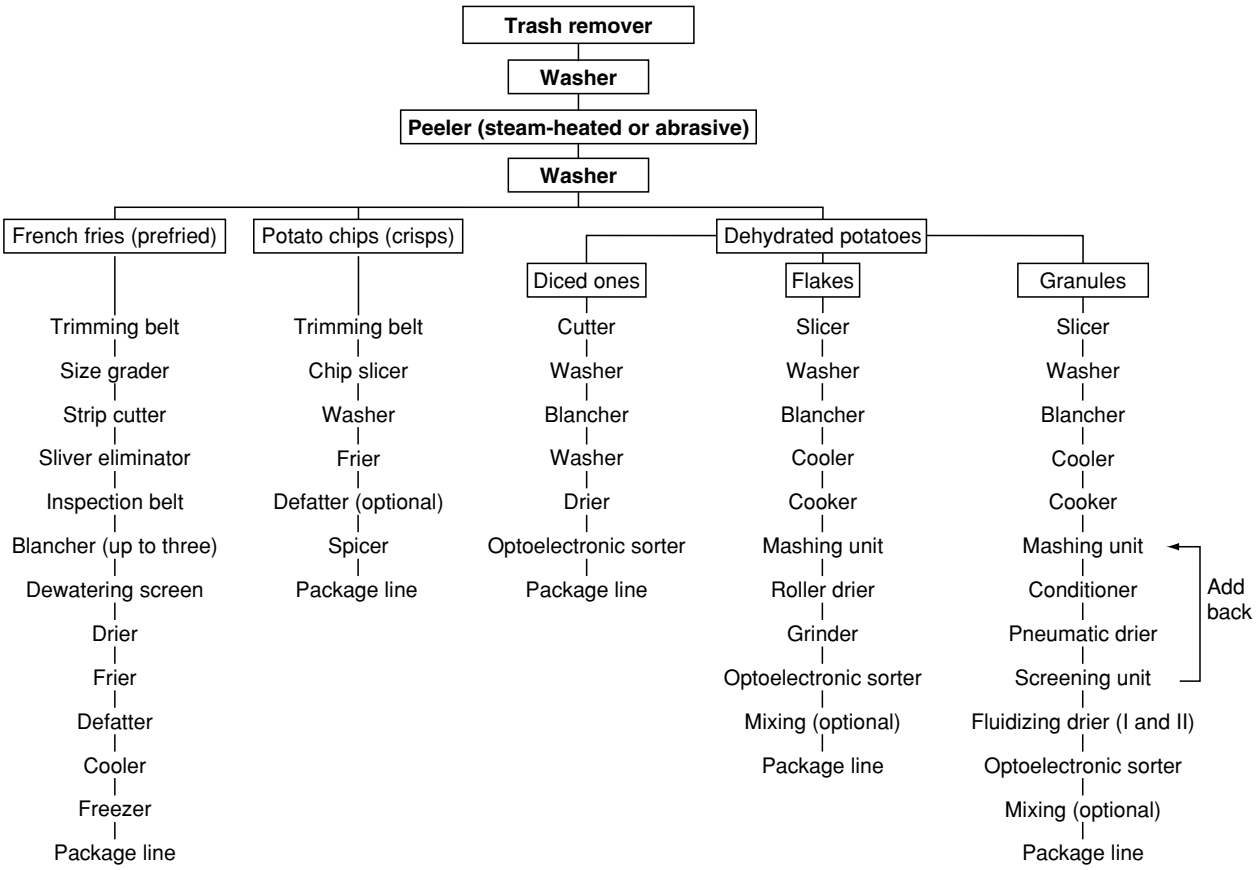

Figure 1 Schematic description of main processing lines.

Tubers come into contact with high-pressure steam (up to 15 bar) for a few seconds. The outer cell layers are softened, and the cohesion of the tissue is loosened. Through fast relaxation of the vessel the peel is separated from the tubers and can be removed by brushes or by a hard water jet. The main disadvantage is the layer of cooked tissue. Therefore, the preferred application is when making French fries and dehydrated products, whereas potato chips (crisps) are predominantly produced using abrasive peelers.

Cutting Several types of cutting exist depending on final use. The stream of tubers is directed to specially designed knives with the help of centrifugal power or water pressure. High-pressure water knives need precise positioning of tubers. Except for when slicing potato chips (crisps), using smooth and crinkled knives, cutting is carried out in several steps. Disks are cut first. Then, stripes are cut with rotating knives. If cubes are to be manufactured, a third cutting is done using chopping knives. Stripes for French fries production can be cut using water knives. High-pressure water leads tubers through a pipe with a cutting fence at its end.

Sorting Irregular cuts must be removed, if the shape of single pieces is a quality criterion, e.g., when manufacturing French fries, and thus is done before and after the main processing. Separation takes place by screening or by roller sorters. Optoelectronic sorters allow an additional sorting according to discoloration. Single pieces are visually inspected by charge-coupled device (CCD) cameras. Next to light and dark differentiation, state-of-the-art systems also offer the possibility of color differentiation. Discolored pieces are removed from the main stream by an ejection system using compressed air.

Blanching Blanching means a short-term heat treatment (70–100 °C) of raw potatoes or potato pieces. Several reactions occur. Enzymes are inactivated (e.g., polyphenoloxidase) to prevent discoloration. Often the peroxidase system is regarded as a key enzyme mirroring the efficiency of enzyme inhibition. Reducing sugars are leached off, to minimize the Maillard reaction, as well as starch pastes, to reduce fat uptake during frying. Blanching for about 20 min at 70–75 °C results in a firm structure. Native pectin methyl esterase is activated to reduce cross-linking

of pectin, and free carboxyl groups may react with calcium or magnesium liberated from starch granules after gelatinization to form a thermostable pectin network. The addition of calcium to the blanching water intensifies that reaction.

Blanching takes place predominantly in a continuous screw motion through a water bath or through a steam chamber. Depending on the raw material and the shape of single pieces, blanching parameters vary widely.

Dehydrated Potato Products

Dehydrated diced potatoes Dehydrated diced potatoes have been produced since the beginning of the twentieth century. Their first use was as a staple food. Today, snack industry and other food manufacturers (e.g., for dumplings, hash brown) are the main users of dehydrated diced potatoes. Because of different outlets, no uniform quality level can be addressed, but discoloration is to be prevented, flavor should be fairly typical of the varietal characteristics, and texture of the reconstituted product should be similar to that of fresh prepared potatoes.

Processing Preliminary inspection by hand or by optoelectronic sorters immediately after washing removes potatoes that are unfit for processing.

Standard peeling equipment uses steam or abrasive peeling. The expense of the inspection and trimming of peeled tubers can be reduced by optoelectronic inspection belts.

Mechanical dicers which can be adjusted to various cutting sizes (e.g., cubes, disks) cut the tubers. Irregular cuts depend on the sharpness of the cutter blades and on the mass flow of potatoes. Released solids (up to 15%) cannot be avoided but should be reduced as far as possible. Often, free starch is separated from the wash water and is used for special purposes.

Blanching for 2–10 min at 90–100 °C reduces adverse enzymatic reactions. Under- and overblanching negatively affects the texture and appearance of the finished product. Therefore it is to be controlled periodically. After blanching, gelatinized starch must be removed from the surface by a further water bath or a rinsing spray.

Sulfiting during or just after blanching protects against nonenzymatic browning reaction (darkening after cooking) during drying and reduces adverse oxidation during storage. Chemicals to be used are sodium sulfite, sodium bisulfite, sodium metabisulfite or combinations thereof. The European Community tolerates up to 400 mg sulfite as sulfur dioxide per kg ground dehydrated potatoes.

Potato drying is a two-stage process by migration of water to the surface and by removal of surface water by evaporation. Slow dehydration at a low temperature (e.g., 30 °C) gives a hard dense product, while a higher temperature results in a more porous material with better rehydration capacity. Hot air driers, constructed as hordes drier with a batch charging, or as a continuous-belt drier (conveyor drier) are used in most cases. During the first stage of drying moisture is readily removed and the drying rate is high. Therefore, the temperature can be high (70–90 °C). Within the second stage of drying, progress is much less and temperature is reduced to 50–70 °C. Potato size, shape, and raw material characteristics influence the efficiency of water removal. Microwave-assisted drying reduces the drying time drastically. The rapid diffusion of moisture through the surface will tend to eliminate surface hardening. Rehydration potential rises. It is most suitable at moisture levels between 6 and 30%, but often energetic and economic disadvantages prevent utilization.

Screening and inspection by pneumatic separators follows drying, to remove small pieces, discolored pieces or peeling left on potato dices, and black spots.

Dehydrated mashed potatoes

Dehydrated flakes Potato flakes are dehydrated mashed potatoes made by drum drying a thin layer of cooked and mashed potatoes, and breaking the sheet of dehydrated solids into a suitable size for packaging. Next to retail consumption in a pure state or prepared with milk solids and other constituents, flakes are taken as a food ingredient for potato snacks (e.g., potato chips made from a dough with uniform size and curvature, and for dehydrated French fries). A finely ground potato flour for soups and baked goods is also available.

Processing Raw potatoes should be washed to remove adhering soil, and sorted (by hand or by optoelectronic sorters) to remove defective tubers.

Peeling may be done by any process described above. In most cases steam peeling is used. Trimming may ignore some peel and defects, because of a final product control by optoelectronic sorters.

The tubers are sliced into disks of 1 cm thickness to obtain a more uniform heat treatment during precooking and cooling. Thinner slicing is possible, but flavor deteriorates and loss of solids clearly increases.

Precooking leads to gelatinization of starch and enzyme inactivation. Cooling below 20 °C for about 20 min reduces the level of free starch in the final flakes. For a long time that effect was described as retrogradation of gelatinized starch, but that reaction needs several hours to become visible. More evidence is given in toughing cell wall components (e.g.,

reduced pectin esterification) for an increased resistance against shear forces during drying.

For cooking, steam of atmospheric pressure is injected into a screw conveyor. To determine the proper degree of cooking, time must be evaluated periodically. Overcooking results in a poorer texture of the finished product, whereas undercooking causes excessive loss of mash from the applicator rolls and a high level of defects.

Mashing immediately follows cooking to avoid cell rupture of cooled and firmed potatoes. Also mixing with additives is easier in the hot stage. Next to emulsifiers (0.5% monoglyceride, to complex free gelatinized starch), chelating agents like sodium acid pyrophosphate (which reacts with iron, preventing darkening after cooking) and antioxidants like butylated hydroxyanisole (which extends storage life and provides reduced rancidity) are used widely. Also sulfur can be added to prevent nonenzymatic browning. The proper dosage of additives is difficult because of high losses during drying (up to 75% of antioxidants is lost and 50% of sulfur dioxide).

Drying takes place on a single-drum drier fitted out with four to six applicator rolls. The drum (e.g., 1.5 m diameter and 5 m length) is steam-heated. The temperature on the surface is between 140 and 160 °C. The mash is applied above the top roll while the direction of drum rotation is downward. Therefore, the distance between the top roll and the drum surface determines the rate of flow of mash to the rolls below. Each applicator roll applies a layer of potato cells to the drum. The distance of the applicator rolls to the surface of the drum must be controlled very carefully, because cell rupture is influenced by distance. A wider distance may result in a nonuniform deposition of potato cells and lumps from larger agglomerates can be in the product. Finally, a knife removes the dry sheet. It drops down into a screw conveyor which transfers the roughly broken sheet to a collecting tank. Then it is ground with hammer mills, creating a product with acceptable texture. High amounts of fines is necessary to prevent a sticky reconstituted product. The shelf-life depends on the atmosphere in the final products packages. Autoxidation of free fatty acids remains a problem.

Dehydrated granules Potato granules are dehydrated single cells or aggregates of cells dried to about 6–7% moisture after prior cooking. The principal process used is the 'add-back' process. Potatoes are partially dried by adding back previously dried granules to give a moist mix, which is air-dried after conditioning. The result is potato flakes, but the product is much less sticky, because most cells remain intact.

Processing The first steps of processing are as for flake processing. Raw potatoes are washed and sorted (by hand or by optoelectronic sorters) before steam peeling. Trimming removes the rest of peel and the defects, and slicing results in disks with 1–2 cm thickness to obtain a uniform heat treatment.

During precooking sulfur dioxide is added to prevent nonenzymatic browning.

Water cooling below room temperature for about 20 min reduces the level of broken cells in the final product.

Steam cooking at atmospheric pressure in a screw conveyor for about 30–50 min gives fully cooked potatoes ready for mashing and mixing with dry add-back granules. Repeated mild shearing and pressing of the added granules against the cooked mash causes separation of the latter into single cells with a low content of broken cells.

The moist mix is cooled to approximately 15–25 °C and held for about 1 h at that temperature (conditioning) by moving the moist mix on rubber belts with a depth of product of 10–20 cm, to avoid excessive compression. Since some agglomeration does occur during conditioning, gentle mixing is advised after that. Very large agglomerates and bruised tissue can be separated by a scalping reed. Poor granulation is a self-perpetuating process. Therefore, the amount of large granules will increase progressively with continued recycling. Because the larger particles do not absorb moisture rapidly enough, the process is to be controlled periodically.

Flash drying with a heated air stream, an inlet temperature of 170 °C, and an outlet temperature of 80 °C reduces the moisture content to about 12%. Material coarser than 60–80 mesh is screened off and returns to the process as add-back. Further drying takes place in a two-chamber fluidizing drier with alternate hot- and cold-air streams towards a final moisture content of about 6%.

For retail purposes the granules can be agglomerated with fat, milk solids, and flavors to give a ready-to-eat product. In that case only rehydration with hot water is necessary.

French Fries

French fries are deep-fat-fried potato strips. Commercially distributed French fries (UK: chips) are semifinished, and must be fried or heated before consumption (par-fried = partially fried). Shelf-life depends on the kind of distribution, either fresh (cooled) or deep-frozen. With respect to the desirable quality profile, large and long oval-shaped tubers (50 mm up) are preferred.

Processing Sorted tubers are cleaned. Subsequent peeling is with steam peelers. After removal of the

skin, strips are cut either by mechanical knife systems or by water knives (e.g., 6×6, 9×9, 11×11, 13×13 mm). In an inspection unit small pieces and defects are removed. The total amount of waste can be up to 50%, but most rejected material is processed to other products, e.g., pommes croquettes. In a washing unit free starch and other solids are washed off. Blanching reduces enzyme activity. A layer of pasted starch reduces fat uptake during frying. To prevent nonenzymatic discoloration, sulfur is often added to the blanching water. After washing, sometimes a second blancher with a low concentration of glucose is implemented to adjust the content of reducing sugars for a more stable frying color. Also dipping in a water bath containing a coating substance occurs, to enhance the texture stability for about 5–10 min after final frying. Predriers remove free water from the surface and the outer layer. Fat uptake will be reduced by the higher dry-matter content. Frying units can have a capacity of $4\,t\,h^{-1}$ of product, or more. The fat content of such units can be more than 5000 l of fat. Temperature is between 140 and 180 °C. The potato strips are moved through the oil bath by conveyor belts. To enhance texture behavior and capacity, two frying units can work in a line. Normally, the total frying time is between 3 and 5 min. After frying a defatting unit removes free fat from the surface by vibration or by hot-air streams. Mechanical cooling reduces the temperature of prefried strips to 4 °C. That product can be packaged and distributed as par-fried fresh French fries. Alternatively, the French fries are frozen inside tunnel freezers, packaged, and distributed as par-fried deep-frozen French fries.

Potato Chips

Potato chips (UK: crisps) are thin slices (1.1–1.6 mm) of fresh potatoes which have been normally peeled and fried in hot oil to reduce the water content to less than 2%. For processing, special varieties with a very low content of reducing sugars (< 0.15% fresh weight) are required.

Processing After cleaning and visual inspection, the tubers are peeled abrasively with losses up to 25%. Thin slices are cut with smooth or crinkled knives. In a washing unit free starch and other solids of disrupted cells are washed off. Optionally, blanching may reduce the content of reducing sugars. Predriers remove free water from the surface and the outer layer. Frying units can have a capacity of $4\,t\,h^{-1}$ of product or greater. The oil content of such units can be more than 5000 l of oil. Temperature is up to 190 °C. The potato slices are of lower specific density than the oil. Therefore specially designed rotating paddles dip and move the slices forward. Total frying time 2–4 min. The slices absorb up to 50% oil. That high amount of oil must be continuously replaced. After frying, a defatting unit removes free fat from the surface by vibration or by hot-air streams. The hot slices are seasoned and packaged.

Others

Peeled potatoes Peeled table potatoes are produced with abrasive peelers, either carborund or knives or combinations thereof. Shelf-life depends on the hygienic status. Preservation with chemicals (e.g., sulfur) leads to a shelf-life of 8 days, whereas a substitution of air by nitrogen or carbon dioxide or combinations thereof leads to a shelf-life of 10 days.

Potato dough Several potato products prepared of dough are available, either fresh or deep-frozen (e.g. pommes croquettes, pommes duchesses). Dough preparation of cooked potatoes and several other ingredients can be from fresh potatoes (e.g., small pieces from French fries production) or from dehydrated potatoes. A final frying or heating is necessary.

Sterilized potato products Peeled potatoes are available as canned potatoes. After peeling, diced or whole tubers are blanched with water at 85 °C, filled in cans and covered with brine, sealed, and sterilized at 121 °C. In addition to table potatoes, other potato products are also sealed in plastic bags and sterilized.

Potato Processing for Industrial Purposes

Ethanol

Ethanol originates from sugar fermentation of yeast (*Saccharomyces cerevisiae*). Processing of ethanol production integrates these steps: first starch is broken down by steaming the potatoes. After mashing the potatoes, yeast fermentation runs in a batch process for up to 3 days. Finally the crude spirit is distilled and rectified.

Starch

Starch is the main component of solids in potato tubers. In comparision with other types of starch, isolated potato starch offers several technological advantages for applications in the food and nonfood industry. Also plastic substitutes (e.g., shopping bags) have become of strong interest. The main disadvantage of potato starch separation is the campaign separation outside the winter season: destroying the cells by rasping liberates the starch granules. After

fruit water separation, starch is washed out in jet extractors of various types. In addition to welded sieves, plate sieves improve the efficiency of this step. After desanding, crude starch milk is purified by countercurrent washing with demineralized fresh water, dewatered, and dried. Optimum engineering results in starch recovery rates of at least 97–98%.

Fruit water is separated and concentrated by decanting for subsequent protein recovery by isoelectric precipitation and heat coagulation. The remaining deproteinized fruit water can be concentrated by ultrafiltration or reverse osmosis. Further evaporation results in a potato protein liquid.

Chicken

A J Maurer[†], Formerly of University of Wisconsin-Madison, Madison, MI, USA

Introduction

Chicken is one of the most widely accepted muscle foods in the world. Its high-quality protein, relatively low fat content, new products, and generally low selling price because of favorable feed conversion make chicken a high-demand food in the marketplace. Furthermore, the absence of cultural or religious taboos allows increased chicken production and consumption worldwide.

This article reviews specific characteristics of chicken, its chemical composition and nutritive importance, production advances, slaughter and further processing, food uses and products, and microbiological problems.

The USA leads the world in poultry meat production, followed by the former Soviet Union, China, and Brazil. Consumption of chicken in the USA has increased dramatically over the last 20 years. **Table 1** shows the changes in chicken consumption and

Table 1 Meat consumption per capita (kg) in the USA

	1994	*1995*	*1996*	*1997*	*1998*
Beef	30.3	30.5	30.6	30.3	30.5

compares those changes with other meats. Broiler consumption in the USA continues to increase.

Chemical Composition, Nutrition, and Dietary Significance

Chicken is a very digestible source of high-quality proteins. Its muscles are differentiated into light meat (primarily the breast) and dark meat (the legs). These muscles vary in myoglobin content as well as in fat content. Table 2 lists the chemical composition of selected chicken parts, and shows some of the proximate changes that occur on cooking. (*See* **Protein**: Food Sources.)

Chicken meat is low in total fat and saturated fat, and light meat is lower in fat than dark meat (Table 2). Most of the fat in poultry is deposited under the skin and is easily removed by pulling the skin from carcasses or parts. Because chicken fat has a high ration of unsaturated to saturated fatty acid (approximately 30% saturated), the fat melting point is relatively low and liquefies easily. Chicken fat is also prone to oxidative rancidity. Although most consumers believe otherwise, sodium and cholesterol contents in chicken are similar to those in most meats. Light meat contains more protein, and dark meat contains higher levels of fat and cholesterol. Older chickens generally contain more fat and less moisture. Cooking tends to concentrate the level of cholesterol and protein because water is lost in the heating process. (*See* **Cholesterol**: Properties and Determination; **Fatty Acids**: Properties; **Sodium**: Properties and Determination.)

Chicken contains all the essential amino acids, and is a good source of B vitamins and minerals such as iron and phosphorus. Poultry meat also provides potassium, calcium, magnesium, and copper, but carbohydrates and fiber are negligible. Light meat contains more nicotinic acid than dark meat, although both are good sources. Conversely, dark meat contains more riboflavin, iron, and zinc than light meat. (*See* **Amino Acids**: Properties and Occurrence; Refer to individual vitamins and minerals.)

Economics of Fast-Growing Broiler Chickens

Chicken broilers have been bred to a uniform size specifically for meat yield. A common broiler strain combines Cornish genes for conformation and fleshing with the White Plymouth Rock for white feathers and faster growth. White-feathered birds are the norm for commercial broiler production because of their cleaner-looking defeathered carcasses.

Many factors have contributed to the efficiency and economics of broiler production. Advances in breeding, nutrition, disease control, and management practices have enabled the broiler industry to produce a chicken weighing 1.8 kg in 6–7 weeks. Vaccines, antibiotics, confinement rearing, and computer-balanced rations assist in producing broilers with a feed conversion ratio of less than 2 kg of feed per kg gain. Vertical integration in the broiler industry has increased efficiency even more by combining most of the activities in producing, processing, and marketing broilers under the same ownership and management.

Chicken Processing

Chicken slaughter and processing have evolved into a sophisticated and automated procedure whereby a processing plant can handle as many as 20 000 broilers per h. Transforming live chickens into a ready-to-cook form involves live bird catching, crating and hauling, unloading, hanging on a conveyor line, stunning, slaughtering and bleeding, scalding,

defeathering, eviscerating, inspecting, chilling, grading, packing, and shipping. (*See* **Meat**: Slaughter.)

Assembly of Live Birds

Broilers should be taken off feed 8–12 h before the time of slaughter to reduce fecal contamination during processing. Bruising in chickens can be minimized by removing feeders and waterers prior to the arrival of the catching crew, and by careful handling of the birds as they are caught and placed into coops. Novel mechanical methods (e.g., herding, sweeping, and vacuum systems) for catching chickens are also available and commercially used by a few companies in Europe.

Hauling and Unloading

After the birds are loaded into wooden or plastic crates or specially built compartments, they are transported via open-sided trucks to the slaughter plant. Large-volume, slow-speed fans or evaporative cooling provides good ventilation and comfort for the birds in the holding shed.

Trailer loads move into the plant unloading area as needed. Various methods (e.g., manual bird removal, or dumping the birds through side-doors) unload the crates. Birds are hung by their shanks on shackles attached to an overhead monorail conveyor for transfer through the slaughtering operations. The unloading area should be dimly lit, and a breast rub bar can be used to calm the birds. According to UK regulations, birds should be slaughtered within 3 min after they are suspended from shackles.

Stunning, Killing, and Bleeding

Stunning is used to enhance bleeding and feather release. The heads of the birds are usually dragged through an electrically charged water bath. For consistent stunning, the water should contain from 0.1 to 1.0% sodium chloride. A fine mist of water spray should be directed at the bird's feet to provide a positive electrical contact prior to entering the stunner. The shackles complete the circuit and cause an electric current to run through the body of the bird as a result of the applied voltage (approximately 50 V). Overstunning can rupture blood vessels and break carcass bones due to excess muscle contraction. It is essential that the electric shock does not kill the bird; bleeding must be the cause of death.

Killing can be either manual or mechanical. In the manual operation, a skilled worker with a sharp knife severs the jugular vein and carotid artery by cutting across the side of the neck at the base of the bird's head. In mechanical neck cutting, a guide bar with grooved rollers holds the head rigid and extends the neck in preparation for the cuts. The bird's head is guided across a single, revolving, circular blade or between a pair of revolving blades.

Bleed time should be 1.5–2 min, and the blood lost accounts for approximately 4% of the live weight. The shackles convey the birds through a blood tunnel, so that the blood can be collected and disposed of properly.

Scalding

After bleeding, the birds are scalded to loosen the feathers by immersion in agitated hot water. Wing flapping and struggling should have ceased by the time birds enter the scalder. In general, a soft- or semiscald temperature of 50–54 °C is used, with an immersion time of 1.5–2.5 min. For the fresh chilled broiler market, low-temperature scalding permits retention of the yellow cuticle on the chicken skin and retards skin drying.

Chickens are subscalded at 59–60 °C for cuticle removal if there is a preference for lighter-skinned birds, if the carcasses are to be frozen, or if the parts are to be battered and breaded. Higher temperatures greatly facilitate feather removal, and necks and wings of semiscalded birds are often scalded at the subscald conditions to achieve cleaner carcasses. In the USA, the US Department of Agriculture (USDA) recommends a minimum overflow from the scalder of 11 per bird to reduce build-up of contamination. Various chemicals added to scald tanks assist feather removal by reducing surface tension and enhancing wetting of the feathers. An alternative to immersion scalding with separate defeathering machines is a combined spray-scalding and defeathering system. This type of scalding may reduce contamination spread from bird to bird.

Defeathering

After the carcasses leave the scalder, they enter a series of online defeathering machines. The picking machines consist of banks of counter rotating stainless-steel disks or drums, with rubber 'fingers' mounted on them. As the birds are conveyed through the rotating picker fingers, the feathers are rubbed or plucked from the carcass. Continuous water sprays flush away the feathers.

Remaining pinfeathers are removed by hand. In the USA, the birds pass through a gas flame to singe the fine hairs. A final step in the defeathering area is an outside spray wash.

The head removal operation may take place in the defeathering area between the picker and the outside bird washer, or in the eviscerating room to facilitate crop removal. The bird's neck passes through a device

which restrains the head as the overhead conveyor pulls the body forward, separating the neck vertebrae at the base of the skull. Some head removal devices can include a set of rollers to separate the neck bones and a rotating knife to sever the neck skin instead of tearing it; yield is improved with this system.

The birds pass through an automatic hock cutter which severs the shanks at the hock joint and causes the carcass to drop onto a conveyor for transfer to the evisceration area. In the UK, the feet of the broilers are cut off just above the spur by means of a rotating knife. The severed feet remain on the shackles and are removed mechanically on the return line.

The scalding, defeathering, and other operations occur in a separate portion of the plant, apart from the evisceration and final processed bird area. The transfer conveyor takes the defeathered carcasses into the evisceration area, where the carcasses are rehung on the clean evisceration line.

Evisceration

The first cutting operation in the evisceration area involves removing the preen or oil gland, located on the top side of the tail next to its base. A sharp, short-bladed knife is used to remove the gland manually, or a machine with a cutting blade can be used online.

An opening cut into the body cavity is then made using a knife, a special drill-like vent cutter with a rotary blade, or an online automated machine. Making an incision in the abdomen and removing the vent can be performed manually or by machine to complete the opening process for evisceration.

Removing or drawing the viscera from inside the bird can be performed by hand or by machine. To retain the identity of the viscera within the carcass and be in a position for easy inspection, the viscera are draped uniformly to one side of the tail but remain attached to the carcass until the carcasses have passed the inspection for wholesomeness.

Mechanized removal of the viscera is very common in large processing plants (Figure 1). An eviscerating spoon is mechanically inserted into the cavity and withdraws the viscera. Back-up workers may be necessary to remove viscera missed by the machine.

Mandatory USDA inspection of every bird for wholesomeness is performed under the supervision of an inspector employed and trained by the government. If evidence of unwholesomeness is detected, the carcass or affected parts are trimmed or condemned.

Workers remove the giblets (heart, liver, and gizzard) from the viscera of inspected birds and clean and chill them. Then the lungs are removed with a vacuum lung gun, or they can be withdrawn with the viscera on a mechanical eviscerator. The neck is generally cracked with shears, the crop and windpipe are removed, and the neck is then pulled off by stationary guide bars.

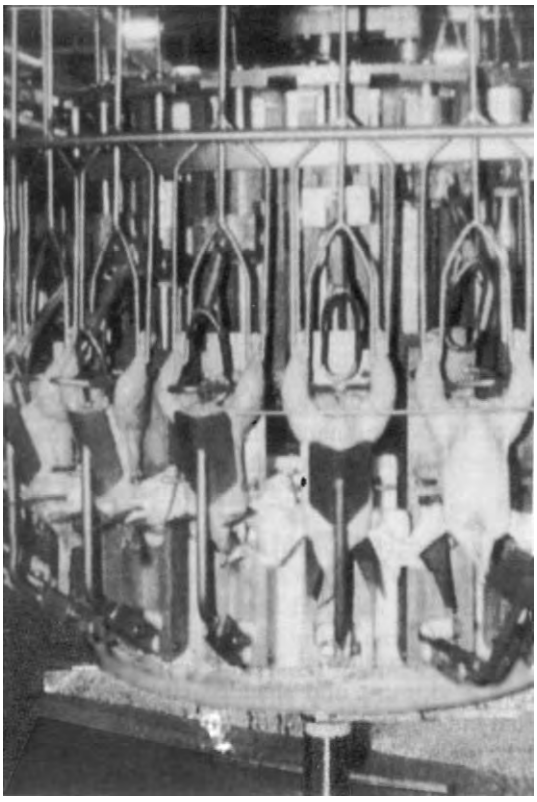

Figure 1 Automatic chicken eviscerator. Reproduced from Poultry: Chicken, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Finally, the shackles convey the carcasses through a bird washer where spray nozzles rinse the inside and outside of the carcasses.

Chilling

The most common chilling operations in the USA immerse carcasses in long flowthrough tanks containing agitated chlorinated water or slush ice. The USDA regulations require that a chiller overflow rate be maintained at 2 l of water per chilled bird, in order to minimize microbial build-up in the chill water.

The chickens are first placed in a prechiller, containing water at 10–18 °C, and then into a slush ice chiller at 0–1 °C. Chickens must be chilled to 4 °C or lower within 4 h to meet USDA requirements; the chilling time generally needed to obtain 4 °C carcasses is about 40–60 min.

After chilling, carcasses are hung by one leg on a drip line for 2.5–4 min for draining, and are then conveyed to the packing area. Although the meat absorbs some moisture during washing and chilling, the drained moisture level is strictly regulated. The

drip line shackles are usually weighing devices which drop the sized birds into appropriate bins.

Air chilling of eviscerated carcasses is used extensively in Europe. Spraying the carcasses with water at intervals avoids weight loss during evaporative chilling. (*See* **Meat**: Preservation.)

Grading

Carcass grading in the USA is a voluntary practice, but is often required by purchasers. Government graders sort the birds into A, B, and C categories according to body conformation, fleshing, fat cover, deformities, bruises, and defects such as pinfeathers, disjointed or broken bones, and missing parts. Europe uses similar grading standards.

Packing

Giblet packs containing a heart, liver, gizzard, and neck are stuffed into the body cavity of chilled, sized carcasses. The carcasses then go into overwrapped trays which are heat-sealed, or into polyethylene bags which are clipped or taped shut ready for market. Another common method in the USA for distributing broiler carcasses from the processing plant is to put them into corrugated, wax-impregnated boxes. After boxing, ice covers the birds to keep the skin moist during shipment. Nearly half of the broilers in the USA leave the processing plant as ice-packed birds. An increasingly popular packing method is chill-packing, whereby a $-6\,^{\circ}C$ air blast lowers carcass temperatures to between $-2\,^{\circ}C$ and $-1\,^{\circ}C$. Refrigeration then maintains that temperature during marketing of the birds.

Waste Products

Poultry processing results in large amounts of waste waters, semisolids, and solids, which require separation and treatment before being discharged into the environment. Waste material that can be reclaimed and, for example, used for animal feeds or fertilizer helps to reduce the overall load for disposal.

There are several ways to handle poultry offal (heads, feet, viscera, inedible parts, condemned whole birds, feathers, and blood). Usually, all offal except the blood and condemned birds is floated in water from the processing areas to an accumulation area for removal by trucks. Screens and rotating drums remove water and separate offal components. Because of its high oxygen demand for decomposition, blood is usually handled separately.

Most of the offal solids goes to a rendering plant, while liquid generally goes through a primary and secondary lagoon treatment system. Some plants can discharge the liquid effluent into a municipal water system after removing the fat and as many solids as possible.

Another method of waste treatment is spray irrigation or spreading the processing effluent on the land. This type of waste disposal requires large fields to prevent overloading. Runoff into streams is a major concern. (*See* **Effluents from Food Processing**: Composition and Analysis; Disposal of Waste Water.)

Food Uses and Products

Most broilers in the USA are sold as fresh (unfrozen) carcasses, but frozen deboned meat is used in further processing. A decline in the sale and consumption of whole chickens in the USA has been counterbalanced by a steady increase in the sale of cut-up carcasses and parts. More than half (53%) of the processed carcasses in 1990 were marketed as cut-up broilers and parts.

Cut-Up

The cut-up operation is usually mechanized with motor-driven equipment and shielded circular blades. Individual cut-up stations or online automated machines can be used. A popular method of packaging is to place the cut-up parts in a tray containing an absorbent pad to collect seepage and then overwrap the tray. The bagged whole carcasses and tray packs may be prepriced before delivery to the retail market.

Deboning

The spectacular growth in the sale of value-added, further-processed poultry products in recent years has placed a heavy demand on the production of deboned meat. Poultry meat has traditionally been removed from the carcass by hand with a sharp knife, while the carcasses hang from special shackles on a slow-moving line or are positioned on static or moving cones.

Several automatic deboning machines are also available for removing breast fillets and thigh and drumstick meat. One system operates by holding a particular chicken part in position above a contoured recess in a base plate. The machine forces the meat from the bone into the depression. Another meat-deboning system pushes the bone lengthwise out of the carcass part (e.g., drumstick) and strips off the meat in the process.

Currently, deboning is primarily done on aged chilled carcasses. Hot-stripping the muscles and skin from defeathered but uneviscerated carcasses is being studied. Some researchers are also testing hot deboning, the removal of meat after evisceration but prior to chilling. Generally, hot deboned meat is tough,

which greatly limits its potential uses. Some poultry meat, especially that of mature hens, is cooked prior to hand deboning.

After the major muscles are deboned from the carcass, the remaining frames (also necks, backs, and low-value parts) can be more completely deboned by special machines. In the first stage of mechanical deboning, a grinder reduces bone and meat particle size. In the second step, a pressure system squeezes the ground meat and bone against a perforated screen or microgrooved cylinder. Advances in mechanical deboning have eliminated pregrinding and produced a more texturally attractive product. An alternative system is a batch operation. Pressure from a ram forces meat to flow from the bones through a sieve screen; the bone cake is ejected, and a new batch is introduced.

Further-Processed Products

Much of the hand- and mechanically deboned chicken meat is directed into value-added products. Deboned meat can be marketed 'as is' fresh, as whole breast or split breast fillets, strips, and chunks. Alternatively, deboned meat can be tumbled, marinated, chopped, formed, ground, emulsified, or prepared in a number of ways for sale.

Many nonmeat ingredients are used in further processing. Salt helps to extract proteins for improved binding and texture, acts as a preservative, and enhances flavor. Up to 0.5% phosphate increases water-holding capacity and final product yield. Other ingredients, such as sweeteners, spices, binders, and curing salts, are used in the wide array of poultry products on the market. (*See* **Curing**.)

The driving force behind poultry product development is the consumer. Fat content in meats is a current concern; many people want healthier diets, and the low fat in poultry is a major reason for its popularity. Fat pads are removed from many whole carcasses in response to consumer desires. As new poultry products are designed, diet and health, microwave ovens, and an aging population cannot be ignored.

The fast-food restaurants have had a tremendous influence on new poultry product popularity for items such as nuggets, tenders, marinated breast fillets, and frozen–fried parts. Ethnic foods are popular in the USA, especially Italian, Mexican, and Chinese. Different flavors in poultry products are in demand, including cajun, barbecue, and honey. Spicy chicken wings are an example of a popular seasoned finger-food appetizer. In addition to less fat, smaller portions, and different flavors, consumers want less salt and cholesterol in their chicken products. The food must be of high quality, convenient, safe, and nutritious.

In the retail supermarket, low-fat chicken products such as patties, rolls, sausages, and sliced luncheon meats are selling well. Poultry frankfurters and bologna are generally lower in fat than similar red-meat products and are a healthy alternative. (*See* **Meat: Sausages and Comminuted Products.**)

Most recent entries among the new poultry products are boneless chicken breasts stuffed with ingredients such as cheese and broccoli or wild rice and mushrooms. These products are sold in a variety of packages and combinations, but are almost always ready for cooking in the microwave. Other gourmet items include chicken Kiev (breaded chicken breasts filled with garlic butter and parsley), chicken cordon bleu (filled with ham and cheese), and herb-roasted chicken dinner (low-fat, low-cholesterol, low-sodium meal). Even the luncheon market has new chicken 'lunchable' products, which are individual packages containing items such as cooked sliced poultry, cheese slices, and crackers.

Microbiological Concerns

Modern poultry husbandry and processing techniques have greatly improved the quality of poultry meat. However, chicken can carry many kinds of organisms. The two major concerns are control of spoilage organisms which cause consumers to reject the product due to odor or flavor, and the minimization of pathogenic organisms which may (under faulty handling) lead to a health hazard.

Spoilage Microorganisms

Although poultry is refrigerated, and even frozen, for shelf-life extension, spoilage will invariably occur owing to the growth and metabolic activities of specific types of bacteria. The psychrophiles, such as *Pseudomonas*, can generally grow at refrigerator temperatures and are responsible for most of the spoilage. Spoilage organisms are present in high numbers when an off-odor becomes apparent (10^7 cells per cm^2) and even greater when slime formation occurs from coalescence of colonies (*c.* 10^8 cells per cm^2). (*See* **Spoilage: Bacterial Spoilage.**)

Pathogenic Microorganisms

Poultry is considered to be a major source of *Salmonella*, which can spread during processing, and even after cooking if raw meat preparation surfaces were not cleaned before placing a cooked product on the same surface. However, normal cooking procedures destroy *Salmonella* and it will not grow well under refrigeration. The most common problems are undercooked poultry or poultry contaminated after cooking. According to data on the vehicle of

foodborne salmonellosis outbreaks in the USA between 1973 and 1987, only 3.8% (30 of 790) of the cases were caused by chicken.

In addition to *Salmonella*, other pathogens sometimes found in poultry include staphylococci, *Campylobacter, Listeria* spp., clostridia, and coliforms. Careful product handling, proper refrigeration, and adequate cooking will almost always insure product safety. (*See* ***Campylobacter***: Campylobacteriosis; ***Clostridium***: Food Poisoning by *Clostridium perfringens*; Botulism; ***Listeria***: Listeriosis; ***Staphylococcus***: Food Poisoning.)

Sources of Bacteria

Microbes in poultry-processing plants are ultimately found on the product and come from three main sources: the birds (feet, feathers, intestinal contents), the environment (water, air, supplies), and the workers. Careful management at the production site and adherence to good manufacturing practices at the processing plant (e.g., filtered air, cool temperatures, thorough cleaning and sanitation, and good worker hygiene) will minimize final product contamination with bacteria.

Ducks and Geese

A J Maurer[†], Formerly of University of Wisconsin-Madison, Madison, WI, USA

Introduction

Ducks and geese (waterfowl) are a delicacy to many people, while others object to the higher amounts of fat in the carcasses compared to broilers and turkeys. However, breeding and mass selection programs are improving the meat-to-bone and meat-to-fat ratios in waterfowl. Annual duck consumption on a ready-to-cook basis in the USA is only about 0.2 kg per person. Goose consumption is somewhat less, at approximately 0.01 kg per person per year. Although chickens and turkeys dominate the world poultry industry, in parts of Asia ducks are commercially more important than broilers (chickens), and there are more geese than turkeys in areas of Europe. This article reviews duck and goose processing and preparation, meat composition and nutrition, food uses and products, waste products, and microbiological problems.

Processing and Preparation

With a few exceptions, duck and goose processing is similar to that of broilers and turkeys. For a more complete slaughter and evisceration procedure, (*See* **Poultry**: Chicken.)

In the USA, White Pekin-type ducks are generally slaughtered at 7 weeks of age and weigh about 3.2 kg live. White Muscovy ducks are also raised for meat, but they are a slower-growing breed and commercially

[†]Deceased.

less popular than the White Pekin. Geese are 3–5 months old at slaughter, and their average live weight is 4.5–6.8 kg. The average ready-to-cook weight of geese varies, but is generally about 4.5–5 kg. Feather maturity (lack of pinfeathers) is an important factor in determining the best time to slaughter waterfowl. (*See* **Meat**: Slaughter.)

Processors transport ducks and geese to slaughter plants on open trucks or trailers. The loading and unloading process is unique as the birds are not usually caught by their legs; they are herded on to the conveyance, and off into holding pens at the processing plant. Processors use turkey-sized crates when there are relatively few geese to transport.

Ducks and geese are driven from holding pens through chutes on to scales for weighing and then into the shackle hanging area. Care in herding the waterfowl is essential to avoid pile-ups, skin scratches, damaged legs, and smothered birds.

It is important to minimize struggling by the birds when hanging them on motorized conveyor line shackles as excessive flapping can result in bruises. In smaller processing plants, killing funnels can be used to restrain and position the birds for slaughter.

The birds are usually stunned with an electric current and then bled. Sometimes a cut inside the mouth is used, but a common method of killing the birds is to cut the outside of the throat on the left side at the base of the jaw, severing the left jugular vein and carotid artery.

Following bleeding, both ducks and geese can be scalded or dry-picked. However, the latter method is slow and laborious. Generally, ducklings proceed through immersion scalders containing agitated water at 58–63 °C. Geese can be scalded in a similar commercial scalder, or they can be hand-scalded for a smallscale operation. Scald water temperature for geese should be 63–66 °C. The duration of the scald varies from 1.5 to 3 min, usually longer for geese than for ducks. The time and temperature will also change depending on the age of the bird, time of year (season), and density of feathering. The lower the temperature, the longer the scald. A little detergent or an alkaline defeathering agent can be added to facilitate thorough wetting of the feathers. Processors can hand-scald waterfowl by pulling the bird repeatedly through the water against the lay of the feathers.

After scalding, the birds may be rough-picked by hand, picked by a conventional rubber-fingered picking machine (online), or placed in a spinner-type picker. Because pins and down remaining on the carcass are difficult to remove, it is common practice to finish rough-picked birds by dipping each bird into melted wax specially formulated for this purpose.

The defeathered birds should be surface-dried (a jet of compressed air can be used) just long enough to allow the wax to adhere. The waxing operation is usually mechanized and often includes conveying the ducks in and out of two wax tanks. A resin-based microcrystalline wax is used for greater resilience and improved stripping.

Good wax penetration and adhesion are achieved in the first tank with immersion in 90 °C wax for 15 s. The second wax dip at 71 °C puts a heavier coating on the birds to thicken the wax for good pulling power and cleaner stripping. After waxing (and sometimes between wax dips), a cold-water spray over the birds or a dip into a tank of cold water will cool and harden the wax to a tacky state. The wax is then removed by hand or by a rubber-fingered wax stripper. Some processing plants dip the wax-picked birds into water at 82 °C to tighten the skin for easier manual removal of any remaining pinfeathers. Grasping pinfeathers between the thumb and a dull knife will assist in this operation.

The wax is reclaimed by remelting and straining out the pins, down, and feathers. Occasionally, the used wax should be 'cooked down' to remove all water that may have been mixed with it by emulsion.

After completely removing feathers, pins, and down, processors eviscerate the carcasses by making an opening cut in the abdomen and pulling out the viscera. Waterfowl viscera are somewhat difficult to withdraw, so that evisceration is most often done manually. However, processing plants in Europe are using automatic duck evisceration and automatic head and trachea pulling with processing rates of 4000 ducklings per h.

Each carcass on the eviscerating line is inspected for wholesomeness before the withdrawn viscera are detached. After the inedible viscera and lungs are discarded, the heads, tracheas, and feet are removed; the giblets are cleaned and wrapped for later placement in the body cavity. In many processing plants, only the two lobes are cut from gizzards because the inner lining is difficult to peel.

Following evisceration, birds receive an inside and outside spray wash before proceeding through a chilling treatment of cold tap water or ice and water. Airagitated cooling vats, a continuous immersion chiller, or air-spray chilling can be used.

After carcass cooling and draining in commercial waterfowl plants, each carcass is graded for conformation, fleshing, fat covering, and defects such as pinfeathers and exposed flesh. Processors then vacuum-package carcasses in barrier bags, heat-shrink the bags, and quick-freeze the packaged carcasses. Young ducks and geese may also be sold fresh, unfrozen. (*See* **Meat**: Preservation.)

Composition and Nutrition

Dressing percentages and meat yield of ducks and geese will vary with breed, age, sex, weight, and grade. The processing loss from live to ready-to-cook (carcass, neck, and giblets) for ducks is approximately 30%, 25–32% for geese, and 24% for broilers.

As the data in Table 1 show, raw ducks and geese contain more fat, less water, and less protein than are found in broiler chickens. Roasting causes fat and some water loss, thereby concentrating (increasing) the protein content. Because of the relatively high fat content of waterfowl, the carcasses become rancid more easily, and frozen shelf-life is shorter than that of broilers or turkeys. (*See* **Fats**: Digestion, Absorption, and Transport; **Protein**: Food Sources.)

Skinning the carcass can remove much of the fat in poultry. For example, the fat content of raw duckling meat with skin is 39.3%; without skin, it is 6.0%. Values for goose are 33.6% with skin and 7.1% without skin. The fat in ducks and geese is highly unsaturated, as is the case in all poultry. Duck and goose skin (including separable fat) makes up 34–38% of the ready-to-cook carcass, but broiler skin is about 15% of the carcass. Conversely, the meat yield from ready-to-cook carcasses for ducks and geese is 34–47%, compared to 52% for broilers.

Duck is a good source of thiamin, and goose is an excellent source of phosphorus. The other vitamins and minerals are also present in ample amounts. Iron content is especially high in waterfowl, contributing to the darker color of the breast meat. (*See* **Phosphorus**: Properties and Determination; **Thiamin**: Properties and Determination.)

Food Uses and Products

Most duck and goose meat is consumed in whole carcass form. The carcasses are roasted in the same way as other poultry, but they yield less cooked edible meat. Because waterfowl contain more fat than broilers or turkeys, they do not require basting during roasting. If the carcasses are excessively fat, it helps to puncture or scratch the skin to permit some fat to cook out during roasting. Thorough cooking of waterfowl (to an internal temperature of at least 85 °C) is important to attain a crispy skin and for complete customer satisfaction.

Food manufacturers sell some further-processed waterfowl products. Duckling breast portions, semi-boneless halves, marinated breasts, fully cooked roast half duckling, and other gourmet items are available to the institutional trade. A few shops market specialty duck and goose products, such as smoked duck, boneless breast of duckling, smoked goose leg, or goose liver sausage.

Goose livers are popular in delicacies such as pâté de foie gras; the product must contain at least 30% goose liver. For a period of time in Europe and in parts of the USA, many people force-fed, or noodled, their geese. The starchy noodling ingredients (corn, wheat, barley, and rye) used in this frequent forced feeding produced an extra large liver (weighing nearly 1 kg each), which was sold at premium prices.

Goose fat is sometimes used in place of butter. It can also be used in frying, baking, cooking, and preparation of gravies, broths, and soups.

Waste Products

Duck and goose slaughtering produces the usual waste products of blood, feathers, feet, heads, inedible viscera, grease, debris, and cleaning water. The control and handling of these waste materials depend on the standards set by individual countries and local authorities. The methods of handling can include disposal to a public sewer after the fat and as many solids as possible have been removed, or treatment

Table 1 Proximate analysis of ducks, geese, and broilers (100 g edible portion, wet-weight basis)

on-site and disposal of the filtered effluent to a lagoon or spray irrigation system.

In general, the first stage of any effluent system is the removal of coarse solids by screening. A fat trap or dissolved air flotation can then remove fine solids, fat, and grease. The effluent is further cleaned by either anaerobic digestion or aeration. (*See* **Effluents from Food Processing**: Composition and Analysis; Disposal of Waste Water.)

In contrast to other poultry-processing waste treatment problems, ducks and geese provide several valuable byproducts. The Far East is a good market for frozen duck feet, where they are stuffed with pork and considered a delicacy. Duck tongues are also valued by orientals as hors d'oeuvres. Some parts (heads and offal) go into mink or other animal food.

Other important byproducts are duck and goose down and feathers, used chiefly by the bedding and clothing industries. The poultry slaughter plant rinses and centrifuges the wet feathers to decrease the water content prior to shipping them to a feather-processing plant. A machine separates the down (15–25% of the feather mixture) and feathers, and washes and dries them. About five ducklings or three goslings are needed to produce 0.45 kg of dry feathers.

On a smaller scale, home processors can wash feathers in soft, lukewarm water which includes either a mild detergent or a little borax and washing soda. After rinsing, feathers are spread out to dry.

Microbiological Problems

In general, microbiological problems in ducks and geese are similar to those in other poultry. Pseudomonads are the main spoilage organisms. However, because of the very low duck and goose meat consumption, few illnesses have been attributed to waterfowl. The combination of scalding at 60 °C, followed by immersion in molten wax at *c.* 90 °C to aid final removal of feathers, appears to have a beneficial effect on the microbial quality of the finished product. (*See* **Spoilage**: Bacterial Spoilage.)

Turkey

A J Maurer[†], formerly of University of Wisconsin-Madison, Madison, WI, USA

Introduction

Chickens and turkeys dominate the world poultry industry. The increasing popularity of poultry meat, including turkey, comes from low cost (value for money), a healthy nutritious image, and availability in a variety of convenient forms. Efficiencies in integrated turkey production, processing, and marketing have helped maintain favorable retail prices. This article reviews specific characteristics of turkey, processing of turkeys, food uses and products, microbiological concerns, waste products, and the nutritional profile of turkey meats and products.

Specific Characteristics

Turkey consumption has increased in many countries throughout the world, with Israel as the leader (over 9 kg per person in 1986). Less than one-third of this per capital consumption (2.7 kg) is of whole-carcass birds. Clearly, the growth in turkey popularity has come in cut-up parts and more fully prepared products.

Turkey hens in the USA, sold at about 16 weeks of age, provide almost 6 kg of ready-to-cook carcass. Toms (male turkeys) are slightly older, at 20–24

[†]Deceased.

weeks, and yield 10–12 kg of marketable carcasses. Desirable characteristics of turkeys include heavy bird weights without excess fat, a high dressing yield, and an ample proportion of valuable parts. The breast (white meat) is 35–40% of the ready-to-cook carcass. Leg meat, 25–30% of the carcass, contains more myoglobin and is darker than breast meat.

Other desirable turkey meat attributes include tenderness, bland flavor (allows further processing and seasoning), and good functional properties, such as protein extraction, protein gelation, water holding, meat binding, and emulsification. Turkey meat is similar to broiler meat in its composition and qualities, easily digestible, high in protein, and low in fat.

Processing of Turkeys

Turkey processing refers to slaughtering, feather removal, evisceration, and chilling. Other operations, such as inspection and packaging, are also important steps in processing turkeys for market. Most of the processing procedures are similar to those used for broilers.

Procurement

Special trailers or trucks with built-in cages haul turkeys to the slaughter plant. If crates are used to transport turkeys, they are considerably higher than those used for chickens. Handlers must catch, load, and unload turkeys very carefully to minimize bruises and broken bones. Escalator-type loaders are sometimes used to elevate turkeys to the built-in truck cages. The turkeys should be off feed 8–12 h prior to slaughter to minimize fecal contamination in the processing plant. Large-volume, slow-moving fans or evaporative cooling provides good ventilation and comfort for the birds in holding sheds at the processing plant.

Because turkeys are large and heavy, shackle line height in the unloading area and truck cages must be adjusted to the same level to minimize lifting required by the hangers. Workers hang the turkeys by both feet to the overhead moving shackles.

A dimly lit hanging area discourages the birds from struggling and flapping. Some processors install a smooth plastic bar parallel to and slightly below the overhead conveyor line so that the turkey's breast rubs against it to provide a soothing effect. The turkeys should move from the hanging area to the stunner within 6 min.

Stunning

The shackle line drags the heads of the birds through 0.1–1.0% saline water which contains a submerged electrode. Careful control of the voltage and current is vital. Too little current will not immobilize the birds, and too much current can cause a violent muscle contraction, often resulting in broken clavicle fragments in the muscle tissue.

Slaughter

Killing is usually performed manually by cutting across the side of the neck at the base of the bird's head, severing a jugular vein and carotid artery. Bleed time should be at least 2 min in a blood tunnel to collect the blood for proper disposal. Workers in some turkey slaughter plants cut both sides of the neck for more complete bleeding. (*See* **Meat**: Slaughter.)

Scalding

After bleeding, processors scald turkeys by immersion in agitated hot water to facilitate feather release. For some fresh chilled markets, they semiscald turkeys at 50–52 °C to retain the epidermal cuticle, which reduces skin dehydration. Most processors, however, scald turkeys at approximately 60 °C for 2–2.5 min. The USA has a requirement for an overflow from the scald tank of approximately 11 of water per bird to help float debris from the water.

Defeathering

After scalding, the shackle line carries the birds through a series of picking machines containing rotating rubber fingers on disks or drums which rub or pluck the feathers from the carcasses. Workers remove the remaining pinfeathers by hand.

The birds pass through a gas flame to singe off the filoplumes or hairs protruding from the skin surface. The final process on the kill line is a thorough washing of the external surface of the carcass with pressurized water jets.

The carcasses then pass through a shank-cutting station. In some plants, an automatic tendon puller removes the shanks and pulls up to nine of the main sinews from the drumstick. At this point, a conveyor transfers the carcasses from the killing, scalding, and defeathering area into another room for evisceration.

Evisceration

For evisceration, turkeys hang from both legs with their heads also placed in a center slot of the shackle, creating a three-point suspension. This presents the birds horizontally, breast-up, for easier cutting and eviscerating. Plants equipped with mechanical eviscerating equipment use the two-point leg suspension.

Evisceration begins with an incision made through the abdominal wall. The cut continues around the vent and enlarges in the abdomen for easier removal

of the viscera. In some plants, a bar (transverse) cut in the abdomen allows evisceration and later trussing of the legs. A mechanical vent cutter with a revolving cylindrical blade is another method to make an opening cut and remove the vent.

Processors withdraw the viscera through the abdominal opening, taking special care to avoid damaging the intestines or spilling the contents. The viscera are left attached to the carcass and draped over the outside of the bird for inspection. An inspector then examines each bird (inside, outside, and viscera) for wholesomeness. Carcasses can be trimmed to remove damaged parts or dressing defects, or condemned if unfit for food.

Workers harvest, clean, and save the giblets (heart, liver, and gizzard). They clean the gizzard by splitting it, washing away the contents, peeling off the hard lining, and washing. They discard the inedible viscera, and remove the lungs with a special tool or vacuum lung gun.

As one of the last operations, the head is cut or pulled off, and the esophagus and crop are removed from the front of the carcass. Finally, the skinless neck is cut off, washed, and retained for packing. Following evisceration, the birds must be washed inside and out before chilling.

It is possible to perform some of the slaughter and evisceration operations mechanically, but the variability in turkey carcass sizes presents unique problems. Fully automated equipment for turkey processing is still being developed.

Chilling

Most processors chill poultry meat in cold water or water and ice, but they use air chilling extensively in Europe, where carcasses are more often soft-scalded and sold fresh. The most-used chillers in the USA drop the birds from the evisceration line into a prechiller which also serves as a very effective washer. The agitated water has a temperature of less than 18 °C. The birds travel to a second chiller with a water temperature of less than 2 °C. Inspectors carefully monitor chiller water overflow, and carcass exit temperature and water uptake.

After chilling, graders evaluate the carcasses according to conformation, fleshing, fat covering, and defects such as pinfeathers and exposed flesh. (*See* **Meat**: Preservation.)

Packaging

In some plants, turkey carcasses move directly to a cut-up or deboning line. If turkeys are sold as whole carcasses, workers place a giblet packet in the crop cavity and a neck in the body cavity. Processors truss the legs into the bar cut, or use a metal or plastic hock lock. These turkeys will probably be frozen, in which case they are placed in an oxygen-impermeable, shrink-film bag. After the air is evacuated, the bags are clipped shut and passed through a hot-water shrink tunnel prior to freezing.

The freezing process is very rapid, with the first step being a brine or blast freezer to set the carcass surface color. Final freezing and storage occur in a holding freezer, where the birds can be stored for relatively long periods of time until they are moved into market channels.

Food Uses and Products

About 75% of the turkeys produced in the USA are cut up or further processed. In some countries, such as Israel, France, and Italy, the proportion of cut-up or further-processed turkey is 90% or more. However, whole birds are still popular at holiday times. Some of the whole carcasses are injected with various flavored solutions to create a self-basting, juicier carcass when roasted.

Deboning

Deboning of chilled turkey carcasses usually occurs as they hang from special shackles on a slow-moving line, or sit on deboning cones which may be static or moving. Precise cuts are made to remove parts, breast meat, thigh meat, and trimmings from the skeleton. The drumsticks (and also the thighs) are often deboned on automated machines, whereby the drumstick bone may be pushed lengthwise out of the meat; thigh pieces may be compressed in a specially designed mold, squeezing the meat away from the bone. More deboning automation will occur in the near future.

After removal of intact muscles using knives or semiautomated procedures, the remaining frames, necks, and backs are usually mechanically deboned. One system uses an auger principle, pressing the meat and bone against a perforated cylinder screen or microgrooved cylinder. The alternative system is a hydraulic-press-type batch design which squeezes the meat through a series of stationary filter rings. Depending on the incoming meat materials (meat-to-bone ratio), screen perforation size, and machine adjustments, the mechanically deboned meat can be a very fine purée or have a particle size of 5 mm, which is ideal for some sausages.

Further Processing

Hand- and mechanically deboned meats are useful in many further-processed products. The term 'further processing' encompasses procedures such as deboning, size reduction, injection, tumbling, massaging, reforming, and emulsifying. The principles of

water-holding, protein extraction, protein gelation, and meat binding are very important in making further-processed products. Other processes, such as battering, breading, cooking, and freezing, may take place. Further processing also refers to whole carcasses that are basted, marinated, or smoked.

The types of products now available are increasing, ranging from cut-up portions to reformed roasts,-breasts, rolls, steaks, hams, burgers, frankfurters, bolognas, coarse-ground sausages, salamis and bacons. More recently, ready-prepared meals have utilized an increasing amount of turkey meat. (*See* **Meat**: Sausages and Comminuted Products.)

Consumers with changing careers and households are the driving force behind trends in the consumption of poultry products. Smaller families often lack time but can afford the convenience of further-processed poultry. Diet and health, microwave ovens, and an aging population are important factors in new product development. Ethnic foods, especially Italian, Mexican, and Chinese, are popular in the USA. Different flavors and marinades, such as honey and barbecue, are well liked in turkey products. Smaller portions, less fat, less salt, and low cholesterol are in vogue. Poultry appetizers, finger foods, sliced luncheon meats, and center-of-the-plate, cooked, vacuum-packaged, chilled boneless breasts are very popular. New turkey products could soon include sous-vide (vacuum-sealed, cooked, refrigerated, ready-to-heat) entrées, or possibly surimi (minced washed gelled protein, usually from fish) seafood-style favorites.

Microbiological Concerns

Turkey meat quality is highest immediately after processing. The maintenance of acceptable quality depends on initial microbial levels and measures taken to minimize organism growth and prevent further contamination. The two major concerns are spoilage organisms which cause odors or off-flavors, and pathogenic organisms which may, under faulty handling such as undercooking or temperature abuse, lead to a health hazard. The cutting, deboning, handling, mixing, and packaging of turkey meat also increase possible microbial contamination and growth. (*See* **Spoilage**: Bacterial Spoilage.)

Although turkey and turkey products are refrigerated or frozen for shelf-life extension, spoilage can occasionally occur as a result of the growth and metabolic activities of specific types of bacteria. Psychrophiles, such as *Pseudomonas*, can grow at refrigerator temperatures and cause problems. Turkey has reached spoilage conditions when an off-odor becomes apparent (10^7 cells per cm^2) or when slime formation occurs (10^8 organisms per cm^2). It is important to maintain refrigeration temperatures at 0–4 °C to minimize microbial growth in turkey and turkey products.

Food pathogens are more serious than spoilage organisms because the food product may not look or smell spoiled. Some of the pathogens of concern in turkey are *Salmonella*, *Staphylococcus*, *Campylobacter*, *Listeria*, and coliforms. Recently, *Salmonella* has been a major worry for consumers, and turkey carcasses do harbor the organism. Surveys in the USA indicate that in food-borne salmonellosis outbreaks only 4.5% are caused by turkey. To prevent food-borne illness from poultry, it must be kept refrigerated and cooked properly, and cross-contamination or postcooking contamination from unclean utensils or equipment must be avoided. (*See* ***Campylobacter***: Campylobacteriosis; ***Listeria***: Listeriosis; ***Staphylococcus***: Food Poisoning.)

Bacteria can come from many sources. At the processing plant, bacteria arrive on the feet and feathers of the birds; they are present in the intestinal contents, and can also come from the workers and the environment (air and water supplies). Bacterial problems can be minimized by following good production and manufacturing practices such as feeding clean feed and keeping the litter dry at the production site, using clean hauling equipment, filtering incoming air at the processing plant, monitoring the water supply, eviscerating carefully, chlorinating chiller water, insisting on good worker hygiene, and using an approved plant clean-up and sanitation program.

Utilization of Waste Products

Poultry processing results in large amounts of highly polluting waste waters, semisolids, and solids, which must be separated and treated before being discharged into the environment. Where practical, the use of waste products for livestock food or fertilizer reduces the overall load for disposal. Rendered poultry byproducts as an animal feed ingredient can provide 50–60% protein. Feather meal and dried blood also have value as a feedstuff. Such products must be carefully processed before being recycled as animal feed, to avoid microbial contamination.

The types of waste and byproducts differ at varying stages of processing. Manure, feathers, blood, viscera, flesh debris, grease, and cleaning water are examples of the pollutants to be treated and either used or discarded.

The methods of disposal are to a public sewer, or treatment on-site followed by disposal to a water course or to fields. Preliminary treatment of turkey-processing wastes using a coarse-solids screen separator as well as a fatty-matter trap, or chemical

flocculation combined with a dissolved air flotation system, will significantly reduce the pollution potential of the effluent before discharge or further biological treatment. Based on the strength of the effluent, a secondary biological treatment uses a mixed culture of microorganisms for anaerobic digestion or aerobic treatment. The cheapest and most cost-effective options for the disposal of stabilized processing sludges arising from the biological treatment of poultry processing effluents are to spread them on the land or to discharge them at land-fill sites. (*See* **Effluents from Food Processing**: Composition and Analysis; Disposal of Waste Water.)

Nutritional Significance

Table 1 shows the nutrient composition of selected raw and cooked turkey meats, and Table 2 lists the composition of several further-processed turkey products.

Turkey and its products have a favorable reputation as nourishing and healthy foods. The composition of raw turkey meat depends on factors such as diet, age, sex, and growth environment. Processed product nutrition (Table 2) is a result of incoming meat and nonmeat ingredients as well as cooking processes and formula variations by different manufacturers. Salt and fat can vary markedly, depending on whether salt was needed for protein extraction and binding, or whether skin (with adhered fat) was added for juiciness and flavor.

Consumers recognize turkey as a good protein source. Turkey meat is easily digestible, contains all the essential amino acids, and is a good source of the B vitamins and iron. (*See* **Amino Acids**: Metabolism; **Vitamins**: Overview.)

Turkey has a relatively low fat content, and the fat is only about 30% saturated. Because the fat is highly unsaturated (more than beef and pork), it is a softer type of fat and prone to oxidation. As turkeys grow, they deposit more fat under the skin. The fat content is higher in dark meat, and protein content is greater in light meat. Moisture and some fat are lost during heating, and protein is concentrated in cooked turkey.

Turkey products are somewhat similar to other processed meat products in protein content but are higher in moisture and lower in fat and energy. This favorable nutritional profile for turkey is one of the major reasons for its increasing popularity. (*See* **Protein**: Food Sources.)

Milk Powders in the Marketplace

M A Augustin and C L Margetts, Food Science Australia, Werribee, Victoria, Australia

Background

The conversion of milk into milk powder enables milk to be preserved in a convenient form for transport and for later use. The drying of milk was used initially as a means of dealing with surplus milk as it preserves the nutrients in milk. This allowed consumers to obtain a liquid milk product similar to fresh milk by reconstituting the milk powder with water. The transformation of liquid dairy products into powder has also paved the way for the effective utilization of byproducts such as skim milk and buttermilk from cream and butter processing and whey from cheese manufacture. Although skim and buttermilk powders were originally considered as byproducts of the dairy industry, these are now regarded as valuable food ingredients.

Commercial manufacture of milk powders began in the second half of the nineteenth century. Through the latter half of the nineteenth century and the early twentieth century, advances in drying technology made possible by improvements to drum and spray-drying equipment led to the growth of the milk powder industry. Drum drying was the major method used for the production of milk powders in the first half of the twentieth century. Today, spray drying is the method most widely used in the commercial manufacture of milk powders. However, drum drying is still used for the production of some specialized milk powders.

The export of milk powders from dairying countries such as Australia, New Zealand, and Europe has made possible the establishment of the recombined dairy products industry in countries that are not self-sufficient in milk. Recombining operations are increasing in South-East Asia, North Asia, Middle East, Africa, and South America, and this has led to a greater demand for milk powders.

A range of powders can be derived from milk (**Figure 1**). Today, dried milk and dairy-based powders represent a significant portion of the trade of dairy products. Milk powders are used directly by consumers and as ingredients in a range of manufactured dairy and food products. This article discusses the production and applications of traditional dried milk products and new tailor-made formulated milk powders on the market. Brief descriptions of casein and whey-based powders, although not strictly milk powders, have been included for completeness.

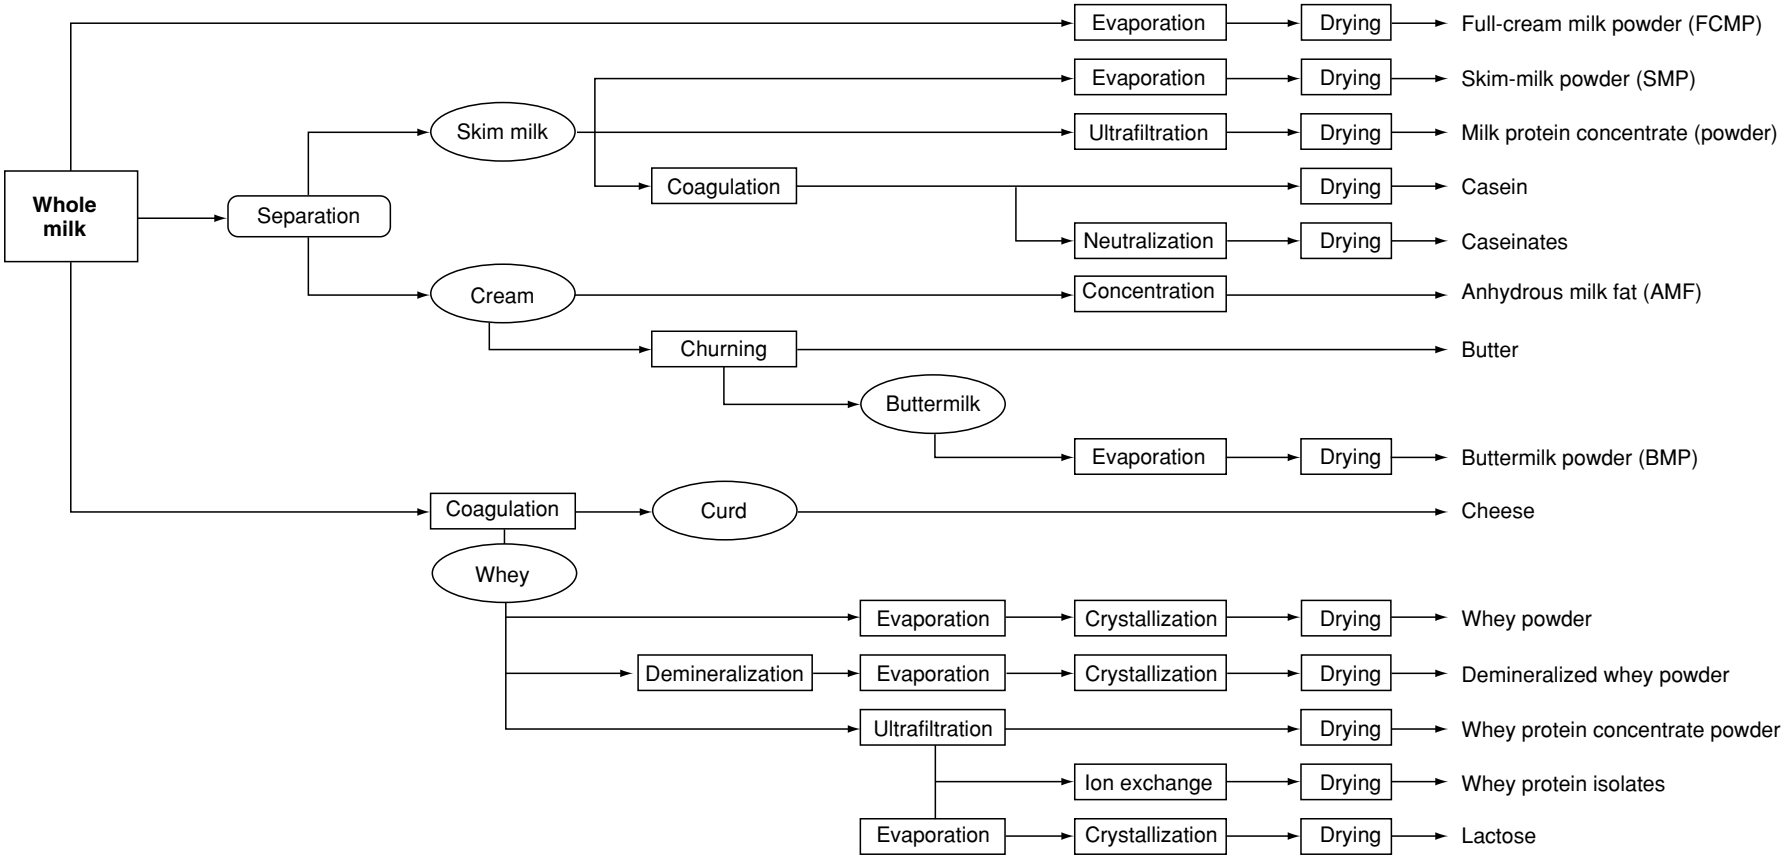

Figure 1 Milk ingredients. Reproduced with permission of the Australian Dairy Corporation.

Principal Spray-Dried Milk Powder Products

Skim, full-cream, and buttermilk powders are the traditional milk powders and are the major milk powders in the marketplace. The typical compositions of these powders are given in Table 1. The powders are dried to achieve specified standards for various grades of milk powders (Table 2).

Production of Skim, Full-Cream, and Buttermilk Powders

The main steps in the commercial manufacture of milk powders are: the preparation of the milk, heat treatment of the milk, concentration by evaporation, and spray drying. During the production of full-cream milk powder, there is an additional step, involving the homogenization of the concentrate prior to drying. Figure 2 shows the main steps in the manufacture of milk powders. Where a powder with instant properties is required, an agglomeration step is included during powder manufacture.

Preparation of milk This step defines the final composition of the powder. For the production of skim-milk powder, the milk is first separated into skim milk and cream by centrifugal separation. The skim milk should have a fat content of < 0.1%.

Table 1 Typical composition of milk powders

Constituent	*Skim-milk powder*	*Full-cream milk powder*	*Buttermilk powder*
Moisture (%)	3.0	2.25	3.0
Fat (%)	0.7	26.75	5.0

For full-cream milk powders, the milk is normally standardized, generally by blending cream or skim to obtain a fat content of 25–28% in the final powder. Supplements such as vitamins and minerals may be added to the skim or full-cream milk to enhance the nutritional value of these powders. Buttermilk powders are made from the aqueous fraction remaining after churning of cream during buttermaking or during manufacture of anhydrous milkfat.

Heat treatment of milk The milk has to receive a heat treatment prior to concentration. A range of heat treatments may be used. These range from low-heat treatment (72 °C for 15 s) for pasteurization to high-heat treatments (e.g., 85 °C for 30 min or ultrahigh-temperature (UHT) at 140 °C for a few seconds). A primary purpose of the heat treatment is to achieve a required microbiological specification. The heat treatment also reduces the enzyme activity in the milk and increases the shelf-life of the powder products. Another consequence of the heat treatment is the denaturation of the whey proteins in milk. Appropriate heat treatments can be used to develop desired physical, chemical, and functional properties in milk powder products.

Skim-milk powders are generally classified on the basis of the heat treatment received during powder manufacture. Although the heat treatment classification is not used in the grading of milk powders, they are used as a general guide to the selection of powders for specific applications. The most commonly used heat classification is that of the American Dried Product Institute which is based on the amount of undenatured whey protein in the powder (Table 3). (*See* **Powdered Milk**: Characteristics of Milk Powders.)

Concentration of milk This is the first stage for removal of water from milk. The milk is concentrated at a low temperature by vacuum evaporation. The temperature of the milk reaches a maximum of 70 °C in modern evaporators. Generally, about 90% of the water is removed by the evaporator, as removal of

water by evaporation requires 16–20 times less energy per kg water than spray drying. The milk concentrate of about 48–50% total solids is then fed into the spray drier.

Homogenization of milk concentrate Homogenization of full-cream milk concentrates is carried out to reduce the 'free-fat' content (i.e., solvent-extractable fat) of the powder. During homogenization, the fat globule size is reduced, proteins are transferred to the surface of the globule, and the globule is stabilized. Homogenization of the milk concentrate results in powders with improved flow properties and resistance to caking and clumping.

Spray drying Spray drying transforms the fluid milk concentrate that is fed into the hot air of the drier to a powder. The moisture content of the spray-dried powder is usually 3–4% (w/w). The main stages of spray drying are atomization of the concentrate into a spray through pressure nozzle atomizers or rotary atomizers, the mixing of the atomized particles with the hot air, the evaporation of moisture from the surface of the particles, and separation of the powder from the air. Single- and double-stage spray driers are used in milk powder manufacture. Commercial milk powders are typically dried to 4% moisture or less.

Agglomeration of milk powders For the production of milk powders with instant properties, the milk powders are agglomerated. This process yields large powder agglomerates. The wettability and dispersibility of powders are improved by agglomeration. Surfactants (e.g., lecithin) may be used during agglomeration of full-cream milk powders to improve their instant properties in cold water. (*See* **Agglomeration**; **Drying**: Spray Drying; **Evaporation**: Basic Principles; **Homogenization**.)

Applications of Skim, Full-cream Milk, and Buttermilk Powders

Milk powders are used in many applications. Instant milk powders, which dissolve readily in water, are used by consumers as a substitute for fresh milk and in beverage mixes. Also available in the market are a range of nutritionally enriched milk powder products that have been tailored to meet the needs of consumers at various stages of life. These

Table 4 World use of skim-milk powder in products

Product	*% Used*

include powders fortified with various nutrients. Most common in the market are milk powders enriched with calcium, iron, and folate.

Milk powders have major applications as ingredients in manufactured dairy and processed food products. A significant amount of milk powder is used in the manufacture of traditional recombined dairy products such as evaporated milk, sweetened condensed milk, and UHT milk in countries which do not have an adequate supply of fresh milk. Milk powders are also used as ingredients in a range of food products, including icecream, cultured milks and yogurts, chocolate, confectionery, bakery products, soups, and sauces. Buttermilk powders are used as replacers for skim-milk powder in applications where enhanced dairy flavors are desired. Table 4 gives the proportion of skim-milk powders used in various applications. Their ability to bind water, thicken and gel, and their emulsifying and foaming properties make milk powders valuable food ingredients. These properties of milk powders can be modulated by the amount of heat treatment received by the powder during manufacture. The characteristics of milk powders that make them useful in food applications are discussed in more detail elsewhere. (*See* **Powdered Milk**: Characteristics of Milk Powders.)

Dried Casein Products

Caseins are the principal milk proteins, accounting for ~80% of the proteins in milk. They can be separated or precipitated from milk. Among the major products in this class of dairy products are acid and rennet casein, caseinates, and coprecipitates.

Production of Casein Products

Acid casein is made by direct acidification of skim milk to pH 4.6 by mineral or organic acids. Rennet casein is made by adding rennet to skim milk. The casein is separated, washed, and dried. Acid casein is insoluble in water. This limits the applications of acid casein in some applications. To obtain a casein product that is soluble, the acid casein is neutralized with an alkali and spray-dried to obtain caseinates. Various types of alkali have been used. Sodium, potassium, and calcium caseinates are the most common types of caseinates on the market. Coprecipitates are total milk protein powders; they contain both casein and whey proteins. The proteins are precipitated from skim milk under controlled conditions of heat, acid, and calcium concentration. The composition of casein products is given in Table 5.

Applications of Casein Products

Casein products have good emulsifying, whipping, and water-binding properties which make them suitable in applications such as desserts, confectionery, bakery products, salad dressings, processed meats, soups, and sauces. They have applications in dairy-based products such as coffee whiteners, yogurt, icecream, and processed cheese and imitation cheese products. As they are high-protein products, they are also used as supplements in dietetic foods. (*See* **Casein and Caseinates**: Uses in the Food Industry.)

Dried Whey and Whey Protein Concentrates

Whey, the serum remaining after the manufacture of cheese or casein, can be converted into powder. Sweet whey (pH ~6.3) is obtained during rennet-coagulated cheese manufacture whereas acid whey (pH < 5.1) is produced during cottage cheese or casein manufacture. Acid whey has a higher mineral content than sweet whey.

Production of Whey-Based Powders

Whey is preheated gently, evaporated, and dried for production of whey powders. To facilitate drying, the lactose in the whey concentrate is precrystallized for the production of nonhygroscopic whey powders. For the production of reduced-lactose or reduced-mineral whey powders, a portion of these components can be selectively removed from the whey. Whey can also be concentrated by membrane separation (ultrafiltration, with or without diafiltration). These

Table 6 Typical composition of whey-based powders

Constituent	*Sweet whey powder*	*Acid whey powder*	*Dried whey protein concentrates*
Moisture (%)	3.5–5.0	3.5–5.0	3.0–4.0
Fat (%)	1.0–1.5	0.5–1.5	1–10
Protein (N × 6.38: %)	11.0–14.5	11.0–13.5	34–80
Lactose (%)	63.0–75.0	61.0–70.0	10–55
Ash (%)	9.8–12.3	9.8–12.3	4–8

Adapted from Chandan R (1997) *Dairy-Based Ingredients*. St Paul, Minnesota: Eagan Press.

processes separate the proteins from the water, lactose, and minerals. The concentrated protein solutions are then spray-dried to obtain dried whey protein concentrates with a range of protein contents, typically between 34 and 80% protein. Table 6 gives the typical compositions of dried whey and whey protein concentrates. Whey protein concentrates with a lower protein content (25% protein) and whey protein isolates (>90% protein) can also be produced and are on the market.

Applications of Whey-Based Powders

Dried whey, reduced-lactose and reduced-minerals whey and whey protein concentrates are used as ingredients in many food applications, including confectionery, bakery products, snack foods, yogurts, dips, desserts, meat products, pasta products, ice-cream, soups, sauces, beverages, and processed cheese products. Whey protein concentrates have been also used as economic egg-white replacers in food formulations. With increasing protein content, the whey protein concentrates provide greater nutritional value as well as improved functional properties such as emulsification, foaming, water binding, viscosity building, and gelling to foods. Whey protein isolates are widely used as nutritional supplements in sports drinks and health foods such as nutritional bars and protein supplements. (*See* **Whey and Whey Powders**: Production and Uses; Protein Concentrates and Fractions.)

Other Milk Powder Products

Nowadays, a range of other types of milk powders may be formulated to achieve a desired fat, protein, lactose, or mineral content, as well as to obtain target functional attributes in the powder. These include a range of cream powders, high 'free-fat' milk powders for the chocolate industry, high-heat 'heat-stable' milk powders for evaporated milk, milk protein concentrate powders, skim milk/whey powder blends, lactose-hydrolyzed powders, yogurt powders, and a variety of customized formulations for use in target food applications. These tailor-made ingredients are finding their way into the marketplace, as food manufacturers increasingly demand ingredients with enhanced performance in their applications.

The major steps in the manufacture of skim milk/whey powder blends and specialized milk powders generally include the same essential unit processes of heating, concentration, and drying that are used in conventional milk powder manufacture, except that sometimes additional processing steps are required during the preparation of the milk or milk concentrate prior to drying.

Cream and High-Fat Powders

Cream and high-fat powders, containing 40–75% fat, may be produced by spray drying of cream or milk with an increased fat content. A typical cream powder obtained from drying of cream contains ~70% fat. Cream powders were developed more than 40 years ago. The early powders were difficult to dry and handle because of their high fat content. Improvements in formulation science and drying technology have enabled cream powders with superior properties to be made. These powders are becoming more prevalent in the marketplace and can be used as an alternative to fresh cream or in formulae where milk fat is required. Some of their applications include chocolate, confectionery, icecream, desserts, soups, and sauces.

High Free-Fat Milk Powders

High 'free-fat' powders for use in chocolate manufacture have traditionally been produced by roller-drying. In roller-dried powder, greater than 90% of the fat in the powder is readily extractable. In addition, roller-dried powders are flaky and do not contain much air. These properties of roller-dried powders make them more suitable for chocolate manufacture than conventional spray-dried powders that have a high level of entrapped air and a low free-fat content. The use of high free-fat powders in chocolate reduces the requirement for cocoa butter in chocolate making. As roller-drying is more expensive than spray drying, there have been attempts to increase the level of free-fat in milk powders intended as ingredients for chocolate. Nowadays, some high free-fat powders are produced by spray drying and have improved performance compared to conventional milk powders in chocolate manufacture. (*See* **Fats**: Uses in the Food Industry.)

High-Heat Heat-Stable Milk Powders

High-heat heat-stable milk powders have been processed to insure that they are suitable for use in the manufacture of recombined evaporated milk. For

the manufacture of this product, reconstituted milk powder is recombined with fat to produce a concentrate containing typically 26% total solids (18% skim-milk solids and 8% fat) and the concentrate is sterilized. A heat-stable milk powder is required in these applications, as the milk concentrate that is prepared from the powder has to withstand in-can sterilization (120 °C for 12 min) without coagulation or excessive thickening.

Milk Protein Concentrate Powders

In the production of milk concentrate powders, skim-milk concentrates obtained using a membrane process that concentrates the casein and whey proteins without precipitation are spray-dried. A range of milk protein concentrates with varying protein, lactose, and mineral contents may be made. The degree of concentration and process conditions used during membrane processing dictates the composition of the final powder. These powders are used in various applications where traditional milk powders and milk protein products have been used previously. As the protein content of these powders is higher than that of skim-milk powder, they have better functional properties.

Skim Milk/Whey Powder Blends

Skim milk/whey powder blends are made by replacing a portion of the skim-milk solids by whey-based solids. These replacers can be dry blends of skim-milk powders and whey-based solids or, alternatively, skim milk and whey may be blended prior to heat treatment, concentration, and drying. There are currently no specifications for the composition of these powders which contain a higher ratio of whey protein to casein than conventional milk powders. Blends are formulated to obtain the desired composition and functionality in the target applications, such as confectionery, bakery, icecream, and yogurts. Skim milk/whey powder blends are used as economic alternatives to skim-milk powder in many recombined dairy products. (*See* **Whey and Whey Powders: Production and Uses; Protein Concentrates and Fractions.**)

Lactose-Hydrolyzed Milk Powder

Lactose-hydrolyzed milk powders are niche products that have been developed for people who are lactose-intolerant. For the production of lactose-hydrolyzed milk powders, an enzyme, β-galactosidase (EC 3.2.1.23), that hydrolyzes lactose to glucose and galactose is added to the milk and allowed to act until the desired degree of hydrolysis is obtained; the enzyme is then inactivated by heat treatment prior to further processing. These powders may be used as alternatives to milk powders.

Yogurt Powder

A small amount of yogurt powder is available in the market. Milk is fermented prior to spraying to yield powder with a yogurt flavor. The powder has applications in confectionary as fillings and pastes, bakery products, and in a range of soups, sauces, and dips.

Milk Protein Hydrolysates

A number of milk protein, casein, and whey protein hydrolysates have been developed. These products are aimed at the nutritional supplement and sports nutrition markets. The hydrolyzed products are soluble and are quickly absorbed by the body.

Milk Powder Production Worldwide

Milk powder is the third largest category of dairy products, after cheese and fresh dairy and liquid milk products. World production of milk has continued to grow at the rate of about 1% a year through both increased cow numbers and better yields from herds. Stagnant sales of drinking milk in high-milk-production countries have meant that there has been a steady increase in manufacturing milk available for drying and milk powder production, particularly in Argentina, New Zealand, and Australia (Tables 7 and 8), with the last two countries exporting the majority of their production (Tables 9 and 10).

China and India have also shown steady increases in their production of full-cream milk powder, which has been used mostly for home consumption to shift production of milk products internally to cover areas and times of low production (Table 8). The

USA and the European Union continue to be major producers and exporters of all forms of milk powder (Tables 7–10).

During the 1990s, skim-milk production increased an average of only 1.7% compared with the average annual increase in full-cream milk powder of 7%. Over this period, conventional skim-milk powder lost market share as a livestock feed component. It also faced increased competition in the food ingredient market from full-cream milk powders and specialist dairy powders, such as whey powders and other milk components, for the production of both dairy and general food products. The demand for dairy products made from preserved milks and manufactured food items with dairy ingredients such as bakery goods, confectionery, processed meats, and beverages continued to grow in all markets.

Factors which have influenced the increased consumption and demand for a greater variety of dairy products and manufactured foods containing dairy products throughout the period include:

- an increased middle class with more discretionary income
- changes in consumption patterns as diet becomes increasingly international in style
- increased identification of dairy products as a healthy food
- newly identified applications for dairy ingredients and components
- growth in food service establishments worldwide
- growth in food-manufacturing capacity in key markets
- extended availability of dairy technology as an increasingly concentrated dairy industry moves into new markets and expands its processing capability in developing countries
- better distribution systems to support and extend the availability of dairy products in developing countries

Whilst milk production has outstripped demand for dairy products in high-production countries, the demand for dairy products and components, including powders, has continued to grow in developing areas. Key markets for imported milk powders in the 1990s included South-East Asia, Africa, and Latin America. Algeria, Japan, the Philippines, and Mexico were the world's largest importers of skim-milk powders throughout the latter parts of the 1990s, with Algeria, Brazil, Venezuela, and Saudi Arabia taking large amounts of the world's production of full-cream milk powders (Tables 11 and 12).

Economic factors, such as the financial crises suffered by Brazil, some South-East Asian and Eastern bloc countries and changing agreements on world trade policies, affected trade in milk powders through the 1990s, with downturns occurring in affected economies. Import trends (Tables 10 and 11) show the influences of these factors on changes in the sales of milk powders throughout this period. Other factors which affect the demand for milk powders and prices obtained on international markets include:

Future of Milk Powders in the Marketplace

Consumers and food product manufacturers recognize that milk powders have many desirable attributes. The nutritional, physical, and physiological functionality of milk powders, coupled with the ease with which they can be handled and stored, make them sought-after ingredients in the market place. This is evidenced by the growing demand for milk and dairy-based powders. As users of ingredients are placing more stringent requirements for consistent performance and enhanced functional performance in food, the trend towards tailored milk powder ingredients that are matched to specific food application sectors is expected to grow.

Characteristics of Milk Powders

M A Augustin, P T Clarke and H Craven, Food Science Australia, Weribee, Victoria, Australia

Background

Milk powders are used by consumers as a substitute for fresh milk and as ingredients for the manufacture of a range of processed food products. In order to be acceptable to consumers and users of ingredients, it is essential that milk powders are of a good quality. Milk powders are manufactured to meet certain specifications and standards for composition. These have been developed for milk powders by authorities such as the American Dairy Products Institute, the International Dairy Federation, the Food and Agricultural Organization of the United Nations and national food authorities in individual countries. In addition, a range of other technical specifications have been developed for the characterization of milk powders to ensure that they have the required functional performance in specific target applications. Milk powders may be similar in composition but have different functional properties.

There are many types of milk powders in the market place. This article focuses on the characteristics of skim and full-cream milk powders, which are the major types of milk powders produced. The microbiological quality, physical and chemical attributes of these milk powders, and their functional properties are discussed. Aspects of deteriorative changes that may occur in milk powders during transport and distribution that have an impact on the sensory properties of powders and their performance as food ingredients are included. The production, composition, and applications of various types of milk powders have been discussed elsewhere. (*See* **Powdered Milk**: Milk Powders in the Marketplace.)

Microbiological Aspects

Standards for Quality and Safety

Milk powder is a microbiologically stable product. It has a water activity of 0.3–0.4, which is too low to support the growth of microorganisms. However, after milk powder has been reconstituted, it is susceptible to microbial growth and spoilage in a similar manner to pasteurized milk. Provided milk powder is protected from moisture contamination before use, the numbers of microorganisms present generally decrease during storage, although the numbers of spores may remain constant.

Although milk powder does not support the growth of microorganisms, the microbiological content is an important consideration in the subsequent use of the powder. For this reason, government bodies and customer groups have developed microbiological limits or specifications that apply to certain groups of microorganisms that may be present in milk powder. These specifications may relate to expectations of raw milk quality, hygiene during manufacture, microbial safety, or compatibility with the intended use of the milk powder.

Common end-product standards relate to the total number of bacteria (mesophilic aerobes), coliforms, *Salmonella*, and *Staphylococcus aureus*. Criteria may also be applied for *Bacillus cereus*, *Listeria*, thermophiles, Enterobacteriaceae and spore-forming bacteria. The standards developed by the International Dairy Federation, for example, are shown in Table 1. Many countries have either adopted these standards or developed their own local specifications based on the principles of the International Commission on Microbiological Specifications for Foods (ICMSF).

The microbiological count of milk powder is influenced by both the numbers and types of microorganisms in the raw milk and the processing conditions under which the milk powder is produced. In powders subjected to a high heat treatment, the microorganisms present will be predominantly spore-formers, belonging to the genus *Bacillus*. When heat treatment is less severe, vegetative cells

Table 1 Microbiological specifications for milk powder, as recommended by the International Dairy Federation

Criteria[a]	*Total count (per gram)*	Salmonella *(per 25 g)*	*Coliforms (per gram)*	Staphylococcus aureus *(per gram)*
m	50 000	0	10	10
M	200 000	na	100	100
n	5	15	5	5
c	2	0	1	1

[a]For a production batch, n = number of samples that must be tested, c = number of samples that may exceed the microbiological limit specified as m, and M is the maximum allowable microbiological limit specified for any of the samples examined.
na = not applicable.

of thermoduric bacteria will be present, with their proportion to spore-formers decreasing with the intensity of the heat treatment applied. Vegetative cells of pathogenic bacteria and Gram-negative milk spoilage bacteria are destroyed during the heat treatment.

Coliforms, *Salmonella*, and other Enterobacteriaceae are killed when the milk is heated prior to evaporation; however, they may contaminate milk powder if conditions are not sufficiently hygienic during drying. These bacteria can enter the dryer through the intake air from the factory environment, or the equipment used to dry or transport the milk powder. Cracks in dryers have been shown to be a particularly significant source of *Salmonella*. Here, *Salmonella* are harbored in the insulation material. Although dryers operate at a high temperature, the concentrated milk offers protection to the bacteria, and they will survive heating at dryer air inlet and outlet temperatures. *Salmonella* spp. are significant pathogens, and several notable outbreaks of illness have been attributed to the presence of this organism in milk powder.

Staphylococcus aureus is significant, as certain strains can produce a heat-stable toxin that is not destroyed during powder manufacture. Although *Staphylococcus aureus* is common in raw milk, it does not normally grow to produce toxin unless the milk is stored at a high temperature prior to processing. The risk of toxin production increases with temperature and storage time. Although the bacteria will be killed during the process, the toxin remains and can be detected only through specific tests. Large outbreaks of illness have been attributed to the presence of *Staphylococcus aureus* toxin in milk powder.

Another bacterium of potential significance in milk powder is *Bacillus cereus*. This is commonly found in milk, and its spores may survive heat processing. Specialty powders such as infant formula often have specifications for this bacterium, owing to the potential risk of the growth of this organism in warmed milk and sensitivity of the target group of consumers.

Sometimes, yeasts and molds or their toxins, and *Listeria* are included in powder specifications. Yeasts and molds may be significant spoilage organisms if powder is contaminated with moisture, and *Listeria* may contaminate powder from the factory environment, especially if the environment is not kept dry.

In the milk powder process, milk is subjected to heat whilst concentrated under vacuum. Such conditions are conductive to the growth of thermophilic *Bacillus* species that may form biofilms in the process lines. When this occurs, the product may be contaminated with thermophiles that can reach more than 10^6 per gram in long production runs. Thermophiles may sporulate in the process, leading to the presence of large numbers of thermophilic spores in the powder. The spores can be extremely heat-resistant and may not be completely destroyed when the reconstituted powder is used in ultrahigh-temperature (UHT) processes. They are significant because they may cause sterility failures or spoilage in other heated products. If not properly cleaned from the plant between production runs, residues of thermophiles will seed subsequent batches of milk powder.

Although milk powder is a microbiologically stable product, the microbial quality of the raw milk may influence the shelf stability of the powder. Some bacteria present in raw milk, particularly *Pseudomonas* species, produce heat-stable spoilage enzymes, including proteases and lipases, that remain active in milk powder over many months. Experience has shown that lipase can act in full-cream milk powder to degrade milk fat to cause rancidity and other objectionable flavors. Proteases retain activity in milk powder and degrade milk proteins to cause objectionable flavors after the milk powder has been reconstituted. Proteases and lipases may be particularly detrimental in recombined milk products, or if milk powder is used to prepare UHT milk. Here, very low levels of protease and lipase may cause spoilage during long storage periods. (*See* ***Bacillus***: Occurrence; Detection; Food Poisoning; **Biofilms**; ***Listeria***: Properties and Occurrence; **Pasteurization**: Principles; ***Salmonella***: Properties and Occurrence; **Spoilage**: Bacterial Spoilage; Fungi in Food – An Overview; Molds in Spoilage; Yeasts in Spoilage; ***Staphylococcus***: Properties and Occurrence.)

Control of Microorganisms

The manufacture of microbiologically sound milk powder is dependent upon processing good-quality raw milk under hygienic conditions. To ensure the supply of good-quality milk, farm milk should be tested regularly for microbial quality. Many countries now use the total count test to monitor levels of bacteria in farm supplies. Thermoduric counts are sometimes used also. Raw milk ideally should be stored at less than 5 °C and used within 72 h of collection to minimize bacterial growth.

The pasteurization of milk is important and is normally identified as a critical control point. An example of process criteria for pasteurization would be heating of the milk for at least 15 s at 72 °C or 5 s at 80 °C.

Within the factory, application of good manufacturing practice is essential to minimize the risk of milk powder contamination with undesirable types or levels of microorganisms. To achieve this, consideration must be given to the design of the premises and control of staff or vehicular movement to separate raw materials from drying areas. Manufacturing

equipment and the processing environment must be maintained, cleaned, and sanitized to ensure that microbial build-up and spread are prevented. Staff must be trained in practices to maintain high standards of hygiene. A supply of good-quality water and air for the process is also essential. Many factories now have ongoing monitoring systems for *Salmonella* and *Listeria* in place. If these bacteria are detected in the processing environment, special clean-up regimes and extra product testing are implemented.

The modern approach to ensuring that milk powder is microbiologically safe involves preventative management to ensure manufacture under appropriate conditions of hygiene. Many factories now either have in place, or are moving towards, the hazard analysis critical control point (HACCP) system. Although end-product testing is still used to verify compliance and to detect gross process failures, it cannot be relied upon to ensure the safety of a batch of product. Testing can be labor-intensive and time-consuming, taking up to 7 days to obtain final results. To overcome these problems, samples may be composited and rapid techniques for detection of pathogens based on ELISA or DNA methods applied. These methods have advanced efficiencies in testing, and product can now be cleared in 24–48 h. (*See* **Hazard Analysis Critical Control Point; Quality Assurance and Quality Control.**)

Physical Properties

The physical properties of milk powders are governed by process variables, the type of dryer, and the composition of the milk. The physical properties of milk powders play an important role in their use as food ingredients. Their ability to be readily incorporated into products and to perform specific functions in a food formulation can be influenced by many physical properties. There are many physical attributes that must be taken into account when either evaluating a current product, setting specifications for new products or designing or modifying a drying system. Tighter and more demanding specifications have meant that powders are now often manufactured on specialist dryers designed specifically to produce the best possible product of defined specification.

Moisture

The final moisture content is critical for several reasons and is therefore defined in all powder specifications. It can affect functionality and microbiological quality, and is an economic consideration in the manufacture of powders. There are several factors during manufacture that can influence the moisture content of powders. These include the characteristics of the concentrate fed into the dryer, the type of atomization used, and the operating conditions during drying.

Insolubility Index

The insolubility index of a powder is a measure of the degree to which it can be readily solubilized in water prior to use. It is related to the amount of sediment obtained under defined conditions of mixing milk powders. The main reason for loss of solubility is the temperature of the particles during the primary stage of the drying process where the majority of the moisture is removed. During this stage, an impermeable crust can form on the particle surface that severely restricts water removal, leading to the production of case-hardened particles and subsequent loss of solubility.

Bulk Density and Particle Density

Bulk density is the amount of powder by weight that is present in a defined volume. It is usually expressed as g ml^{-1} and is obtained by measuring the volume of a fixed weight of powder after it has been tapped for a defined number of times. A high bulk density is very important in packaging and transportation, and is desirable as it can significantly reduce costs. The bulk density is influenced by a range of factors. These include the amount of air entrapped in the powder particles (occluded air), the overall density of the particle (determined by the composition), the air between the individual powder particles (interstitial air), the particle size distribution and the particle shape. The bulk density of powders is influenced by dryer design and configuration (Tables 2 and 3). Particle density is the density of the solids (determined by the composition), which determines the particle density, together with the amount of occluded air.

Particle Size Distribution

The individual particles produced during drying can vary greatly in size. The distribution of particle size then can be further altered by the degree of agglomeration or after grinding. An indication of the range of particle sizes obtained from different dryer configurations is given in Table 4.

Interstitial Air and Occluded Air

Interstitial air is the amount of air that exists between particles or agglomerates as well as the air inside porous agglomerates. The sphericity of the particles, the particle size distribution, and the degree of agglomeration determine the amount of interstitial air. To obtain minimum interstitial air, the particles need to be smooth, have a range of particle sizes, and be in compact agglomerates.

Table 2 Ability of various spray dryers to manufacture nonagglomerated and agglomerated skim milk powder with low or high bulk densities

Type of drying process	*Chamber configuration*	*Postprimary treatment*	*Atomizer type*	*Nonagglomerated skim milk powder*		*Agglomerated skim milk powder*	
				Low BD[a]	*High BD*[a]	*Low BD*[a]	*High BD*[a]

Table 4 Mean particle size obtained from dryers of different configuration

Powder characteristics	*Dryer configuration*	*Particle size (μm)*
Individual particles	Concurrent with pneumatic conveying	20–200
	Tall form – tower	30–250
Flakes	Roller dryer	200–5000
Loose agglomerate	Mixed flow with integrated fluid bed	100–400
– open structure	Concurrent with integrated fluid bed	100–200
Compact agglomerate	Concurrent spray dryer with integrated belt	300–2000
– porous structure	Mixed flow with integrated fluid bed	100–400

From personal communication (E. Refstrup), Niro A/S, Denmark.

Occluded air is the amount of air entrapped within the powder particles. It is affected by the preheat treatment of the original milk, with a higher pretreatment of milk resulting in less occluded air, and the amount of air incorporated in the concentrate. Higher total solids generally result in lower occluded air. Powders atomized by a nozzle contain less air than rotary atomized powders, despite improvements to the modern rotary atomizers. Gentle drying also reduces the level of occluded air, and therefore, the use of multistage dryers is recommended for the production of powders with low occluded air.

Flowability

With the ever-increasing diversity of use of milk powders today, the need for properties such as

flowability is increasing. Powders are used in applications ranging from dispensing machines through to the large-scale recombining operations that utilize mechanical handling and dosing. For both agglomerated and nonagglomerated powders, a better flowability can be obtained by producing larger powder particles with smooth and rounded particle surfaces within a narrow particle size distribution. Flowability is also influenced by other factors such as total fat in the powder and the amount of 'free fat.'

'Free Fat'

'Free fat' in powder is defined as the fat fraction that is extractable by organic solvents under specific conditions of solvent type, time, and temperature of extraction. In most instances, 'free fat' is considered a defect. The exception is where 'free fat' is required for a specific application, e.g., chocolate manufacture. One of the most critical influences of 'free fat' is the moisture content of the powder. If the moisture is too low (< 2.5%), 'free fat' increases and then decreases as the moisture content is raised from 2.5 to 4–5% but increases again if the moisture content is > 6–7%.

Instant Properties

Very fine powder particles are difficult to handle and have poor reconstitution properties. Agglomeration of powders allows water to permeate the powder particles more readily, breaking up the agglomerate and allowing the individual powder particles to dissolve. Instant milk powder is highly soluble and designed to reconstitute completely in water at both hot and cold temperatures. The other properties required in instant powders are wettability and dispersibility. The wettability of a powder is measured by determining the time taken for a given amount of powder to pass through the surface of water. Wettability may be enhanced by lecithination. The dispersibility of a powder is a measure of how completely a powder dissolves under controlled conditions. Other tests carried out on milk powders related to their instant properties include slowly dispersible particles, coffee test, white flecks number (minute particles that are seen on the surface of reconstituted milk), and the sludge test.

Color

The color of a powder is determined by composition, preheat treatment, drying conditions, and particle size distribution. Scorched particles can be a visual defect that will often show up as deposits on the bottom of mixing vats and in strainers.

Other Properties

Apart from the properties described above, there are others that influence a powder's acceptability. These include the mechanical stability of the powder, which influences the degree of agglomeration breakdown during transport and storage, hygroscopicity, which is related to the degree of water attraction a powder exhibits, and cakiness, an attribute that is a measure of the extent to which a powder adheres to itself, especially under compression. (*See* **Agglomeration**; **Drying**: Spray Drying; **Rheological Properties of Food Materials**.)

Chemical Characteristics

The chemical properties of milk powders are determined by the composition of the milk and the heat treatment applied during powder manufacture.

Chemical Composition

Skim and full-cream milk powders are obtained by dehydration of skim milk and full-cream milk to ~ 4% moisture. Full-cream milk is usually standardized to a fat:solids-nonfat ratio of 1:2.67 to meet the 26% legal minimum fat content for this powder. The protein content of skim milk powders may be standardized also. Variations in milk composition owing to factors such as cow breed, feed, stage of lactation, and season are reflected in the composition of milk powders. The American Dairy Products Institute standards for skim and full-cream milk powder compositions are as follows: skim milk powder should have a maximum fat content of 1.25% and a maximum water content of 4.0%, whereas full-cream milk powder should have a minimum fat content of 26% and a maximum water content of 4.0%. Control of the moisture content of milk powders to a maximum of 4% is essential for good shelf-life stability. Table 5 shows the range of values observed in milk powder.

Table 5 Composition of milk powders[a]

Constituent	*Skim milk powder*	*Full-cream milk powder*
Moisture (g per 100 g)	3–5	2–4
Fat (g per 100 g)	0.7–1.3	25–28
Crude protein (g per 100 g)	35–37	25–27
Lactose (g per 100 g)	49–52	36–38
Citric acid (g per 100 g)	1.8–2.1	1.3–1.4
Ash (g per 100 g)	7.5–8.0	6.0–7.0
Sodium (mg per 100 g)	400–550	370–420
Potassium (mg per 100 g)	1550–1750	1150–1350
Calcium (mg per 100 g)	1200–1300	900–1000
Magnesium (mg per 100 g)	110–140	85–100
Phosphorus (mg per 100 g)	950–1050	700–770
Chloride (mg per 100 g)	~1100	750–800

[a]Adapted from Walstra P and Jenness R (1984) *Dairy Chemistry and Physics*, pp. 418–419. New York: John Wiley.

Another important indicator of milk powder quality is the titratable acidity of the reconstituted powder. This is an indicator of the microbiological quality of the milk. The American Dairy Products Institute sets a maximum of 0.15% for titratable acidity of skim milk powder.

Heat-treatment Classification

The characteristics of milk powder can be influenced by the heat treatment received by the milk powder during manufacture. The time and temperature of the preheat treatment affects the level of whey-protein denaturation. The whey-protein nitrogen index, which is a measure of the undenatured whey-protein nitrogen in the powder and was developed by the American Dairy Products Institute, is commonly used to classify powders into low-heat, medium-heat and high-heat milk powders. Typical preheat treatments used for the manufacture of these powders are listed in Table 6. As the composition of milk, including the initial level of whey proteins in milk, can vary with season, the same heat treatment can result in a different whey-protein nitrogen index. Other methods for heat classification of milk powders, such as the heat number, cystine number, and thiol number also may be used as a measure of the heat treatment given to the milk during powder manufacture. (*See* **Heat Treatment**: Ultra-high Temperature (UHT) Treatments.)

Functional Properties of Milk Powders

When milk powders are used as ingredients in food applications, they contribute to the physical attributes of the food. The ability of milk powders to impart desirable properties to food is related primarily to functional properties of milk-protein components in the powders. These functional properties include solubility, hydration, heat stability, viscosity, gelling, foaming, and emulsifying. In milk powders, the functional properties of the milk proteins may be modulated by heat, ions, and other components. Heat treatment of milk prior to concentration and drying is the most common method used to alter the functional properties of milk powders. Milk powders with the same composition given different preheat treatments prior to concentration and drying have different functional attributes when used as ingredients.

Table 6 Heat classification of skim milk powder

Heat class	*Whey protein nitrogen index*[a] *(milligrams of undenatured whey protein N per gram of powder)*	*Preheat treatment of milk*[b]
Low heat	Not less than 6	72 °C for 15 s
Medium heat	1.51–5.99	75 °C for 3 min
High heat	Not more than 1.5	90 °C for 10 min 120 °C for 2 min

[a]From American Dairy Products Institute (1990) *Standards for Grades of Dry Milks including Methods of Analysis, Bulletin 916*.
[b]A range of other preheating conditions may be used to achieve a desired whey protein nitrogen index.

Solubility

Solubility is a fundamental functional property that is a prerequisite for most other desired functionalities. The solubility of milk powders is dependent on pH. Proteins have a minimum solubility at the isoelectric pH, and solubility is increased on the acid and alkaline side of this pH. Caseins, the major proteins in milk, are least soluble at pH 4.6.

Hydration

Hydration is related to the ability of the milk proteins to bind or entrap water. Caseins hold about 3.3 g of water per gram, whereas undernatured whey proteins hold ~0.4 g of water per gram. Heat denaturation of whey proteins increases the water holding to 2.5 g of water per gram. Milk powder contains other components, such as lactose, that bind water in addition to the protein. Skim milk powders have a water sorption of 0.96–1.28 g water per gram, depending on the conditions used during powder manufacture.

Heat Stability

Heat stability is an important property in certain applications such as the manufacture of recombined evaporated milk. Single-strength milks made from low-, medium- or high-heat milk powders have a similar heat stability to fresh milk. They are heat-stable at the pH of milk (pH 6.7), being able to withstand coagulation for up to ~20 min at 140 °C. However, for adequate heat stability of evaporated milks under sterilization conditions (e.g., 120 °C for 12 min), high-heat milk powders are necessary. Heat stability is affected by the pH of the milk, mineral content, and other components in the milk (e.g., lecithin, urea).

Viscosity

The viscosity of milks reconstituted from milk powders is dependent on their state of dispersion, concentration of solids, and temperature. Increasing the concentration of milk solids increases the viscosity. Decreasing the temperature increases the viscosity, but heating milk to a temperature that results in denaturation of whey proteins also increases the viscosity.

Gelation

Milks reconstituted from milk powders have the ability to form gels under similar conditions to those required for the formation of gels from fresh milk, i.e., by rennet action for formation of rennet gels and by acidification of milk under quiescent conditions.

Foaming and Emulsifying

Milk powders can be used in applications where foaming and emulsifying properties are required. The ability of milk proteins in the milk powders to stabilize foams and emulsions may be exploited when these properties are required. (*See* **Aerated Foods**; **Emulsifiers**: Uses in Processed Foods; **Mixing of Powders**.)

Functional Requirements of Milk Powders in Major Food Applications

For milk powders to have the desired performance in food applications, the functional characteristics of the powders have to be matched to the application. This requires an understanding of the required functional properties of the milk powder ingredients in the target application.

Milk Powders for Recombined Dairy Products

A significant amount of milk powder is used in the manufacture of reconstituted and recombined dairy products. In these applications, the milk powders are combined with water and milkfat to reestablish the fat:solids-nonfat:water ratio of milk or other dairy products. Some of the major applications of milk powders in the recombination industry are for the preparation of pasteurized fluid milk, UHT milk, cream, evaporated milk, sweetened condensed milk, yogurt and cultured dairy products, recombined cheese, and icecream. Different functionalities of the milk powder ingredients are needed in these various recombined dairy products. Table 7 lists the major functional requirements of milk powders for recombined dairy products.

Table 7 Functional requirements of milk powders in recombined dairy products and selected processed foods

Product	*Functional properties required in milk powder*	*Heat treatment of milk powder*
Pasteurized milk	Good flavor Emulsifying	Low–medium heat
UHT milk	Good flavor Heat stability Emulsifying	Low–medium–high heat
Cream	Good flavor Emulsifying	Low–medium heat
Evaporated milk	Heat stability Viscosity	High heat
Sweetened condensed milk	Viscosity	Low–medium heat
Yogurt	Water-binding Viscosity Gelling	Low heat[a]
Cheese	Rennetability	Low heat
Icecream	Foaming/whipping Emulsifying	Low–medium–high heat
Confectionery	Water-binding Foaming/whipping Emulsifying Heat stability	High heat
Bakery	Water-binding Foaming/whipping Emulsifying Gelling	High heat

[a]If a low-heat milk powder is used, the yogurt milk has to be given a high-heat treatment during yogurt manufacture. Alternatively, a high-heat milk powder may be used, in which case, the yogurt milk requires only a low-heat treatment to pasteurize the milk during yogurt manufacture.

Pasteurized milks and UHT milks These products have a similar composition to fresh milk. For pasteurized milks, low-heat or medium-heat powders are used to obtain a flavor similar to milk and to minimize heat-induced flavors. In the case of UHT milks, any type of powder can be used, as single-strength milks made from low-, medium-, or high-heat powders are stable to UHT conditions.

Evaporated milks It is essential to use high-heat powders for this application to obtain evaporated milk with the desired viscosity. A high-preheat treatment improves the heat stability of a recombined milk concentrate (typically 26% total solids; 18% solids-nonfat: 8% fat) to in-can sterilization conditions used in its manufacture. Additionally, high-heat powders are screened using heat-stability tests to ensure that they withstand sterilization without excessive thickening or coagulation.

Sweetened condensed milk This is a traditional dairy product containing 74% total solids (20% milk solids nonfat: 8% fat: 46% sucrose). The most important physical attribute of this product is its viscosity. Low- and medium-heat powders are used in this application. Milk powders given a high-heat treatment (e.g., 85 °C for 30 min) cannot be easily processed, because the high viscosity of concentrates made from these powders also results in rapid age thickening during storage of the product. There are a number of viscosity tests that may be used as indicators of suitability of powders for sweetened condensed milk manufacture.

Yogurt Milk powders may be used as a partial or total replacement for fresh milk in this application. Viscosity development, gelling, and good water-binding properties are necessary for the production of high-quality yogurts. These properties are obtained in yogurt by preheating the yogurt milk at a temperature that causes significant denaturation of whey proteins (e.g., 90 °C for 10 min). Low-heat milk powder may be used if a high-heat treatment is given during yogurt manufacture. If a high-heat milk powder is used, the yogurt milk requires only a low-heat pasteurization treatment during yogurt manufacture.

Cheese Only low-heat milk powders are suitable for recombined cheese manufacture. This ensures good rennetability of the reconstituted milk. With a high-heat treatment of milk, there is association of the denatured whey proteins with the casein, which hinders the reaction of the rennet.

Ice cream Milk powders contribute to the flavor and texture of ice cream. The milk powder aids in the emulsification of the ice cream mix and has a role in the development of an aerated matrix. (*See* **Condensed Milk**; **Evaporation**: Basic Principles; Uses in the Food Industry; **Recombined and Filled Milks**.)

Milk Powders for Selected Food Applications

Milk powders are used as functional ingredients in a number of processed foods.

Chocolate and confectionery products Milk powders contribute to the flavor, color, and texture development in chocolate and confectionery applications. The emulsifying properties of the milk proteins influence the miscibility of the ingredients used in chocolate and confectionery, hence influencing flow properties and texture. In confectionery products such as toffee, good water-binding properties of milk proteins contribute to the texture of these products. The Maillard reaction, which is the reaction of the amino groups of the proteins with reducing sugars in the formulation, is responsible for color development and for the production of caramelized flavors; the lactose in milk powders participates in the Maillard browning reactions.

Bakery products High-heat milk powders are useful in bakery applications. In addition to enhancing the nutritive value of cereal-based baked goods, milk powders contribute to the texture and flavor of these products. Their emulsification and foam-stabilization properties and their ability to participate in the Maillard browning reaction are important requirements in bakery applications.

Other applications The functional properties of milk powders also make them useful in a number of other applications, such as processed meat products, soups, gravies, and dips.

Characteristics of Stored Milk Powders

The characteristics of milk powder are dependent on the quality and composition of the raw milk and the manufacturing process used during its manufacture. However, even if milk powders are manufactured to meet the desired standards and specifications, changes in the properties of milk powders may occur during storage and distribution. The composition of the powder, the type of packaging material used, and the conditions of handling and storage influence the shelf-life of the powder.

Deterioration of milk powders resulting from Maillard browning, lactose crystallization, and oxidation of fat may lead to flavor and physical defects in the powder. It may also affect the functionality of the milk powder when it is used in a food product. Some of the changes that may occur during storage include the development of a brown color, a reduction in pH, reduced solubility, development of off-flavors, and reduced heat stability of powders.

POWER SUPPLIES

Use of Electricity in Food Technology

D Graham, R and D Enterprises, Walnut Creek, CA, USA

Introduction

The food industry in the USA consumed 17.4 billion kcal in 1999. Fifty-eight percent of total food industry energy costs are from electricity. The industry purchases 64.0 billion kWh of electricity annually at a cost of $3.36 billion. Purchased energy is 1.3% of the value of product shipments for the food industry compared with 1.7% for the total US industry.

Major uses of electricity include freezer and refrigeration compressors, conveyors, air handling, pumping, lighting, process controllers and monitors, and packaging forming and sealing. Natural gas is the primary source of thermal energy for ovens, fryers, dryers, evaporators, and boilers, with relative costs being the main reason. Closely related uses of electricity in agricultural food production include crop irrigation, pest control, produce disinfection, grain harvesting and storage, weed reduction, livestock waste management, and fish farming.

Irradiation, ohmic heating, microwave processing, ozonation, freeze concentration, nonthermal pasteurization, and the use of heat pumps are examples of relatively new electrotechnologies that the food industry may apply increasingly in the future. Application of these technologies provides opportunities for food processors to improve operating efficiencies and helps insure the quality and safety of processed food products.

Electricity Use by Food Industry Sectors

Food energy costs rose steadily over the past two decades. In 1996, purchased electricity comprised over half of the total energy used in food processing. Electrical consumption by grain milling, meat processing, preserved fruits and vegetables accounts for 23, 19, and 13%, respectively, of the total food industry use of electricity. Some food processors operate cogeneration facilities using surplus heat to produce electricity, but approximately 92% of total electricity used by the food industry in the USA is purchased from utility companies. Approximately 87% of the electricity is used by motor-driven equipment such as compressors, pumps, mixers, grinders, fans, etc. **Table 1** compares the cost of electricity with total energy costs in food processing. Electricity consumption has increased approximately 3% annually from 48.9 billion kWh in 1986 to 69.1 billion kWh in 1999. **Table 2** shows the trends in electric energy cost from 1980 to 1996.

radiation, laser, ultraviolet light, freeze concentration, and pulsed electric fields are developing technologies that offer future potential for improvements in food safety, quality, and more efficient processing.

Irradiation of Food Products

Treatment of a food product with a controlled source of irradiation can be very effective for improving the safety of the food product, since the irradiation can destroy any viable food pathogens that may be present. Food products are not made radioactive when irradiated, and no toxic byproducts are formed. Irradiation has been used successfully on a variety of products, including cereals, fruits, vegetables, prepared foods, dairy products, meat and poultry, beverages, spices, and seasonings. Products can be irradiated after being sealed in packaging material, which reduces the possibility of contamination by handling after treatment.

Safety of irradiated foods Controversy has surrounded the use of food irradiation since its discovery in the late 1940s. Much concern has resulted from fear that the irradiation process might make the food radioactive. Treatment of food with gamma irradiation does not inject radioactivity into the food. High-energy electrons pass through the food product and, if sufficient energy is applied, kill microorganisms that they impact. In approving food irradiation, the Food and Drug Administration (FDA) reviewed over 400 toxicity studies, including animal feeding studies before issuing any approvals. The FDA concluded that food irradiated up to 1 kGy is "wholesome and safe for human consumption, even where the food that is irradiated may constitute a substantial portion of the diet . . . "

Electron beam irradiation may provide an effective way to control harmful *E. coli* 0157:H7 and other emerging pathogens in ground beef and other processed meat products such as pork sausage and refrigerated poultry. Electron beams (gamma rays) from machine sources up to 10 million electron volts (10 MeV) and X-rays generated from machine sources up to 5 MeV are permitted commercially. Similar energetic rays also can be produced by decay from sealed units of radioactive sources such as cobalt-60 or cesium-137. Gamma rays are used effectively for sterilizing a variety of products including food packaging materials, syringes, bandages, and other heat-sensitive pharmaceutical products. X-rays also are effective in some applications. One kilogray is 1 J of energy absorbed per kilogram of the substance being irradiated. The FDA has approved electron beam radiation providing absorbed doses of radiation from 0.2 to 7.0 kGy, depending of the particular food product. Table 3 lists the radiation levels approved by the FDA for food products.

Microwave Heating

Microwave ovens found extensive use in home food preparation and in commercial food service during the past two decades. Industrially, microwaves are used primarily for tempering, thawing large blocks of frozen meat, and preheating. Studies of microwave application for sterilization of food products have shown limited success.

Microwaves are electromagnetic waves similar to TV, radio, light, radar, or infrared waves, with the main difference being the frequency of the wave motion. Food products contain molecules such as water, salts, and proteins that have dipolar properties. Microwave energy passing through a food product causes these dipolar molecules to vibrate. The resulting internal friction produces heat. Thus, the food product is heated from within, and heating time is greatly reduced compared with heating by external application of heat. This rapid heating provides improved food quality and energy savings in many applications.

Table 3 Food irradiation processes approved by the FDA

Year approved	*Food product*	*Dose (kGy)*	*Purpose*
1963	Wheat and wheat flour	0.2–0.5	Disinfestation of Insects
1964/5	White potatoes	0.05–0.15	Inhibit sprouting
1983	Spices and seasonings	30 max.	Disinfestation of insects
1985	Pork, fresh unheat-processed	0.3–1.0	Control of *Trichinella spiralis*
1985/6	Dry of dehydrated enzymes	10 max.	Control of insects and pathogens
1986	Fruit	1 max.	Disinfestation and delay ripening
1986	Fresh vegetables	1 max.	Disinfestation of insects
1986	Herbs and spices	30 max.	Control of microorganisms
1986	Vegetable seasonings	30 max.	Control of microorganisms
1990	Poultry, fresh or frozen	3 max.	Control of microorganisms
1995	Meat, frozen and packaged (limited to use by NASA)	44 minimum	Sterlization
1995	Animal feed and pet food	2–25	Control of *Salmonella*
1997	Red meat, uncooked, chilled	4.5 max.	Control of microorganisms
1997	Red meat, frozen	7.0 max.	Control of microorganisms

Table 4 Microwave energy penetration

	Material temperature (°C)	*Half power depth (cm)*	
		915 MHz	*2450 MHz*
Ice	−12	1600	780
Water	2	4	0.6
Water	45	14	2
Water	75	21	3
Water	95	30	5
Beef, lean	−51	70	46
Beef, lean	−18	10	8
Beef, lean	4	2	2
Beef, lean (freeze-dried)	−18	550	190

Microwaves are in the radio frequency portion of the electromagnetic spectrum between 300 and 300 000 MHz. Microwaves are generated by a magnetron that converts electrical energy into an electromagnetic field with centers of positive and negative charges that change direction billions of times a second. In the USA, the Federal Communication Commission limits commercial microwave sources to 915 and 2450 MHz.

Microwave heating is used for cooking or partial cooking of meat, chicken, other prepared foods, rapid thawing of frozen meat, poultry, and seafood, drying of pasta, fruits, and cereal products, freeze drying of meat and juices, and, pasteurization of milk, yogurt, beer, and wine. Table 4 shows the penetration of microwave energy into a variety of food substances at different temperatures.

Ohmic Heating

Ohmic heating describes an innovative process in which an electric current is passed directly through a food product to generate heat by internal resistance without any need for intermediate heat exchangers. The electric energy is applied from electrodes inserted into the product and is converted directly to thermal energy within the food product with an overall conversion efficiency of 90%.

Food products sterilized by ohmic heating undergo less damage to flavor and color as compared with conventional heating methods. Electrical conductivity of the food product influences the flow of electric current through the food and can cause uneven heat distribution. This has been troublesome with some prepared foods that contain ingredients of varied composition, size, and shape. Ohmic heating can process a wide variety of pumpable products including stews, dairy sauces, eggs, custards, soups, diced fruits, pie fillings, etc. Microorganisms present in the food are killed by heat, just as in conventional heat processing. The temperatures required to assure commercial sterility are identical to the temperatures required in conventional heat processing. The ohmic advantage stems from the rapid temperature increase due to internally generated heat, making conductance of heat through the food to the center of the mass unnecessary, and the 90% conversion of electrical energy to heat. Conventional heat exchangers achieve only about 50% transfer of heat to the food product. Figure 1 shows a typical electrode assembly for ohmic heating.

A typical 75-kW commercial unit capable of heating $750\,kg\,h^{-1}$ uses a 5-cm-diameter electrode housing. A 300-kW, $3000\,kg\,h^{-1}$ unit requires a 10-mm-diameter housing. A basic ohmic heating system typically consists of four electrodes in series connected by short spacer tubes. The top and bottom electrodes are connected to one phase of a three-phase transformer and are grounded. Each of the two middle electrodes is connected to one of the other phases of the transformer. The voltage required for heating the product is varied by adjusting the primary side of the transformer.

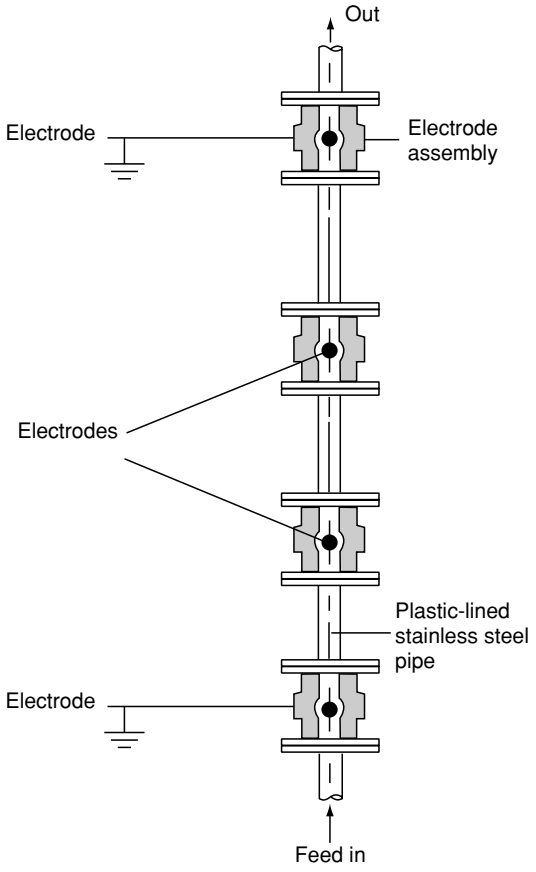

Figure 1 Typical electrode assembly. Drawing courtesy of APV.

Membrane Technology

Membrane technologies separate fluid mixtures in many different applications. They can separate materials based on size, electrical nature, physical properties, and are used widely in the food processing and chemical industries, as well as in water treatment. All membrane processes are electrically driven, using high-velocity/high-pressure pumps.

This technology originated in the early 1930s with cellulose acetate membranes, and has developed rapidly as new and improved media have been created. The arsenal of membranes now includes a wide range of polymeric membranes, ceramic, and sintered stainless steel. Among many applications are: concentration of fluid products; sterilization by removal of bacteria or viruses; removal of constituents such as proteins, acids, and fats from process streams; desalination; purification; demineralization; refining of oils; and clarification.

Membrane separation could be considered as a modern, highly efficient, versatile form of the traditional filtering process. The objective is still the same, i.e., to remove one component such as small solid particles from a second component such as a liquid or to separate a given molecular component from a solution.

The efficiency with which separations can be made and the wide range of components that can be processed with membranes are noteworthy. Separations can be based on particulate size differences of a less than 1 μm down to a molecular level. Separation depends on the passage of specific molecules through a semipermeable membrane while the membrane retains other molecules.

In traditional simple filtration, the osmotic pressure due to differences in concentration on the two sides of a membrane, a differential pressure, and/or gravity were the only driving forces. In membrane processes, pumps apply high pressure and high cross-flow velocity to the solution being filtered to speed up the separation process. High-velocity turbulent flow at the membrane/liquid interface continuously cleans the membrane surfaces and extends their useful life. In some instances, when strongly highly ionic systems are being filtered, an electrical potential will be applied to accelerate the process and increase selectivity of the separation process.

Membrane separations typically are classified into subtechnologies based on the pore size of the filter media. Common classifications include microfiltration (coarsest), ultrafiltration, nanofiltration, and reverse osmosis (finest). Figure 2 illustrates the tremendous range and flexibility of the filtration spectrum. Particle sizes are measured in microns and alternatively stated as Daltons. (MWCO, molecular weight cutoff).

The ability to concentrate delicately flavored solutions such as fruit juices or dairy products without the application of heat provides the food processor with the potential to significantly improve product quality. The ability to separate components selectively from a product stream or effluent stream can lead to the creation of new products, allow recycling or reclaiming of valuable ingredients, or simplify and reduce the cost of effluent disposal.

Membrane filtration has been commercially used in the USA since about 1930, primarily in the water and beverage industries. Widespread applications and use were initially limited due to the lack of practical membranes. Early membranes tended to clog easily, were hard to clean, and had short process lives. Development of new polymeric membranes, or ceramic membranes in the 1980s provided the food processor with filtering systems with greater durability, greater efficiency, far more versatility and lower costs. These membranes have a higher capacity, are less prone to clog, are easier to clean, and withstand multiple

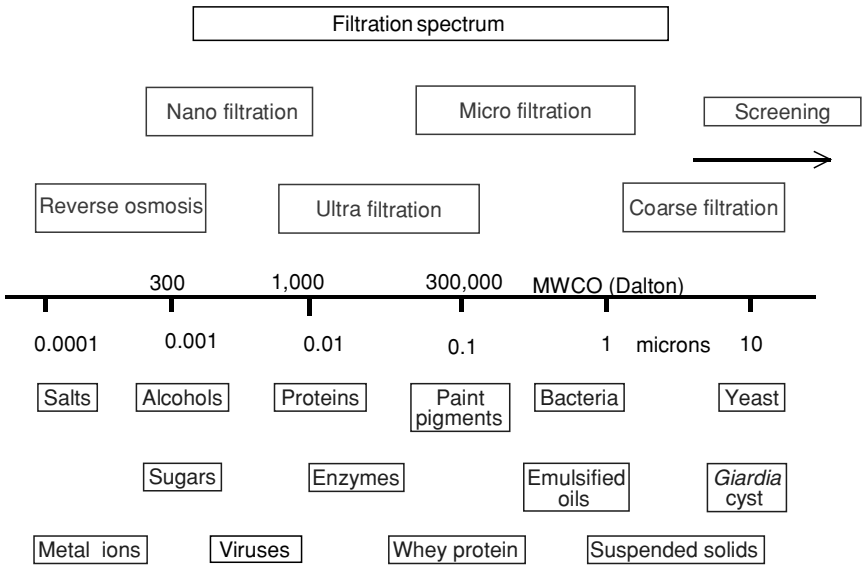

Figure 2 Membrane filtration spectrum. Drawing courtesy of J. Strasser, Process & Equipment Technology.

filtration/cleaning cycles. Many of today's routine commercial applications of membrane separation technology were only dreams two decades ago.

The cost for many types of membranes has dropped significantly in the past 10 years, e.g., from $800 to $350 for similarly sized spiral wound modules. Energy efficiencies have improved partially due to lower pressure differential required across the membranes, higher throughput and more sophisticated computer controls. These efficiencies, coupled with lower cost membranes, have made membrane separation processes not only more cost-effective but also more dependable and easier to maintain and operate.

Membrane separation technology is finding multiple industrial applications not only in food processing but also in process water and plant effluent treatment. Most food processors are very aware that water management has become a major consideration to an efficient operation. Effluent discharge requirements have become more stringent, dependable supplies of process water can no longer be taken for granted, and both effluent disposal and water supply costs have increased.

Ozone: Antimicrobial Agent

Ozone (CAS No. 10028-15-6) is a gas at ambient and refrigerated temperatures and is partially soluble in water. In the stratosphere, UV and lightening generate ozone naturally from atmospheric oxygen; ozone is generated industrially by passing oxygen through a high-voltage electric corona discharge field.

Ozone (O_3) is a molecule composed of three oxygen atoms, in contrast to ordinary oxygen (O_2), which has only two oxygen atoms. Because of its atomic structure, ozone is an unstable gas that quickly decomposes into ordinary oxygen, especially in water. This tendency to decompose naturally makes ozone an important chemical. As ozone changes into oxygen, the extra oxygen atom splits off from each ozone molecule. These free oxygen atoms have two important characteristics: they are toxic to microorganisms, and they oxidize many chemical compounds, usually changing them into nontoxic substances.

Ozonation is used extensively for sanitizing bottled water, and may become widely used as an antimicrobial agent in processing foods for human consumption. Ozone is a powerful oxidant, can be dissolved in water, and can be used effectively to kill harmful microorganisms such as *Listeria*, *E. coli*, *Salmonella*, and other pathogenic bacteria, viruses, fungi, and cyst organisms such as *Giardia*. Ozone degrades to oxygen in a few minutes and thus leaves no chemical residue like chlorine, iodine, or other common disinfectants. Current food uses in the USA include aqueous ozone for cleaning sausage curing racks, washing apples, garlic cloves, strawberries, and fresh-cut produce including celery and lettuce; gaseous ozone is used in dry storage of onions, garlic, potatoes, and citrus products.

A schematic of a typical corona discharge system used to generate ozonated water from dry air or oxygen is shown in Figure 3. Figure 4 shows an ozone system installed in a food processing plant. In the foreground is a pressure swing absorption (PSA) air dryer. The sealed cabinet in the corner houses the ozone generator; the cabinet to the right contains the electronic operating controls for the system.

Freeze Concentration

Separation is an important step in every food processing operation. Evaporators heated with steam produced from coal or gas fired boilers is the dominant separation process used in the food industry. Freeze concentration (FC) technology is an electrically driven alternative for conventional evaporation technologies. The dairy industry is the food industry's largest user of energy for evaporation. FC offers both energy and economic savings to dairy processors using this innovative freeze concentrate technology. In addition, the food processing industry and the environment benefit by shifting from fossil fuels to more environmentally clean electrical energy.

FC is a process for removing water from food by crystallizing the water and mechanically separating ice crystals from the unfrozen liquid medium. The FC concentration process has been installed in more than 100 locations throughout the world. It has helped improve the quality and reduce the operating costs for concentrating orange juice, grapefruit juice, mandarin juice, coffee extract, vinegar, and ice beer, and to remove toxic organic residues from problematic process waste streams in the chemical and refining industries.

FC stemmed from fundamental research at the University of Eindhoven in 1960, and the first prototypes were developed by Grasso/Grenco in The Netherlands from 1970 to 1975. Early commercial applications were mainly for the production of soluble coffee in 1975 and orange juice in 1980. Pioneering work by the Electric Power Research Institute (EPRI), the Dairy Research Foundation (DRF), and Niro Process Technology successfully applied the freeze concentration process to milk and milk products. Freeze concentration yields milk products with a remarkably improved product quality, no heat degradation, lower operating costs, reduced waste burden, and a sustained continuous operation.

Freeze concentration provides several unique advantages over traditional thermal concentration technologies. FC products have a better product quality with no heat degradation and are clearly superior in taste, color, and functionality compared with other commercial concentrates. In addition, the improved operating efficiencies reduce the processors' bottom line cost. Freezing consumes 80 kcal (335 kJ) per kilogram of water made into ice versus 526 kcal (2200 kJ)

per kilogram of water converted to steam. The bottom-line additional cost of FC concentrate is no more than 6 cents per kilogram of milk solids higher than the cost of the best thermal evaporators of \$2.05 to 2.20 kg^{-1}.

How freeze concentration works The process works by pumping the milk through a scraped surface heat exchanger to form crystals. It is then fed to the recrystallizer, where the small crystals are mixed with a population of larger ice crystals. The larger crystals are grown through a ripening process. A continuous supply of small crystals from the scraped surface heat exchangers provides the fuel for this ripening growth. The ice crystals need to be removed to complete the concentration step. The wash column provides the most efficient method to remove these ice crystals and minimize the loss of product. Figure 5 provides a simplified schematic of the process.

The ripening process takes advantage of the equilibrium temperature at which crystals form. The equilibrium temperature of the solution is when crystals neither grow nor melt. When placed in the same concentration solution, small crystals have a slightly lower equilibrium temperature than larger crystals. The bulk solution temperature of a mixture of small and large crystals will be somewhere between the equilibrium temperature of the small and large crystals. The smaller crystals will be in a warmer environment and will melt, and the larger crystals will be in a colder environment and will grow. The heat of crystallization is exactly balanced by melting and growing crystals. The driving forces are therefore very small, producing spherical crystals, as shown in Figure 6.

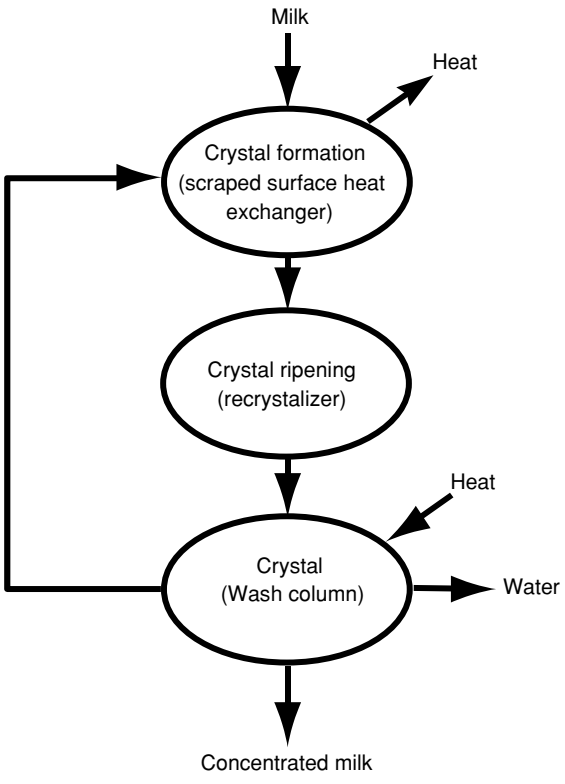

Figure 5 Overview of the freeze concentration process.

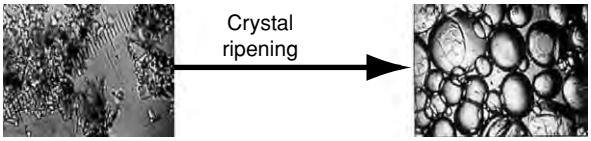

Figure 6 Ripening of crystals.

Once crystals are formed in the solution, the remaining liquid is concentrated in the solute(s) contained in the original feed because a portion of the original water is now in the form of ice crystals. The ice crystals need to be removed to complete the concentration step. The wash column provides the most efficient method to remove these ice crystals and minimize the loss of product.

Other Developing Electrotechnologies

Ultra-high-pressure processing Pressure can kill microorganisms in food products at room temperature with little or no damage to the food product. The most promising results to date have been with acidic liquid foods such as orange juice. Ultra-high-pressure processing, also called high-pressure processing (HPP) can extend the shelf-life of food products without the application of heat or chemical treatment.

In HPP, food products are exposed to pressures in the range of 103 422–620 000 kPa for a few minutes. Spores and common food enzymes appear to tolerate high pressures and are not destroyed.

Pulsed electric fields Pulsed Electric Field (PEF) is a unique nonthermal method of inactivating microorganisms, including many of the common food pathogens, without heating the product to the usual pasteurization temperatures. The destruction or inactivation of the microorganism is achieved by the breakdown of the microorganism's cell membranes during exposure to electric fields.

PEF applies multiple short pulses (1 μs each) of high-intensity electric fields (20–50 $kV\,cm^{-1}$) between two electrodes. The food product being treated flows between the two electrodes and is exposed to the electric field. The degree of treatment is adjusted to the characteristics of the food product being processed by:

- exposure time (related to flow rate and fluid volume of the electrode chamber);

- frequency of the pulses;
- intensity (kV cm^{-1}) of the electric field; and
- shape of the pulse wave (rate of build and decay of the electrical intensity).

Even though this technology has been applied only recently in the USA, it was described in German Patent 1,237,541 issued in 1960. PEF can be an effective pasteurization process, but the FDA has expressed concerns about the consistency of some of the microbial destruction data. These apparent inconsistencies may be due to the effect of the growth phase, type of organism, media, and pH. PEF presently is *not* recommended as a food sterilization method. Promising test results have been obtained with liquid eggs, milk, emulsions, juices, rice wine, some sauces, fermented products, and water.

PREBIOTICS

M B Roberfroid, Université Catholique de Louvain, Louvain-la-Neuve, Belgium

Background

The microbial flora that live symbiotically within the large intestine represent an essential element of the physiology of most mammals. The flora constitute a complex ecosystem that needs to be correctly fed in order to maintain a well-balanced composition in which the health-promoting bacterial species quantitatively predominate over the potentially harmful species. Foods that resist hydrolysis by the digestive enzymes and are not absorbed in the upper part of the gastrointestinal tract, including the small intestine, become substrates for the colonic microflora. These dietary components pass into the large bowel, where most of the indigenous intestinal microflora are located in a healthy human individual. A wide variety of dietary carbohydrates, especially resistant starch, dietary fiber, some polyols and nondigestible oligosaccharides, have such characteristics, and they provide quantitatively the majority of colonic food, i.e., dietary components available for bacterial fermentation in the colon. The colonic fermentation of such 'malabsorbed,' 'non-digestible,' or 'resistant' carbohydrates (oligosaccharides and polysaccharides) plays a role in salvaging part of the energy of these dietary components, in controlling transit time, stool bulking, and stool frequency, in influencing nutrient, especially mineral, bioavailability, in producing short-chain fatty acids that are known to play physiological roles such as control of mucosal motility and epithelial cell proliferation, or in modulating immune activity and endocrine functions. Amongst colonic foods, it has been shown recently that some components are especially beneficial to health. These compounds have been called 'prebiotics,' defined as 'nondigestible food ingredients that beneficially affect the host by selectively stimulating the growth and/or activity of one or a limited number of bacteria in the colon.' Prebiotics are thus colonic foods, but they are more than simply malabsorbed, nondigestible, or resistant carbohydrates; when they reach the large bowel, they have specific effects that promote the growth of advantageous species of bacteria to the detriment of adverse species. The inclusion of prebiotics in the diet can lead ultimately to a marked change in the composition of the colonic microflora, e.g., by selectively stimulating the growth of bacteria that are generally recognized as being beneficial for health and, at the same time, reducing the number of potentially harmful bacteria. The most efficient prebiotics identified today stimulate the growth of bifidobacteria, and sometimes lactobacilli, whilst reducing the numbers and activities of potentially pathogenic organisms. (*See* ***Bifidobacteria*** **in Foods**; **Lactic Acid Bacteria**.)

The contents of the human gut are not readily accessible for microbiological analysis; therefore, demonstration of changes in the composition of the fecal microflora is often used as a surrogate marker for the prebiotic effect. However, for such a demonstration to be convincing, it is critical that as many components of the fecal microbiota as possible are measured. These should include at least bacteroides, bifidobacteria, clostridia, eubacteria, Gram-positive cocci, coliforms, lactobacilli, total aerobes, and total anaerobes. Simple stimulation of growth of bifidobacteria and/or lactobacilli is insufficient to substantiate a prebiotic property without determining the effects on other fecal microorganisms, since it is the selectivity of effect that determines classification as a prebiotic. Clearly, studies using pure bacterial cultures are of very limited, if any, value in this respect, unless they are supported by mixed culture work in a well-validated set-up. But the ultimate proof must come from human studies in which correctly collected and stored fecal samples are analyzed for their composition in terms of bacterial species that are further well characterized using classical techniques combined with a conventional microbiological approach towards identification and/or modern molecular genotyping methods. Indeed, it is the effect of the prebiotic in a competitive ecological environment that is important.

The Prebiotics

At present, the food components for which a prebiotic effect has been reported are nondigestible carbohydrates that consist of mixtures of oligomers of different chain lengths and are characterized by the average number of osyl moieties, referred to as the 'degree of polymerization' (DP). They have been classified as 'nondigestible oligosaccharides,' or NDOs, the osidic bond of which is in a spatial configuration that confers resistance to the hydrolytic activities of the digestive enzymes of the upper gut. But once they reach the large bowel, the NDOs are fermented by at least some of the colonic bacteria. This fermentation produces gases which are excreted, and short-chain fatty acids, which may be absorbed by the host and

thus represent a source of energy. The NDOs affect the growth and, ultimately, the selective proliferation of these bacteria. Currently, there are few data on the relative efficiencies of different prebiotic oligosaccharides, or on their selectivity at a species, or even genus, level; however, the newly developed methodologies based on hybridization with specific rRNA probes will help us to make progress in that direction. It is often the case that a prebiotic effect is claimed for certain NDOs, or other dietary carbohydrates, without a full and careful investigation of their fermentation profile. Such data can never be accepted as a proof for a prebiotic attribute. (*See* **Carbohydrates**: Classification and Properties.)

Among the nondigestible oligosaccharides, those composed primarily of fructose units occupy a leading position in food science. Fructooligosaccharide is used as a generic name for all nondigestible oligosaccharides composed mainly of fructose. Strictly, however, the linear β-(2–1)-fructans are inulin-type fructans, which are different from levans, which are β-(2–6), often branched, fructans. The inulin-type fructans are by far the most extensively studied compounds and are clear market-leader prebiotics. They are composed of β-D-fructofuranose moities attached by β-2–1 linkages. The first monomer of the chain is either an α-D-glucopyranosyl or a β-D-fructopyranosyl residue. They constitute a series of homologous oligosaccharides derived from sucrose and may be represented by the formula GF_n or FF_n (where G = glucose and F = fructose). The naturally occurring NDOs, which are extracted from the roots of the chicory plant (*Cichorium intybus*), are a mixture of either GF_n (α-D-glucopyranosyl-[β-D-furanosyl]$_{n-1}$-D-fructofuranoside) or GF_n + FF_n (β-D-fructopyranosyl-[β-D-fructofuranosyl]$_{n-1}$-D-fructofuranoside) molecules, with the number of fructose units varying from 2 to ~60–65 units. As food ingredients, they are available as native inulin (inulin ST, average DP 10) and high-molecular-mass inulin (inulin HP, average DP 20), enzymatically hydrolyzed inulin (oligofructose, average DP 4), and a mixture of inulin HP and oligofructose (synergy 1), all of which occur naturally in a variety of food plants such as garlic, onion, asparagus, artichoke, banana, and wheat. Oligofructose can be produced by enzymatic conversion of sucrose to give a mixture composed of only GF_2, GF_3, GF_4 (average DP 3.8), sucrose, glucose, and fructose. The galactooligosaccharides, or transgalactooligosaccharides, are a potentially important class of prebiotics; they are produced industrially from lactose by transglycosylation reactions and consist of galactosyl derivatives of lactose with β1–3 and β1–6 linkages. The purported bifidogenic (i.e., stimulation of growth of bifidobacteria) nature of fructooligosaccharides and galactooligosaccharides is explained, at least in part, by the linkage specificity of the bifidobacterium β-fructosidase and β-galactosidase enzymes, respectively. These enzymes are cell-bound.

The glucose-based maltooligosaccharides and xylooligosaccharides are candidate prebiotics; however, specific bacterial enzymes for the degradation of these molecules have not been identified.

Malabsorption of the Nondigestible Oligosaccharides

The β configuration of the anomeric C-2 in the fructose moieties of the inulin-type fructans as well as in the galactose monomer subunits of galactooligosaccharides explains why they are resistant to hydrolysis by human digestive enzymes (α-glucosidase, maltase-isomaltase, and sucrase), which are mostly specific for α-osidic linkages. In normal physiological conditions, the inulin-type fructans and the galactooligosaccharides are resistant to acid hydrolysis in the stomach. The most convincing data have been obtained from human intervention studies with ileostomy volunteers. These studies show that 86–88% of the ingested dose (10–30 g) of inulin or oligofructose is recovered in the ileostomy effluent, supporting the claim that these carbohydrates are practically nondigestible in the small intestine of man. Using an intubation technique in human volunteers, it has been concluded that fructooligosaccharides are malabsorbed in the human small intestine (89% recovery). The small, but still significant, loss of fructooligosaccharides in the upper part of the gastrointestinal tract could be due to fermentation by the microbial population colonizing the ileum, especially in ileostomy patients, and/or to hydrolysis of the lowest-molecular-mass oligomers such as the enzymatically synthesized oligomers. In a recent review of the malabsorption characteristics of inulin-type fructans, the authors concluded that 'inulin and oligofructose pass through the small bowel without degradation and (furthermore) without influencing the absorption of nutrients and minerals especially calcium, magnesium and iron.'

There are fewer data on the resistance of other oligosaccharides to digestion in the human upper gastrointestinal tract than for the inulin-type fructans. The available evidence comes predominantly from *in vitro* experiments or is based on hydrogen production and exhalation as an indirect marker of colonic fermentation, or on stimulation of growth of specific fecal microorganisms in animal models. No *in vivo* human data are available. Thus, the nondigestibility of isomaltooligosaccharides, soybean

oligosaccharides, galactooligosaccharides, palatinose condensates, or xylooligosacchairdes *in vivo* remains to be demonstrated.

Fermentation in the Large Bowel: the Prebiotic Effect

The large bowel is by far the most heavily colonized segment of the human gastrointestinal tract, with up to 10^{12} (mostly anaerobic) bacteria per gram of gut content. These bacteria belong to a wide variety of genera, species, and strains. Through the process of fermentation, these colonic bacteria produce a wide variety of metabolites, among which the short-chain fatty acids represent salvage of part of the energy of malabsorbed food components, especially malabsorbed carbohydrates, and they play important systemic physiological roles.

Evidence for the fermentation of inulin-type fructans by bacteria colonizing the large bowel has come from *in vitro* and *in vivo* studies. At nutritional doses (up to 20–40 g per day), these malabsorbed carbohydrates are fermented quantitatively and are not excreted in the feces; the products of fermentation are gases and short-chain fatty acids, mainly acetate, butyrate, and propionate. Compared with most other malabsorbed carbohydrates (e.g., resistant starch and dietary fiber), the colonic fermentation of inulin-type fructans is accompanied by a significant change in the composition of the colonic microbiota due to selective proliferation of bifidobacteria and a concomitant reduction in the number of other bacteria, like bacteroides, fusobacteria, and pathogenic clostridia. On the basis of the results of well-designed human studies that have shown significant changes in the composition of human fecal flora, it can be concluded that inulin-type fructans (5–15 g per day for a few weeks) are prebiotic. But even though some studies showed a significant reduction in the number of pathogenic clostridia, the health benefits (e.g., reducing the risk of intestinal infections) of such a change in the composition of the colonic microbiota have yet to be established. A recent report has shown that oligofructose (daily dose of 6 g (3×2 g)) had no therapeutic value in patients with irritable bowel syndrome. But in an experimental model of necrotizing enterocolitis in quails, data have been reported that support the hypothesis that oligofructose might prevent overgrowth of the bacteria known to play a role in this pathology in preterm neonates.

For the other NDOs, studies *in vivo* have been performed with doses ranging from 3 to 15 g per day, given for periods of 1, 2, or 3 weeks. For soybean oligosaccharides, a dose of 10 g given twice daily for 3 weeks significantly increased the number of bifidobacteria, whilst slightly decreasing clostridia counts. A dose of 3 g per day increased bifidobacteria, bacteroides, and eubacteria. For the galactooligosaccharides, an increase in bifidobacteria and lactobacilli in response to doses ranging from 3 to 10 g per day has been reported. Similarly, a daily dose (5 or 10 g) of galactosylsucrose stimulated the growth of bifidobacteria after 1 and 2 weeks of ingestion. A dose of isomaltooligosaccharide of 13.5 g per day for 2 weeks significantly increased the number of bifidobacteria in adult and elderly volunteers. Early results suggest that platinose condensate may stimulate the growth of bifidobacteria. For all these NDOs, except the galactooligosaccharides, only a single human intervention study has been performed, and this will need to be repeated before any prebiotic effect can be substantiated. Moreover, as discussed above, great care should be taken to quantify the component species of the fecal microflora and to identify changes in its composition.

Physiological Effects in the Gastrointestinal Tract

The fermentation of prebiotics in the colon has a series of consequences that affect large-bowel physiology. Firstly, it contributes to the production of short-chain fatty acids, thus creating a more acidic environment, which is favorable for the development of bacteria like bifidobacteria or lactobacilli but unfavorable for the growth of potentially pathogenic species like *Clostridium* spp. or *Escherichia coli*. Furthermore, in this acidic environment, ammonia and amines become protonated and are thus much less absorbable and hence more readily excreted. Secondly, it leads to a proliferation of colonic bacteria, which increases fecal mass and thus contributes to a beneficial bulking effect and a regularization of stool production. As a consequence of these two large-bowel processes (i.e., production of acids and proliferation of bacteria), only part of the metabolizable energy of the NDOs is salvaged. As compared with absorbed carbohydrates (e.g., nonresistant starch or sucrose), NDOs represent, weight for weight, a lower energy value for the host. Caloric values of 1–2.1 kcal g^{-1} (4.1–8.8 kJ g^{-1}), i.e., 25–50% of the caloric value of sucrose, have been reported, especially for inulin-type fructans. But, as stated recently by a group of European experts, 'all carbohydrates that are more or less completely fermented in the human colon should be given a caloric value of 1.5 kcal g^{-1} (6.3 kJ g^{-1}).' In fact, the daily intake of these carbohydrates is likely to remain small, probably often not representing more than $\sim 5\%$ of total daily energy intake. Therefore, it is not justifiable to

spend a great deal of effort in trying to give, for such carbohydrates, a precise calorie value, the determination of which will depend on the protocol used and probably also on the diet in which they are included.

Another physiological consequence of the consumption of NDOs that has been reported recently for the inulin-type fructans is an increased bioavailability of Ca^{2+}. Such an effect has been studied extensively in rat and hamster. These studies have led to the conclusion that, most probably because of their malabsorption and colonic fermentation, these food ingredients facilitate Ca^{2+} absorption from the large bowel compartment, thus complementing the process that takes place in the small bowel. A change in colonic pH, production of short-chain fatty acids, and increase in mucosal concentration of the protein calbindin in the colon have been proposed as hypotheses to explain that effect. Besides increased Ca^{2+} bioavailability, it has been shown both in rat and in hamster that feeding fructooligosaccharides increases Ca^{2+} concentration and improves the structure and density of the bones. More recently, three human trials (two in adolescents and one in adults) have shown that supplementing the diet every day with 16.8 g of oligofructose, 8 g of a mixture of oligofructose and high-molecular-mass inulin, or 40 g of inulin significantly increases the apparent absorption of Ca^{2+} by 10–12%. One of these studies used measurement of Ca^{2+} balance, and two used a double stable isotope technique.

NDOs, because they are malabsorbed and fermented in the colon, may be considered to be part of the dietary fiber complex. In particular, it has been shown that inulin-type fructans have a fecal bulking effect that is comparable on a weight-for-weight basis with that of soluble fiber such as pectin. Moreover, an internationally validated method derived from the AOAC method for dietary fiber analysis has been developed to quantify inulin and oligofructose in plants and food products. For the purpose of food labeling, the NDOs are thus classified as dietary fiber in most countries. (*See* **Dietary Fiber**: Properties and Sources; Determination; Physiological Effects.)

Prebiotics and the Risk of Colon Cancer

Over the last two years, experimental reports have been published that repeatedly demonstrate that feeding inulin-type fructans to rats previously treated with a colon carcinogen (i.e., dimethylhydrazine or azoxymethane) reduces the incidence of the so-called aberrant crypt foci in the colon. In one of these studies, the synbiotic approach that combines oligofructose (prebiotic) and bifidobacteria (probiotic) was reported to be more active than either the prebiotic or the probiotic alone. Even though still experimental, these data suggest that inulin-type fructans might play a role in reducing the risk of developing preneoplastic lesions and possibly cancer in the colon. Moreover, such an effect might not be limited to the inulin-type fructans. Indeed nondigestible oligosaccharides may exert anti-carcinogenic effects first because they have been shown to beneficially affect certain biomarkers known to be associated with cancer risk (e.g. increase in apoptotis in colonic mucosa, reduction of bacterial β-glucuronidase and nitrate reductase, pH, and conversion of a dietary carcinogen to its genotoxic metabolite in caecal contents or feces of NDOs fed rats and human volunteers respectively), and second because they stimulate the growth of lactic acid bacteria for which evidence of anti-genotoxic and anti-carcinogenic effects have been reported. (*See* **Colon**: Cancer of the Colon.)

Conclusion: Prebiotics, what Benefit(s) for Human Health?

Prebiotics have nutritional properties that, according to the present state of knowledge, derive mainly from resistance to the hydrolytic activities in the upper part of the gastrointestinal tract of monogastric organisms followed by extensive fermentation in the large bowel, which leads to significant and possibly health-beneficial changes in the composition of the colonic microbiota. The gastrointestinal target functions that are associated with a balanced microflora together with an optimal gut-associated lymphoid tissue (GALT) are relevant to the state of well-being and health and to the reduction of the risk of diseases. The colonic microflora is a complex ecosystem, the functions of which are a consequence of the combined action of the microbes that, besides interacting with the GALT, contribute to salvage of nutrient energy and yield metabolic end products like the short-chain fatty acids (SCFAs) that play a role in cell differentiation, cell proliferation, and metabolic regulatory processes. It is generally assumed that the group of potentially health-promoting bacteria includes principally bifidobacteria, lactobacilli, eubacteria, and bacteroides, which are, and possibly should remain, the most important genera in humans. Changes in the composition of the fecal flora, a recognized surrogate marker for the residual colonic microbiota, can be considered as a marker, both indicator and factor, of large-bowel functions. They might play a role in gastrointestinal infections and diarrhea, constipation, irritable bowel syndrome, inflammatory bowel diseases, and colorectal cancer. Probiotics (e.g., lactobacilli or bifidobacteria), prebiotics (like chicory inulin and its hydrolysate oligofructose), and synbiotics (a

combination of probiotics and prebiotics) are recent concepts in nutrition that are being used to support the development of functional foods targeted towards gut functions. Their effects may include:

- stimulation of the activity of the GALT (e.g., increased IgA response, production of cytokines, etc.);
- reduction of the duration of episodes of rotavirus infection;
- change in the composition of the fecal flora to reach/maintain a composition in which bifidobacteria and/or lactobacilli become predominant in number, a situation that is considered optimal;
- increase in fecal mass (stool bulking) and stool frequency;
- increase in calcium bioavailability via colonic absorption (e.g., inulin).

By reference to the recently published European consensus on scientific concepts of functional foods, prebiotics, especially inulin-type fructans (but also synbiotics) are good candidates to be recognized as functional food ingredients for which claims shall become authorized. Such claims should relate to enhanced gastrointestinal functions (composition of colonic flora, bulking effect and bowel habit, Ca^{2+} bioavailability) or risk of developing a disease like colon cancer.

PREGNANCY

Contents

Metabolic Adaptations and Nutritional Requirements

D J Naismith, University of London, London, UK

Predicted Energy and Nutrient Costs

Women during pregnancy are generally believed to be nutritionally 'at risk.' There are obvious energy and nutrient costs arising not only from the growth of the fetus and placenta, but also from enlargement of the maternal reproductive tissues and the deposition of a substantial energy reserve in the form of fat. These have been determined by direct chemical analyses and by indirect measurements (**Table 1**) and have been used as the basis for predicting additional nutritional needs for a successful outcome in pregnancy.

Importance of Body Fat

The relationship between nutrition and reproduction, however, begins at an earlier stage. In late childhood, body fat accounts for about 12% of body weight in both boys and girls. With the onset of puberty, the proportion of body fat rises in girls to reach around

Table 1 Calculated energy and nutrient costs of pregnancy

Energy/nutrient	*Cost*
Energy (fat reserve, new tissue synthesis increase in basal metabolic rate)	335 MJ (80 000 kcal)
Protein (maternal reproductive tissues, conceptus)	910 g
Calcium (fetal skeleton)	28 g
Iron	300–400 mg

17% at menarche, and 24% in the physiologically mature woman some 12 months later. The attainment of this additional fat deposit, amounting on average to 226 MJ (54 000 kcal) of stored energy, is believed to be the major determinant of fertility in normal healthy women. Young women who, for professional reasons, must maintain a low proportion of body fat, such as track athletes and ballet dancers, are frequently infertile, and the cessation of menstruation is an early symptom of the wasting disease anorexia nervosa. Should conception occur, total body fat is calculated to be sufficient to meet the energy costs of pregnancy (excluding further deposition of fat during gestation) and to sustain a 3-month period of lactation. (*See* **Anorexia Nervosa**; **Fats**: Requirements; **Lactation**: Human Milk: Composition and Nutritional Value.)

Effects of Undernutrition

The validity of this argument was revealed in a study of the effects of acute severe malnutrition that occurred in the winter of 1944 and in the following spring in cities of the western regions of The Netherlands. Immediately before the famine, the nutritional status of the population had been generally satisfactory. Thereafter, however, the situation deteriorated rapidly, and food from all sources provided no more than 2.1–2.5 MJ (500–600 kcal) per day. The incidence of amenorrhea rose dramatically in the young female population. At the height of the famine, the number of infants conceived fell to 50% of the previous conception rate. Nevertheless, in the most vulnerable women, exposed to famine in the third trimester, the average birthweight declined to a maximum of about 300 g below the prefamine level. Since the body of a healthy newborn infant contains more than 500 g of fat, most if not all of the deficit in birthweight may have been attributable to an inability to accumulate fat, priority being given to lean tissue growth.

Acute severe malnutrition, however, occurs rarely among normally well-nourished populations, and might give a misleading picture of the interaction of undernutrition and reproductive performance. In most developing countries, chronic moderate malnutrition is commonplace, and nutritional surveys invariably report mean birthweights significantly below the average for Europe and North America. Although this has commonly been thought to reflect the poor nutritional status of the mothers, it has been impossible to isolate the putative influence of maternal diet on fetal growth from that of other environmental factors associated with endemic malnutrition, perhaps the most important being the smaller stature of the mothers. Even within an affluent society, an association between birthweight and maternal height and weight-for-height is found. (*See* **Malnutrition**: Malnutrition in Developed Countries.)

Nutrition Intervention and Pregnancy Outcome

A number of well-controlled nutrition intervention studies were carried out in developing countries in the early 1970s, no doubt with the aim of demonstrating the need for, and benefit to be derived from, diet supplementation during pregnancy. The subjects lived in countries in which protein–energy malnutrition was endemic. Energy intakes ranged from 5.86 to 7.53 MJ (1400–1800 kcal) per day. Given the small stature of the mothers, such a marginal plane of nutrition would just satisfy the needs of a nonpregnant woman. The dietary supplements provided energy alone or energy with protein, and were administered on a scale that often exceeded the estimated additional costs for energy and protein during pregnancy. The findings were as surprising as they were informative.

Only in one study, conducted in rural Guatemala, was a significant increase in mean birthweight achieved, amounting to 117 g. Although most women showed no improvement in reproductive performance, the response was very variable, those with the lowest customary energy intakes experiencing the greatest benefit, and the proportion of low-birthweight infants (< 2500 g) was consequently reduced.

It was evident from these studies that there exists an 'energy threshold,' around 6.7–7.1 MJ (1600–1700 kcal) per day, above which diet supplementation has no effect, but below which fetal growth may be stimulated, the improvement being directly related to the degree of energy deprivation. It was also revealed that the major determinant of fetal growth was the maternal energy supply; the inclusion of protein in the supplements had no effect independent of the energy it provided.

Dietary Habits in Well-nourished Populations

The results of the various intervention studies clearly indicate that if a woman is adequately nourished,

then pregnancy entails no appreciable additional energy (food) cost. It could be argued that the fetus is remarkably protected from the influence of maternal malnutrition, and that women exposed to generations of deprivation have simply adapted to a limited food supply. Small stature is often cited (incorrectly) as an example of adaptation. Studies of the dietary habits of women living in affluent circumstances, however, have shown that this is not so.

As long ago as 1953, analyses of the diets of 2300 well-nourished women in Nashville, USA failed to show any association between maternal food intake and birthweight. Furthermore, on average, no increase in food consumption during pregnancy was apparent (Figure 1). During the second trimester, an increase of around 251 kJ (60 kcal) per day was noted, but during the last trimester, when a marked acceleration in fetal growth occurs, energy intake fell by 753 kJ (180 kcal) per day. This surprising discovery, ignored for 30 years, has been amply confirmed by studies in the 1980s in Paris, Cambridge, and Glasgow.

How, then, is the obvious requirement for increased nutrition during pregnancy (Table 1) to be reconciled with the mother's failure, even under the most favourable environmental circumstances, to increase food intake? Only a small fraction of the fat stored in the first two trimesters of pregnancy is mobilized before term, and there exists no *ad-hoc* store of minerals and water-soluble vitamins. The answer to this question is to be found in the complex mechanisms whereby nutrients are transported from the maternal circulation to the fetus, and in the adjustments that occur in the maternal physiology in response to the gravid state.

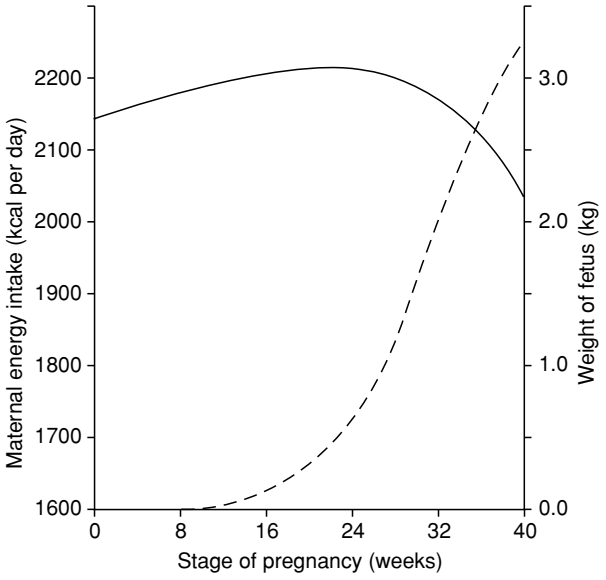

Figure 1 Diagram showing changes in maternal energy intake (—) and weight of the fetus (– – –) at different stages of pregnancy. Reproduced from Pregnancy: Metabolic Adaptations and Nutritional Requirements, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Role of the Placenta

The role of the placenta is discussed in **Pregnancy**: Role of Placenta in Nutrient Transfer. It is primarily an organ for nutrition of the fetus, but functions also as an endocrine gland throughout the greater part of gestation, regulating nutrient utilization by the mother.

Glucose provides the energy for fetal growth, the fetus being unable to oxidize fatty acids. Transfer of glucose across the placenta is by 'facilitated diffusion,' and is therefore influenced by the maternal blood glucose concentration. A prolonged low blood glucose concentration, as may occur in mothers in the developing world engaged in hard physical work, or an abnormally high concentration associated with gestational diabetes can therefore lead to growth retardation, or to excessive growth and fat deposition (macrosomia). From early pregnancy, the fasting blood glucose concentration is reduced, a change that may favor transfer to the fetus since the placenta is particularly effective at extracting nutrients from low concentrations in the blood. Glucose tolerance following a glucose load is also progressively relaxed so that the glucose concentration remains elevated for a longer period, again facilitating placental uptake. Whether or not the metabolic response to carbohydrate consumed as part of a meal is similarly affected is unclear. (*See* **Glucose**: Maintenance of Blood Glucose Level; Glucose Tolerance and the Glycemic (Glycaemic) Index.)

Fat-soluble vitamins also cross the placenta by diffusion, maternal blood levels being maintained by dietary input and mobilization of tissue stores. In contrast, amino acids, minerals, and the water-soluble vitamins are actively transported, the concentrations in the fetal circulation being much higher than in the maternal circulation. Furthermore, there is evidence that some vitamins are chemically altered by the placenta to a form that is unable to diffuse back into the maternal bloodstream, so reinforcing the one-way transport mechanism. Thus, the fetus has prior claim on the nutrient supply, much of which is maintained, by homeostatic regulation, within narrow concentration limits in the maternal plasma. In adverse nutritional circumstances, it is the mother, not the fetus, who is 'at risk.' (*See* **Amino**

Acids: Metabolism; **Minerals – Dietary Importance**; **Vitamins**: Overview.)

Metabolic Adjustments in Pregnancy

Under normal circumstances, the integrity of the tissues is assured by homeostatic regulation of the absorption, excretion and catabolism of the nutrients. During reproduction, these control mechanisms are adjusted, under the influence of hormones secreted by the placenta, in order to make available an additional nutrient supply for growth of the conceptus.

Absorption of the Nutrients

The macronutrients, fat, carbohydrate, and protein, are almost completely digested and absorbed in the small intestine, so that no appreciable change occurs in pregnancy. The absorption of minerals, however, is carefully regulated. Most Western diets provide a considerable excess of calcium, and no more than around 30% is normally absorbed. From early in pregnancy, the blood concentration of the physiologically active form of vitamin D (1,25-dihydroxycholecalciferol) is elevated, leading to an increased uptake of calcium from the gut, thus allowing the mother to satisfy the needs of her developing fetus without recourse to her own skeletal calcium or the need to increase her dietary intake. Only when her customary calcium intake or the biosynthesis of vitamin D is severely restricted is calcification of the fetal skeleton compromised. (*See* **Calcium**: Physiology; **Cholecalciferol**: Physiology.)

As with calcium, the proportional absorption of iron from a diet providing 12–14 mg per day is very small (about 10%), but as gestation advances, iron uptake increases progressively and may exceed 40%. This adjustment in absorption, in association with a reduction in iron loss resulting from the cessation of menstruation, is sufficient to satisfy the iron cost of pregnancy. Judged by normal standards, the characteristic fall in hemoglobin concentration that is noted in pregnancy would indicate a state of anemia. Blood volume, however, is considerably increased so that the total amount of hemoglobin in circulation, and consequently the oxygen-carrying capacity of the blood, is actually raised. Supplementation of the diet of women who begin pregnancy in an iron-sufficient state may therefore be injurious as it has been shown to increase red cell size and could adversely affect blood flow in the small capillaries. (*See* **Iron**: Physiology.)

Other minerals, such as copper and zinc, may also show improved absorption. (*See* **Copper**: Physiology; **Zinc**: Physiology.)

Urinary Excretion of Nutrients

The glomerular filtration rate is increased during pregnancy. It is suggested that the presence of traces of glucose in the urine at some stages of pregnancy in most women merely indicates that more glucose has been filtered from the plasma than can be reabsorbed by the kidney tubules at that time. Some women, however, may lose large amounts of glucose in their urine, particularly those who develop gestational diabetes.

The urinary excretion of most nutrients is altered, but whether or not this reflects specific modifications in kidney function is unclear since the picture is obscured by withdrawal of nutrients from circulation by the placenta, which changes with time. The pattern of excretion of amino acids is most consistent. In nonpregnant women, about 1% of total nitrogen excretion is accounted for by free amino acids, but urinary loss rises in early pregnancy, reaching a plateau in midpregnancy at a level approximately double that found in the nongravid state. Most of the increase is accounted for by the nonessential amino acids, possibly reflecting selective uptake by the placenta. Since the plasma amino acid concentrations show little change, the large increase in urinary excretion cannot be attributed to kidney overload and is most likely the result of altered hormonal status affecting kidney function. The return to normal levels of excretion during lactation supports this conclusion.

One example of altered kidney function that favors conservation has clearly been identified. The amino acid taurine, a derivative of the nonessential amino acid cystine, shows a dramatic and sustained reduction in excretion from early pregnancy. It has been suggested that taurine may act as a membrane stabilizer, as an inhibitory neurotransmitter or neuromodulator, and as a growth modulator in fetal tissues. Tissue concentrations are particularly high in the fetus, and the suppression of urinary excretion of taurine during pregnancy is seen as a means of satisfying the needs of the developing fetus, which lacks the ability to synthesize taurine *de novo*.

Metabolism of Protein

The rate of accretion of nitrogen by the fetus and maternal reproductive tissues is known to rise 10-fold between the first and last quarters of gestation. Since, on average, no appreciable change in food intake, and thus protein intake, occurs in pregnancy, one would expect to find a positive nitrogen balance, rising continuously throughout pregnancy. In the few nitrogen-balance studies carried out on pregnant women, however, no differences have been found between the values for nitrogen retention measured

at different stages of gestation. This apparent paradox was resolved by the study of reproduction in the rat. (*See* **Protein**: Digestion and Absorption of Protein and Nitrogen Balance.)

During the first 2 weeks of pregnancy, when competition between the dam and her fetuses for nutrients is minimal, a substantial reserve of protein is built up in the muscles (the 'anabolic phase'). During the final week, the period of rapid fetal growth, the protein reserve is broken down, the amino acids released being taken up by the placenta for growth of the conceptus. This 'catabolic phase' is not influenced by the protein content of the maternal diet, and is controlled by the hormone progesterone. (*See* **Hormones**: Steroid Hormones.)

Evidence for a similar biphasic system of protein metabolism in women was provided by measurement of the excretion of the amino acid 3-methylhistidine. This amino acid is found predominantly in muscle. Histidine undergoes methylation after its incorporation into the peptide chains of the contractile proteins actin and myosin, and, in the course of muscle protein turnover, the 3-methylhistidine released is not reutilized, but is quantitatively excreted in the urine. In pregnancy, the excretion of 3-methylhistidine rises sharply during the last trimester, indicating the hydrolysis of an amount of protein approximating the estimated protein cost of pregnancy.

Such a redistribution of amino acids from maternal to fetal tissues would not be detected in measurements of nitrogen balance.

This cyclic course of protein metabolism has important nutritional implications. The protein cost of pregnancy is distributed over the whole gestational period, and the influence of acute or chronic maternal undernutrition on fetal growth is minimized.

Nitrogen retention occurs when the intake of protein-nitrogen exceeds nitrogen losses from the body, largely the products of amino acid catabolism in the urine (mostly urea) and undigested dietary protein in the feces along with cells shed from the gut epithelium. If, during pregnancy, the catabolism of amino acids were in part suppressed, the fraction spared could be used for fetal protein synthesis. In the case of a woman existing on 40 g of protein per day, as in many developing world populations, a reduction of less than 9% in amino acid oxidation would spare enough protein to cover the entire estimated requirement for pregnancy.

The hypothesis was tested in the rat. The activities of two rate-limiting enzymes (alanine aminotransferase and argininosuccinatesynthetase), which regulate the oxidation of amino acids and the conversion of amino-nitrogen to urea, were measured in the livers at different stages of gestation. The activities of both enzymes were markedly depressed by the end of the first week, and declined even further (by around 50%) as pregnancy advanced. A parallel change in plasma urea was also noted.

Evidence for a similar adjustment in amino acid catabolism in pregnant women was later obtained in a metabolic study using urea labeled with a stable isotope of nitrogen. Measurements made in the last trimester and in the postpartum postlactational period showed a reduction of 30% in the rate of urea synthesis in late pregnancy and a similar fall in the plasma urea concentration.

The mechanism for protein sparing, which operates progressively throughout pregnancy, combined with the biphasic system of early storage and later breakdown of stored protein, ensures a supply of amino acids commensurate with the demands of the growing fetus. The suppression of hepatic amino acid oxidation was also shown to be induced by the placental hormone progesterone. The fetoplacental unit thus indirectly controls its supply of amino acids as well as its energy needs.

Metabolism of Energy

As stated earlier, the dietary energy supply is the major determinant of fetal growth. In healthy pregnant women, energy balance becomes positive during the first trimester, probably in response to the rising secretion of progesterone. The purpose of the augmented fat reserve, amounting, on average, to some 4 kg of fat, is primarily to subsidize the high energy cost of lactation, but a small amount is mobilized in late pregnancy to provide an alternative fuel for use by the maternal tissues and enhance the availability of glucose for use by the fetoplacental unit. The human fetus derives its energy almost exclusively from the oxidation of glucose. (*See* **Energy**: Energy Expenditure and Energy Balance.)

The discrepancy between the measured energy intakes of healthy pregnant women and the values predicted for energy expenditure has yet to be explained. There is no doubt that some saving is made in energy expenditure from a reduced level of physical activity, but this is difficult to quantify.

The alterations in carbohydrate metabolism that are characteristic of pregnancy could also lead to the sparing of energy. In pregnancy, there is an increased output of insulin in response to a glucose stimulus, and reduced glucose uptake by the peripheral tissues (muscle and adipose tissue). Insulin antagonism has been attributed to the action of placental lactogen. Consequently, more of the ingested carbohydrate is directed to the liver, the organ that maintains the blood glucose concentration. The conversion of

carbohydrate to fat is a very costly process. Approximately 20% of the energy that is available from the direct oxidation of glucose is lost as heat if the glucose is first converted to fat, and the fat is later oxidized to produce energy. This adjustment in carbohydrate utilization, therefore, not only conserves energy for anabolic purposes, but also safeguards the fetal energy supply. (*See* **Carbohydrates**: Digestion, Absorption, and Metabolism.)

Dietary Recommendations for Pregnancy

Growth of the fetus is little affected by transient or prolonged moderate undernutrition of the mother. Relatively small deficits in birthweight may be accounted for by a lower proportion of body fat resulting from maternal dietary energy restriction in late pregnancy, from the diversion of glucose (the fetal fuel) to the muscles should the mother be engaged in hard physical work throughout pregnancy, or from malfunction of the placenta.

The security of the fetus is provided by the placenta, an organ designed not only to ensure a priority claim on all nutrients present in the maternal circulation, but also, by the secretion of hormones, to modulate the homeostatic regulation of nutrient utilization at all levels – absorption, excretion, and catabolism, in order to augment the nutrient supplies. No government committee responsible for devising dietary guidelines would be so incautious as to suggest that women during pregnancy require no more food than when in the nongravid state, although all evidence points very clearly to that conclusion. One obvious *a priori* condition would be that nutritional status should be satisfactory before conception and throughout pregnancy.

Attention has been focused on the latter half of pregnancy, when fetal growth is most rapid, the need for nutritional input is at its greatest, and the effects of maternal food deprivation most apparent. These considerations led a Joint FAO/WHO (Food and Agriculture Organization, World Health Organization) Ad Hoc Expert Committee in 1973 to propose an additional 628 kJ (150 kcal) per day for the first trimester, rising to 1464 kJ (350 kcal) per day for the second and third trimesters, the stage of pregnancy when women, unencumbered by professional advice, would spontaneously reduce their food consumption. In the light of continuing research, however, estimates of energy and nutrient requirements are being revised in a downward direction. In 1974, the US report on Recommended Daily Allowances proposed an additional daily supplement of 30 g of protein, 400 mg of calcium and 30–60 mg of iron for the pregnant woman, acknowledging that such a high intake of iron could not be met by the iron content of habitual US diets. The implication was that pregnancy was a clinical condition that required therapeutic intervention. One decade later, the proposed increments in energy and calcium were little changed, but the supplement of iron was reduced to 15 mg, and the protein allowance was changed to anticipate the pattern of accretion by the fetus, rising from 1.2 g per day in the first trimester to 10.7 g in the final trimester of pregnancy. (*See* **Dietary Requirements of Adults**.)

The UK dietary recommendations for pregnancy have consistently been on a less generous scale. Over a similar period, the daily allowance for energy has fallen from 1004 kJ (240 kcal) in the second and third trimesters to 837 kJ (200 kcal) during the third trimester only. Protein is unchanged at 6 g per day throughout pregnancy, but the recommendation for calcium has fallen from 700 mg per day in the third trimester to zero. Likewise, no recommendation was made for an increase in iron intake in the 1991 report on Dietary Reference Values, compared with the small increase of 1 mg per day in the earlier 1979 edition.

There is no doubt that as scientific opinion changes, other values will also be reduced, and nutritional guidelines for pregnancy ultimately will correspond to the dietary practices of healthy women satisfying their natural appetites on a well-balanced diet.

Role of Placenta in Nutrient Transfer

Y Kudo[†] **and C A R Boyd**, University of Oxford, Oxford, UK

Introduction

During intrauterine life, the developing fetus effectively receives all of its nutrition across the placenta, which, in the human, has a chorionic villus structure in which maternal blood directly superfuses the external surface, the trophoblast of the placenta. This trophoblast forms an unusual epithelium separating the maternal plasma from the fetal extracellular space of the villus core through which the fetal capillary circulation flows. For the fetus, the trophoblast is thus equivalent to the epithelium lining the small intestine of the newborn, since, from a nutritional perspective, it must absorb those molecules required for both growth and maintenance of the organism. The trophoblast also has an important role in acting as the lung for the fetus (since all gas exchange between mother and baby must occur across this surface), as the fetus's kidney (since excretion from the conceptus to the mother occurs across this structure), as well as being an important endocrine tissue secreting peptide and steroid hormones into the mother. The placenta itself also plays a very substantial role in intermediary metabolism, so that it cannot be assumed that there is no metabolism of absorbed nutrients during solute movement from mother to fetus.

As an epithelium, the trophoblast has two surfaces, the one facing the mother and the other facing the fetus. These surfaces differ structurally; for example, microvilli are found projecting into the maternal bloodstream at the apical surface, where they form a brush border, whereas the basal surface facing the fetus does not have this surface specialization. From the functional point of view, it is the differences in the distribution of transport membrane proteins (channels, carriers, and pumps) that determine the overall transport of nutrients from mother to baby, at least as far as water-soluble molecules are concerned. In the placenta, all transport appears to be across the trophoblast since, uniquely, the cells that compose this structure are fused to form a syncytium; this is in contrast to other epithelia where transport between adjacent epithelial cells allows a functional paracellular route to lie in parallel to the route through the epithelial cells themselves (the transcellular route). The question in the human as to whether there is a special route available for the transport of large molecules (MW 5000) is not yet resolved: certainly, at term, the human placenta does appear to be able to permit the transport of larger molecules at a slow rate from baby to mother. This route is unlikely to be of nutritional significance, since the rate of transport is low, but it may be important with regard, for example, to immunological sensitization.

The placenta, together with the growing fetus, has a very substantial metabolic energy requirement, and in the human, ATP synthesis appears to be met by the very substantial rate of glucose delivery from the mother. The glucose transporter systems that are found in both the apical and basal surfaces of the human trophoblast appear to be the type named GLUT1; in other words, they are sodium-independent facilitated transporters that are not regulated by insulin. The Michaelis constant (K_m) for glucose transport at both surfaces is relatively high (approximately 30 mM), and the maximal transport rate (V_{max}) is very substantial. The result of this is that glucose delivery across the brush-border membrane of the placenta will be in a direction and rate that are dependent solely on the chemical driving force from mother to baby (maternal–fetal plasma glucose concentration). It seems likely that this fundamental property is the basis for the macrosomia ('large-for-dates') found in the babies of mothers with elevated plasma glucose concentration, as typically found in diabetes mellitus. Transport of glucose, which is stereospecific, may be inhibited by glucose analogs that share the chemical structure of D-glucose at carbon 1; for example, both 3-0-methylglucose and 2-deoxyglucose are transported, whereas α-methylglucoside (with a methyl group on carbon 1) is not. The transport of other monosaccharides has been studied rather little; in the human, fructose is transported much more slowly than glucose itself (in contrast to other nonprimate species). The question of regulation of carbohydrate delivery across the placenta is not fully resolved since some glucose transporters may be regulated by phosphorylation, and the gradient for transplacental glucose delivery will also depend upon factors regulating glucose utilization and production by the placenta itself; little is known of the physiological regulation of either of these processes. (*See* **Carbohydrates**: Digestion, Absorption, and Metabolism; **Glucose**: Maintenance of Blood Glucose Level.)

In contrast to glucose transport, amino acid transport can be powered. The overall gradient of amino acid between maternal plasma and fetal plasma varies

[†]Deceased.

for individual amino acids. Typically, individual amino acid concentrations are twice as high in fetal as in maternal plasma. Current understanding of the mechanisms responsible for this relates to the distribution of the membrane transport proteins between the two faces of the trophoblast and in particular to the distribution of sodium-coupled transporters that are found predominantly (although not exclusively) in the brush border. Recent work using isolated membranes that reseal to form artificial structures (vesicles) has been useful in establishing the numbers and properties of such transporters. In addition to the direct effect of sodium ions in moving amino acids into the trophoblast across the brush-border membrane against a concentration gradient, these transporters are often electrogenic and are thus also driven physiologically by the membrane potential. One example of such a process is the transport system called 'A,' which uses alanine, serine, and proline as transported substrates and accumulates these amino acids in the trophoblast against a concentration gradient. These amino acids then leave the trophoblast across the basal membrane by a different transport system. Other amino acids may be transported via tertiary active transport; for example, leucine is found in higher concentrations in fetal plasma than in maternal plasma, but it is not itself a substrate for sodium-coupled transport; rather, it appears to exchange with amino acids, such as alanine, that have been accumulated in the trophoblast as just described.

The cationic and anionic amino acids are unusual in that, having their own charge, they will be accelerated or retarded by the membrane potential in crossing each of the plasma membrane surfaces of the trophoblast. For cationic amino acids (lysine, arginine, histidine), entry into the placenta appears to be largely by system y^+ (Na^+-independent), whereas exit into the fetus involves an electroneutral system (y^+L), which exchanges the cationic amino acid for a neutral amino acid (e.g., leucine) and a sodium ion, thus effectively solving the problem of permitting positively charged amino acids to exit against an inside-negative membrane potential. For anionic amino acids (glutamate and aspartate), very high intratrophoblast concentrations are achieved by a transport system that is coupled to K^+ efflux as well as Na^+ entry. Essential amino acid requirements for the fetus are different from those of adults. However, it is not clear whether transport of specific amino acids across the placenta ever becomes rate-limiting for fetal growth. In the human, intrauterine growth retardation not associated with other disease has been shown to be associated with reduced placental delivery of amino acids through specific systems, e.g., associated with decreased function of system A. IGF (insulin-like growth factor) and IGFBP (insulin-like growth factor binding protein) are now recognized as having an important role in either normal or abnormal fetal growth via controlling placental amino acids and glucose transport (e.g., IGF-I (insulin-like growth factor-1) selectively enhances system A activity). In certain unusual metabolic disorders (e.g., maternal phenylketonuria (PKU)) maternal levels of one particular amino acid may be elevated; this results in competition between this amino acid and others that share the same transporters. Some of the abnormalities found in the developing babies of such mothers may be a consequence of nutritional deprivation of tyrosine, for example, owing to competition by raised maternal phenylalanine levels for the delivery of this amino acid across the placenta. The fact that amino acid transport across the placenta involves a family of transport proteins with overlapping substrate (amino acid) specificities means that the nutritional consequences for the fetus of changing the level of one amino acid in the mother will be complex. This follows because, in contrast to placental glucose transporters, the K_m and V_{max} of the amino acid transporters are relatively low.

Lipid transport across the placenta in relation to human nutrition has been studied less rigorously, in part because it is likely to be perfusion- rather than membrane-limited, since the lipid-soluble nature of such a substrate allows ready transmembrane transport. Nutritionally, the nervous system of the developing fetus requires substrate delivery of precursors for myelin synthesis. Studies suggest that placental binding proteins may provide a pool of essential fatty acids for fetal utilization. (*See* **Amino Acids**: Metabolism; **Fatty Acids**: Metabolism.)

Transport of the inorganic cations of sodium and potassium involves both channels and transporters. Sodium transport into the trophoblast is coupled to the entry of those solutes (which include both organic and inorganic molecules) powered by secondary active transport. The extrusion of sodium across the basal surface of the trophoblast is likely to be a result of sodium pumping by Na^+/K^+ ATPase activity. In contrast, potassium, accumulated in the trophoblast, as in other epithelia by the sodium pump, requires channel-mediated release to account for its movements between mother and baby. Potassium channels have recently been shown to be sensitive to modulation in this tissue (e.g., by G proteins, by arachidonic acid, and by pH). These regulatory factors may themselves be controlled by circulating factors in both mother and fetus. It is clear that fetal plasma potassium is carefully regulated by control of placental transport of this cation.

The divalent cation of calcium is found in higher concentrations in fetal than in maternal plasma. Active transport processes are therefore involved in placental calcium metabolism, and these are unusual in that regulation of transport is clearly precisely controlled. It seems likely that calcium extrusion across the basal surface of the trophoblast is ATP-driven and regulated by calmodulin. Entry of calcium across the brush border is now known to be via ECaC (epithelial calcium channels) that are regulated: membrane potential hyperpolarization activates, and intracellular calcium inhibits, these channels. Fetal parathyroid hormone and vitamin D are likely to regulate all of these events.

Iron is also transported from mother to fetus in a regulated fashion, and again, there is a greater concentration of iron in the fetal circulation. In some species, transport of iron has been shown to be active in that it is inhibited by anoxia. The role of the transferrin receptor found in the human placental microvillus membrane is now known to be related to the mechanisms of iron entry into the cytosol. From this compartment, iron has to leave, but the mechanisms responsible for this are not fully understood. (*See* **Calcium**: Physiology; **Hormones**: Thyroid Hormones; **Iron**: Physiology; **Potassium**: Physiology; **Sodium**: Physiology.)

Anion entry into the placenta has been studied using isolated membrane preparations. These studies show that for monovalent ions (chloride and other halides), two routes are available, an exchange and a conductive route, the latter likely to be via channels. The anion exchange system appears to be functionally linked to the transport of organic anions (bicarbonate, lactate) from placenta into the maternal circulation. Phosphate transport is also regulated and appears to involve a sodium-dependent cotransporter at the maternal-facing surface and an efflux mechanism (possibly driven by the membrane potential) at the basal surface of the tissue. As for calcium transport, phosphate delivery is regulated by parathyroid hormone concentration in the fetus.

Trace-element delivery across the placenta also involves specific placental binding proteins analogous to those found in adult liver; however, membrane transport is also required to allow such ions to gain access to and from the trophoblast. The nature of such transporters varies greatly, although the role of the divalent cation transporter (DCT-1) in the placenta may be more generally important. For zinc, there is evidence that the histidine amino acid transporter is responsible for delivery of a histidine–zinc complex, whereas for transition-metal oxides, it appears that anion exchange is important. The transport of iodide across the human placenta is also likely to be by anion exchange since SCN can inhibit it, but the mechanisms responsible for the concentration of this element in the fetal compartment are not clear. Selenate appears to share a pathway with sulfate for entry across the brush border, and the transport of both of these ions is inhibited by blockers of anion exchange. This pathway appears to be shared with those available for transport of the trace elements chromium and molybdenum as chromate and molybdate. (*See* **Trace Elements**.)

Vitamin transport also is highly specific for individual substrates; thus, for ascorbic acid, a sodium-independent transporter for the reduced from of this nutrient has been described in the brush-border membrane; this transporter appears to be functionally coupled to a placental system that maintains ascorbate in this chemical form. The Na^+-dependent multivitamin transporter that transports pantothenate, biotin, and lipoate is expressed in human placenta.

Safe Diet

R B Fraser and F A Ford, University of Sheffield, Sheffield, UK

Introduction

Would-be pregnant and pregnant women have heightened concerns about their diet, which can be summarized by the common question, 'Will it harm my baby?' Because the question is so common, many sources of advice are available in the lay press, not all as scrupulously researched and scientifically based as they might be. Another source of potentially misleading advice is the food industry and written media, the agents of which possess a lack of objectivity that may not be obvious to the casual reader. Articles proliferate with titles such as 'How to have a beautiful baby' and 'How to have a perfect baby'. These tend to contain a mixture of dietary and lifestyle advice with the implication that, if followed, the undesirable outcomes of pregnancy such as miscarriage, congenital malformation, and fetal death are avoidable. Professionals in the field of nutrition must be aware of this for the following reason. If a woman learns of such advice only after her pregnancy has failed in some way there is a potential for a lifelong burden of guilt. For this reason purveyors of advice should restrict themselves to that which has been demonstrated in scientifically valid experiments. In particular, they should be guarded in their extrapolations from observational studies and animal experiments.

This article highlights the principal areas in which women have dietary concerns. Some of these are dealt with in more detail elsewhere and are cross-referenced.

Periconceptional Nutrition

In an ideal world, pregnancies would be planned but in the real world a high proportion are not. It is important to remember that many women who have not planned their pregnancies and have not subsequently followed the advice outlined below may need reassuring that they have probably not caused harm to their baby.

The work of Frisch in the USA identified the link between body composition and ovulation in the human female. She suggested that fat must comprise at least 22% of body weight for the maintenance of ovulatory cycles and also observed that in normal postpuberty women fat is about 28% of body weight. It is well recognized that the relationship is to the fat content of the body rather than absolute body weight, as trained athletes of average or above-average body weight may have very low body fat content and may be oligo- or amenorrheic. Frisch observed that amongst trained athletes who became fit after a normal menarche, 60% continued regular cycles, but 40% had irregular cycles and presumably associated subfertility. Other causes of secondary amenorrhea leading to infertility include psychological stress, thyrotoxicosis, and the various malabsorption syndromes. Eating disorders such as anorexia nervosa and bulimia nervosa which may have been underdiagnosed in the past are now been seen as contributing to the problem. Particularly for bulimics, a remission in the disorder may allow the body fat to build up to a stage where ovulation and conception can take place, but the disorder may relapse during the pregnancy, leading to serious nutritional deficiencies for the mother and possibly for the fetus.

The Nurses Health Study in the USA has also produced some interesting information about the relative risk of menstrual cycle irregularity, not only in underweight but also in overweight women. For women with a body mass index (BMI) below 20, at the age of 18 years, ovulatory infertility was found with a relative risk of about 1.2 compared to women with a BMI between 20 and 25. Interestingly, however, the relative risk of ovulatory infertility was 1.5 in those with a BMI of 28 and more than 2 in the obese group with a BMI above 30. About half of the risk is associated with polycystic ovarian syndrome (PCOS) in which ovulatory infertility and obesity coexist but there is still a doubling in relative risk of ovulatory infertility in women with a BMI above 30 who do not have ultrasonically detectable polycystic ovaries.

Vitamin Intakes and Congenital Malformations

Folic Acid

In 1991, the Medical Research Council (MRC) vitamin trial reported that a significant reduction in the recurrence of neural tube defects (NTD) had been obtained by a daily dietary supplement of 4 mg of folic acid in women who were at high risk. Women at risk of a recurrence of NTD should be advised to take a folic acid supplement of 5 mg (5000 μg) per day when planning a pregnancy and continue with it until 12 weeks' gestation. A later study reported that first occurrence of NTD could also be prevented by daily supplements containing 800 μg of folic acid. In the UK, in line with many other nations, women are advised to take a prepregnancy supplement of 0.4 mg (400 μg) of folic acid as a daily medicinal supplement from when they begin trying to conceive

until 12 weeks' gestation, in addition to eating a folate-rich diet and breads and breakfast cereals fortified with folic acid.

The mechanism for the effect of folic acid in reducing the risk of NTD is not clear. The most likely explanation is that it overcomes genetically determined defects in folate metabolism that interfere with normal neural tube development. One other hypothesis is that it might decrease the likelihood of an affected pregnancy surviving, and there is some concern that folic acid supplementation could be associated with a higher risk of fetal death. However, the generally accepted explanation for this is that folic acid might initially permit the survival of affected or nonviable pregnancies to a point where they are recognized as spontaneous abortions.

Educational campaigns conducted since 1995 have had a substantial effect in increasing the number of women in the UK who are aware of the link between folic acid and NTD. However, such education can only have a limited effect because it is estimated that only 50% of all pregnancies are planned. NTD arise very early in gestation and by the time a woman realizes that she is pregnant it is usually too late to prevent an NTD by taking supplements. For this reason it has been suggested that the most effective way of reducing NTD in the UK would be to fortify the food supply with folic acid so that even women with unplanned pregnancies would be less likely than at present to have offspring with NTD. The Department of Health Committee on Medical Aspects of Food and Nutrition Policy (COMA) has recently recommended universal fortification of flour at 240 μg $100\,g^{-1}$, which would reduce the risk of NTD by 41% without resulting in unacceptably high intakes in any group of the population.

Retinol

It has been known for a long time from animal studies that high levels of vitamin A in the form of retinol are teratogenic in the periconceptional period. This led to the Department of Health in 1990 advising women to avoid food sources containing high levels of the retinal form of vitamin A in the periconceptional period and indeed during pregnancy. The Department of Health advises that very high intakes of retinol, i.e., more than 10 times the recommended dietary allowance either in liver/liver products or vitamin/fish liver oil supplements, can damage the developing embryo. This advice remains current and all women of child-bearing age should avoid liver and its products and should not take supplements containing more than four times the recommended daily amount of retinol.

The same risks do not seem to be present for vitamin A derived from β-carotene. Manufacturers of multivitamin supplements recommended for pregnancy have generally recognized this and switched the source of vitamin A to β-carotene.

Nutritional Management of Common Symptoms in Pregnancy

Heartburn

Heartburn is thought to be caused by gastroesophageal reflux. Although occasionally experienced in the first trimester, it is generally more common in the last trimester and occurs in 30–50% of women.

Small, frequent meals or snacks are usually tolerated better than large, well-spaced meals. Common foods cited as causing heartburn as spicy and fatty foods, fizzy drinks, citrus fruits, fruit juices, and cucumber. Milk and milk products can help to relieve symptoms but antacids are frequently used.

Nausea and Vomiting

Psychological factors, changing hormone levels, hunger, altered carbohydrate metabolism, and vitamin deficiencies have all been proposed as possible causes for nausea and vomiting, but none has been confirmed.

Symptoms may start before the woman knows she is pregnant or in later pregnancy but commonly they are worst between weeks 6 and 10, and subside by about 13 weeks. Nausea is experienced at any time of day or night and can be either slight or severe. It often becomes worse when the stomach is empty, and eating small, frequent meals based on starchy carbohydrates may relieve it. Morning sickness is common and consuming dry biscuits or toast before getting up can relieve this.

Nausea can also be triggered by traveling, fried and spicy foods, and smells such as coffee, perfume, and cigarette smoke.

Some women just feel nauseated while others actually vomit as well; this may cause minor weight loss but rarely causes nutrient deficiency. Women need reassurance that not eating proper cooked meals or losing some weight and their taste alterations will cause no problems for their developing fetus. The more severe cases of pregnancy vomiting (hyperemesis gravidarum) require hospital admission, intravenous fluids and, sometimes, parenteral nutrition.

Constipation

Constipation is common at all stages of pregnancy. It may be related to a general reduction in motility in the gastrointestinal tract, with prolonged transit

times and increased water resorption from the stool. General advice about constipation is also suitable for pregnancy, i.e., increased intake of fiber, particularly cereal fiber, and increased fluid intake.

Constipation may be aggravated by the consumption of iron tablets; if it is not appropriate to reduce or stop them, bulking agents may be prescribed.

Qualitative Aspects of Diet

The following section refers to common questions of dietary safety; some arise because of suspicion of harm when items are included in the diet, others for the paradoxical reason that their omission from the diet might be dangerous.

Alcohol

As far as alcohol is concerned, the picture is confusing. There is no doubt that a heavy intake of alcohol can damage the unborn baby and cause miscarriage. Many women choose to give up alcohol and this seems to be a sensible practice but there is no evidence of harm from occasional drinking or the consumption of less than 2 units per day (Table 1). Despite this, many women do give up alcohol when trying to conceive or whilst pregnant, and this seems a sensible but not mandatory practice. (One unit is 15 g of absolute alcohol, e.g., 0.28 l of beer, one glass of wine, or one measure of spirits.)

A well-defined group of anomalies referred to as the fetal alcohol syndrome is now recognized. The major defects of affected infants are weight and length below the 10th centile for gestational age, and microcephaly. Microcephaly is a condition of small head size associated with an underdeveloped brain. Such children are likely to be mentally retarded and their physical growth is stunted. The syndrome has been reported in up to 40% of the infants of women drinking more than 6 units of alcohol per day.

Definite harm has been recorded to the offspring of women drinking between two and six units of alcohol per day and long-term growth retardation and mental retardation to offspring of those drinking more than 6 units a day (fetal alcohol syndrome).

Table 1 Congenital malformation rates and maternal alcohol consumption

Drinks per day	*Malformation rates (per 1000)*[a]
None	78
Less than one	77
One to two	83

[a]No statistically significant difference.

From Mills JL and Graubard BI (1987) Is moderate drinking during pregnancy associated with an increased risk for malformations? *Pediatrics* 80: 309–314.

A recent study showed that a woman's alcohol intake is associated with decreased fertility, even among women with a weekly alcohol intake corresponding to five or fewer drinks. This finding needs further corroboration, but it seems reasonable for the moment to encourage women to avoid alcohol if they are having trouble conceiving.

Caffeine

Concern about the detrimental effects of caffeine during pregnancy is not new but to some extent the literature is conflicting. Caffeine is present in tea, coffee, cola drinks, and many over-the-counter remedies for colds and allergic symptoms. Animal experiments with high doses have shown that some congenital malformations may be induced but there is no evidence of harm in humans. Current recommendations are that pregnant and breast-feeding women should limit their caffeine intake to 300 mg day^{-1}, which is equivalent to 4 cups ordinary-strength coffee per day (or 6 cups of tea or 7 cans of cola). A recent review from the UK Committee on Toxicity of Chemicals in Food, Consumer Products and the Environment (DoH 2001) issued a statement on the reproductive effects of caffeine in October 2001. A meta-analysis of studies of maternal caffeine intake during pregnancy and the risk of spontaneous abortion or low birth weight, compared maternal caffeine intakes during pregnancy of more than 150 mg/day with less than 150 mg/day. Calculated odds ratios were significantly increased for spontaneous abortion (miscarriage) (odds ratio = 1.36; 95% confidence interval, 1.29–1.45) and low birth weight (odds ratio = 1.51; 95% confidence interval, 1.39–1.63), for low birth weight (< 2.5 kg).

Two studies, which examined the links between caffeine intake and pregnancy in SIDS, received a huge amount of publicity and caused a lot of worry for women. However, the results were conflicting.

Peanuts

Peanut allergy is increasing in children, although the cause is unclear. The use of peanuts and peanut oil in the British diet has increased rapidly over the last few years and it is thought that being exposed to peanuts at a young age may cause the allergy. However, it is not known if this can happen as a result of a mother eating peanuts when she is pregnant or breast-feeding. Current advice is that women, their partners, and existing children who have a family history of atopic disease should avoid peanuts.

Over-the-Counter Remedies

As a general rule, self-prescribing in pregnancy should be kept to a minimum. Those drugs that

have been used most widely and have been shown to be safe should be preferred to anything new or untested. Small doses of simple analgesic drugs such as aspirin and acetaminophen (paracetamol) appear to be safe, as do common cold remedies, which often have these drugs as their active contents.

No problems have been reported with the use of homeopathic remedies in pregnancy. There has been much interest in possible therapeutic benefit from the consumption of oil of evening primrose in pregnancy. It has been hypothesized that the linoleic acid and γ-linoleic acid in the compound may stimulate production of vasodilatory prostaglandins and be of benefit in lowering blood pressure in abnormal states of pregnancy such as preeclampsia. The limited studies so far reported do not support this hypothesis.

Recent reports have compared women who are on diets rich in natural fish oil, the Faroese, with women on the Danish mainland whose diets contain much less fish oil. The Faroese had fewer premature babies, fewer problems with blood pressure, and heavier babies than the mainlanders. Unfortunately, these studies cannot be interpreted as showing uniform benefit from fish oil supplements as the Faroese also lost more babies as stillbirths. A further report, comparing women in Aberdeen with women in the North Sea Orkney Islands, showed the latter to have average birth weights 250 g higher. After correction, a small but significant proportion of the difference was found to be related to genetic or environmental factors. The latter included a diet in Orkney containing 30% more fish than in Aberdeen.

Ginger root may act as an antiemetic by a local effect in the stomach. Evidence of benefit in pregnancy nausea exists.

Garlic is widespread in the human diet. There has always been a recognition of possible benefits of garlic supplements on a wide range of disorders, including hypertension, hyperlipidemia, and thrombosis. No studies of supplementation in pregnancy have been reported.

Vitamin and Mineral Supplementation

Some pregnant women benefit from iron and/or folic acid supplements when dietary deficiency provokes anemia. Although self-medication with vitamin and mineral supplements is widespread, there is a good case during pregnancy to restrict such supplements to those prescribed by doctors or preparations containing less than 100% of the recommended dietary allowance. Vitamin A in the form of retinol and its analogs can cause congenital malformations in megadosage, and vitamin D supplementation is thought to have been the cause of idiopathic hypercalcemia. This was a congenital syndrome consisting of abnormal facial features, mental retardation, and abnormal calcium metabolism. It was common in the UK in the late 1950s and early 1960s when vitamin D supplementation of a variety of foods was practiced. (The relationship of periconceptional multivitamins to NTDs is discussed elsewhere.)

It seems clear that some members of dark-skinned races are at risk of vitamin D deficiency when resident in temperate climates. Their newborns may be at risk of hypocalcemia, a cause of convulsions in the newborn period. These children may also have delayed growth in the first year of life. Both problems may be corrected by vitamin D supplementation in pregnancy.

At various times, maternal zinc deficiency has been proposed as a cause of both congenital malformation and retarded fetal growth. No valid evidence has yet emerged of any benefit derived from maternal zinc supplementation with regard to either outcome in humans.

Food Safety in Pregnancy

Pregnant women share the concerns of the general public about food poisoning but there is a great deal of confusion in the mind of the public and the clinicians treating them about which foods are safe to eat during pregnancy.

Listeria monocytogenes

This organism is widely distributed in the environment and the low incidence of infection suggests that infection requires the ingestion of a large dose by a susceptible individual. Listeriosis is a significant problem in pregnancy because infection of the mother can cause fetal death following transmission of the organism across the placenta. It is not certain at the present time whether the apparent increase in fetal loss from this infection represents improved ascertainment or a genuine increase in disease frequency.

Most women do not realize that the symptoms of *Listeria* infection are not the same as those for some other foodborne pathogenic organisms: *Listeria* symptoms are often described as mild 'flu-like symptoms' rather than diarrhea and vomiting. The perceived risk of *Listeria* infection in pregnancy for many women appears to be much greater than the actual risk.

During pregnancy the following foods should be avoided to reduce the risk of *Listeria* infection:

- Mold-ripened cheese and some types of sheep and goats' milk cheese
- Pâté – meat, fish, and vegetable (unless canned or ultra heat-treated)

- Cook–chill foods that have not been thoroughly reheated

However, many health professionals advise women to avoid 'unpasteurized soft cheeses' which, to most pregnant women, means avoiding all types of cream and cottage cheese together with yogurt and fromage frais. In fact, it is only mold-ripened cheeses with either a skin such as that found on Brie and Camembert or a mold inside such as Danish blue that should be avoided, together with sheep and goats' milk cheese that has not been made with pasteurized milk. Unnecessary avoidance of these dairy foods will substantially decrease calcium intake.

Toxoplasmosis

Toxoplasma is a protozoan organism which can cross the placenta when primary infection occurs in pregnancy. It can lead to fetal death, mental handicap, and/or blindness in an estimated 30% of offspring of infected mothers. To reduce the risk of infection during pregnancy women are advised to:

- Avoid eating raw and undercooked meat.
- Always wash vegetables and salads well to remove soil.
- Wear gloves when gardening.
- Avoid unpasteurized sheep and goats' milk.
- Wash hands after contact with cats and kittens and avoid contact with stray cats.
- Wear rubber gloves when cleaning out cat litter trays or get somebody else to do this job if possible.

(*See* **Vegetarian Diets**.)

Salmonellosis

Salmonella bacteria are one of the most common causes of food poisoning in the UK, giving rise to sickness and diarrhea. Steering clear of raw eggs and products containing uncooked egg and exercising appropriate food hygiene can reduce this risk.

Campylobacteriosis

The main source of *Campylobacter* infection is raw milk and poultry but a large number of foods have been implicated in outbreaks. Again, campylobacter may not have any direct effect on the fetus, but the Department of Health advises women in the UK to avoid this distressing illness.

Shellfish

Pregnant women are advised not to eat oysters and other shelled seafood, such as prawns, mussels, and crab, unless they are part of a hot meal and have been thoroughly cooked. When raw these foods may be contaminated with harmful bacteria and viruses.

Bovine spongiform encephalopathy

In 1996 evidence of a new variant of Creutzfeldt–Jacob disease (CJD) began to be observed, which is most probably the result of eating beef infected with bovine spongiform encephalopathy (BSE). A particular source of concern at the moment is vertical transmission which, although common in cattle, has not been shown to occur in humans. However, there has recently been a possible case reported in the media of mother to child infection.

Other concerns of pregnant women in the area of food safety include the hazards of fungicide and pesticide residues. and possible harmful effects of natural food toxicants. At present it seems unlikely that there are toxic residues on foods which can be associated with harm in pregnancy, but this observation should not be taken as grounds for complacency. One of the main difficulties for scientists wishing to explore this matter is the limited availability of reproducible assays for the minute quantities to be studied. Similarly, the study of natural food toxicants for possible harmful effects on the fetus is in its infancy.

Conclusions

It is important to monitor continuously any effects our dietary habits may be having on child-bearing and child development, but we should be able to achieve this without causing unnecessary scares. Most women who consume a good general diet, and are not addicted to tobacco, alcohol, or other drugs, can contemplate pregnancy without concern that their dietary habits can 'harm the baby'.

Maternal Diet, Vitamins, and Neural Tube Defects

M L Watkins, National Center on Birth Defects and Developmental Disabilities, Atlanta, GA, USA
S L Carmichael, March of Dimes/California Birth Defects Monitoring Program, Oakland, CA, USA

Background

The most interesting work relative to neural tube defect (NTD) etiology and prevention in the last few years has focused on nutritional factors. This chapter summarizes what is known about the relation between NTDs and various nutritional factors, with particular emphasis on folate, and includes a discussion of the methodologic challenges inherent in identifying such associations.

Neural Tube Defects

NTDs result from failure of normal closure of the embryonic neural tube at one or more of five separate closure sites. Complex forces are involved, with varying closure mechanisms at different sites within the neural tube. Of the several NTD types (**Figure 1**), spina bifida is the most common. The extent of physical disability (e.g., paralysis, bowel and bladder dysfunction) associated with spina bifida depends on the lesion level, size, and extent of spinal nerve involvement. Developmental, learning, and social problems are common. Most children born with spina bifida in developed countries now survive because of extensive medical and surgical treatment. Many of these children, however, face lifelong physical and developmental disabilities. The death rate for affected infants in the USA is about 10%, but the rate is much higher in countries with less accessible medical care. Clinical deterioration and secondary conditions occur in many affected children in a variety of body systems, resulting in complex medical and surgical care. Because of a lack of information about the natural history of untreated children, a lack of randomized trials, and a lack of diagnostic criteria for neurologic complications, there are controversies about optimal care. The economic costs of spina bifida are huge. The role and effectiveness of intrauterine myelomeningocele repair is controversial; clinical trials have been recommended.

NTDs affect at least 300 000 newborns worldwide each year. NTD rates vary considerably around the world, with northern China reporting some of the

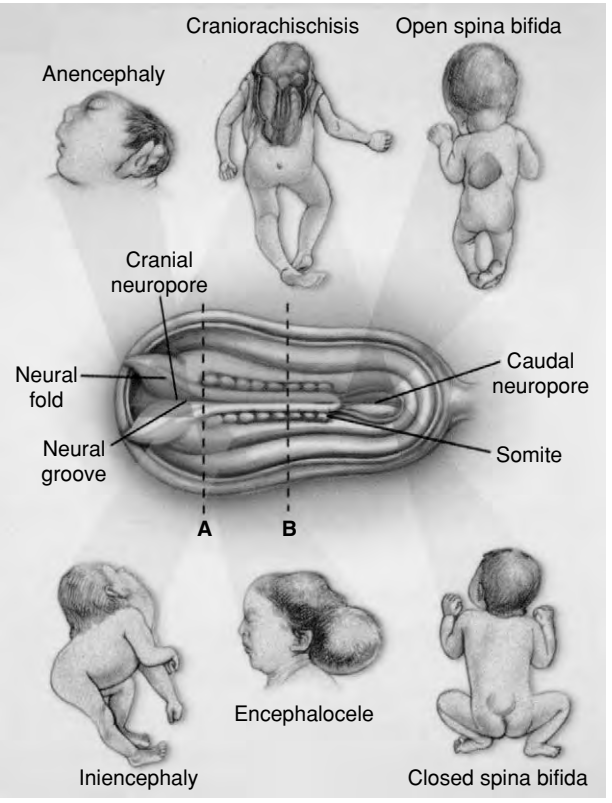

Figure 1 Neural tube defects. Schematic view (from above) of a neural tube. Main clinical types of neural tube defects. Anencephaly (lateral view): the absence of the brain and skull can be total or partial, always fatal. Craniorachischisis (posterior view): anencephaly occurs with contiguous bony defect of the spine and exposed neural tissue. Open spina bifida (posterior view): bony defect of the vertebrae (in this case, of the lower thoracic vertebrae), accompanied by exposure of neural tissue and meninges that are not covered by skin. Closed spina bifida (posterior view): bony defect of the vertebrae and, if present, the herniated meninges and neural tissue, are covered by skin. Extent of the disability associated with spina bifida related to the level and size of the lesion and the extent of spinal nerve involvement. Encephalocele (lateral view): the brain and meninges herniate through a skull defect. Iniencephaly (lateral view): the dysraphic process in the occipital region is accompanied by severe retroflexion of the neck and trunk. Spina bifida and anencephaly are more common than encephalocele, craniorachischisis, or iniencephaly. Adapted from Botto LD, Moore CA, Khoury MJ and Erickson JD (1999) Neural-tube defects. *New England Journal of Medicine* 341: 1509–1519, with permission.

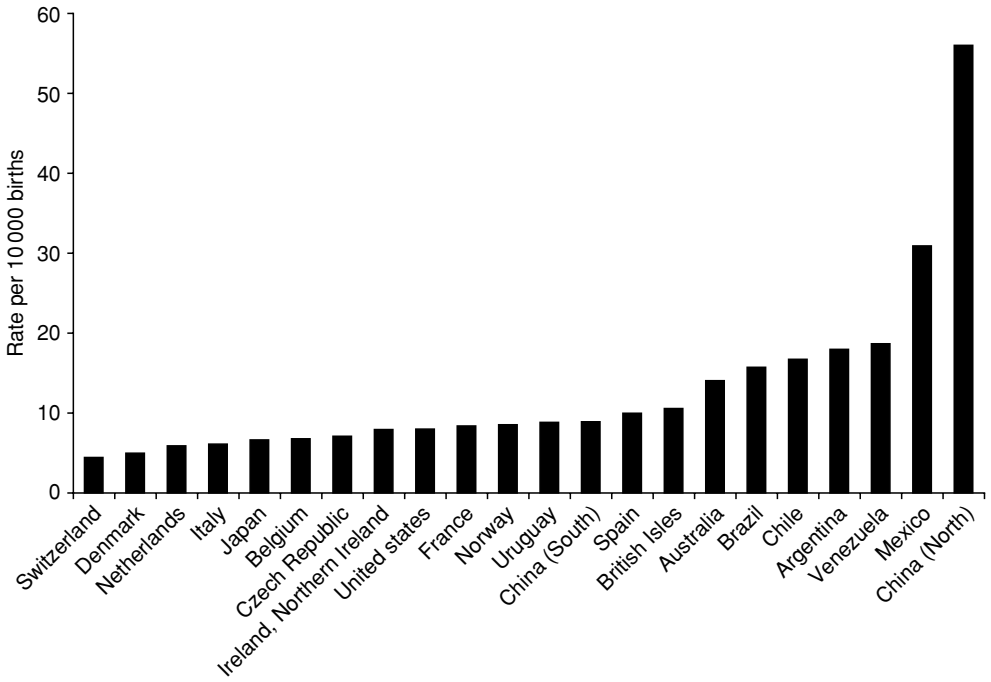

Figure 2 Rates of spina bifida and anencephaly by country. Cases reported in pregnancy terminations are included, where available. Rates for Latin-American countries and Japan are estimated from hospital-based registries. Rates for other locations are based on data from birth defects registries that usually monitor only part of a country's birth population. The following countries and registries are included: Switzerland (selected counties), Denmark (Odense), The Netherlands (North), Italy (Campania, Emilia-Romagna, Toscana), Belgium (Hainaut-Namur), Czech Republic, Ireland (Dublin, Belfast), United States (Atlanta, Hawaii), France (Bouches-du-Rhone, Paris, Strasbourg, Central East France), Norway, Spain (Basque country), UK (Glasgow, North Thames), Australia (Victoria, South Australia), and China (selected counties). Data from the International Center for Birth Defects and the European Registration of Congenital Anomalies (1998) *World Atlas of Birth Defects*, pp. 20–31. Geneva: World Health organization.

highest rates (Figure 2). Both environmental and genetic factors likely explain the variation in rates. Of NTDs, 80% are thought to be 'multifactorial,' meaning that they are influenced by both genetic and environmental factors. A minority of NTDs are caused by chromosomal abnormalities, single gene mutations and teratogens. Risk factors include maternal diabetes, use of folic acid antagonists, fever or hyperthermia in early pregnancy, low socioeconomic status, and obesity. In the USA, NTD rates are higher among Hispanic whites than non-Hispanic whites; blacks have the lowest rates. NTD-rate monitoring is complicated by the increasing use of prenatal diagnosis and selective termination, which results in lower birth prevalence. Because the neural tube develops very early in pregnancy (closure by 28 days postconception) before most women are aware they are pregnant, prevention efforts are challenging, especially in populations with high unplanned pregnancy rates. Approximately 95% of all NTD-affected pregnancies occur in women with no previous history, which is referred to as 'occurrence.' However, women who have already had an NTD-affected pregnancy have a 10-fold greater risk for having an NTD-affected subsequent pregnancy than women who have not. Having more than one NTD-affected pregnancy is referred to as 'recurrence.'

The increased prevalence of NTDs in lower socioeconomic groups, decreasing NTD rates, and seasonal patterns of occurrence are consistent with a dietary etiology for NTDs. Certain nutrients (specifically folic acid) were thought to be involved because of their role in human growth and because birth defects occurred with maternal use of folic acid antagonists (e.g., aminopterin, when used as an abortifacient, induced fetal NTDs). Also, animal data have demonstrated NTD inducement resulting from various nutritional deficiencies and excesses, suggesting the plausibility of nutritional causes of NTDs.

Methodologic Issues in the Study of Nutrition and NTDs

However plausible the link between nutrition and NTDs, studying these associations presents inherent challenges. Approaches to measuring nutritional status can be broadly classified as dietary, biochemical, anthropometric, or genetic. Many of the

difficulties in studying nutrition and birth defects stem from the fact that most studies are retrospective in nature, resulting from the relatively low prevalence of NTDs. This limitation has varied implications, depending on the particular approach used to measure nutritional status.

The food-frequency questionnaire is a tool commonly used to assess dietary intake retrospectively. This method produces reasonably valid and reliable, comprehensive, and semiquantitative data on usual or average intake of foods and nutrients. The validity of the data depends, however, on several factors, including the appropriateness of the food list for the study population; the accuracy of the nutrient database; and variability in individual nutrient requirements and in the bioavailability and absorption of nutrients from foods (which are affected by, for example, food processing, fiber intake, alcohol consumption, cigarette smoking, and infection). Challenges related to the analysis of dietary data include whether to analyze intake from foods and supplements separately or together; foods versus nutrients; or single versus multiple nutrients simultaneously. The high correlation that exists between nutrients makes it particularly difficult to isolate the independent effects of individual nutrients.

Depending on the particular nutrient, biochemical measures of nutritional status may vary by time of day, by the tissue from which the measurement is made (serum and toenail zinc, for instance, reflect more short-term versus long-term zinc status, respectively), and by various host factors (e.g., genes, behaviors such as smoking and alcohol consumption, health status, physical activity, stress, and medications). Furthermore, pregnancy itself is a time of changing nutritional requirements and absorption. These factors must be taken into consideration when interpreting results from individual studies and when comparing results across studies.

Anthropometric measurements (e.g., height and prepregnancy weight) can be recalled reasonably well. Whether retrospectively collected data on more complex measures (e.g., skinfold thickness and waist-to-hip ratio) can serve effectively as proxies for these parameters around the time of conception is questionable.

Genetic material is most commonly obtained from blood samples or buccal smears. The challenge is in discovering functionally relevant polymorphisms and in having sample sizes large enough to detect meaningful differences in risk. Recent advances in technology are enabling more rapid identification and analysis of polymorphisms, and innovative approaches to epidemiologic study design are being developed that enable smaller numbers of subjects for examination of certain types of genetic hypotheses.

Folic Acid and NTDs

In 1930, Dr. Lucy Wills discovered a factor that cured the nutritional deficiency anemia of pregnancy among women in India. This factor was later isolated from spinach and named 'folic acid' (*folium* is Latin for 'leaf'). Because humans are unable to synthesize folate, they must depend solely upon dietary sources. Folate-rich food sources include green leafy vegetables, grains, legumes, certain fruits, and liver. Because heat, ultraviolet light, and air inactivate food folate, food processing, preparation, and cooking can reduce the amount of food folate ingested by an estimated 50–95%. *Bioavailability*, the extent to which folates are available for use at the cellular level, varies widely across foods. The bioavailability of synthetic folic acid (monoglutamate form), which is used in cereal grain fortification and multivitamin/mineral supplements, is estimated to be about twice that of food folate (polyglutamate form).

Studies in the mid-twentieth century linked nutrition and NTDs. Lower vitamin C and folate levels in one study and poorer diet quality (in terms of macronutrient and fresh fruit and vegetable intake) in another were found among women with NTD-affected children. Intervention and observational studies followed (Figure 3). The most convincing and solid evidence for a preventive effect of folate is provided by two intervention trials. The international Medical Research Council (MRC) trial, a large UK-sponsored *recurrence* prevention trial, was conducted at 33 sites in seven countries. Women who had a previous NTD-affected pregnancy were randomized to one of four vitamin-use groups. Among 1195 pregnancies with known outcomes, folic acid (alone or with other vitamins) was associated with a 72% reduction in risk.

In 1992, a Hungarian randomized trial provided strong evidence for the efficacy of folic acid-containing multivitamin supplementation to prevent NTD *occurrence*. Results from this trial, combined with results from several observational studies (Figure 3) provided convincing evidence that occurrence is preventable. As a result, several countries recommended in 1992 that women of childbearing potential consume periconceptional folic acid daily (most commonly 400 μg) to prevent NTDs. The recommendation was made for all women capable of becoming pregnant (not just those planning a pregnancy), because these birth defects occur before many women are aware that they are pregnant, and because many pregnancies are unplanned. Since then, a large, nonrandomized community intervention in China demonstrated significant NTD reductions associated with the use of a 400-μg supplement containing only folic acid. Risk reductions were greater (85%) in the

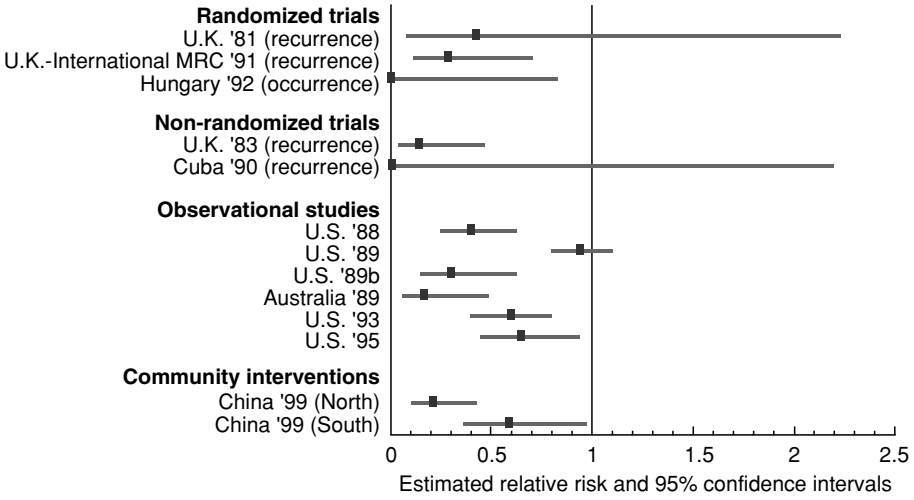

Figure 3 Risk of neural tube defects and use of folic acid or multivitamin supplements: summary of studies 1980–95, by country and year of publication. The figure shows risk estimates (boxes) and 95% confidence intervals. Risk estimates < 1 indicate a reduction in risk among the 'exposed' mothers (periconceptional use of folic acid or multivitamins). If the upper limit of confidence intervals is > 1, the risk estimate is not statistically significant. Some studies used folic acid (varying doses); some used multivitamins. Two randomized controlled trials (UK'81 and UK-international-MRC'91) and two nonrandomized trials (UK'83 and Cuba'90) examined the efficacy of folic acid with or without other vitamins among women with a previously affected pregnancy (recurrence). One randomized trial (Hungary'92) assessed the efficacy of a multivitamin containing folic acid among women without a previously affected pregnancy (occurrence). Of the observational studies, five (US'88, US'89, Australia'89, US'93, US'95,) were case-control studies, whereas one (US'89b,) was an observational cohort. The community intervention study (China'99) was conducted in two areas, one in Northern China and one in Southern China; it assessed the effectiveness of 0.4-mg folic acid supplements (without other vitamins) among women without a previously affected pregnancy in areas of high (North) and low (South) occurrence rates of neural tube defects. From Botto LD, Moore CA, Khoury MJ, and Erickson JD (1999) Neural-tube defects. *New England Journal of Medicine* 341: 1509–1519, with permission.

high-prevalence northern countries than in the lower-prevalence southern counties (40%). Additional evidence for the efficacy of folic acid comes from another study that found that periconceptional exposure to folic acid antagonist medications more than doubles the risk for NTDs and that folic acid supplementation reduced the risk elevation associated with certain folic acid antagonists.

Efficacy Issues

Based on the risk reduction observed in several studies, estimates are that at least 50% of NTDs could be prevented by the use of folic acid. The proportion of NTDs that are preventable may be less in low-prevalence areas than in high-prevalence areas. Some studies also suggest a smaller reduction in risk for NTDs associated with folic acid use for Hispanics than for non-Hispanic whites or blacks, and for obese women compared with average weight women. These observations require more study. The minimum daily effective dose of folic acid for NTD prevention is unknown; it may be < 400 μg for occurrence prevention, but determining the effectiveness of lower dosages is difficult because of the size and cost of studies necessary to assess the relative efficacy of various dosages.

The reasons for variability in folate efficacy are unknown, largely because the biologic mechanism by which periconceptional folic acid use protects against NTDs is unknown. Folic acid plays a role in transfer of methyl groups in the amino acid methylation cycles, a process essential for recycling homocysteine back to methionine (Figure 4). It is also a cofactor for enzymes involved in DNA and RNA synthesis, providing single carbon units for the synthesis of nucleotide bases, a process that is essential to the rapid cell division that occurs in early fetal development. Extrinsic folic acid may work by increasing tissue folate levels enough to override a failure in folate metabolism, or it may compensate for deficiency or metabolic defects related to other nutrients closely related to folate metabolism. Recent research has focused on the role of mutations in the genes that code for enzymes involved in folic acid metabolism.

Approaches to Increasing Folic Acid Consumption

Although the mechanism is unknown, a significant proportion of NTDs can be prevented with folic acid. The challenge is in how to translate science into public health policy and practice. Table 1 summarizes three approaches for increasing folic acid consumption.

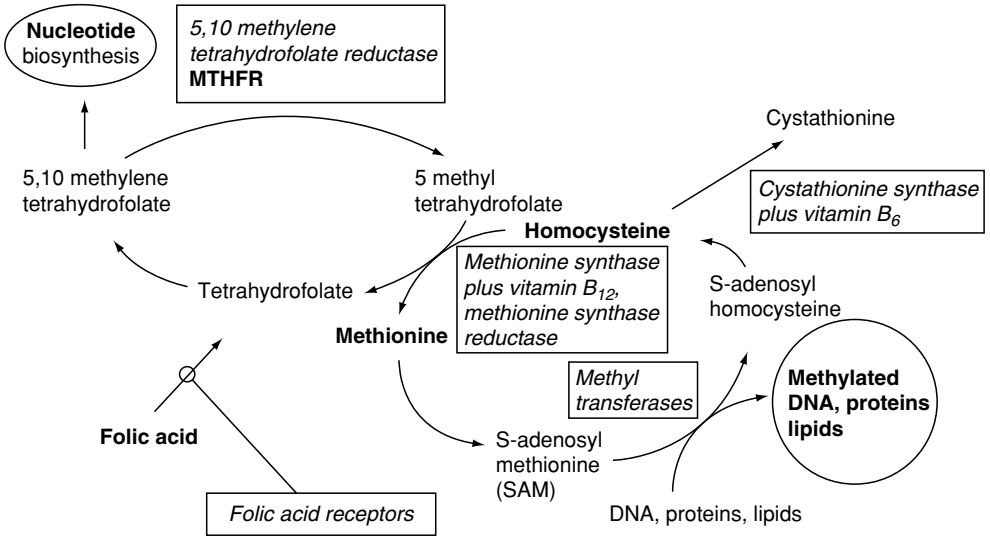

Figure 4 Metabolic roles of folic acid and related dietary factors. Simplified schematic of some of the metabolic processes that involve folic acid and other related factors. Folic acid (bottom left), after entering the cell (aided by folate receptors), participates in the transfer of carbon units used for the synthesis of nucleotides (top left) or, through the conversion of homocysteine to methionine (center), for methylation purposes. These processes are regulated by many factors including enzymes (in rectangular boxes) and vitamins other than folic acid (e.g., vitamins B_6 and B_{12}). The activity of some enzymes (e.g., methionine synthase) may be influenced by other enzymes (e.g., methionine synthase reductase). Adapted from Botto LD, Moore CA, Khoury MJ, and Erickson JD (1999) Neural-tube defects. *New England Journal of Medicine* 341: 1509–1519, with permission.

Table 1 Ways to increase folic acid/folate consumption to prevent neural tube defects

Approach	*Advantages*	*Disadvantages*	*Status*
Fortify staple foods	Proven to increase blood folate level Reaches almost all women Behavior change not necessary unless higher intakes needed Inexpensive	All consumers (not just target population) increase intake; concern that some will have excess intake Variable staple consumption results in variable folic acid intake Sustained behavior change required for consumption of higher amounts	Mandatory fortification in the USA, Canada, and several Central and South American and eastern European countries; proposed in the UK
Increase use of supplements	Efficacy proven by clinical trials Proven to increase blood folate level Relatively inexpensive	Requires sustained behavior change Reservations of some medical and nutritional professionals	Varies by country and survey question (e.g., in the USA, 30% of reproductive-age women report regular use; in The Netherlands, 54% of women report 'any periconceptional use' and 21% 'appropriate use')
Increase consumption of foods with high levels of natural folates (e.g., fruits and vegetables)	Other benefits of healthy diet that includes fruits and vegetables	Efficacy not proven Much smaller increases in blood folate levels than supplements or fortified foods Requires significant and sustained behavior change May be expensive	Various healthy diet campaigns under way

Fortification of a food staple provides wide population coverage at low cost without requiring behavior change. The optimal fortification level is controversial. Some experts had concerns that daily folic acid intakes in excess of 1 mg could adversely affect some persons, particularly persons with untreated cobalamin deficiency. Folic acid can ameliorate the anemia associated with cobalamin deficiency, possibly leading to a failure to detect and treat the cobalamin deficiency, which could result in the initiation or

progression of neuropathy. Although some experts in the study of birth defects advocated a higher fortification level, the US Food and Drug Administration ruled that, effective January 1, 1998, all flour, corn meal, pasta, and rice labeled as 'enriched' be fortified with folic acid at 140 mg per 100 g of cereal grain product. Canada and several Central and South American and eastern European countries also have mandated fortification of wheat flour. The fortification level in some countries (e.g. Chile) was established at a higher level, with the goal of achieving a higher average daily intake of folic acid. In 2000, the UK Committee on Medical Aspects of Food and Nutrition Policy recommended folic acid fortification at 240 μg per 100 g of flour. At the time of writing, this proposal is under review but not yet approved, although voluntary optional fortification is allowed in the UK. Serum and red blood cell folate levels among reproductive aged women in the USA have more than doubled since fortification of cereal grain products. In addition, preliminary analyses suggest an approximate 20% decline in NTD rates postfortification.

Although multivitamin supplements containing folic acid are of proven efficacy in preventing NTDs, their use requires a sustained behavior change by most women. Educational campaigns in the USA have increased awareness and knowledge about folic acid more than they have increased actual supplement use. In 2001, although 80% of childbearing aged women in the USA had heard of folic acid, only 29% took a daily vitamin containing folic acid, up only slightly from 25% in 1995. In the UK and in The Netherlands, public-awareness campaigns significantly increased both knowledge about, and use of, folic acid. For example, after a 1995 campaign in The Netherlands, use of folic acid for 'any period around conception' increased from 25% before the campaign to 54% after, and 'appropriate' use increased from 5 to 21%. Whether increases in supplement use can be sustained and whether levels of use plateau at a certain level is unknown. Supplement use is less common among younger women, less educated women, and those with lower incomes – populations that are often harder to reach through health education efforts.

Attempts to increase population consumption of folate-rich foods (e.g., fruits and vegetables) through programs like the 'Five-a-Day' campaign in the USA have generally resulted in only modest increases. One small study found that neither dietary advice nor folate-rich foods significantly increased women's red cell folate levels, whereas supplements and fortified foods did. This could result from the lower bioavailability of food folate and/or the challenges of making dietary behavior changes.

Folate-related Nutrients

As noted previously, the preventive effects of folate supplementation are more likely to result from its compensation for metabolic errors closely related to folate metabolism, rather than overt folate deficiency. Folate is involved in an intricate network of reactions that include many enzymes, nutrients, and other substrates that could affect NTD risk through a variety of mechanisms (**Figure 4**). The conversion of 5-methyl tetrahydrofolate to tetrahydrofolate produces the substrate necessary for the transmethylation of homocysteine to methionine; the enzyme methionine synthase (MS) catalyzes the reaction, and vitamin B_{12} is a cofactor for this enzyme (**Figure 4**). Homocysteine may also be metabolized to cystathionine via cystathionine β synthase (CBS), of which vitamin B_6 is a cofactor.

Hyperhomocysteinemia, which has been shown to cause NTDs in animal models, may reflect impaired metabolism of folate, B_{12}, B_6, or homocysteine, may reflect a defect in the enzymes 5,10-methylenetetrahydrofolate reductase (MTHFR), MS, or CBS, or may be harmful on its own. Several studies have reported an increased NTD risk associated with high homocysteine levels in humans, in the amniotic fluid of mothers carrying affected fetuses, in maternal serum during pregnancy and postpartum, and among children with NTDs, although results have not been entirely consistent.

Animal models indicate that methionine is also important to neural tube closure. Although the mechanism is unknown, methionine is necessary for protein synthesis and transmethylation reactions. Two population-based, case-control studies have reported a 30–50% reduction in risk for NTDs with increasing quartiles of methionine intake. Other studies have been inconsistent: some have demonstrated higher levels of methionine in the amniotic fluid of mothers carrying NTD-affected fetuses, whereas another study reported no difference in maternal serum methionine post-partum.

Several studies have indicated lower levels of vitamin B_{12} in the amniotic fluid and serum of women with affected pregnancies. Studies of methyl malonic acid (an indicator of B_{12} deficiency or a defect in B_{12} metabolism) and B_{12} carrier proteins also suggest a defect in B_{12} metabolism among case mothers. Other studies have not supported these differences or have been inconsistent in their findings depending on the timing of and tissues used for measurement. Although the results are mixed, they do not seem to provide strong evidence for a relation between B_{12} deficiency and NTD risk. Few studies have examined the association between vitamin B_6 and risk for NTDs;

significant differences have not been observed, but studies have involved only small sample sizes.

There is some evidence that polymorphisms in the genes for MTHFR, MS, and CBS contribute to altered levels of these nutrients and to NTD risk, but again, results have been mixed.

The individual contributions of each of these indicators of metabolic disturbances to NTD risk, and their interdependence, are unclear at this point. Folic acid supplementation might play a role in overcoming the negative effects of many of these disturbances. However, until the exact causes of NTDs are determined, the understanding of the implications of these findings and the way in which they should be used for prevention purposes remains limited.

Other Nutrients

At least 30–50% of NTDs are folate-resistant; therefore, other nutrients have been implicated as possible causes of these cases. The evidence for the role of vitamin A, zinc, and inositol in NTD etiology is reviewed here. Other nutrients – including vitamin C, riboflavin, iron, calcium, magnesium, selenium, lead, and copper – also may be associated with increased NTD risk, but evidence is very limited.

The finding that isotretinoin, a synthetic derivative of vitamin A, is teratogenic led to investigations of whether naturally derived vitamin A is associated with increased risk for NTD-affected pregnancy. Most studies have found no evidence of an association of high vitamin A levels with NTD risk, based on intake from foods and supplements and on serum samples taken during the first trimester of pregnancy or postpartum. The safe level of vitamin A intake is still debatable, in part because of its potential association with other types of malformations and its association with other negative health outcomes. The effects of deficient vitamin A intake on NTD have not been explored.

Zinc is important to cellular growth and differentiation and to folate absorption. Various experimental studies in animals and case reports of women with specific disturbances of zinc metabolism have suggested an association between zinc and increased risk for NTD-affected pregnancy. Results for analytic studies of zinc and NTDs in humans are inconsistent. Postpartum studies have reported NTD case mothers to have levels of zinc in the hair that were higher, lower, or the same as those in control mothers, higher levels in toenails, and the same as control mothers in serum levels. Studies of pregnant women have reported that mothers with NTD-affected pregnancies have higher levels of zinc in serum, lower levels in white blood cells, and lower dietary intakes, whereas other studies have reported no difference in serum or amniotic fluid. Despite the number of studies, inference is limited by the wide variability in zinc measurement and by the limited understanding of the relationships between these measures.

Inositol is a 6-carbon polycyclic alcohol that is present in all cells, with especially high levels in nerve cells. It protects against NTDs in the curly-tailed mouse, a folate-resistant NTD model, leading some researchers to recommend supplementation with a combination of folate and inositol. However, the applicability of these findings to humans has not been studied.

Limitations

In general, the proposed associations reviewed here are biologically plausible and supported by animal models. Unfortunately, systematically testing these associations in humans is difficult, and most existing evidence is clinical or experimental and speculative. Sample sizes for many of the studies have been small (often involving < 20 case-patients). Study population characteristics and selection methods have been highly variable; very few have been population-based. Few studies have adjusted for potential confounding or effect modification by other maternal characteristics, including status with respect to other nutritional factors or individual nutrients.

The ability to measure maternal nutritional status is also limited. Because pregnancy is a time of tremendous metabolic change, the ability of measurements taken later in pregnancy to represent the status during the time of neural tube closure is questionable. For example, the fetal contribution to levels of nutrients in amniotic fluid is uncertain and may vary by timing of measurement and by nutrient. Also, many women begin taking multivitamin/mineral supplements soon after the time of neural tube closure.

The cause of observed variability in nutrient levels is usually unknown, limiting the understanding of how to use such information for preventive measures. Nutrient metabolism is highly complex, and many reactions are interdependent. For example, depending on their cause, high homocysteine levels could be remedied with supplementation of B_{12}, methionine, folate, or B_6; low calcium intake may result in increased bioavailability of lead, reduced bioavailability of vitamin B_{12}, and, accordingly, reduced methionine synthase activity; and calcium, fiber, protein, and methionine are all important to zinc bioavailability. Therefore, it is critical that future studies examine interrelationships, including nutrient–nutrient interactions as well as gene–nutrient interactions, whenever possible.

Other Nutritional Factors

Evidence for a link between tea and NTDs is weak. A study in England and Wales showed an excess of anencephaly among women drinking three or more cups of tea per day, but no dose–response effect was observed, and the relation was observed only in regions with higher NTD prevalence rates. Furthermore, a study in Boston, Philadelphia, and Toronto found no elevated risk for NTDs associated with tea drinking. Nor is the link between coffee and NTDs strong. In the Boston study, no significant differences in coffee consumption were observed between the mothers of NTD-affected infants and control mothers. Also, no association with decaffeinated coffee or cola drinks has been found. A Finnish study found no association between central nervous system defects and coffee intake. Although there are case reports of NTDs occurring among infants of mothers who consumed significant amounts of alcohol during pregnancy, epidemiologic studies have provided little evidence for a link between NTDs and alcohol, especially for mothers consuming minimal or moderate amounts.

Some food contaminants have been proposed to be NTD teratogens. Potato blight, caused by a fungus (*Phytophthora infestans*) that rots potatoes, was hypothesized to cause NTDs in the early 1970s, although most evidence does not support this hypothesis. Fumonisin, a potent mycotoxin prevalent in corn and a carcinogen and cause of various animal diseases has been suggested as a possible cause of high NTD rates among persons living along the Texas–Mexico border who commonly consume corn products. Recent research suggests that fumonism may be involved in NTD formation by inhibiting folate uptake by cells. Also, fumonisins have been shown to produce NTDs in mouse whole embryo cultures; folic acid has ameliorated this teratogenic effect. More research is needed to establish the link between fumonisin consumption and NTD risk in humans.

About one-fourth of childbearing age women in the USA and almost as many such women in Canada, the UK, and Continental Europe, are obese, and obesity prevalence is increasing rapidly. Studies consistently find a twofold elevated risk for NTDs among children of obese women compared with mothers of average weight, although risk estimates vary with the body mass index cutoffs and referent groups used (Figure 5). Most studies found a higher risk estimate for spina bifida than anencephaly and found no risk elevation for encephalocele. Reasons for the increased risk are unknown. Potential explanations include teratogenic metabolic abnormalities associated with obesity including elevated levels of glucose, insulin, uric acid, and endogenous estrogens. Obese women may be more likely to be nutritionally deficient because of a self-imposed diet restriction, poor choice of foods, or increased requirement for folate or other nutrients. More studies are needed to help elucidate the mechanism. The population burden of NTDs associated with obesity is substantial and increasing.

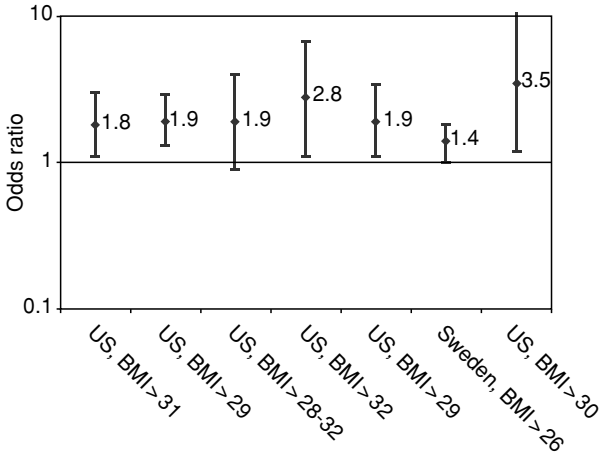

Figure 5 Risk of neural tube defects in offspring of obese women, odds ratios, and 95% confidence intervals. All studies except one (Sweden) were performed in the USA. The body mass index (BMI) used to define obesity varied (see *x*-axis). The referent group was average-weight or nonobese women.

Conclusion

There is still much to be learned about the complex link between nutrition and birth defects. Evidence is emerging regarding the role of nutritional factors in the etiology of birth defects other than NTDs (e.g., heart defects and orofacial clefts). Despite the challenges in studying nutritional causes of birth defects, the prevention potential is substantial and worthy of pursuit.

Preeclampsia and Diet

E Abalos, G Carroli and L Campodónico, Centro Rosarino de Estudios Perinatales, Rosario, Argentina
J Villar, World Health Organization, Geneva, Switzerland

Background

Hypertensive disorders during pregnancy are one of the main causes of maternal death worldwide, most of these deaths being attributed to eclampsia. Hypertensive disorders occur in 6–8% of all pregnancies, contributing significantly to stillbirths and neonatal morbidity and mortality. Babies are also at increased risk of intrauterine growth restriction, low birth weight and preterm delivery. Pregnant women with hypertension, either newly diagnosed or pre-existing, are prone to the development of potentially lethal complications, notably abruptio placentae, disseminated intravascular coagulation, cerebral hemorrhage, pulmonary edema, hepatic failure, and acute renal failure. The etiology of hypertensive disorders related to pregnancy, particularly preeclampsia, remains unknown. The most important consideration in the classification of the disease is differentiating hypertensive disorders that antedate pregnancy from those that are pregnancy-specific, from which the more ominous are preeclampsia and eclampsia. Preeclampsia is a pregnancy-specific syndrome of reduced organ perfusion secondary to vasospasm and activation of the coagulation cascade. Although our understanding of this syndrome has increased, the criteria used to identify the disorder remain a subject of confusion and controversy. In chronic hypertension, elevated blood pressure is the primary pathophysiologic feature, whereas in preeclampsia, increased blood pressure is important primarily as a sign of the underlying disorder. As might be expected, the impact of the two conditions on mother and fetus is different, as is their management **Table 1**.

Classification

There are controversies about the definition of hypertensive disorders during pregnancy, and several classifications have been suggested. Recently, the National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy updated the 1990 report, and classified the hypertensive disorders during pregnancy

Table 1 Effectiveness of nutritional interventions in hypertension during pregnancy and preeclampsia

Intervention	*Hypertension during pregnancy*		*Preeclampsia*	
	Practice	*Research*	*Practice*	*Research*
Nutritional advice	No evidence		No effect RR = 0.89 (0.42–1.88)	
Balanced protein (<25%) / energy	No evidence		No effect RR = 1.20 (0.77–1.89)	
Isocaloric balanced protein (<25% of total energy)	No evidence		No effect RR = 1.00 (0.57–1.75)	
Energy/protein restriction for high PI or high weight gain	No effect RR = 0.97 (0.75–1.26)		No effect RR = 1.13 (0.59–2.18)	
Salt restriction	No effect RR = 0.97 (0.49–1.94)		No effect RR = 1.11 (0.46–2.66)	
Calcium	Possibly beneficial for women at high risk RR = 0.45 (0.31–0.66) and with low baseline intake RR = 0.49 (0.38–0.62)	RCT in progress	Possibly beneficial for women at high risk RR = 0.21 (0.11–0.39) and with low baseline intake RR = 0.32 (0.21–0.49)	RCT in progress
Iron and folate	No effect RR = 1.15 (0.41–3.18)		No evidence	
Folate	No effect RR = 1.26 (0.90–1.76)		No evidence	
Magnesium	No evidence	Needed	No effect RR = 0.87 (0.57–1.32)	Needed
Fish oil	No effect RR = 0.96 (0.86–1.07)		Possibly beneficial (data from low quality studies) RR = 0.70 (0.55–0.90)	
Zinc	No effect RR = 0.87 (0.65–1.15)	Needed	No evidence	Needed
Antioxidants	No evidence	Needed	Possibly beneficial for vitamins C and E (data from one RCT) RR = 0.46 (0.24–0.91)	Needed

as (1) chronic hypertension defined as hypertension observable before pregnancy, or diagnosed before the 20th week of gestation; (2) preeclampsia, which is a pregnancy-specific syndrome usually occurring after 20 weeks' gestation, determined by hypertension with proteinuria; (3) preeclampsia superimposed on chronic hypertension; and (4) pregnancy-induced hypertension or gestational hypertension, which is transient hypertension detected for the first time after midpregnancy if preeclampsia is not present at the time of delivery and blood pressure returns to normal by 12 weeks post partum (a retrospective diagnosis). The system suggested by the International Society for the Study of Hypertension in Pregnancy (ISSHP) defines hypertension as a diastolic blood pressure of 90 mmHg or above on two consecutive occasions at least 4 h apart, or a single diastolic blood pressure of 110 mmHg or more. The definition of preeclampsia has the same criteria for high blood pressure, but with the addition of significant proteinuria, usually at least 300 mg per 24 h or 1+ on dipsticks.

Pathophysiology of Preeclampsia

Preeclampsia is a syndrome with both fetal and maternal manifestations. The maternal disease is characterized by vasospasm, activation of the coagulation system, and perturbations in many humoral and autacoid systems related to volume and blood pressure control. The pathologic changes in this disorder are primarily ischemic in nature and affect the placenta, kidney, liver, and brain. Of importance, and distinguishing preeclampsia from chronic or gestational hypertension, is that preeclampsia is more than hypertension; it is a systemic syndrome, and several of its 'nonhypertensive' complications can be life-threatening, even when blood pressure elevations are quite mild.

The cause of preeclampsia is not known. Many consider the placenta as the pathogenic focus for all manifestations of preeclampsia because the delivery of both the baby and the placenta is the only definitive cure of this disease. There is no disease without the placenta. Thus, research has focused on the changes in the maternal blood vessels that supply

blood to the placenta. Failure of the spiral arteries to remodel is postulated as the morphologic basis for decreased placental perfusion in preeclampsia, which ultimately may lead to early placental hypoxia. Oxidative stress and inflammatory-like responses may also be important in the pathophysiology of preeclampsia.

Research on how alterations in the immune response at the maternal interface might lead to preeclampsia addresses the link between placenta and maternal disease. A nonclassical human leukocyte antigen (HLA), HLA G, is expressed in normal placental tissue and may play a role in modulating the maternal immune response to the immunologically foreign placenta. Placental tissue from preeclamptic pregnancies may express fewer or different HLA G proteins, resulting in a breakdown of maternal tolerance to the placenta. Additional evidence for alterations in immunity in pathogenesis includes the disease prominence in nulliparous gestations with subsequent normal pregnancies, a decreased prevalence after heterologous blood transfusions, long cohabitation before successful conception, and observed pathologic changes in the placental vasculature in preeclampsia that resemble allograft rejection. Finally, there are increased levels of inflammatory cytokines in the placenta and maternal circulation, as well as evidence of increased 'natural killer' cells and neutrophil activation in pre-eclampsia.

The mechanisms underlying vasoconstriction and altered vascular reactivity in preeclampsia remain obscure. Research has focused on changes in the ratio of vasodilative and vasoconstrictive prostanoids, since there is evidence suggesting decrements and increments in the production of prostacyclin and thromboxane, respectively. More recently, investigators have postulated that the vasoconstrictive potential of pressor substances (e.g., Angiotensin II and endothelin) is magnified in preeclampsia as a consequence of a decreased activity of nitric oxide (NO) syntheses and decreased production of NO-dependent or -independent endothelium relaxing factor (EDRF). Also under investigation is the role of endothelial cells (the site of prostanoid, endothelin, and EDRF production), which, in preeclampsia, may be dysfunctional, owing perhaps to inflammatory cytokines (e.g., tumor necrosis factor α) and increased oxidative stress. Other systems postulated to play a role in pre-eclamptic hypertension are the sympathetic nervous system, calciotrophic hormones, insulin, and magnesium metabolism.

Finally, some nutritional factor deficiencies have been postulated as playing a role in the pathogenesis of preeclampsia. This chapter discusses their possible role on the hypertensive disorders of pregnancy.

Possible Role of Nutrition in the Pathophysiology of Preeclampsia

Nutrient supplements in addition to food sources of nutrients are provided to populations either to increase the intake among those with a deficiency (in order to prevent or treat functional outcomes related to such a deficit) or to obtain a pharmacological, perhaps nonnutritional effect, among individuals with an adequate intake of the nutrient in question.

Epidemiological observations have long suggested a role for nutritional deficiencies in preeclampsia (i.e., calcium, proteins, vitamins, etc.). However, intervention evaluations have failed to confirm such promising observations. We will describe here the evidence from randomized-controlled trials that support the relationship between different nutrients and preeclampsia.

Calcium

There is considerable evidence linking calcium intake and hypertension during pregnancy from observational and experimental studies. However, there is still no satisfactory explanation for the mechanisms involved in the calcium-mediated effect on blood pressure prevention. It was postulated that parathyroid hormone could be involved in this relationship. Demonstrated alterations in extracellular calcium homeostasis in preeclampsia include hypocalciuria and decrease serum levels of calcitriol. Increased parathyroid hormone (PTH) and decreased plasma ionized calcium concentration have not been consistently observed. Also, consistent abnormalities of intracellular calcium metabolism have been described in pre-eclamptic women, such as increased intracellular free calcium concentration in platelets and lymphocytes. Increases in intracellular free calcium concentration in circulating cells are hypothesized to result from fluctuation in hormones or vasoactive substances that cause similar alteration in vascular smooth muscle. Pregnancy is a state of high calcium requirements as a result of fetal demands while maternal adaptive mechanisms are partially inhibited. These phenomena lead to the hyperparathyroid state of pregnancy. An increase in parathyroid hormone serum levels would involve an increase in free intracellular calcium. Thus, the concentration of intracellular free calcium in vascular smooth muscle cells determines the degree of tension and is the trigger for muscular contraction. So, the vasoconstrictive effect, with a rise in blood pressure, results from an increase in vascular smooth muscle tension.

Antioxidant Agents

An additional role for nutrition in the genesis of preeclampsia could be nutritional factors that strengthen oxidative stress, leading to preeclampsia. A nutritional factor could be the deficiency of antioxidant intake, specifically vitamins C and E. Vitamin C is central for the neutralization of both water-soluble and lipid-soluble free radicals. As a water-soluble molecule, its ability to neutralize free radicals in the aqueous compartment is clear. Also, ascorbate is not made in humans and must come from the diet. Vitamin E, a potent antioxidant, has been suggested to play a role in preventing preeclampsia. Vitamin E is not usually reduced by dietary deficiencies, and reductions are more likely due to consumption.

Other Nutrients

Nutritional factors other than antioxidants can also contribute to oxidative stress. Hyperhomocysteinemia can be a result of dietary deficiencies. Hyperhomocysteinemia is a risk factor for preeclampsia and atherosclerosis, and endothelial function is said to be altered, at least in part, by the genesis of oxidative stress. Vitamins B_6 and B_{12} and folic acid are involved at different steps in the metabolic pathway for removing or recycling homocysteine to methionine. Dietary deficiencies of any of these micronutrients can increase circulating homocysteine. Preeclampsia is characterized by increased triglycerides that favor the formation of small, dense low-density lipoprotein (LDL). This lipoprotein variant has increased access to the subendothelial space, where it is sequestered from bloodborne antioxidants. The relevant role of triglycerides in the genesis of preeclampsia is indicated by the fact that they are increased long before clinically evident disease. Similarly, free fatty acids are increased in preeclampsia, and this increment was observed months before the diagnosis. Recent studies indicate that this effect may be secondary to altered copper binding by albumin to which large amounts of free fatty acids are bound. Unbound copper is a potent stimulator of free radical formation. Normally, this effect of copper is prevented by protein binding (quantitatively, primarily to albumin). However, with fatty acid binding, albumin binds copper differently. In this configuration, copper bound to albumin maintains its ability to participate in redox reactions. Thus, it appears that increased free fatty acids can also contribute to oxidative stress.

All of these nutritional alterations may be agreeable to dietary modification raising the possibility of nutritional prophylaxis.

Nutritional Interventions and Hypertensive Disorders of Pregnancy

Prevention

The ability to prevent hypertensive disorders of pregnancy is limited by a lack of knowledge of its underlying etiology. Prevention is focused on identifying women at higher risk of developing pregnancy-induced hypertension or preeclampsia during pregnancy, followed by close clinical and laboratory monitoring to recognize the clinical symptoms of the disease in its early stages. These women and their pregnancies can then be selected for more intensive monitoring or delivery. Although these measures do not prevent the disease, they may be helpful for preventing some adverse maternal and fetal sequelae.

As part of many other nonpharmacological interventions, some dietary interventions were proposed to prevent the development of pregnancy-induced hypertension and preeclampsia.

Nutritional advice in pregnancy Literature was reviewed in order to assess the effects of advising pregnant women to increase their energy and protein intakes on the outcome of pregnancy, and maternal and fetal/infant morbidity and mortality. Nutritional advice appears to be effective in increasing pregnant women's energy and protein intake, but the implications for fetal, infant, or maternal health cannot be judged from the available evidence. Preeclampsia prevention was assessed only in one small trial involving 136 women with no beneficial effects [relative risk (RR): 0.89, 95% confidence intervals (CI) 0.42–1.88].

Protein/energy supplementation The effect of balanced protein/energy supplements for pregnant women on gestational weight gain and pregnancy outcomes was assessed on a Cochrane systematic review. Preeclampsia prevention was evaluated in three trials involving 516 women, with no significant beneficial effects (RR: 1.20; 95% CI: 0.77–1.89). However, these trials had methodological flaws, alternate allocation, and large lost-to-follow-up for the main outcomes, so results should be taken cautiously. In another Cochrane systematic review, only one trial involving 782 women evaluated preeclampsia prevention when isocaloric balanced protein/energy supplements were given to underweight pregnant women, showing no effect (RR: 1.00; 95% CI: 0.57–1.75).

Energy/protein restriction for obese pregnant women Excessive weight gain during pregnancy

has long been recognized as a clinical sign of edema and impending preeclampsia. Epidemiological studies suggest that a high maternal weight is positively associated with the risk of preeclampsia.

Energy/protein restriction for high weight-for-height or weight gain during pregnancy was assessed in a Cochrane systematic review. Preeclampsia was evaluated in two trials (284 women) showing no reduction in the risk of occurrence (RR: 1.13; 95% CI: 0.59–2.18), and the same as for pregnancy-induced hypertension (three trials, 384 women; RR: 0.97; 95% CI: 0.75–1.26). The limited evidence available suggests that protein/energy restriction of pregnant women who are overweight or show a high weight gain is unlikely to be beneficial and may be harmful to the developing fetus. Although weight reduction may be helpful in reducing or preventing high blood pressure in nonpregnant women, it is not recommended during pregnancy, because there is no effect on preventing preeclampsia, even in obese women. Clinicians frequently ask pregnant women to restrict their food intake in an attempt to prevent preeclampsia, despite the absence of evidence that such advice is beneficial.

Salt restriction Even in an early phase of pregnancy, marked hemodynamic changes occur, including a fall in vascular resistance and blood pressure and a rise in cardiac output. To compensate for the increased intravascular capacity, the kidney retains more sodium and water. Apparently, the set point of sodium homeostasis shifts to a higher level at the expense of an expansion of extracellular volume. In nonpregnant women, a strong positive association of sodium intake with blood pressure has been established, but the relationship between sodium intake and blood pressure in human pregnancy remains obscure up to date. For decades, a low salt diet has been often recommended as treatment for edema, with the idea that restricting salt intake would treat, and also prevent, preeclampsia. Recently, this practice was questioned, and even a high sodium intake was proposed for preeclampsia treatment and prevention.

Concerns about the effect of a low sodium diet during pregnancy on maternal nutritional status led researchers to investigate whether such changes could alter other nutrient intakes. It was shown that the reduction in sodium intake also caused a significant reduction in the intake of energy, protein, carbohydrates, fat, calcium, zinc, magnesium, iron, and cholesterol. Even though women are no longer advised by many clinicians to alter their salt intake during pregnancy, this is still current practice in many other settings around the world.

A recently published Cochrane systematic review evaluates the effect of the advice about low dietary salt intake during pregnancy. The review includes two trials with data reported for 603 women. Both compared nutritional advice to restrict dietary salt with advice to continue a normal diet. Women with established preeclampsia were not enrolled, so this review provides no information about the effects of advice to restrict salt intake for the treatment of preeclampsia. No effect was found in preventing pre--eclampsia (RR: 1.11; 95% CI: 0.46–2.66) or pregnancy-induced hypertension (RR: 0.97; 95% CI: 0.49–1.94). Women's preferences were not reported, but authors presumed that a low-salt diet was not very palatable and was therefore difficult to follow.

Calcium supplementation A role for altered calcium metabolism in the pathogenesis of preeclampsia is suggested by epidemiological evidence linking low dietary levels of calcium with increased incidence of the disease. In agreement with these observations, several modifications in calcium metabolism have been observed in pre-eclamptic women and in calcium-supplemented mothers.

A Cochrane systematic review of calcium supplementation during pregnancy has been published. Authors pre-specified comparison groups taking into account women's risk of hypertensive disorders of pregnancy (low versus increased) and women's baseline dietary calcium intake (low, < 900 mg per day, versus adequate, ≥ 900 mg per day).

High blood pressure with or without proteinuria was evaluated in nine trials, involving 6604 women. Overall, there is less high blood pressure with calcium supplementation (RR 0.81; 95% CI: 0.74–0.89), but there is a variation in the magnitude of the effect across the subgroups. The effect was considerably greater in women at high risk of developing hypertension (four trials, 327 women: RR: 0.45; 95% CI: 0.31–0.66) than in those at low risk (11 trials, 6894 women: RR: 0.68; 95% CI: 0.57–0.81). Taking into account women's calcium intake, the effect was also greater in those with low baseline dietary calcium (five trials, 1582 women: RR: 0.49; 95% CI: 0.38–0.62) than in those with adequate calcium intake (four trials, 5022 women: RR: 0.90; 95% CI: 0.81–0.99).

There is a reduction in the risk of preeclampsia, evaluated on 10 trials involving 6864 women (RR: 0.70; 95% CI: 0.58–0.83). When predefined subgroups are considered, there is a significant reduction in women with low baseline dietary calcium intake (six trials, 1842 women: RR: 0.32; 95% CI: 0.21–0.49), but not in those with adequate calcium intake (four trials, 5022 women: RR: 0.86; 95% CI: 0.71–1.05).

Preeclampsia was considerably reduced in women at high risk of hypertension (four trials, 557 women: RR: 0.22; 95% CI: 0.11–0.43), and less consistently in those at low risk of hypertension (six trials, 6307 women: RR: 0.79; 95% CI: 0.65–0.94).

The results from the largest trial conducted by NIH, which studied low-risk women with adequate baseline calcium diet, and in whom all women in both groups received low-dose calcium supplementation as part of their routine antenatal care, showed no significant effect on hypertension and preeclampsia. Based on this, authorities from developed countries where adequate dietary calcium intake is common discourage the use of routine calcium supplementation during pregnancy. Evidence from this review supports the idea that calcium supplementation might benefit women at high risk of gestational hypertension and women with a low dietary calcium intake at risk of developing preeclampsia. However, further methodologically sound randomized controlled trials with adequate sample size are needed to confirm or reject this hypothesis.

Iron and folate supplementation Numerous trials involving various populations of pregnant women with normal hemoglobin levels have evaluated the effects of iron and/or folate supplementation on several outcomes, some of them including hypertensive disorders of pregnancy. A Cochrane systematic review of two trials involving 87 women with normal hemoglobin levels, in which iron and folic acid were compared with no treatment, showed no effect on the occurrence of gestational hypertension (RR: 1.15; 95% CI: 0.41–3.18). Preeclampsia was not evaluated. Another Cochrane review that included two trials involving 696 pregnant women already receiving iron, in which women were allocated to receive folic acid or no treatment/placebo, showed no effect on prevention of gestational hypertension either (RR: 1.26; 95% CI: 0.90–1.76).

Although evidence shows that iron and folate supplementation is not effective in preventing hypertensive disorders during pregnancy, they should be prescribed for other established beneficial effects on pregnancy such as prevention of anemia.

Magnesium supplementation Magnesium is one of the essential minerals needed by humans in relatively large amounts. Magnesium works with many enzymes in regulating body temperature and synthesizing proteins as well as maintaining electrical potentials in nerves and muscle membranes. Magnesium occurs widely in many foods; dairy products, breads and cereals, vegetables, and meats are all good sources. It is therefore not surprising that genuine clinical magnesium deficiency has never been reported to occur in healthy individuals who eat standard diets. However, dietary intake studies during pregnancy consistently demonstrate that many women, especially those from disadvantaged backgrounds, have intakes of magnesium below recommended levels. Observational studies based on medical records have reported that magnesium supplementation during pregnancy was associated with a reduced risk of fetal growth retardation and preeclampsia, and that magnesium intake was associated with increased birth weight. Stimulated by these encouraging epidemiological studies, randomized clinical trials have been undertaken to evaluate the potential benefits of magnesium supplementation during pregnancy on pregnancy and neonatal outcomes.

A Cochrane systematic review of these randomized-controlled trials was carried out in order to assess the effects of magnesium supplementation during normal or high-risk pregnancies on maternal, neonatal, and pediatric outcomes. Results from two trials (474 women) showed no apparent effect of magnesium treatment on prevention of preeclampsia (RR: 0.87; 95% CI: 0.57–1.32). However, these results may have been confounded by the fact that in the largest trial all women (both magnesium-supplemented and placebo groups) received a multivitamin and mineral preparation containing low doses of magnesium. Trials also have a poor methodological quality, especially related to concealment of allocation, which could give biased results. Authors conclude that dietary magnesium supplementation of pregnant women cannot be recommended for routine clinical practice because of the poor methodological quality of the current evidence.

Fish oil supplementation Studies of nonpregnant subjects suggest that fish oil, rich in long-chain *n*-3 fatty acids, has a moderate effect on blood pressure in normotensive as well as hypertensive individuals. A meta-analysis of controlled clinical trials of the effect of fish oil on blood pressure has demonstrated a significant reduction in systolic and diastolic blood pressure in untreated hypertensive nonpregnant individuals, but found no other significant effect on normotensives. Fish oil has been shown to interfere with prostaglandin metabolism, and its effect on blood pressure has often been assumed to be due to such interference. Epidemiological studies suggested that marine diets could have a preventive effect on early delivery and hypertensive disorders of pregnancy.

Fish oil supplementation during pregnancy was evaluated in a systematic review of two trials (5135 women), showing no effect on pregnancy-induced hypertension (two trials, 5135 women; RR: 0.96;

95% CI: 0.86–1.07). There was a statistically significant, but modest, reduction in the rate of preeclampsia (RR: 0.70; 95% CI: 0.55–0.90). However, this reduction is strongly influenced by a large nonrandomized trial conducted in 1942, in which vitamins and minerals were given to women in addition to fish oil. Another seven trials of fish oil supplementation involving more than 2000 women have been published recently, none of which demonstrates any differences in the incidence of hypertension and preeclampsia between groups. Based on current evidence, fish oil supplementation is not recommended during pregnancy.

Zinc supplementation Zinc is thought to play an important role in many biological functions, including protein synthesis and nucleic acid metabolism. There are controversies in the literature in demonstrating the relationship between low serum zinc levels with abnormalities on pregnancy outcomes such as pregnancy-induced hypertension, prolonged labor, post partum hemorrhage, preterm or postterm pregnancies, small-for-gestational-age babies, or poor perinatal outcomes.

The role of routine zinc supplementation during pregnancy on outcomes for both mother and newborn was assessed in a Cochrane systematic review. Routine zinc supplementation in pregnancy had no detectable effect on gestational hypertension (four trials, 1962 women; RR: 0.87; 95% CI: 0.65–1.15). However, there appears to be inconsistency between trials regarding the effects from other pregnancy outcomes. This may be related to varied population characteristics of women recruited in the various trials, as some included normal pregnant women with no systemic illness, other studies specifically selected women at high risk of low zinc status, and in one study, participants were selected on the basis of proven low plasma zinc levels. There is at present no evidence of overall benefit from routine as opposed to selective zinc supplementation in pregnancy on pregnancy-induced hypertension or preeclampsia.

Vitamin supplementation In terms of vitamins A, E, and C, an oxidant/antioxidant imbalance has been suggested among the pathogenic factors involved in preeclampsia. As vitamin E is one of the most important antioxidants in body components, its levels and their relation with circulating levels of lipids peroxides on pre-eclamptic women have been intensively studied in recent years. As with other antioxidants, several studies found decreased vitamin E levels in serum from women with gestational hypertension and preeclampsia compared with controls. However, these findings could not be demonstrated in other studies. Increased ascorbate radical formation and ascorbate depletion were also found in plasma from women with preeclampsia. Recently, a randomized-controlled trial involving 283 women at high risk of developing preeclampsia was conducted. Women were randomly assigned to vitamin E and vitamin C supplements, or placebo at 16–22 weeks of gestation. Authors found a significant reduction in the risk of developing preeclampsia in the vitamin-supplemented group compared with controls (RR: 0.46; 95% CI: 0.24–0.91). The authors concluded that supplementation with vitamins C and E may be beneficial for preventing preeclampsia in women at increased risk of the disease. However, these findings need to be evaluated further in different settings and populations, as well as in low-risk women.

The role of vitamin A in pregnancy-induced hypertension and preeclampsia is a subject of controversy. It was proposed as a chain-breaking antioxidant on free radical cascade. Some studies found significantly reduced serum vitamin A levels in pre-eclamptic and eclamptic women when compared with those found in healthy women in the third trimester. To date, no trials have been published that assess the effect of vitamin A supplementation on pregnancy-induced hypertension or preeclampsia. A double-blind, cluster randomized trial of low dose supplementation with vitamin A or β-carotene carried out in Nepal in 44 646 married women showed a 40% reduction in maternal mortality related to pregnancy in vitamin A-supplemented women. However, differences in cause of deaths, including preeclampsia/eclampsia, could not be reliably distinguished between supplemented and placebo groups. The future prospect of giving vitamin A supplements for the prophylaxis/management of pregnancy-induced hypertension and preeclampsia needs to be evaluated further before it is recommended.

Treatment

The objectives of treatment for established preeclampsia, or pregnancy-induced hypertension are to prevent eclampsia as well as other severe maternal complications. Close maternal evaluation is aimed at observing the progression of the condition, both to prevent maternal complications and to determine whether fetal well-being can be assessed. As this disorder is often completely reversible and usually begins to abate with delivery, an imbalance between the mother's condition and the chance of the fetus surviving without any significant neonatal complications *in utero* or in the nursery must be continuously evaluated. Even though the only definitive treatment of preeclampsia is delivery, several nonpharmacological approaches were proposed as part of an overall

strategy of management of the disease to achieve these goals.

Unfortunately, there is no information from randomized controlled trials related to dietary approaches on the management of the disease in its mild to moderate stage, when conservative management is decided on.

Pre-existing (Chronic) Hypertension

Mild and uncomplicated chronic hypertension during pregnancy has a better prognosis than preeclampsia. However, there is an increased risk of superimposed preeclampsia and possible complications if pre-existing renal disease or systemic illness is present. The primary aim of therapy, if necessary, is to prevent cerebrovascular complications and to avoid the progression to superimposed preeclampsia with worse prognosis. Nonpharmacological management of this condition during pregnancy remains controversial.

In a published review of management of mild-chronic hypertension during pregnancy, no trials were found that compared non-pharmacological interventions with either pharmacological agents or no intervention in pregnant women. This comprehensive search identified 50 randomized controlled trials, but they involved either normotensive women or women with a history of preeclampsia. For the management of established chronic hypertension during pregnancy, no relevant evidence could be located to assess the effects of non-pharmacological interventions, such as limiting activity, diet modifications or stress reduction.

Weight reduction during pregnancy, even in obese women, is generally not recommended to improve pregnancy outcomes. As weight reduction may be helpful in reducing blood pressure in nonpregnant women, for obese hypertensive women planning a pregnancy, weight reduction before conception is advisable. Even though obesity may be a risk factor for superimposed preeclampsia, there is no evidence that limiting weight gain during pregnancy reduces its occurrence.

Pregnant women with hypertension have a lower plasma volume than do normotensive women, and some studies suggest that the severity of hypertension correlates with the degree of plasma volume concentration. For this reason, sodium restriction is generally not recommended during pregnancy for the reduction of blood pressure. In addition, an increase in plasma volume concentration is a risk factor for intrauterine growth restriction. If, however, a pregnant woman with chronic hypertension is known to have salt-sensitive hypertension and has been treated successfully with low salt diet before pregnancy, it is reasonable to continue some sodium restriction for blood pressure control during pregnancy, but not for preventing superimposed preeclampsia.

High alcohol intake is related to hypertension in nonpregnant women but is not associated with an increased risk for gestational hypertension, preeclampsia, or eclampsia. There is no conclusive evidence of adverse effects on pregnancy outcomes, including fetal growth, at levels of consumption below 120 g of alcohol per week. However, there are suggestions that excessive consumption of alcohol can cause or aggravate maternal hypertension.

There is no reliable information from well-designed, randomized controlled trials assessing the best dietary approach for the management of pre-existing hypertension during pregnancy. Recommendations come from experts' consensus and authorities' statements. It seems that mild-to-moderate pre-existing (chronic, essential) hypertension without any risk factor should be managed in the same way as in the nonpregnant state. However, additional concerns include effects on fetal well-being (mainly intrauterine growth restriction) and worsening of hypertension, particularly as a result of superimposed pre-eclampsia.

Conclusions

In short, based on the available data from systematic reviews (presented in the Appendix), we can conclude that there is some evidence that calcium supplementation in populations with a low calcium intake and/or at risk of developing pregnancy-induced hypertension could be beneficial. Antioxidants (particularly vitamins E and C) are promising, but there is a need for adequately sized and designed randomized controlled trials to confirm these findings before any widespread recommendation. Although pregnant women living in developing countries could be exposed to several other nutrient deficiencies, no evidence precludes recommending other nutrient supplementations as part of their routine antenatal care in order to prevent the occurrence of pregnancy-induced hypertension or preeclampsia.

Appendix

The Cochrane Collaboration

The Cochrane Collaboration is an international non-for-profit organization that aims to help people make well-informed decisions about healthcare by preparing, maintaining, and promoting the accessibility of systematic reviews of the effects of healthcare interventions. The Cochrane Collaboration's work is based on principles of collaborative efforts in order to avoid duplication by good management and coordination to maximize economy of effort. A variety of approaches such as scientific rigour, insuring broad participation, and avoiding conflicts of interest are promoted to minimize bias. Published reviews are keeping up to date by a commitment to insure that Cochrane Reviews are maintained through identification and incorporation of new evidence.

Randomized Controlled Trial

This is an epidemiologic experiment in which the investigators randomly allocate eligible subjects into intervention groups, usually called 'study' and 'control' groups, to receive or not to receive one or more interventions that are being compared. The results are assessed by comparing outcomes in the treatment and control groups.

Systematic Review

A systematic review is a systematic search and critical evaluation of all primary studies answering the same question. Statistical methods may or may not be used to analyze and summarize the results of the studies included in the review. The metaanalysis involves the use of statistical techniques within a systematic review to integrate the results of the included studies. Systematic reviews are important tools that help clinicians, health providers, researchers, and policymakers to summarize the existing information in order to make evidence-based decisions.

Relative Risk (RR)

The ratio of risk in the intervention (exposed) group to the risk in the control (unexposed) group. A RR = 1 indicates no difference between comparison groups. For harmful or undesirable outcomes, a RR that is less

than 1 indicates that the intervention was effective in reducing the risk of that outcome.

Confidence Interval (CI)

This is the range within which the 'true' value is expected to lie with a given degree of certainty (e.g., 95 or 99%). Confidence intervals represent the probability of random errors.

Nutrition in Diabetic Pregnancy

A Dornhorst and G Frost, Nutrition and Dietetic Research Group, Imperial College of Science and Medicine, London, UK

Introduction

Gestational diabetes mellitus (GDM) is glucose intolerance first recognized in pregnancy. For the majority of women this is a transient deterioration in glucose tolerance which is due to the hormonal changes of pregnancy. In a minority of women the glucose intolerance continues after pregnancy and these women have either had previously unrecognized type 2 diabetes or are in the early stages of type 1 diabetes. Older, obese women of high parity are most at risk of GDM, especially when from an ethnic background with a high prevalence of type 2 diabetes.

Gestational diabetes predisposes to accelerated fetal growth which is the main contributor to the obstetric complications of GDM. Both cesarean section rates and birth trauma are increased in GDM pregnancies. The stillbirth rate is increased when GDM remains either unrecognized or untreated. Many women with GDM are obese, with a prepregnancy body mass index (BMI) $>29\,kg\,m^{-2}$; this itself is associated with an increased risk of a large-for-gestational-age (LGA) infant, operative delivery, pregnancy-induced hypertension, and thromboembolic disease. Neonatal complications of GDM include transient hypoglycemia and hypocalcemia. The long-term sequelae of GDM are future type 2 diabetes in the mother and future obesity, insulin resistance and type 2 diabetes in the child.

Dietary management of GDM can alone, or in combination with insulin, reduce maternal hyperglycemia sufficiently to improve pregnancy outcome. Providing dietary education and advice that extends beyond the pregnancy is also important and this has the potential to lessen the future risk of GDM in subsequent pregnancies as well as type 2 diabetes in the mother and her child.

Despite the recognition of the importance of dietary management for GDM, there is little consensus regarding the optimal diet to prescribe. There are too few controlled dietary studies during a GDM pregnancy with sufficient nutritional detail to provide the necessary guidelines. There are no long-term prospective studies on whether the dietary advice given during pregnancy reduces future recurrence of GDM or diabetes in either the mother or her child in later life. Different and sometimes conflicting dietary advice is advocated for the management of GDM. Debate surrounds the energy content of the diet and optimal proportions and type of carbohydrate and fat that should be prescribed. The minimum weight gain that is safe in the obese GDM woman still needs to be defined. Below we attempt to provide a rational framework on which we believe dietetic advice should be given for the management of GDM. We discuss the potential short- and long-term benefits to the mother and her child which may be gained from dietary intervention while emphasizing the need for future dietary studies.

Background: General Dietetic Principles Applicable to Pregnancy

Energy Requirements in Pregnancy

Pregnancy is an anabolic state. During pregnancy, sufficient energy sources need to be acquired to cover the products of conception, the fetal–placental unit, and the changes in maternal tissues. This last includes mammary, uterine, adipose deposits, and the expansion in blood volume. The basal metabolic rate increases by 15–26% during pregnancy to meet the metabolic demands of these newly synthesized tissues. The total energy cost for pregnancy was theoretically calculated by Hytten and Leitch in the 1960s to be 355 640 kJ (85 000 kcal), equivalent to an extra 1191.3 kJ (285 kcal) a day. Subsequent longitudinal studies during pregnancy, using the latest physiological techniques, in well-nourished nonobese women confirm these original calculations. These early calculations have formed the basis of the dietary recommendations for pregnancy. Cross-sectional and longitudinal nutritional studies during pregnancy have repeatedly shown that these energy costs are seldom met by an equivalent increase in food intake. The increase in dietary energy appears to provide only 20% of the total energy costs of pregnancy.

How any one women meets the energy needs of pregnancy is highly variable and it is this variability

and adaptability to environmental pressures that allow pregnancies to occur under adverse circumstances, such as food deprivation or the need to perform physical labor during pregnancy. These highly adaptive processes include limiting adipose deposition, reducing diet-induced thermogenesis, and limiting physical energy expenditure. Any reduction in diet-induced thermogenesis is either small or of marginal significance. It has been estimated that a 20% reduction in physical activity during pregnancy alone would save the necessary energy to complete pregnancy. Recent work, however, suggests that significant energy savings from reducing physical activity only occur in women with high physical expenditures before pregnancy and those involved in high physical work loads during pregnancy. Under conditions of extreme calorie restriction, a fall in basal metabolic rate has been observed in the first half of pregnancy.

Rigid guidelines for increasing dietary energy consumption in pregnancy in well-nourished and obese pregnant women are probably misguided. Overall, there is a poor correlation between dietary intake and gestational weight gains. In nonobese and underweight women, pregnancy outcome improves when the minimal weight gain targets are achieved. In obese mothers minimal or no weight gain in pregnancy does not appear to jeopardize the pregnancy. As most women with GDM are obese, these women should not be expected to meet their energy costs of pregnancy through increased dietary intake alone. Despite firm evidence, it is generally proposed that all obese women should have weight gains in pregnancy to account for the products of conception and significant calorie restriction should be avoided.

Postabsorptive and Postprandial Metabolism in Normal Pregnancy

The metabolic changes in pregnancy insure optimal maternal fetal fuel transfer. Glucose is the primary fetal oxidative substrate and by late pregnancy the fetus utilizes an estimated 17–26 g glucose per day. This high obligatory fetal oxidative metabolism results in an increase in maternal carbohydrate oxidation and an accompanying rise in the 24-h respiratory quotient. Glucose is preferentially diverted from the mother to the fetus by the fall in maternal insulin sensitivity. This reduction in insulin sensitivity is due to the antagonistic actions of placental hormones, many of which are also lipolytic. The rise in circulating free fatty acids in late pregnancy also contributes directly to the increase in peripheral insulin resistance. Increased maternal insulin resistance helps maximize the transfer of glucose postprandially to the fetus as glucose uptake into maternal peripheral tissues is impaired due to the insulin resistance. Postprandial glucose and insulin concentrations rise during pregnancy in well-nourished women consuming western-style diets and insulin resistance falls. By contrast, little or no rise in postprandial glucose concentrations or insulin occurs in rural populations consuming more traditional low glycemic index diets and in these women insulin resistance does not fall. This observation strongly suggests that habitual diets and lifestyles can influence maternal glucose tolerance and insulin sensitivity.

The high postprandial insulin levels associated with decreased maternal insulin sensitivity facilitate maternal fat deposition. The metabolic milieu of pregnancy is very permissive for fat accumulation and even undernourished women have a 2-kg increase in their adipose stores. In well-nourished women body fat increases by approximately 9% with 2–5 kg of tissue being accumulated by the end of pregnancy. Fatty acid oxidation falls in late pregnancy and this too will further favor adipose accumulation.

Metabolic changes in maternal fat metabolism insure a constant supply of fetal glucose in the postabsorptive state. This is achieved by a faster switchover from lipogenesis to lipolysis. Human placental lactogen and other placental hormones increase maternal lipolysis which generates ketone bodies and glycerol – two important gluconeogenic substrates that help spare maternal glucose and amino acids for the fetus. Ketone bodies, but not nonesterified acids, can cross the placenta and be used as fetal fuels. Despite lower fasting glucose values, hepatic glucose output increases in pregnancy due to the glucogneogenic nature of many of the pregnancy-related hormones and the increase in hepatic insulin resistance. This increase in hepatic glucose output under fasting conditions also helps maintain a steady supply of glucose to the fetus.

Metabolic Changes Associated with GDM

A degree of deterioration in glucose tolerance in pregnancy is characteristic of well-nourished women consuming western-style diets. However, only in a minority of women is the deterioration sufficient to warrant the diagnosis of GDM. Most women remain glucose-tolerant through their ability to treble their insulin secretion in the face of increasing insulin resistance. Women who do develop GDM have subtle abnormalities of β-cell function and, despite being able to maintain glucose tolerance outside pregnancy, are unable to when faced with the high insulin resistance levels encountered in pregnancy. A degree of β-cell dysfunction is universal in women who

develop GDM, both during and following pregnancy. By the time GDM has developed insulin resistance, both peripheral and hepatic insulin resistance are higher than for glucose-tolerant women. There appears to be a relatively greater β-cell defect in the nonobese women who develop GDM than the obese women in whom insulin resistance is a greater contributing factor. The combination of inadequate β-cell secretion and increased insulin resistance results in inadequate nonesterified free fatty acid (NEFFA) suppression postprandially in GDM. Postprandial increases in NEFFA levels would be anticipated to reduce insulin sensitivity further and compromise β-cell function.

The Principle of Dietary Management GDMs

The dietary advice given in GDM needs to lessen the metabolic abnormalities while insuring adequate nourishment for the mother and fetus. Dietary advice should prevent unnecessary weight gain in all pregnancies, especially in obese women. Dietetic advice should in addition provide general guidelines for healthy eating beyond the pregnancy.

General Dietary Recommendations for GDM

The diet should include the recommended vitamins and minerals for pregnancy and potentially harmful foods such as uncooked meats and soft cheese should be avoided. Alcohol is potentially harmful to pregnancy and should be actively discouraged in the first trimester and severely limited for the rest of pregnancy.

When diabetes predates the pregnancy, 5 mg of folate acid should be started before conception and continued throughout the period of organogenesis (12th gestational week/4th week from last menstrual period). Higher doses of folic acid than 400 μg are recommended for nondiabetic pregnancies for the prevention of neural tube defects despite any direct evidence that folate protects against glucose-mediated neural tube defects. All women with GDM diagnosed before the 12th gestational week should start 5 mg of folic acid, as should all previous GDM women in future pregnancies. A recent large nutritional analysis of over 1000 British pregnant women showed relatively low folate intakes – fewer than 10% of women were taking folate supplements in early pregnancy.

Dietary antioxidants protect diabetic rodents against the teratogenic effects of hyperglycemia. Although similar evidence is not available for human pregnancies, insuring adequate antioxidants in the diets of diabetic mothers during organogenesis seems reasonable.

Calcium and vitamin D supplements during both pregnancy and lactation should be considered for Asian Indian women and others with poor sunlight exposure and/or low calcium intakes. Recently a relationship between insulin resistance and certain vitamin D receptor polymorphism has been reported, providing a potential association between the risk of vitamin D deficiency and diabetes.

Recommended Maternal Weight Gains for Normal Pregnancies

The published guidelines on recommended maternal weight gains are based on large obstetric surveys in the USA (Table 1). The maternal weight gain required to minimize the frequency of small-for-gestational-age (SGA) infants is higher for underweight (BMI $< 19.8\,kg\,m^{-2}$) than overweight or obese women. When the prepregnancy BMI is $> 35\,kg\,m^{-2}$ with little or no maternal weight gain, there is no added risk of an SGA infant. Overweight (BMI 26.1–29 $kg\,m^{-2}$) and obese (BMI $> 29\,kg\,m^{-2}$) women are more susceptible to giving birth to an LGA infant and this risk increases further as maternal weight gain increases. The US obstetric recommendation for a 7-kg minimum weight gain for all obese women may not be universally appropriate, especially for morbidly obese women (BMI $> 35\,kg\,m^{-2}$).

The dietary management of GDM women includes the management of obese pregnant women. Unnecessary weight gain in pregnancy contributes to postpartum obesity, which will increase the likelihood of future GDM recurrence, diabetes, and other obesity-related comorbidities. The American Diabetic Association (ADA) has endorsed dietary guidelines for management of diabetes in pregnancy recommending a daily calorie allowance based on prepregnancy ideal body weight (IBW) and current pregnancy weight. These guidelines recommend 36–40 $kcal\,kg^{-1}$ when IBW < 90%, 30 $kcal\,kg^{-1}$ for IBW of 90–120% and 24 $kcal\,day^{-1}$ for IBW 121–150% and as little as 12–18 $kcal\,kg^{-1}$ during pregnancy

Table 1 The 1990 guidelines of the US Institute of Medicine on maternal weight gain targets according to prepregnancy body mass index

	Underweight ($< 19.8\,kg\,m^{-2}$)	*Normal weight* ($19.8–26\,kg\,m^{-2}$)	*Overweight* ($> 26\,kg\,m^{-2}$)
Weight gain term target	12.5–18 kg	11.5–16 kg	7.0–11.5 kg

when the prepregnancy IBW > 150% IBW. The ADA currently endorses the minimum recommended weight gain of 7.0 kg for obese (BMI > 29 kg m^{-2}) women, as published by the American College of Obstetricians and Gynecologists. No equivalent weight or daily calorie guidelines exist for the UK.

Calorie Restriction in the Obese Woman with GDM

To date there are no long-term studies on the psychological or physical development of infants whose obese mothers are mildly calorie-restricted in late pregnancies for GDM. Long-term follow-up studies are available from infants born to well-nourished Dutch women with severe calorie-restricted daily allowance of 800 kcal, in late pregnancy during the 5½-month famine of 1944–45. These infants were thinner at birth but had normal subsequent childhood development and were reported to be less obese than other recruits on entry into the army at 18 years old. However, subsequent follow-up has shown that among this cohort of children born to calorie-restricted mothers in late pregnancy, the incidence of glucose intolerance and diabetes was increased in middle age. It is these long-term studies combined with genuine concerns relating to the harmful effect of maternal ketosis, caused by calorie restriction, on fetal neurophysiological and cognitive development that have resulted in a general reluctance to advocate calorie restriction in pregnancy.

While no one recommends severe calorie restriction in pregnancy, there is probably a place for modest calorie constraint for obese women with GDM. Women with GDM are relatively more ketosis-resistant to mild calorie restriction than glucose-tolerant women; this may be attributable to their higher hepatic glucose outputs. Theoretically, modest calorie-restricted diets that are given as small frequent meals containing slowly absorbed carbohydrates will help minimize maternal ketosis as these diets are associated with attenuated insulin responses which delay lipolysis and therefore ketogenesis.

We have previously reported that in obese GDM women modest calorie restriction of 20–25 kcal kg^{-1} day^{-1} from the 24th gestational week reduces the frequency of LGA infants compared with obese glucose-tolerant women not dieted. In this study the GDM women gained only half the weight of the controls from 28 weeks to term (1.7 ± 1.6 versus 4.1 ± 3.1 kg) and this was associated with fewer LGA infants than for obese non-GDM controls. Other studies using hypocaloric diets have also shown improvements in glycemic control with mild calorie restriction in pregnancy.

On today's evidence it would seem appropriate to limit weight gain in GDM pregnancies to the bottom rather than the top for those recommended for average, overweight, and obese women, while setting no minimum weight gain for the grossly obese (> 34 kg m^{-2}). This would insure that following pregnancy there would be no overall weight gain in the overweight women and potentially allow weight loss in the morbidly obese woman.

The Optimal Amount and Type of Dietary Carbohydrate and Fat for GDM

Glucose crosses the placenta in both a concentration-dependent manner and by specific glucose transporters. The reduction of postprandial peak glucose concentrations has a greater impact on limiting accelerated fetal growth than lowering postabsorptive levels. Therefore diets that prevent excessive postprandial placental uptake of glucose should be the basis of our dietary advice to all women with GDM.

Controversy surrounds the optimal dietary proportion that should be taken as carbohydrate. Recent advice from the USA has advocated limiting the overall percentage of dietary carbohydrate to < 45%, as in short-term studies this has been shown to improve glycemic control. The current guidelines approved by the ADA suggest limiting carbohydrate to 40% of the total energy content while increasing dietary fat to 40%. Like others, we would argue that it is the type rather than the absolute amount of carbohydrate that dictates postprandial glycemia. The glycemic index of different ingested carbohydrates quantifies their different glycemic responses. Starches, fiber, and refined sugars are the main dietary carbohydrates and their rates of intestinal absorption are different. The highest postprandial glucose and insulin values occur with refined sugars, the most rapidly absorbed, while the lowest values are with the soluble fibers that have the slowest absorption rates. In pregnancy, if the carbohydrate is predominantly refined, any increase above 45% of the total dietary energy content is associated with a deterioration in glycemic control, especially if given first thing in the morning. However, 60% of the total energy content of the diet can be consumed as low glycemic index carbohydrates with no change in glucose tolerance or an actual improvement. Both during and outside pregnancy the introduction of low-glycemic-index diets has been shown to reduce insulin sensitivity. There is a degree of gastric stasis in pregnancy and this itself can further lower the glycemic index of many carbohydrates.

The basis of the dietary management of GDM is to reduce postprandial glycemia. This theoretically can

be achieved either by limiting the total amount of carbohydrate ingested or insuring that the dietary carbohydrates consumed have a low glycemic index. Reducing carbohydrates for breakfast has also been advocated by some as the postprandial glucose values tend to be highest mid-morning. However, limiting carbohydrates will result in a higher proportion of the diet consumed as fat, which is more energy-dense and is likely therefore to result in weight gain. In addition, diets that emphasize limiting the proportion of carbohydrate over fat are, we believe, sending out the wrong educational message. In practice it is often difficult to achieve compliance when greater than 50% of the energy content of the diet is given as carbohydrate. This is especially so with the low-glycemic-index carbohydrates, which produce greater satiety than refined sugars or fats.

Dietary Fat

We believe the current American recommendations, endorsed by the ADA, that 40% of the GDM diet should be derived from dietary fat, are misguided. The short-term dietary studies which demonstrated a benefit of high-fat diets on postprandial blood glucose values may, as discussed above, have been accounted for by the high glycemic index of the carbohydrates used in these studies. In addition, promoting high-fat diets in women destined to develop diabetes and therefore cardiovascular disease is highly questionable. High-fat diets have also been linked with both β-cell toxicity and increased insulin resistance. There are currently insufficient data to know if chain length and degree of saturation of fatty acids are important dietary factors in determining glucose tolerance during pregnancy.

Diet and Insulin Therapy for GDM

The aim of medical management of women with GDM is to insure maternal glycemia can be kept at a safe level. The aim of management is not to delay insulin treatment if required. The fasting and postprandial glucose levels at which insulin therapy should be introduced in addition to diet have been specified as a fasting value $> 5.5\,\mathrm{mmol\,l^{-1}}$ and 1-h postprandial value $> 7\,\mathrm{mmol\,l^{-1}}$. However, the time that dietary management should be tried before starting insulin is less well-specified. Even when very tight glycemic targets are being achieved, most women can be managed with diet alone. The women who require insulin are the most metabolically compromised and have the highest perinatal complications and the fastest deterioration postpartum for the development of diabetes. It is important to recognize these women early in pregnancy and not to lay any sense of failure or noncompliance on them or to delay the introduction of early insulin treatment. Insulin is also occasionally introduced later in pregnancy for obstetric rather than pure glycemic reasons; these would include evidence of accelerated fetal growth and unexplained polyhydramnios.

The principles of dietary management for GDM change little with the introduction of insulin. One should continue to limit weight gain in obese women while providing sufficient carbohydrate snacks throughout the day to prevent hypoglycemia.

Whenever insulin is prescribed with the intention of achieving euglycemia, the frequency of hypoglycemia increases. Although short periods of hypoglycemia are not detrimental to the fetus, it is both frightening and unpleasant for the woman. In addition, after an episode of hypoglycemia the blood glucose rises acutely, both through the action of the counterregulatory hormones and the usual subsequent consumption of a sugary drink. Frequent episodes of hypoglycemia often result in women chasing these high-rebound glucose levels by increasing their insulin dosage and this can result in further hypoglycemic attacks.

Women on insulin should have a regular intake of carbohydrate throughout the day. This needs be taken with each meal, as well as in a snack between meals and at bedtime. To avoid unnecessary calorie intake, snacks that are low in fat should be advised: fruit is ideal for this purpose. Meanwhile, low-glycemic-index carbohydrate should be advised for meals. This strategy will increase the absorption period postprandially, thereby minimizing the risk of hypoglycemia. The use of the soluble fiber supplement guar gum can be introduced if blood glucose levels cannot be controlled adequately without increasing insulin to levels that are causing hypoglycemia.

Long-Term Dietary Advice for the Mother and her Child

Women with GDM are at greatly increased risk of future diabetes. Many of these women are obese and all have at least one child at increased risk of adolescent obesity and diabetes. Given this, it is obvious that dietary advice, education, and reinforcement should continue beyond the pregnancy. Women should be made fully aware of their added risk of both future GDM pregnancies and type 2 diabetes and the importance of not gaining weight postpartum. Low-fat diets have been shown to minimize the recurrence of subsequent GDM pregnancies. Suitable healthy living advice should be given to all women following a GDM pregnancy, emphasizing the benefits of such a

diet for the whole family. Ideally, all these women would receive annual long-term dietetic input within the community. The case for continual follow-up of these women will become more apparent with the result of the ongoing diabetic prevention studies currently being carried out among high-risk groups, of which previous GDM women are included.

The Need and Feasibility of Future Dietary Studies in Pregnancy

There remains a lack of good randomized studies on the dietary management of GDM. Such studies are required for both short-term pregnancy outcomes and long-term outcomes for the mother and her child. One of the main difficulties in conducting such studies is the control arm: even when no dietary advice is given, once diagnosed with GDM women make lifestyle changes based on family beliefs of information gathered from a variety of sources. Also if the health care providers are aware of the diagnosis they too unintentionally are likely to influence lifestyle factors. The need to blind both the women and the health care staff of the diagnosis is difficult and often considered unethical, as, if ignored, GDM does carry a risk to that pregnancy.

Summary

Gestational diabetes is a common complication of pregnancy. Controlling maternal hyperglycemia with diet alone and diet and insulin can reduce the risk of inappropriate accelerated fetal growth. The prescribed diet for GDM needs to include regular meals and snacks. These should contain a large component of slowly absorbed carbohydrate. As many women with GDM are obese, the diet must not allow excessive maternal weight gain as this further compromises pregnancy outcome and adds to the mother's risk of future diabetes. Dietary advice in pregnancy should extend beyond pregnancy as a woman with GDM has a lifetime risk of future diabetes, as does her child. There remains a need for future dietary studies in the management of GDM.

PREMENSTRUAL SYNDROME: NUTRITIONAL ASPECTS

F Ford, University of Sheffield, Sheffield, UK

Background

Many women seek medical help for symptoms related to premenstrual syndrome (PMS). Physicians, dietitians, and nutritionists often recommend some form of nutrition advice, including incorporating extra vitamin B_6, vitamin B_1, vitamin E, calcium, magnesium, essential and ω-3 fatty acids, herbal remedies, carbohydrates, low-fat and vegetarian diets, and chocolate. Although much (but not all) of this advice is part of a healthful diet, there is relatively little sound scientific evidence that they relieve or prevent symptoms.

PMS is a condition characterized by a number of physical, emotional, and psychological symptoms that appear in the second half of the menstrual cycle, after ovulation. It can affect women in the reproductive age

from adolescence until the menopause. There is a list of menstrual symptoms identifying over 150 different symptoms linked to the menstrual cycle. The main symptoms reported are irritability, depression, anxiety, weight gain, edema, breast pain, fatigue, and headache. Greene and Dalton first used the term premenstrual syndrome in 1953. The first author to describe the syndrome known as premenstrual tension was Frank, in 1931. The intensity of symptoms may vary considerably between women and for each cycle. Severe cyclical symptoms cause suffering to many women in their daily activity and personal relationships.

PMS is perceived to be a common complaint, but data on prevalence vary according to different measurement scales and cultural variations. It is estimated that up to 95% of women suffer mild symptoms, and 5–10% of women have symptoms severe enough to disrupt their lives in the 2 weeks before the onset of menstruation. PMS can be defined as a regular pattern of symptoms occurring just before the start of menstruation and which gradually abate soon after the start of bleeding. Severe PMS can be defined as causing functional impairment in work, relationship, or usual activities. The social consequences of premenstrual syndrome are important and have been the focus of much research. It has been reported that PMS is responsible for a high incidence of crimes, alcoholism, school absence, and admittance to hospital for accidental injury.

The etiology of PMS is unknown, although many theories have been suggested. Factors such as estrogen levels, deficiency of progesterone and progesterone metabolites, increase of adrenal activity, subclinical hipoglucosemy, increase of prolactin and monoaminoxidases, imbalance of renin–angiotensin–aldosterone, deficiency of pyridoxine and other vitamins, and neuroendocrine dysfunction have all been cited.

The diagnosis of the PMS is essentially based on clinical symptoms. A prospective evaluation of three consecutive months that show these clinical symptoms occurring during the luteal phase of the menstrual cycles characterize PMS. However, diagnosis of the condition may be difficult, as there is no standardized diagnostic tool. Women's experiences of PMS are so varied that it is difficult to fit them into categories or even subgroups of symptoms. In the past, some doctors have regarded PMS as a psychological syndrome, so women report finding it difficult to receive satisfactory treatment and attention. This might be one of the reasons why it is a condition that women often diagnose and treat themselves.

Treatment of PMS has been largely empirical. The following dietary components have been manipulated for the treatment of PMS.

Vitamin B_6 (Pyridoxine)

Vitamin B_6 is involved in the production of prostaglandin E2 (which contributes to myometrial relaxation) and in the utilization of magnesium, so higher levels of vitamin B_6 could also influence dysmenorrhea cramps. Vitamin B_6 has been used in the doses of 50–500 mg daily in the second half of the menstrual cycle. It has been suggested that vitamin B_6 may act by correcting a deficiency at the hypothalamic end of the complex psycho-endocrine reproductive pathways. Pyridoxal 5′ phosphate, the active form of vitamin B_6, serves as the coenzyme of a wide variety of enzymes of amino acid metabolism. For example, it serves as a cofactor in the metabolism of tryptophan (the precursor of serotonin) and also in the metabolism of tyrosine (leading to dopamine and noradrenaline) and glutamate (leading to γ-aminobutyric acid). Low levels of dopamine and serotonin lead to high levels of prolactin and aldosterone, thus explaining the fluid retention, and the effect on the neurotransmitters could explain the psychological symptoms in PMS.

In recent years, a systematic review on the efficacy of vitamin B_6 in the treatment of PMS concluded that:

- Randomized placebo controlled studies of vitamin B_6 treatment for PMS were of insufficient quality to draw definitive conclusions.
- Limited evidence exists to suggest that 100 mg of vitamin B_6 daily (and possibly 50 mg) is likely to be beneficial in the management of PMS.
- Vitamin B_6 was significantly better than placebo in relieving overall premenstrual symptoms and in relieving depression associated with PMS, but the response was not dose-dependent.
- No conclusive evidence was found of neurological side-effects with these doses.
- A randomized controlled trial of sufficient power and quality is needed to compare vitamin B_6 with placebo to establish definitive recommendations for treatment.

A systematic review published in the Cochrane Database concluded that no definite results could be reported regarding the efficacy of vitamin B_6 in improving dysmenorrhea.

Calcium

Previous reports have suggested that disturbances in calcium regulation may underlie the pathophysiologic characteristics of PMS and that calcium supplementation may be an effective therapeutic approach. In one study, each participant received 6 months of treatment, involving 3 months of daily calcium supplementation

(1000 mg of calcium carbonate) and 3 months of placebo. Three premenstrual factors (negative affect ($p = 0.05$); water retention ($p = 0.005$); pain ($p = 0.05$)) and one menstrual factor (pain ($p = 0.05$)) were significantly alleviated by calcium.

Another study evaluated the effect of 1200 mg of elemental calcium on the luteal and menstrual phases of the menstrual cycle in 497 women with PMS, in a prospective, randomized, double-blind, placebo-controlled, multicenter clinical trial. During the luteal phase of the treatment cycle, a significantly lower mean symptom complex score was observed in the calcium-treated group for both the second ($p = 0.005$) and third ($p < 0.001$) treatment cycles. By the third treatment cycle, calcium effectively resulted in an overall 48% reduction in total symptom scores from baseline compared with a 30% reduction in placebo. All four-symptom factors were significantly reduced by the third treatment cycle.

Magnesium

Results from a recent metaanalysis have suggested that magnesium supplements of 500 mg per day may be a promising treatment for one of the major symptoms of PMS, i.e., dysmenorrhea. Magnesium treatment has been shown to be more effective than placebo, with those taking magnesium requiring significantly less absence from work and less use of additional medication. Minimal adverse effects have been experienced in both magnesium and placebo groups with no significant differences shown. However, overall, there has been little conclusive evidence for the effectiveness of magnesium for symptom relief. Although all the trials have been randomized and double blind with adequate methodological quality, they were all small trials, and there was poor measurement and reporting of pain outcomes. Two of the included trials had withdrawal rates of over 30%. Many of these participants may have failed to complete the trial due to a lack of efficacy or adverse effects from the treatments, and so the high withdrawal rates have an impact on the strength of the evidence. It is also unclear which treatment regimen was more effective, as the trials both administered treatment in quite different ways, one daily and the other during menses only, and at different doses. Therefore, no strong recommendation can be made about the efficacy of magnesium until a further evaluation is carried out. A randomized controlled trial of magnesium with a larger number of participants and adequate outcome measurement is needed.

The largest of the included trials also reported data on the levels of prostaglandin F2 α in menstrual blood. Overproduction of this prostaglandin has been shown to be a substantial contributing factor to the painful cramps associated with dysmenorrhea. Women taking the magnesium therapy had substantially lower levels of PGF2 α in their menstrual blood than those on placebo ($p < 0.05$), which mirrored the therapeutic decrease in pain experienced by the participants. This highlights the possible biological rationale behind magnesium therapy for dysmenorrhea; it inhibits the biosynthesis of PGF2 α as well as having a role in muscle relaxation and vasodilation.

Vitamin B_6 and Magnesium

Magnesium was shown to be no different in pain outcomes from both vitamin B_6 and a combination of vitamin B_6 and magnesium by one small trial. The same trial also showed that a combination of magnesium and vitamin B_6 was no different from placebo in reducing pain. However, vitamin B_6 alone was more effective at reducing pain than both placebo and a combination of magnesium and vitamin B_6. In a recent systematic review, no definite conclusions could be made about the efficacy of the combination of vitamin B_6 and magnesium supplements.

Vitamin B_1 (Thiamin)

Vitamin B_1 plays an important role in metabolism, and vitamin B_1 deficiency can be characterized by fatigue, muscle cramps, various pains, and a reduced tolerance to pain, all factors that could be associated with dysmenorrhea and PMS. Vitamin B_1 was shown to be an effective treatment for dysmenorrhea, taken at 100 mg daily, although this conclusion is tempered slightly because it is based on only one large randomized controlled trial (RCT). This RCT trial demonstrated a significant effect of vitamin B_1 taken daily compared with placebo in reducing pain. Results from phase one of the trial only, before participants were crossed over to the other treatment group, were used when calculating odds ratios. After crossover, those swapped from vitamin B_1 treatment to placebo maintained pain relief. The authors of the trial interpreted this as a curative effect of vitamin B_1 treatment. The length of the trial (2 months of either treatment) makes this interpretation difficult to confirm, as no longer-term follow-up was made, and the strong placebo effect that is typical in dysmenorrhea trials could account for some of the maintenance of effect. Vitamin B_1 needs to be assessed further by a randomized trial, preferably a large multicentered trial with different study populations that would generate generalizable

results that could confirm the positive results of the above trial.

Vitamin E

It has been suggested that vitamin E has analgesic and antiinflammatory properties. A randomized trial of vitamin E for rheumatoid arthritis has shown a significant reduction in pain parameters, which lends further support to this theory. One trial comparing a combination of 100 mg per day of vitamin E and ibuprofen with ibuprofen alone on dysmenorrhea showed no significant difference between the two groups for the outcome of pain relief after 1 month of treatment. Both treatment groups experienced excellent treatment responsiveness, although this conclusion is based on a comparison of baseline scores with post-treatment scores, which is more subject to bias than if a placebo control group had been used. Overall, the addition of vitamin E supplements to the diet has no further effect on pain over that of standard treatment with ibuprofen. The treatment time of 1 month of each treatment was a limitation of the trial, as the efficacy of a dietary therapy cannot really be assessed adequately over such a short period of time.

Essential Fatty Acids

Findings from uncontrolled studies have indicated that essential fatty acid (EFA) metabolism may be abnormal in women with PMS. EFAs are the precursors of prostaglandins. Low levels of prostaglandins are thought to lead to increased sensitivity to prolactin. Women with PMS may be abnormally sensitive to normal amounts of prolactin. This hypothesis – that there is a deficiency in EFAs, leading to low levels of prostaglandin E1 that may attenuate the effects of prolactin – is one rationale for using EFAs as a treatment for women with PMS.

Evening primrose oil (EPO) contains two EFAs – linoleic acid and γ-linolenic acid (GLA). Linolenic acid is needed for the synthesis of prostaglandin E, and GLA is needed for the synthesis of prostaglandin E1. Whilst EPO is generally accepted as a safe product, reported side-effects include occasional nausea, indigestion, and headache. A small number of less common side-effects have also been documented. A potential risk of inflammation, thrombosis, and immunosuppression with prolonged use of GLA has been described.

EPO is available in most countries without a prescription and is heavily promoted for women as being an effective treatment for a range of conditions including PMS. It is, however, an expensive treatment that many women have to pay for themselves. In a systematic literature search of clinical trials of EPO for the treatment of PMS with a view to performing a meta-analysis, only seven placebo-controlled trials have been found, and randomization was clearly indicated in only five trials. Inconsistent scoring and response criteria made statistical pooling and hence a rigorous metaanalysis inappropriate. The two most well-controlled studies failed to show any beneficial effects for EPO, although, because the trials were relatively small, modest effects cannot be excluded. From the current evidence, EPO is of little value in the management of PMS.

ω-3 Fatty Acids

One trial has compared ω-3 fatty acids (fish oil) and placebo, and data have shown that the treatment is significantly more effective than placebo after 2 months' administration. A meta-analysis has examined the outcome of the use of additional medication and showed that the fish oil treatment group consumed significantly fewer tablets than the placebo group. Minimal adverse effects were significantly more likely in the fish oil group compared with the placebo group. None of the adverse effects were particularly serious (nausea, acne exacerbation, and difficulty swallowing capsules), but they were acute enough to cause some women to discontinue treatment. One methodological limitation of this trial is the poor reporting of data. Pain relief was reported, as the average of the two groups after the treatments allocated was crossed-over, and so it is not an adequate assessment of efficacy. The trial was of short duration, only 2 months in each treatment arm, which may not be enough time to properly assess the effect of a dietary intervention.

Levels of polyunsaturated fatty acids (PUFAs) have been correlated with menstrual pain, with higher levels of the ω-3 fatty acids associated with milder menstrual symptoms. The PUFA ω-6 is metabolized into the specific prostaglandins associated with dysmenorrhea, and it appears that the ratio of ω-3 to ω-6 is associated with menstrual symptoms, therefore a diet higher in ω-3 fatty acids is possibly associated with less dysmenorrhea.

Herbal Remedies

It is advisable that women consult a qualified medical practitioner who specializes in complementary medicine before taking unproven herbal remedies. There is a Practitioner Directory, which lists a selection of the best doctors and practitioners who specialize in treatment using complementary medicine.

Japanese Herbal Combination (Toki-Shakuyaku-San)

The combination herbal remedy Toki-shakuyaku-san (TSS) has been compared with placebo in one trial. Pain was assessed using a visual analog scale (VAS). TSS was significantly more effective in reducing VAS scores, after 2 months of treatment. This difference was maintained after a 2-month untreated followup period. The use of additional medication in the treatment group was significantly less than in the placebo group. One major limitation of this trial was that participants were included in the trial using a particular traditional Chinese medicine diagnosis of a complex set of symptoms as well as the typical diagnosis of PMS. It is not clear how this would translate into Western therapeutics, or if this remedy would help women without this particular pattern of diagnosis.

Agnus Castus

Agnus Castus has been reported to be a hormone regulator and tonic for the nervous system, being used for PMS to treat mood swings, depression, water retention, and breast pain. The efficacy and tolerability of agnus castus fruit (*Vitex agnus castus* L extract Ze 440) with placebo has been investigated in women with PMS in a prospective, randomized, placebo controlled study. The main efficacy variable was a change from baseline to end point (end of the third cycle) in women's self-assessment of irritability, mood alteration, anger, headache, breast fullness, and other menstrual symptoms including bloating. Results have shown a significant improvement in the active group compared with the placebo group ($p < 0.001$). Some women have reported mild adverse events, none of which caused discontinuation of treatment. It has been concluded that a dry extract of agnus castus fruit is an effective and well-tolerated treatment for the relief of symptoms of PMS.

Hypericum perforatum

A pilot observational study has been carried out to investigate whether *Hypericum perforatum* could relieve the symptoms of PMS in a small group of women. Participants took hypericum tablets for two complete menstrual cycles (1×300 mg of hypericum extract per day standardized to 900 μg of hypericin). The degree of improvement in overall PMS scores between baseline and the end of the trial was 51%, with over two-thirds of the sample demonstrating at least a 50% decrease in symptom severity. The results of this pilot study suggest that there is scope for conducting a RCT to investigate the value of hypericum as a treatment for PMS.

St John's Wort

St John's Wort has been reported to raise serotonin levels, which helps to alleviate the mild to moderate depression associated with PMS. It should not be taken with prescription antidepressants, progesterone, or other hormone treatments.

Dong Quai – (*Angelica sinensis*) or Chinese Angelica

Dong Quai (*Angelica sinensis*), or Chinese Angelica, is sometimes known as 'women's ginseng' and is used for PMS.

Natural Progesterone

Natural progesterone is sometimes prescribed where low progesterone levels are indicated in PMS. Overall, there is insufficient evidence to recommend the use of any herbal remedies apart from *Agnus castus* for the treatment of PMS. The Complete German Commission E Monographs list a number of herbal products as being used for dysmenorrhea or menstrual disorders, yet no evidence from clinical trials to support the use of any of these herbal products has been found to date.

Chocolate

Chocolate's ingredients satisfy many aspects of PMS. Its high sugar content induces the brain to make new serotonin and make the chocolate eater feel calm and relaxed. Moreover, chocolate is usually eaten by itself rather than as part of a meal. Thus, there is little chance that protein foods will interfere with the body's ability to make new serotonin. The high butterfat content of chocolate may also change premenstrual mood. High-fat foods can have a numbing effect on mood and on mental and physical energy, and the combination of the fat and sugar content of the chocolate is reported to soothe and tranquilize women. However, chocolate has other ingredients – like phenylethylamine – that are also claimed to have positive mood effects. There are no reliable studies proving this, but anecdotal evidence supports the view that chocolate may have some ingredients that women with PMS crave.

Carbohydrates

The effect of a carbohydrate-rich beverage on mood, appetite, and cognitive function was investigated in a small group of women with PMS. Twenty-four women with confirmed PMS took a beverage or placebo for three menstrual cycles after a 1-month

placebo run-in period, in a double-blind placebo-controlled study. Patients were tested for mood, cognition, and food cravings, using an interactive computer-telephone system, during the luteal phase of the menstrual cycle. The beverage, but not the placebos, significantly decreased self-reported depression, anger, confusion, and carbohydrate craving, and improved memory word recognition.

Isoflavones (Plant Estrogens)

These are often derived from soya and are suggested as a natural hormone replacement for postmenopausal women. However, many are also advocating their use for PMS. There is little evidence for a beneficial effect on PMS, and in fact supplementing with soya protein and other sources of plant estrogens is now controversial, many experts believing that they can also have a harmful effect. They should certainly not be taken if a woman has had breast cancer or a family history of the disease.

L-Tryptophan

Serotonin reuptake inhibitors have been shown to be beneficial in the treatment of PMS. The efficacy of L-tryptophan, which acts specifically on serotonergic neurons, was investigated in a RCT. Results suggested a significant ($p = 0.005$) therapeutic effect of L-tryptophan relative to placebo for the cluster of mood symptoms comprising the items of dysphoria, mood swings, tension, and irritability. These results suggest that increasing serotonin synthesis during the late luteal phase of the menstrual cycle has a beneficial effect in patients with PMS.

Low-fat Vegetarian Diets

A low-fat vegetarian diet has been associated with increased serum sex-hormone binding globulin concentration and reductions in body weight, dysmenorrhea duration and intensity, and PMS duration. The symptom effects might be mediated by dietary influences on estrogen activity.

The UK PMS society states, 'a healthy diet, particularly one which is low in fat and high in fibre can relieve PMS,' and they recommend the following:

- Eating three main meals per day with three smaller snacks in between, all of which should contain starchy foods. This is particularly important in the luteal phase of the cycle.
- Cutting down on sugar and sugary food, as these provide sudden bursts of energy rather than a steady release, which will help combat fatigue and mood swings.
- Eating fiber helps avoid premenstrual constipation, but it is important to drink plenty of water or sugar-free drinks (six to eight glasses a day) to prevent bloating associated with PMS.
- Having one pint of milk a day of either skimmed or semi-skimmed, or an alternative source of calcium such as low-fat cheese or yogurt,
- Reducing salt intake.
- Eating five portions of fruit and vegetables per day.
- Reducing alcohol intake to no more than 2 units per day (1 unit = half a pint (284 ml) of lager or beer, or one small glass of wine, or one measure of spirits).
- Limiting tea and/or coffee to no more thtrun an 5 cups per day, as excess caffeine can make premenstrual symptoms worse.

PRESERVATION OF FOOD

M F Sancho-Madriz, California State Polytechnic University, Pomona, CA, USA

Introduction

Food preservation consists of the application of science-based knowledge through a variety of available technologies and procedures, to prevent deterioration and spoilage of food products and extend their shelf-life, while assuring consumers a product free of pathogenic microorganisms. Shelf-life may be defined as the time it takes a product to decline to an unacceptable level. Deterioration of foods will result in loss of quality attributes, including flavor, texture, color, and other sensory properties. Nutritional quality is also affected during food deterioration. Physical, biological, microbiological, chemical, and biochemical factors may cause food deterioration. Preservation methods should be applied as early as possible in the food production pipeline and therefore include appropriate postharvest handling before processing of both plant and animal foods (Figure 1). Processing techniques usually rely on appropriate packaging methods and materials to assure continuity of preservation. Handling of processed foods during storage, transportation, retail, and by the consumer also influences the preservation of processed foods.

Selection of technology and procedures for food preservation depends on factors inherent to the product, common pathogenic and spoilage microorganisms, and cost. Product-inherent factors include customary ways of consuming the particular food, sensitivity to heat or other principle used to inactivate microorganisms, and other physical and chemical characteristics of the food.

Rationale and Goals of Food Preservation

Many food products are seasonal, and from year to year the yields of agricultural production vary depending on weather, pests, and other factors. During the production season, especially when the yields are high, the offer of fresh products often exceeds the demand. The products that are not consumed in the fresh market can be used in processed form for long periods of time and by people in regions located far from the production areas. Processed foods not only reduce the waste of food but also offer the consumer many convenient features that make preparation at home easier and faster. Food preservation plays an important role in special circumstances like wars or space missions far from earth. In the nineteenth and twentieth centuries many new developments in food preservation occurred during war times, in both industry and government-owned laboratories. More recently, the development of foods suitable for space missions that spend a significant amount of time away from earth has posed new challenges to food scientists.

If the food production system is pictured as a long pipeline that carries food from producers to consumers, one will discover a number of leaks in the pipeline that prevent large amounts of food reaching their final destination. Those leaks or losses represent different forms of food deterioration and spoilage, and are likely to happen from the beginning of food production (Figure 2).

Food preservation aims to prevent and reduce the loss of food in the production system and extend its shelf-life. While developed nations have been very successful in reducing food losses and increasing efficiency of the production system, food deterioration remains an important issue in developing nations and very poor countries where undernutrition of the population is common. In many instances the food problems of those countries could be significantly reduced by the implementation of adequate postharvest handling and food preservation methods without increasing food production. (*See* **Food Security.**)

Appropriate postharvest handling of food products is essential in food preservation, especially for products sold in the fresh market or as minimally processed items. Exposure to sunlight and heat, high

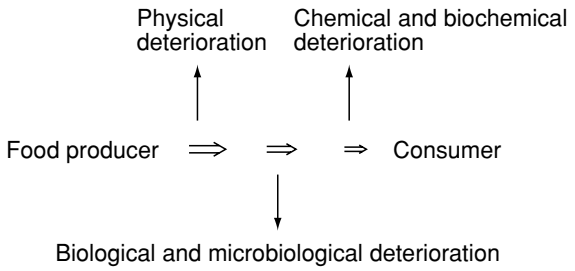

Figure 1 Losses in the food production pipeline.

Food preservation = Adequate postharvest handling
+ food-processing technology + packaging technology
+ adequate transport and storage

Figure 2 Main components of food preservation.

relative humidity, rain, dirt, insects, and rodents increases food deterioration by accelerating chemical reactions in the food and favoring microbial growth. Fast cooling of produce after harvest, storage under temperature- and humidity-controlled conditions, protection of the products by physical barriers, and minimizing the time between harvest and processing are all forms of reducing postharvest losses.

Factors that Cause Deterioration and Spoilage of Food

The factors that cause food deterioration may be grouped under physical, biological and microbiological, and chemical and biochemical factors. Most of the time more than one factor is responsible for the spoilage of a food product and some factors may favor or enhance the effect of others. Light and other forms of radiation, heat, cold, moisture loss, or gain, and the application of force that may alter the structure of the food are examples of physical factors that cause food deterioration. Chemical and biochemical factors include reactions of food components with oxygen or with each other, and reactions catalyzed by enzymatic activity. Maillard browning is caused by a chemical reaction between proteins and carbohydrates and it results in changes in color, flavor, and odor of the food product. This type of browning is desirable in baked products and roasted coffee amongst others, but it is detrimental in foods where browning is not desired. Oxidative rancidity is a chemical change in unsaturated fats and oils and it produces off-flavors and odors. These and other chemical reactions affect sensory qualities of food and can significantly alter the nutritional value of products. (*See* **Browning**: Enzymatic – Biochemical Aspects; **Oxidation of Food Components**; **Spoilage**: Chemical and Enzymatic Spoilage.)

Biological factors include birds, rodents, insects, and parasites. (*See* **Insect Pests**: Insects and Related Pests; Problems Caused by Insects and Mites.) These may consume or destroy the food and contaminate it with pathogenic or spoilage microorganisms. Bacteria, yeasts, and molds are different types of microorganisms that may cause food deterioration and foodborne illness. (*See* **Aflatoxins**; **Microbiology**: Classification of Microorganisms; **Mycotoxins**: Classifications; Occurrence and Determination; Toxicology; **Spoilage**: Bacterial Spoilage; Fungi in Food – An Overview; Molds in Spoilage; Yeasts in Spoilage.) Some viruses may also be transmitted through food but they are not associated with the deterioration of products. Not all microorganisms are detrimental to food; some are indeed very useful and have been utilized since ancient times for the production of fermented products like wine, yogurt, and cheese. Fermented cassava and corn are typical in some African and Latin American countries. (*See* **Fermented Foods**: Origins and Applications; Dietary Importance.)

Because consumers assume that processed foods are safe, the goals of food preservation must include not only measures for the prevention of quality deterioration, but also destruction of pathogenic microorganisms that may cause foodborne illness. A food product that does not show evidence of deterioration may not necessarily be free of pathogenic microorganisms. (*See* **Food Poisoning**: Classification; **Food Safety**.) A preventive strategy for assuring safe food products is the Hazard Analysis Critical Control Point (HACCP) system. HACCP considers biological, physical, and chemical hazards. (*See* **Hazard Analysis Critical Control Point**.)

Factors that Affect Microbial Growth

In addition to the common nutrients found in most foods, microorganisms require certain conditions to survive and grow. The control and optimization of those factors is a fundamental principle of food preservation. The main factors are discussed below.

pH The degree of alkalinity or acidity of a water solution is based on the concentration of hydrogen ($H+$) or hydroxyl ($OH-$) ions. The term pH is by definition the negative logarithm of the hydrogen ion concentration. The pH scale ranges from 0 to 14, and pure water has a pH of 7. Each microorganism will grow only within an optimum pH range. (*See* **pH – Principles and Measurement**.)

Water activity Water activity is a measure of the availability of water in a food product. Solutes dissolved in water bind the water molecules and make them not available for microorganisms to use. Water activity may be defined as the ratio of the vapor pressure of water in food to the vapor pressure of pure water at the same temperature. Microorganisms require a minimum level of water activity in order to grow and thus water activity reduction can be used to control microbial growth. (*See* **Water Activity**: Principles and Measurement; Effect on Food Stability.)

Oxygen Microorganisms that require the presence of free oxygen for their growth are known as aerobes, whereas oxygen inhibits the growth of anaerobes. When they can tolerate the presence of oxygen to a certain level they are known as facultative anaerobes.

Temperature An optimum temperature range is required for microbial growth. Bacteria have been classified into groups depending on their required

temperature range. The temperature range for psychrotrophs is 14–20 °C, for mesophiles is 30–37 °C, and for thermophiles is 50–66 °C. Some thermophiles can grow at temperatures up to 77 °C.

Traditional Methods of Food Preservation

The following section provides a brief description of traditional food preservation methods currently used by the food-processing industry. For more details on each method see the indicated articles within this encyclopedia or the suggested publications for further reading. (*See* **Traditional Food Technology.**)

Acidification

The use of acid to preserve foods, whether by fermentation of the product or by addition of acid foods or acids, is a very common method to preserve foods that does not require a high level of technology or special processing equipment. The acid acts as a preservative by controlling microbial growth and pH meters are used to determine if the food has reached the target pH level. (*See* **Acids**: Properties and Determination; Natural Acids and Acidulants; **pH – Principles and Measurement.**) Acidified foods, sometimes called pickled foods (*see* **Pickling**), have been defined by the US Food and Drug Administration (FDA) as low-acid foods to which acid(s) or acid food(s) is (are) added to produce a product that has a finished equilibrium pH of 4.6 or less and a water activity greater than 0.85. The pH value under 4.6 is necessary to prevent the growth of *Clostridium botulinum*; however, an additional preservation method such as pasteurization, refrigeration, or chemical preservatives is used to destroy or control the growth of deterioration microorganisms. (*See* ***Clostridium***: Botulism.) Foods have different degrees of buffering capacity against acids and therefore different foods require different amounts of acid to reach a desired pH level; the higher the buffering capacity, the higher the amount of acid needed to acidify the product. Other changes in fermented foods such as metabolites produced by some microorganisms also have an effect on microbial inactivation. (*See* **Beers**: History and Types; **Cheeses**: Types of Cheese; **Fermented Foods**: Origins and Applications; **Fermented Milks**: Dietary Importance; **Wines**: Types of Table Wine; **Yogurt**: The Product and its Manufacture.)

Thermal Processing

The development of canning as a preservation method for foods can be traced back to Nicolas Appert (1749–1841), a French chef who published his procedures in 1810. Appert was awarded 12 000 francs for his proposal for preserving foods by heating them in hermetically sealed containers. Not only did Appert not have scientific training but also microorganisms were not known at the time he developed his method, long before Louis Pasteur laid the foundations for the science of bacteriology.

The degree of microorganism destruction achieved by thermal processing varies, depending on the specific temperature and time of the thermal treatment. Thermal process design is based on a target microorganism and desired number of logarithmic reductions in microorganism concentration. Blanching, pasteurization, commercial sterilization, and sterilization are different kinds of thermal processing. Blanching is a mild heat treatment utilized mostly for enzyme inactivation but it also serves other functions. Although it reduces the number of containing microorganisms on the surface of foods, it is not intended as a sole preservation method. Pasteurization involves heating the product under atmospheric pressure without exceeding the boiling point of water (100 °C). Milk and other low-acid foods (pH > 4.6) are pasteurized to eliminate pathogenic microorganisms and extend their shelf-life in combination with refrigeration or other preservation methods. In acid or acidified foods pasteurization is used to destroy spoilage microorganisms and sometimes to inactivate enzymes.

The US FDA defined commercial sterility of thermally processed food as the condition that renders the food free of microorganisms capable of reproducing under normal nonrefrigerated conditions of storage and distribution, and viable microorganisms (including spores) of public health significance. According to the FDA definition, commercial sterility may be achieved by the application of heat alone or combined with water activity control. (*See* **Canning**: Principles; **Heat Treatment**: Ultrahigh Temperature (UHT) Treatments; **Pasteurization**: Principles; Pasteurization of Liquid Products; Pasteurization of Viscous and Particulate Products.)

Concentration by Evaporation

Concentration by evaporation consists of partially removing water from liquid foods by the application of heat. Native Americans used natural evaporation in wooden or bark vessels to manufacture maple syrup using sap. Water removal causes a reduction in water activity. The rate of heat transfer into the food and the rate of mass transfer of vapor from the food are the factors that determine the rate of evaporation. This method of food preservation has a high level of energy consumption and is therefore more expensive. It offers the convenience of a concentrated product that the consumer can dilute at home and it

reduces the cost of transportation and packaging. For example, a can of concentrated orange juice weighs less than the single-strength juice and it requires a smaller package. Destruction of heat-sensitive vitamins and loss of aroma are important issues in evaporation; however, the addition of vitamins and the use of aroma-recovery systems reduce the effect of those factors. (*See* **Evaporation**: Basic Principles; Uses in the Food Industry.)

Dehydration

In drying or dehydration, water is removed from the food by hot air or heated surface driers. Examples of the former include cabinet, tunnel, conveyor, and fluidized bed driers, and the latter include drum and vacuum shelf driers. As water in the surface evaporates it is replaced by water from inside the food by several mass transfer mechanisms, resulting in a reduction of the water content and water activity of the product. In addition to preserving the food, dehydration reduces the weight and bulk of the food, lowering transportation and packaging costs. Despite added convenience, dehydration also has a significant effect on the sensory properties of food. Some dehydrated products such as prunes or raisins are consumed in dehydrated form or used as ingredients in recipes; however, other dehydrated products such as dry milk or vegetables in a soup mix are reconstituted with water before consumption. (*See* **Drying**: Drying Using Natural Radiation; Fluidized-bed Drying; Spray Drying; Dielectric and Osmotic Drying; Hygiene.)

Freeze-drying or lyophilization is a method that accomplishes dehydration of the food by sublimating the water. When water sublimates it goes directly from a solid to a gas without passing through the liquid phase. Freeze-dried foods exhibit superior sensory and nutritive qualities when compared with products dehydrated by other methods. This method can be used to dehydrate high-value solid and liquid foods such as shrimp, strawberries, coffee, and juices, and it is also used by the pharmaceutical industry. (*See* **Freeze-drying**: The Basic Process.)

Refrigeration or Chilled Storage

Chilled storage in refrigerated chambers at temperatures above freezing is a widely used food preservation method. Refrigeration temperatures usually range from 0 to 7 °C in commercial and household refrigerators. The low temperatures lower the rate of metabolic reactions in unprocessed fruits and vegetables and other chemical reactions in foods. Microbial growth is usually slowed at refrigeration temperatures because metabolic reactions of microorganisms are enzyme-catalyzed and their rate depends on temperature. Refrigeration will preserve perishable foods for days or weeks, depending on the food. This method of preservation has very mild effects on sensory and nutritive attributes of products; however, it does not prevent food deterioration in the same degree and for as long as freezing or most other preservation methods. Refrigerated foods require low storage temperatures during transportation, retail, and home storage and their use is limited in rural areas of developing nations. (*See* **Chilled Storage**: Principles; Attainment of Chilled Conditions; Quality and Economic Considerations; Microbiological Considerations.)

Freezing

Foods were frozen in ancient times using ice and snow. Frozen storage cabinets were developed in the nineteenth century. Nowadays, food is frozen using several types of industrial mechanical refrigerators through cooled surfaces, and cooled liquid or air. Cryogenic freezing uses liquid nitrogen or carbon dioxide in solid or liquid form in direct contact with the food. Frozen food storage requires temperatures that maintain the food in frozen condition, usually −18 °C or less, and will preserve foods for months or years if properly packaged. A proportion of the water in the food is frozen and the concentration of solutes in unfrozen water increases, lowering the water activity. Freezing usually stops microbial growth but it does not destroy bacteria and molds. The parasite *Trichinella spiralis* and fish parasites are killed during frozen storage. Freezing temperatures significantly reduce the rate of chemical reactions in foods. Freezing has a low effect on nutritive quality of the food but sensory qualities, especially texture, may be affected by the formation of ice crystals. Fish and seafood, meats, fruits, and vegetables have been sold in frozen form for a long time. Baked goods and other prepared foods have become popular for their convenience, especially because of the use of microwave ovens in households. (*See* **Freezing**: Principles.)

Salting, Sugaring, and Curing

The addition of large amounts of salt or sugar to food is an old method of food preservation. Fish preservation by salting was used in Mesopotamia, Egypt, China, and the Mediterranean basin since ancient times. Meat was also preserved in old Mesopotamia by the addition of salt. Salt has also been used to preserve butter, cheese, and milk curds. Jams and preserves are the most common products preserved by adding sugar. When salt or sugar is added water moves from inside the cells to the outside solutes by osmosis, causing a partial dehydration of the cell, known as plasmolysis, that interferes with microorganism multiplication.

Both salting and sugaring have a significant effect in lowering water activity in food.

Curing is a method to preserve meats that also changes the flavor, color, and tenderness of the product. With more effective preservation methods available, the main purpose of curing is to produce characteristic products with unique flavor and to preserve the red color of meat after cooking. The main ingredients for curing or picking meat are sodium chloride, sodium nitrate and/or sodium nitrite, sugar, and spices. Sodium nitrate and nitrite have been linked with the formation of nitrosamines, compounds shown to be carcinogenic in animal studies. Nitrates and nitrites are naturally present in some vegetables and other foods and therefore cured meats may not be the main source of these compounds in human diets. (*See* **Curing**; **Jams and Preserves**: Methods of Manufacture; Chemistry of Manufacture.)

Smoking

Smoking is an old method of food preservation and it continues to be used today for fish and meats. The smoke is obtained by burning hickory or a similar wood and it contains formaldehyde and phenolic compounds that have antimicrobial properties. The heat also dries the food, increasing preservation. Smoking of foods is currently used more for its unique flavor properties than for its preservative action.

Chemical Preservatives

A number of chemical substances are used to inhibit the growth of microorganisms in foods. Sodium benzoate, sodium and calcium propionate, sorbic acid, ethyl formate, and sulfur dioxide are examples of commercially used food preservatives. Preservatives must undergo a review process that includes data on toxicological aspects prior to their approval. The allowed amount of a preservative in a product varies depending on the substance and the food. The pH level is also an important consideration as preservatives have an optimum pH range for their antimicrobial activity. Antioxidants prevent oxidative rancidity of fats and oils. Examples of commonly used antioxidants are butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), tertiary butylated hydroquinone (TBHQ), and propyl gallate. Ascorbic acid (vitamin C) and tocopherols (vitamin E) are also used as antioxidants. (*See* **Antioxidants**: Natural Antioxidants; Synthetic Antioxidants; Synthetic Antioxidants, Characterization and Analysis; Role of Antioxidant Nutrients in Defense Systems; **Preservatives**: Classifications and Properties; Food Uses.)

Increased interest in natural antimicrobials has been noted in recent years due to toxicological concerns about synthetic preservatives and market trends that show increased popularity of foods with no artificial substances. Several naturally occurring substances have been identified and studied for their antimicrobial properties.

Role of Packaging in the Preservation of Foods

Adequate food packaging is essential and it must be used in combination with all food preservation methods. Packaging must protect the processed food against chemical attack, physical damage and contamination with microorganisms, insects, and rodents. Hermetic packaging refers to containers that are completely sealed against the ingress of vapors and gases and therefore also resistant to bacteria, yeasts, molds, and dust. Glass and metal cans are the most common hermetic containers. Nonhermetic containers may allow gas exchange but should provide protection against microbial contamination. Other packaging materials are plastics, paper, paperboard, and combinations of more than one material by lamination. Combinations are also achieved by simultaneous extrusion of two or more layers of different polymers to form a single film. Packaging must also be nontoxic, act as a barrier to moisture loss or gain, protect against oxygen and odor absorption, protect the food against ultraviolet light, be tamper-resistant or tamper-evident, and be compatible with the food. Food packages have other important functions in marketing the product and educating consumers on product use and handling. Food packages often carry the date of manufacturing or an expiration date, and some include a code that allows companies to trace the product in case of a recall. Expiration dates inform the consumer of the approximate shelf-life of the product. Shelf-life depends on the type of food, the processing method, packaging, and storage conditions. (*See* **Packaging**: Packaging of Liquids; Packaging of Solids.)

Active packaging is an innovative concept that has received a lot of attention in recent years. Active packaging may be defined as a type of packaging that changes the condition of the packaging to extend the shelf-life or improve safety or sensory properties while maintaining the quality of the food. Major active packaging techniques involve the absorption of oxygen, ethylene, moisture, odors, or carbon dioxide; they may also involve the release of antimicrobial agents, carbon dioxide, antioxidants, and flavors.

Controlled- or Modified-Atmosphere Storage and Packaging

Modification of the gas composition in storage rooms or inside the food packaging reduces the rate of respiration of fresh fruits and vegetables and also inhibits microbial and insect growth. Lowering respiration rates reduces biochemical and enzymatic activities that promote ripening and senescence. Gas modifications include oxygen reduction and increase in carbon monoxide or nitrogen. This method may also be combined with chilled storage, resulting in extended shelf-life and high quality of the products. (*See* **Chilled Storage**: Use of Modified-atmosphere Packaging; Packaging Under Vacuum.)

Aseptic Packaging

Aseptic processing and packaging is a sophisticated food preservation method where the food is sterilized or commercially sterilized outside the container and then placed in previously sterilized containers and sealed in an aseptic environment. Aseptic systems use ultrahigh-temperature (UHT) sterilization, a fast heating treatment at temperatures higher than pasteurization temperatures. Paper and plastic packaging materials are sterilized, formed, filled, and sealed in a continuous operation at the end of the processing line. Aseptic packaging is also used with metal cans, large plastic or metal drums, or large flexible pouches. Packages for aseptic processing may be sterilized using heat, chemicals, irradiation, or a combination of these methods.

Nontraditional or Alternative Methods of Food Preservation

Several alternative methods for food preservation are currently used or considered for future use. Some methods have been approved by regulatory angencies only for certain products and after a review of available scientific information on kinetics of microbial inactivation, toxicological aspects, and the effects of the treatment on the food products. The US FDA has identified several research needs applicable to alternative technologies. The following are brief descriptions of alternative food-processing methods evaluated by the FDA.

Irradiation

Irradiation is a preservation method where food is exposed to radiation. Irradiated food does not become radioactive. Machine or radionuclide radiation sources are used. Machine sources include electron acelerators and X-ray generators, and radionuclide sources include radioactive materials that give off ionizing gamma-rays. Bacteria, molds, yeasts, and insects are inactivated by irradiation. In 1963 the US FDA first approved irradiation for use on wheat and wheat flour. FDA requires that foods that have been irradiated bear both a logo and a statement that the food has been irradiated. The safety of irradiated foods has been studied extensively. (*See* **Irradiation of Foods**: Basic Principles.)

Microwave and Radiofrequency Processing

Electromagnetic waves of certain frequencies generate heat in foods by dielectric and ionic mechanisms. Microwave and radiofrequency heating have the advantage that they require less time than conventional heating, particularly for solid and semisolid foods. Industrial microwave pasteurization has been used for at least 30 years, but not radiofrequency processing systems. Food does not heat uniformly during microwave processing, and this remains an important issue when considering this technology. Several methods have been used to improve the uniformity of heating but equipment design can significantly influence processing parameters and establishing general conclusions has proved difficult.

Ohmic and Inductive Heating

In ohmic heating electric currents are passed through the food in order to heat it. This technology is also known as Joule heating, electrical resistance heating, electroheating, and electroconductive heating. Inductive heating is a process that induces electric currents within the food by the use of oscillating electromagnetic fields generated by electric coils. Microbial death kinetics data have been published for ohmic heating but not for inductive heating. The main advantage of ohmic heating is its ability to heat materials in a fast and uniform fashion, including products with particulates. Potential future uses of ohmic heating are in dehydration, evaporation, blanching, and extraction.

High-Pressure Processing (HPP)

HPP is also known as high hydrostatic pressure (HHP) or ultrahigh pressure (UHP) processing. During HPP, liquid or solid foods are subject to pressures between 100 and 800 MPa, at temperatures below 0 °C to above 100 °C and for times ranging from a millisecond pulse to more than 20 min. Temperatures ranging from 45 to 50 °C during treatment appear to increase the inactivation of pathogens and spoilage microorganisms. Temperatures in the range of 90–100 °C, together with pressures from 500 to 700 MPa, have been used to inactivate spore-forming bacteria. The effect of HPP works instantaneously

and uniformly throughout the mass of food, independent of size, shape, and food composition. The temperature of the food increases by approximately 3 °C per 100 MPa of applied pressure. Water activity and pH are critical product factors in microbial inactivation by HPP. Process factors that affect HPP include pressure, time at pressure, time to achieve treatment pressure, decompression time, treatment temperature, product initial temperature, vessel temperature distribution at pressure, packaging material integrity, and concurrent processing aids.

Pulsed Electric Fields (PEF)

This method involves the application of pulses of high voltage (20–80 $kV\,cm^{-1}$) to foods placed between two electrodes. Most PEF systems are at the laboratory phase with not many commercial systems in use. Application of PEF is restricted to foods that can withstand high electric fields, have low electrical conductivity, and do not contain or form bubbles. Although various theories have been proposed to explain the microbial inactivation by PEF, the most studied are electrical breakdown and electroporation. Process factors that affect microbial destruction by PEF include electric field intensity, pulse width, treatment time, and temperature.

Ultraviolet (UV) Light

This type of processing involves the application of radiation from the UV region of the electromagnetic spectrum. Microbial inactivation occurs by DNA mutations upon absorption of the UV light and exposure must be at least 400 $J\,m^{-2}$ in all parts of the product. Critical factors during UV light processing include the transmissivity of the product, the radiation path length, the geometric configuration of the reactor and the power, the wavelength, and physical arrangement of the UV source(s). UV light is used for bottled-water processing and for sanitizing food contact surfaces. There has been an increased interest in using UV light as a preservation method for fruit juices to replace pasteurization and other thermal treatments that have more impact on sensory attributes. (*See* **Ultraviolet Light**.)

Other Alternative Technologies

High-voltage arc discharge, pulsed light technology, oscillating magnetic fields (OMF), ultrasound, and pulsed X-rays are other types of technology that have been explored for their potential to inactivate microorganisms and may show promise for use in food preservation; however, more extensive research is needed at this time.

PRESERVATIVES

Contents

Classifications and Properties

B L Wedzicha, University of Leeds, Leeds, UK

Background

Preservatives are substances added to food to inhibit microbial spoilage. Chemical food spoilage by enzymatic and nonenzymatic mechanisms may be controlled by specific additives, e.g., antioxidants and antibrowning agents, which are described in the relevant articles. Substances such as common salt, sugar, vinegar, or spices, which are effective antimicrobial agents under appropriate conditions, are not regarded as food preservatives. Reactions of food preservatives, which are not part of the chemistry of food preservation but nevertheless affect food quality, will also be considered. The chemical reactions that lead to cured meat color and flavor are reviewed elsewhere.

Need for Preservatives

The use of preservatives to extend the life of foods and improve their safety has been recognized for thousands of years. Traditional methods of preserving foods have relied on fumigation by sulfur dioxide, curing with brines containing nitrites and nitrates, and smoking, in which phenolic antimicrobial agents are added to the food. These processes not only ensure that stored food is of acceptable microbiological quality but also frequently provide it with unique organoleptic characteristics.

Food preservatives ensure the safety and organoleptic quality of food when sold in the type of marketing environment now found in the developed countries. A particular problem associated with multiuse packs of food, e.g., beverages and spreads, is that an initially sterile, pasteurized or hygienically assembled, food becomes infected with bacteria, fungi, and yeasts, and begins to spoil. The instability might arise because the food has been formulated in such a way that it has little or no natural protection against microorganisms. For example, a low-fat spread contains significantly larger water droplets than butter and can, therefore, support microbial growth more readily. A preservative is particularly useful in such a product. A relatively short increase in storage life can be of significant economic and practical advantage. This is well illustrated with advantages gained by extending the shelf-life of bread by a few days.

Food preservatives are often used in conjunction with other methods of food preservation, e.g., some preservatives allow a milder thermal treatment to be applied for the preservation of food with consequent improvement in textural and nutritional properties.

Structures of Food Preservatives

Substances commonly used to preserve foods are listed in Table 1. These represent a wide range of molecular structures and tendency to form ions. The carboxylic acids sorbic, benzoic, formic, acetic, lactic,

Table 1 Substances recognized as suitable for use as food preservatives

Sorbic acid and Na^+, K^+, Ca^{2+} salts	E200–E203
Benzoic acid and Na^+, K^+, Ca^{2+} salts	E210–E213
Ethyl, methyl, and propyl *p*-hydroxybenzoate and Na^+ salts	E214–E219
Sulfur dioxide, Na^+ and Ca^{2+} sulfites and hydrogen sulfites (bisulfites), Na^+ and K^+ disulfites (metabisulfites or pyrosulfites)	E220–E227

Propionic acid and Na^+, K^+, Ca^{2+} salts	E280–E283
Hydrogen peroxide	
Nisin	

Those that are approved for use within the EC have their E-number shown alongside. The presence of any substance in this list does not imply that its use is permitted throughout the world. Biphenyl, orthophenylphenol, and thiabendazole are used for surface treatment.

and propionic are monobasic. Aqueous solutions of sulfur dioxide are commonly referred to as sulfurous acid, despite the fact that H_2SO_3 does not exist in measurable amounts. It is established that SO_2 does not interact significantly with water molecules, and the term 'molecular SO_2' is more appropriate. Aqueous solutions of SO_2 behave as solutions of a dibasic acid. The hydrogen sulfite ion is also in equilibrium with the disulfite ion. Significant amounts of disulphite ion are formed in concentrated systems. When sodium or potassium disulfite is used as a food preservative, the salt is hydrolyzed to the hydrogen sulfite ion.

The nitrites are salts of nitrous acid, which is also the source of the nitrosating species, N_2O_3, and oxides of nitrogen, particularly NO.

Regardless of the chemical form of a preservative when it is added to food, its ionic state is determined largely by the pH of the food and the pK_a of the acid. The pK_a values of those preservatives that have an acid group capable of ionizing within, or close to, the pH range of foods are given in Table 2. The fraction, x, of an acid that remains undissociated at a given pH may be found using

$$x = (10^{(\mathrm{pH}-\mathrm{p}K_a)} + 1)^{-1}.$$

Since significant changes in x occur in the range (pK_a − 2) to (pK_a + 2), the proportions of ionized and unionized forms of the acids listed in Table 2 change substantially over the pH range of foods. However, the hydroxybenzoate esters do not ionize significantly in the pH range of foods and are, therefore, uncharged.

An essential feature of food preservatives is that their molecules should have an appropriate balance of lipophilic and hydrophilic behavior, so as to be capable of traversing relatively nonpolar membranes and yet be sufficiently soluble in the aqueous environment of the microorganisms. This applies to the undissociated carboxylic acids, which will consequently tend to *partition* between the aqueous and oil phase of food. The ionized acids are relatively insoluble in nonaquous environments. A partition coefficient, P, is defined by

$$P = C_{\mathrm{oil}}/C_{\mathrm{aq}},$$

where c refers to the concentration of undissociated acid in each phase. Values of P vary from 0.17 and 2.5 for propionic and sorbic acids, respectively, to 26 and 88 for the ethyl and propyl esters of *p*-hydroxybenzoic acid. The latter two preservatives therefore show a marked bias for the oil phase. Numerous surfactants exist in solution as micellar structures, which are also found in the lipid bilayers of cell membranes. The interior of such structures is markedly hydrophobic, and carboxylic acids are able to partition into micelles. When expressed in the same way as the oil–water partition coefficient, but using mole fractions instead of concentrations, values of the micellar partition coefficients for benzoic and sorbic acids are in the range 1000–2000. The presence of an oil phase and/or surfactants in solution can significantly reduce the availability of food preservatives.

Table 2 pK_a values of commonly used food preservatives

Sorbic acid	4.76
Benzoic acid	4.18
Sulfur dioxide	1.86
Formic acid	3.75
Nitrous acid	3.40
Acetic acid	4.76
Lactic acid	3.08
Propionic acid	4.88

Mechanism of Antimicrobial Action

Carboxylic Acids and Esters

The antimicrobial action of a food preservative depends on the concentrations of both the ionized and unionized forms, and the specific efficacy of each. In general, the undissociated acid is the better antimicrobial agent, but the presence of the ionized form cannot be neglected, particularly when, at high pH, its concentration may be much larger than that of the undissociated acid. The minimum concentration of an undissociated acid required to inhibit microorganisms is generally one to two orders of magnitude smaller than that of the corresponding anion.

There is no general theory to explain the mechanisms whereby these carboxylic acid and ester preservatives exert their effect. Transport of these preservatives across cell membranes is passive, but accumulation in the cell causes a reduction in the protonmotive force through the membrane and a reduction in pH within the cell. These contribute to the cessation of cell growth or cell death. Certain preservatives could also exert specific effects on metabolic enzymes. Sorbic acid is alleged to react with the sulfhydryl groups of fumarase in catalase-positive bacteria, molds and yeasts, and aspartate, succinic, and yeast alcohol dehydrogenase. It is suggested that this might apply to sulfhydryl-containing enzymes in general. Benzoate inhibits enzymes in oxidative phosphorylation and at various stages in the tricarboxylic acid cycle.

Microorganisms are able to metabolize some food preservatives when present at sublethal concentrations. A significant example is the conversion of

sorbic acid to hexadienol by certain strains of lactic acid bacteria. This product can react with ethanol to form 1-ethoxy-2,4-hexadiene and 2-ethoxy-3,5-hexadiene, which give rise to a geranium-type odor, occasionally detected in wines treated with the preservative.

Sulfur Dioxide and Sulfites

Molecular sulfur dioxide passes into yeast cells by passive transport and possibly into some other microbial cells by active transport. As with carboxylic acids, it interferes with membrane transport processes. However, sulfites are much more chemically reactive than any of the carboxylic acids referred to above. Thus, the sulfite ion acts as a powerful nucleophile causing the cleavage of disulfide bonds of proteins; it reacts with coenzymes (NAD^+), cofactors, and prosthetic groups (flavin, thiamin, heme, folic acid, and pyridoxal). Consequently, a broad range of metabolic enzymes are inactivated, and structural proteins that contain disulfide bonds may be denatured. Prior to the death of yeast cells treated with sulfite, there is a rapid decrease in ATP content. This has been attributed to the inactivation of glyceraldehyde-3-phosphate dehydrogenase by sulfite species. The additive also reacts with carbonyl constituents of the metabolic pool, to form hydroxysulfonates. When treated with sublethal concentrations of sulfite, yeasts tend to excrete increased amounts of acetaldehyde. This is due to the trapping of this metabolic intermediate as the particularly stable hydroxysulfonate, thereby preventing its conversion to ethanol. Glycerol is formed instead of ethanol by reduction of glyceraldehyde-3-phosphate to glycerol-3-phosphate, which is subsequently dephosphorylated.

Nitrite Ion

Nitrite ion is believed to exert its action on the phosphoroclastic system of enzymes, which causes the conversion of pyruvate to acetate and is a source of ATP. Evidence for this involvement comes from the fact that in the presence of nitrite, the ATP concentration in the cell rapidly decreases, and pyruvate is excreted. Nitrite ion is in equilibrium with nonionic forms, including NO. This is a good ligand for iron, and the mechanism of inhibition is likely to be the reaction of NO with the nonheme iron-containing pyruvate:ferredoxin. In aerobic bacteria, the heme iron of cytochrome oxidase is also a likely target for NO. Inhibition of enzymes with sulfhydryl groups as a result of the formation of *S*-nitroso products is also possible at relatively high nitrite concentrations.

When nitrite-containing bacteriological media are heated, they become more inhibitory towards *Clostridium botulinum* than media that have been heated prior to the addition of the preservative. This so-called Perigo effect can be modeled using mixtures of cysteine, nitrite, and iron(II) salts. When heated, such mixtures give rise to iron–sulfur-bridged complexes, of which Roussin's black salt is a well-known example. These compounds have been shown to be effective inhibitors of clostridial spores.

Nisin

Nisin is a polypeptide (molecular weight 3500) that usually exists as a dimer. It is produced by *Lactococcus lactis* and may be formed naturally in cheese. The polypeptide chain contains L-amino acids and the unusual sulfur-amino acids lanthionine and β-methyl-lanthionine. A specific enzyme, nisinase, has been widely reported, and its formation is possibly one reason why many lactic acid bacteria inactivate nisin. The peptide is also susceptible to α-chymotrypsin but not to pepsin, trypsin, and carboxypeptidase A, among other proteolytic enzymes.

Chemical Reactivity of Preservatives towards Food Components

Chemical reactions between food preservatives and components of microbial cells, or with food components where there are implications with regard to antimicrobial action, have been described above. However, some food preservatives, and particularly sorbic acid, sulfur dioxide, sulfites, and nitrite ions are capable of more extensive reactivity with food components. This may lead to the formation of reaction products of toxicological importance and a reduction in the concentration of available preservative.

Sulfur Dioxide and Sulfites

It is well known that the concentration of sulfite species in a food decreases with time, and the shelf-life may be limited by this reactivity. The conversion of sulfite to sulfate through autoxidation is catalyzed by transition metal ions and involves the formation of oxidizing free radicals. There is evidence to suggest that the facile autoxidation of ascorbic acid, which is less easily controlled by antioxidants, may promote the oxidation of sulfite in foods containing the vitamin. The free-radical intermediates ($^{\bullet}OH$, $^{\bullet}O_2^-$) in sulfite autoxidation are known for their ability to cause the oxidation of unsaturated organic compounds in the absence of suitable antioxidants. Free-radical sulfonation of unsaturated organic compounds by $^{\bullet}SO_3^-$ is also possible. An important nucleophilic reaction of the sulfite ion is its addition

to the α,β-unsaturated carbonyl moiety of 3,4-dideoxyosulos-3-enes formed as reactive intermediates in Maillard and ascorbic acid browning. This reaction can cause a considerable depletion of the additive in foods susceptible to these forms of nonenzymatic browning.

Nitrite

The reaction of secondary amines with nitrosating species derived from nitrite to give *N*-nitroso compounds is very well known and has been given much publicity on account of the possible carcinogenicity of the products. The reaction proceeds at a maximum rate in the pH range 2.25–3.4 and is catalyzed by weakly acid anions, notably thiocyanate. In meat products, the reaction is most probably associated with the adipose tissue, and it is suggested that nonionic amine and the nitrosating species N_2O_3 partition into the nonaqueous phase where a facile reaction takes place. A similar explanation has been suggested for the catalytic effect of surfactants and cell membranes on nitrosation, but in this instance, the reaction takes place within the micellar environment. *C*-Nitrosation of phenolic components of food, particularly in smoked products, leads to the formation of nitrosophenols, which can readily oxidize to the corresponding nitro compounds. The *C*-nitrosation of activated methylene groups is also established; suitable reactants in food include the 3-deoxyosuloses formed as intermediates in Maillard and ascorbic acid browning reactions, when the product is an oxime. *S*-Nitroso compounds are readily formed by the nitrosation of thiols and represent a reversibly bound form of the preservative.

Chemical Interactions between Preservatives

Sulfite species, nitrite, and sorbic acid are chemically incompatible. Sulfite ion reacts readily with nitrite ion to form the imidodisulfonate ion. The mechanism of the reaction between sorbic acid and sulfite species depends on whether or not oxygen is present. Under aerobic conditions, a sulfite-mediated oxidation of sorbic acid takes place. Under anaerobic conditions, a much slower nucleophilic addition of sulfite ion gives 5-sulfo-3-hexenoic acid. Mixtures of sorbic acid and nitrite ion give rise to ethylnitrolic acid and 1,4-dinitro-2-methylpyrrole, both of which give a positive result in the Ames mutagenicity test.

Food Uses

B L Wedzicha, University of Leeds, Leeds, UK

Factors Affecting Choice

General Considerations

The type of preservative applicable to a particular need is determined by the composition of the food, the type of microbial spoilage that takes place, and the desired shelf-life. Important compositional variables include pH, since the efficacy of a given preservative generally decreases with increase in pH. The maximum pH at which a preservative is useful is often quoted. Some components of food can also potentiate the action of preservatives, e.g., chelating substances such as ethylenediaminetetraacetic acid or critic acid can render preservatives more effective and at the same time protect the food from other forms of spoilage. Salt is a common food component that acts synergistically with several food preservatives. Ideally, the use of preservatives should be regarded within a 'preservative systems' approach to include interactions, rather than in terms of individual substances. This concept is extended to include other methods of food preservation, e.g., the use of thermal processes in conjunction with chemical preservatives, to optimize the use of each. Such effects of food components and processing on antimicrobial activity also make theoretical predictions of the efficacy of a given preservative unreliable, and the levels of application are usually decided upon empirically.

Preservatives are also chosen for their specific physical properties such as solubility in particular foods and ease of handling. Calcium sorbate, for instance, is sparingly soluble in water (1.2 g per 100 g water) and is suitable for the surface treatment of foods such as cheeses as it does not quickly dissolve in surface moisture or migrate into the cheese. Chemical stability is important with regard to the handling of sulfites; the disulfites (metabisulfites) tend to be the most stable sulfite species towards autoxidation and dissolve in water to give solutions with pH values in the middle of the pH range of foods.

Cost may be an important consideration; sulfites are the cheapest to use, whilst sorbic acid, sorbates and the *p*-hydroxybenzoate esters are the most expensive.

Spectrum of Antimicrobial Action

In general, benzoic acid, its salts and esters of *p*-hydroxybenzoic acid have the broadest spectrum of antimicrobial activity and are useful against many spoilage bacteria, fungi, and yeasts. Benzoic acid cannot, however, be relied upon to preserve foods against bacteria effectively because, whilst food poisoning and spore-forming bacteria are inhibited at normal levels of use in low pH foods, many spoilage bacteria are more resistant. Benzoic acid is most suitable for foods at pH 2.5–4, whilst the esters of *p*-hydroxybenzoic acid may be effective to pH 7 or higher. However, the latter tend to be less effective against bacteria and particularly Gram-negative organisms. Thus, in relatively acidic products where yeasts and molds are the greater causes of spoilage, benzoic acid and its salts offer an effective means of preservation.

Sorbic acid and its salts are useful additives against yeasts and molds but are less effective against bacteria. They provide antimicrobial activity up to pH 6.5 and are good preservatives for foods with a high fat content and pH, e.g., low-fat spreads, processed cheeses; the *p*-hydroxybenzoate esters tend to be too soluble in the nonaqueous component of such foods, whilst benzoate is relatively ineffective at the higher pH values.

Sulfur dioxide and sulfites also represent broad-spectrum antimicrobial agents in acidic foods, particularly beverages. In general, this preservative is more effective against bacteria than molds and yeasts, but Gram-positive bacteria are less susceptible than Gram-negative bacteria. The effect against yeasts is greatest around pH 3.5 and falls off markedly as the pH is raised above this value. There is a tendency for desirable fermentation yeasts to show a greater resistance to this preservative than undesirable 'wild yeasts' and lactic acid bacteria. This is exploited in the use of sulfites during wine-making. Despite the relatively high pH associated with meat products such as the British sausage (often pH 6–6.5), sulfites tend to inhibit enterobacteriaceae, and particularly salmonellae, in this environment. In some situations, sulfites are added also to inhibit chemical spoilage, notably enzymic browning caused by oxidation of *o*-diphenols, other forms of oxidative spoilage, and nonenzymatic browning of reducing sugars and ascorbic acid.

Propionic acid and its salts are effective against molds despite the fact that some species of *Penicillium* can grow on media containing as much as 5% propionic acid. Yeasts and most bacteria are generally less affected. However, a specific target for propionic acid is the rope-forming *Bacillus subtilis* in bread, which is effectively controlled at pH 6. The preservation of a wide range of foods with vinegar (acetic acid) has been known since ancient times; acetic acid is more effective against yeast and bacteria than molds. Its effect on bacteria is, however, predominantly due to the associated reduction in pH. *Acetobacter* and some lactic acid bacteria are unaffected by this preservative. Lactic acid is similarly a preservative associated with traditionally prepared and particularly fermented foods. As with acetic acid, its antimicrobial action is mainly due to a reduction of pH to below that at which bacteria can grow. It does, however, inhibit spore-forming bacteria at pH 5.0 but is ineffective against yeasts and molds.

The most important effect of nitrite ion in food is its inhibition of *Clostridium botulinum* in cured meat products. Whilst it also has an inhibitory effect towards a wide range of different species of bacteria, some, particularly *Salmonella*, lactobacilli, and *Clostridium* perfringens, tend to be more resistant. Nitrite and nitrate are essential for the development of cured meat color and flavor.

Thiabendazole, orthophenylphenol, and biphenyl inhibit fungi and are suitable only for surface application.

Specific Applications

Beverages

Nonalcoholic beverages, including fruit juices, are usually preserved with benzoic acid and its salts, esters of *p*-hydroxybenzoic acid, sorbic acid and its salts, or the sulfites. Typical concentrations of benzoic acid required are in the range of 500–1000 mg kg^{-1}. In the event that these levels lead to a noticeable taste, benzoic acid is replaced wholly or partly by mixtures of methyl and propyl esters of *p*-hydroxybenzoic acid (usually 2:1, methyl:propyl) at a combined

concentration of 300–500 mg kg^{-1}, or sorbic acid and its salts at 200–1000 mg kg^{-1}. Whilst sulfites are effective antimicrobial agents in beverages at concentrations of 50–500 mg of SO_2 per kilogram, they tend to undergo significant oxidation when beverage containers are repeatedly opened and air admitted. A combination of sulfite with another preservative, e.g., sorbic or benzoic acid, is frequently used for fruit juices such that the sulfite acts to control forms of chemical spoilage, and lactic and acetic acid fermentation, whilst the second preservative acts as a longer-lasting agent against yeasts and molds. A significant disadvantage of adding sulfites to beverages colored with anthocyanins is that these are decolorized, even at low concentrations of preservative, and additional sulfite-stable food-color agents are required. Fruit juice concentrates used for the manufacture of normal-strength juice may contain any of the preservatives used in the final beverage. In practice, it is not feasible to add sufficiently high concentrations of the carboxylic acid or ester preservatives to the concentrate to provide an acceptable level of additive in the finished product. In general, such concentrates need to be protected against browning, which demands high levels (e.g., 2.5–10 g of SO_2 per kilogram) of sulfite; this also acts as a preservative. In any case, the concentration of preservative in the finished product is a result of further addition after dilution and blending.

Sulfites are the major preservatives for alcoholic beverages. Their most important function is the control of the so-called wild yeasts in grape juice, and after fermentation, the preservative is required at levels of 50–150 mg of SO_2 to inhibit further microbial action. A specific problem associated with the use of sulfites to preserve wine, cider, and perry is that fruit that has been affected by molds may contain significant amounts of acetaldehyde, pyruvic acid, α-ketoglutaric acid, and other aldehydes and ketones, which are able to bind the preservative reversibly as hydroxysulfonate adducts. When present in this form, sulfite is unable to act as a preservative; however, the concentration of hydroxysulfonates is included in the analytical concentration of the preservative in the beverage. When grapes affected by *Botrytis* are used for wine-making, as much as 80% of the total preservative can be found as hydroxysulfonate adducts. During fermentation in the presence of sulfites, yeasts form sulfite-binding compounds and particularly acetaldehyde. Sorbic acid is also a good preservative for wine, and despite its chemical reactivity towards sulfite, mixtures of the two are advocated; in such a situation, sorbic acid serves to prevent further fermentation, whilst the sulfite protects against chemical and bacterial spoilage. However, depletion of sulfite through chemical reactions could result in malolactic bacteria metabolizing sorbic acid to intermediates, which ultimately lead to off-flavors. In general, potassium sorbate is the preferred salt on account of its higher solubility than that of the sodium salt. In some wines, however, potassium tartrate may precipitate, in which case, the sodium salt is used.

Fruit Products

Sulfur dioxide is an effective fumigant in the control of postharvest decay of grapes caused by the fungus *Botrytis cinerea*. Raspberries may be similarly treated for *Botrytis* and *Cladosporium*. Another unique application of sulfite is for the storage, as pulp, of soft fruit to be used for jam manufacture. A typical 'sulfite liquor' would contain up to 3000 mg of SO_2 per kilogram of solution and is capable of preserving fruit for up to 2 years with a high retention of ascorbic acid. Whilst the anthocyanins are bleached in this process, the color of the fruit reappears as the preservative is 'lost' during jam-making. An endopolygalacturonase enzyme from *Rhizopus sexualis* is not inactivated by sulfite and can cause the breakdown of strawberries in pulp. Jam and related products, e.g., fruit purees and pie fillings, may be successfully preserved with benzoic acid (1000 mg kg^{-1}), *p*-hydroxybenzoate ester (methyl:propyl ester, 3:1; 700 mg kg^{-1}), sorbic acid (800–1500 mg kg^{-1}), and sulfite (100 mg of SO_2 per kilogram in jam).

Dried fruits are frequently prepared with the aid of sulfite as an antibrowning agent. In such products the concentration of additive may be as high as 2500 mg of SO_2 per kilogram, and this will also effectively preserve the product. When a relatively moist unsulfited product is desired, a preservative is necessary, and a potassium sorbate dip or spray to give 200–500 mg of sorbic acid per kilogram, or similar application of sodium benzoate at 1000 mg of benzoic acid per kilogram is effective.

Vegetable Products

One of the most common traditional methods of preserving vegetables is by pickling with vinegar, acetic acid contributing to the reduction of pH, a specific antimicrobial effect and a characteristic taste. Typically, raw vegetables are immersed in 0.5–3% acetic acid solution, but some yeasts and molds are still capable of causing long-term spoilage. The combined use of acetic acid with benzoic acid, *p*-hydroxybenzoate ester mixtures (methyl:propyl, 2:1) or sorbic acid (all up to 1000 mg kg^{-1}) allows lower acetic acid concentrations and safeguards against spoilage. In sweet relishes, sorbic acid is more effective than benzoic acid on account of the relatively

high pH. The selective control of yeasts, molds, and putrefactive bacteria is the reason why sorbic acid is useful at levels of 500–2000 mg kg^{-1} in vegetable fermentations, where it allows the growth of the desired lactic acid-producing organisms.

Fresh vegetables are generally dipped in sulfite solutions to prevent enzymatic browning, though this also protects against microbial spoilage. It is feasible to preserve vegetarian burger-type products with sulfite. However, dehydrated vegetables are microbiologically stable but require sulfite as an anti-browning agent for the dehydration process and subsequent storage, at a final level of some 2500 mg of SO_2 per kilogram of dried product.

Baked Products

Propionic acid is widely used in the making of bread and cakes to inhibit surface mold and *Bacillus subtilis*, which causes rope. The sodium salt is used chiefly in confectionery products, whilst the calcium salt is used for bread. Levels of propionic acid up to 3000 mg kg^{-1} may be found in such applications. Sorbic acid is also an effective preservative for cereal products, at concentrations similar to those of propionic acid, and inhibits the mold *Trichosporon* found in rye bread and cakes. Unfortunately, sorbic acid also inhibits yeast. A potential solution could be to use sorboyl palmitate, which has no antimicrobial activity but degrades on heating, liberating sorbic acid. Mixtures of esters of *p*-hydroxybenzoic acid (methyl:propyl, 3:1) at 300–600 mg kg^{-1} are useful preservatives for cakes (particularly fruit cakes) but inhibit yeasts and cannot be used in bread. Some components of flour confectionery, e.g., icing, fillings, and marzipan, can be preserved with benzoic acid, esters of *p*-hydroxybenzoic acid, and sorbic acid.

Dairy Products

Apart from the small-scale use of hydrogen peroxide to preserve milk by reducing the severity of heat treatment required for sterilization, the major use of preservatives in dairy products is for cheese. Propionic acid is formed naturally during the ripening of certain cheeses but may be used as an added preservative for surface treatment to prevent mold growth. Nitrite ion, which is formed from added nitrate in cheese, inhibits fermentations caused by clostridia and coliforms such as *Enterobacter*, which are undesirable because they may give rise to the production of carbon dioxide with resultant blowing of the cheese. Nitrite ion is to be avoided in cheeses where the production of propionic acid is important because nitrite also inhibits the bacteria required for its formation. Nisin is a good antimicrobial agent for cheese because it is particularly effective against clostridia such as *Cl. tyrobutyricum* in cheeses with a higher pH. The egg white antimicrobial enzyme, lysozyme, is employed for a similar purpose. Cheesemaking represents a major use of sorbic acid, where it serves two purposes: to inhibit surface mold growth, achieved by dipping, dusting (preferably with calcium sorbate), or incorporation of the preservative into wax coatings or packaging films, or to protect packs of processed cheese after opening, by incorporation of the preservative into the cheese at levels of 500–700 mg of sorbic acid per kilogram.

Meat and Fish Products

The curing of meat is probably the best known use of nitrites and nitrates. They are used in conjunction with salt, which has the effect of reducing the water activity sufficiently to reduce spoilage by *Pseudomonas* and related organisms, whilst nitrite prevents the growth of germinating spores. Curing is regarded as protection against food poisoning caused by *Clostridium botulium*. Eventual spoilage in cured meat is caused by lactic acid bacteria if the salt content is low, or by micrococci and vibrios if it is high together with a variety of molds and yeasts. Off-flavors are associated with hydrolysis of fat. The storage life of cured meat is extended by smoking as a result of additional antimicrobial agents from the smoke; again, when the meat ultimately spoils, it is dominated by lactic acid bacteria. Typical concentrations of sodium nitrite and nitrate in cured meat are 50–200 and 500 mg kg^{-1}, respectively.

Sulfites are added to a small number of comminuted meat products (sausages, burgers) at levels of 600 mg of SO_2 per kilogram, to achieve a maximum of 450 mg of SO_2 in the finished product. Whilst the total sulfite content of such a product falls slightly during storage, a large proportion becomes reversibly bound to carbonyl compounds of microbial origin. The success of sulfite in this application is the result of its inhibition of salmonellae, whilst spoilage of sulfited meat is confined to Gram-positive microflora consisting of lactobacilli and *Brochothrix thermosphacta*. The result is that the spoilage is associated with a sour odor, unlike the spoilage of untreated meat, which gives rise to a 'putrid' smell. The use of sulfites in meat products leads to the destruction of thiamin and is not permitted in important meat sources of the vitamin. Mold growth on the surface of dry sausage, during the drying period, may be controlled by dipping the casings in a solution of potassium sorbate prior to stuffing.

Fish may be preserved in acetic acid (10–30 g kg^{-1}) by the traditional process of marinating. Whilst this

provides basic protection against pathogenic microorganisms, lactobacilli may grow, and the use of acetic acid should be combined with a mild thermal process or other antimicrobial agents. Benzoic acid is slightly more effective than sorbic acid in this application (1000 mg kg^{-1}), and esters of *p*-hydroxybenzoic acid (300–600 mg kg^{-1}) may also be used.

Fat Products

Although benzoic acid had been used for some time for the preservation of margarine at concentrations of 800–1500 mg kg^{-1}, it is far from ideal for this application owing to the relatively high pH of the food. However, it is a good preservative for mayonnaise, though improved performance against acid-producing bacteria can be obtained by using mixtures of benzoic and sorbic acids. Margarine and low-fat spreads can be preserved most effectively by means of sorbic acid.

Miscellaneous Uses

Food ingredients that are normally manufactured in the form of solutions, or have a water activity sufficient to sustain microbial growth, may be treated with preservatives. Examples include flavoring preparations, gelatin, malt extracts, and antifoam agents.

Carbon Dioxide

Carbon dioxide is not a preservative in the usual meaning of the word. However, in most of the modified-atmosphere-packaged foods, it does help to preserve the food. It specifically inhibits the growth of the typical fast-growing oxidative Gram-negative bacteria that quickly spoil food, e.g., meat and fish. Slower-growing, less obnoxious microorganisms, such as lactic acid bacteria, often then take over, but the shelf-life can be substantially extended. The extent of such inhibition by CO_2 is greatly enhanced as the temperature is reduced. It has been speculated that this results mainly from the increased solubility of the gas at low temperatures. The shelf-life increases for meat and fish can be by two to three times if chill control is effective.

Analysis

B L Wedzicha, University of Leeds, Leeds, UK

Background

Food preservatives constitute a group of compounds of widely different molecular structures; they are organic and inorganic substances with different functional groups and tendencies to form ions. There are no procedures that are generally applicable to the analysis of preservatives as a class of food additive; the procedures are specific to the preservative being analyzed. The lowest concentrations of commonly used preservatives are of the order of a few milligrams per kilogram of food, and, with few exceptions, recommended or statutory methods of analysis are designed to give a good accuracy at levels of 10 to > 1000 mg of preservative per kilogram of food. The question of the lower limit of detection is rarely an issue, unless it is desired to use small sample sizes, e.g., < 1 g, or to determine whether or not a food or its ingredients had been treated with a preservative. For solid foods, small sample sizes often lead to nonrepresentative sampling and should be avoided. Not all the procedures described constitute official methods of analysis. Frequently, for routine analysis, a food manufacturer would use a rapid or cheap analytical technique standardized against an official method. The official status of given procedures varies from country to country.

Organic and inorganic acid preservatives may be added in the form of the undissociated acid or a variety of salts. In food, the ionic composition is determined largely by concentration and pH, but it is generally impossible to predict this accurately for any given situation. In order to avoid complications with the specification of the amount of preservative in a food, this is usually referred to as the weight-for-weight concentration of the undissociated acid, e.g., benzoic acid, sorbic acid, or sulfur dioxide. Nitrite and nitrate levels are expressed in terms of the weight of the sodium salt.

There are, of course, a very large number of possible analytical procedures available for each preservative. Those given here represent a selection to illustrate the variety of methods recommended for use on food samples.

Carboxylic Acids and Esters

Extraction

All the carboxylic acid and ester preservatives are steam-volatile from acidified food samples, and steam distillation offers an effective means of separating them from the sample. The nonionic nature of these preservatives in acid solution also allows extraction with a variety of organic solvents, e.g., diethyl ether, and dichloromethane. Such organic solvents may also be used to isolate, or concentrate, preservatives obtained in large volumes of steam distillate. The subsequent detection and determination of preservatives depend on the substance to be analyzed. (*See* **Acids**: Properties and Determination.)

Analysis of Extracts and Distillates

Rapid screening of extracts and distillates for sorbic and benzoic acid and the esters of *p*-hydroxybenzoic acid is possible by thin-layer chromatography (TLC) on silica gel. If separated on plates containing an F_{254} (fluorescent indicator), these acids may be readily visualized under UV light. Acetic and propionic acids can be identified by paper chromatography using an acid–base indicator for visualization of spots.

The total acidity in steam distillates is an acceptable measure of the concentration of an acid preservative provided that only one such preservative is used and that a blank for the food sample is known. Propionic and acetic acids can be separated using a silica gel column with butanol–chloroform solvent and the eluate titrated for quantitation. Solvent extracts of food samples can only be subjected to direct spectrophotometric analysis with caution. For example, benzoic acid, extracted into diethyl ether from tomato products, jams, jellies, and soft drinks, may be determined by measuring its absorbance at 267.5, 272, and 276.5 nm, and using the average of the highest and lowest wavelength readings as the background value for the absorbance at 272 nm. In general, solvent extracts and steam distillates can be analyzed directly by reverse-phase high-performance liquid chromatography (HPLC) or by gas–liquid chromatography (GLC) after forming trimethylsilyl or methyl esters. Internal standards for chromatography are chosen to have extraction and chromatographic behavior similar to that of the preservative being analyzed. Standards are generally added to the food before extraction, and any derivatization is carried out on both the analyte and the standard. Examples of internal standards include phenylacetic and caproic acids for gas chromatographic analysis of benzoic and sorbic acids, respectively. (*See* **Chromatography**: Thin-layer Chromatography; High-performance Liquid Chromatography; Gas Chromatography.)

Esters of *p*-hydroxybenzoic acid are determined in steam distillates or extracts either by reversed-phase HPLC or by direct spectrophotometry as *p*-hydroxybenzoic acid after saponification.

Oxidation of sorbic acid to malonaldehyde by means of dichromate and subsequent reaction with thiobarbituric acid (TBA) offers a specific nonchromatographic assay of this preservative in steam distillates from all types of food. Frequently, crude solvent extracts can be analyzed in the same way without any undue interference from other TBA-reactive substances either present in food or formed during dichromate oxidation.

Enzymatic Methods

Specific enzymatic procedures for the determination of acetic and formic acids are available. Acetic acid is determined by conversion to pyruvate (using ATP and coenzyme A in the presence of acetylcoenzyme A synthetase), which reacts in turn with oxaloacetate (citrate synthetase) obtained by the reduction of malate by NAD^+ (malate dehydrogenase). The rate of utilization of NAD^+ is a measure of acetic acid concentration. Formic acid is determined more simply by measuring the rate of utilization of NAD^+ during the oxidation of the acid to hydrogen carbonate (formate dehydrogenase). In general, sample preparation for enzymatic methods involves the preparation of aqueous extracts of solid foods, separating fat, precipitating protein (perchloric acid), decolorizing strongly colored samples (charcoal), and adjusting to pH 7–8.

Sulfur Dioxide and Sulfites

Classification

Sulfur dioxide and sulfite are considered to exist in food in two forms: free and bound. The former includes all species of sulfur in oxidation state +4, i.e., SO_2, HSO_3^-, SO_3^{2-}, and $S_2O_5^{2-}$. The latter term is used to describe that preservative which is in the form of hydroxysulfonate (carbonyl-HSO_3^-) adducts. Legislation requires that total (free + bound) preservative be determined. In food processing, the concentration of free additive determines its

antimicrobial effect and is frequently measured. A specific problem that exists with this preservative is that itsmeasured concentration falls with time as a result of reactions with food components, and as a result of autoxidation after packaged foods are opened and exposed to air. Samples must be analyzed without delay and exposure to air minimized.

A broad classification of analytical methods for sulfur dioxide and sulfites is based on whether or not a separation procedure is involved. Methods are usually referred to as direct, when a specific analytical reaction is applied to the whole food sample, and indirect, when the additive is recovered before determination.

Direct Methods of Analysis

The simplest analysis of sulfites in foods involves iodimetric titration after allowing for a blank representing the reactivity of the food sample itself towards iodine. This is normally found by adding an aldehyde or ketone (formaldehyde, acetaldehyde, acetone) to combine with free sulfite before the blank titration. The free sulfite content of a food is determined by acidifying the sample and titrating with iodine. The total (free + bound) sulfite may be determined by raising the pH of the sample to pH 10 to decompose any hydroxysulfonates before acidifying and titration. Iodimetric titration is applicable to beverages and aqueous extracts/homogenates of solid foods. Dark-colored beverages may be titrated using electrometric detection of the end point.

Sulfites in solution may be determined spectrophotometrically by reaction with tetrachloromercurate + pararosaniline + HCHO reagent, 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB), or malachite green. These reactions depend on the nucleophilic behavior of the sulfite ion and suffer interference from nucleophiles in foods, particularly thiols. Despite this, the pararosaniline method has been used widely for direct determination of the preservative in beverages, solutions of sugars, and aqueous extracts or homogenates of solid foods including fruits and vegetables, and has been adapted successfully for an 'autoanalyzer' system.

Few chromatographic methods of analysis of sulfites in foods have gained acceptance, mainly because of the problems associated with detection of the species. Ion-exclusion chromatography of the sulfite ion with amperometric detection is the best-established chromatographic method available and can be applied directly to beverages and aqueous extracts of foods.

Other direct analyses include the use of polarography and sulfur dioxide-sensitive electrodes but are not in widespread use. Enzymatic methods of analysis make use of the oxidation of sulfite to sulfate + H_2O_2 (sulfite oxidase) and assay of H_2O_2 with NADH (NADH-peroxidase). The rate of formation of NAD^+ is used to determine the sulfite concentration. Sulfite oxidase may also be immobilized at the tip of an oxygen-measuring electrode for a direct indication of the rate of utilization of oxygen by the enzyme in sulfite oxidation. The pH requirement for these enzymatic analyses is slightly alkaline (pH 7.5–8), and the method can give only the total additive concentration.

Indirect Methods of Analysis

All indirect methods of analysis of sulfur dioxide and sulfites in foods involve the conversion of the ionic forms to gaseous SO_2 as the method of separating the additive from the food. The Monier–Williams distillation technique, described in 1927, is still the standard by which other methods are evaluated. This method, and variants of it, involve the distillation, under reflux, of the food sample acidified with HCl, H_2SO_4, or H_3PO_4, in a gentle stream of an inert gas. SO_2 is trapped in H_2O_2 or iodine. Some variations of this technique include the codistillation of SO_2 with water with a downward sloping condenser, to speed up the procedure. The most serious interference arises from the presence of volatile compounds, which are oxidized by H_2O_2 to acid, or react with iodine. Such interfering components are found in onions, leeks, and cabbage. Small samples may be analyzed by replacing the conventional trapping agents by pararosaniline reagent or DTNB, which allow spectrophotometric determination of SO_2 at a much greater sensitivity than is possible by titration. Polarographic analysis of the distillate offers a good alternative. Desorption of SO_2 from cold acidified samples enables free preservative to be determined; prolonged boiling (e.g., 1.75 h) or pretreatment with alkali causes the decomposition of hydroxysulfonates and gives the total preservative present. In general, distillation methods do not require any sample preparation and are equally applicable to solid and liquid foods.

An automatic distillation unit ahead of an 'autoanalyzer' with spectrophotometric detection provides an effective automatic indirect method of analysis for liquid samples and aqueous extracts. An ingenious approach to separating dissolved SO_2 from an acidified food sample is by diffusion through polytetrafluoroethylene membrane. This may be used in a flow injection arrangement where the diffusion cell carries streams of acidified liquid food or extract solution on one side of the membrane and a suitable reagent for spectrophotometric analysis on the other.

Analysis of gaseous SO_2 in the headspace above acidified liquid foods or homogenates of solid foods, or transfer of SO_2 through the headspace from the sample to a reagent for spectrophotometric analysis in a microdiffusion cell, offers an alternative indirect method of analysis.

Nitrites and Nitrates

The most important uses of nitrite and nitrate as food preservatives are in meat products, and the majority of analytical procedures for food have been devised especially for this application. There are, however, numerous published procedures for the determination of the ions in water, and soil, and those occurring naturally in plant material. (*See* **Nitrates and Nitrites**.)

Since nitrites and nitrates are readily soluble in water, aqueous extracts from homogenates of the food at neutral or weakly alkaline pH are sufficient. A low extraction pH leads to the loss of nitrite. Apart from pH, important variables in extraction are time and the addition of heavy-metal salts (e.g., $BaCl_2$, $CdCl_2$, $HgCl_2$). A proportion of nitrite present in food may exist in bound form as nitrosothiols, nitrosylmyoglobin, etc.; methods of extraction that involve the heavy-metal ions and long extraction times (e.g., 1–4 h) cause the release of such bound additives. Techniques based on short extraction periods (e.g., 10 min) at neutral pH measure mainly the free nitrite. Nitrosyl hemoproteins may be decomposed to species convertible to nitrite if the extracting medium contains 80% acetone.

Extracts generally contain dissolved and suspended protein. This is removed, and solutions are clarified by means of zinc acetate + potassium ferrocyanide, alumina cream, potash alum or zinc sulfate + borax. In general, the reagents allow recoveries of nitrite of >98% with standard deviations no greater than 0.75%, from meat samples, with the exception of the procedure involving the use of alumina cream, for which the recovery is slightly lower at 95%.

Nitrate may be determined directly using a reaction in which it is used as a nitrating agent for variety of organic substrates and particularly the xylenols (dimethylphenols); the nitro-compounds so formed may be determined spectrophotometrically. This reaction can also be used to determine the concentration of nitrite if it is first oxidized to nitrate with permanganate. Alternatively, nitrate may be reduced to nitrite by spongy cadmium or enzymatically with NADPH (nitrate reductase). The rate of formation of NADP in the enzymatic procedure may be used to measure nitrate concentration directly. The most widely used reaction for the determination of nitrite is that with an aromatic primary amine (usually sulfanilic acid) in acid solution to form a diazonium salt, which is coupled to an aromatic amine or hydroxy compound to give an azo dye. This can be determined spectrophotometrically. Typical coupling agents have included 1-naphthylamine and 1-naphthol, which are carcinogenic, and 1-naphtholsulfonic acid and *N*-1-naphthylethylenediamine dihydrochloride are now frequently recommended. Both oxidizing and reducing agents interfere; ascorbic acid is a particular problem.

The sample blank can represent a significant error in analysis. There is no completely satisfactory way of preparing this; suggestions have included the passing of the deproteinized sample through an ion-exchange resin to remove nitrate and nitrite before determining the blank.

Other Preservatives

Biphenyl

Steam distillation of citrus peel homogenates and extraction of distillate with heptane provides a sample that may be analyzed for biphenyl by TLC on silica gel with heptane as the developing solvent. Quantitative analysis is by extracting biphenyl from the TLC medium with ethanol and measuring the absorbance of resulting solutions at 248 and 300 nm. The absorbance at 300 nm is used to correct for background absorbance. GLC methods of analysis are also available.

Thiabendazole

Thiabendazole may be extracted from food with acid (HCl), in which it is subsequently reduced with zinc in 30% glycerol+phenylenediamine. Subsequent oxidation with ferric ions gives rise to a blue complex, which is extracted into butanol for spectrophotometric measurement.

Lactic Acid

Standard methods for the determination of lactic acid involve its conversion to the Fe(III) complex for spectrophotometric measurement, or by GLC after complete methylation. In an enzymatic procedure, lactic acid is converted to pyruvate by NAD^+ (lactate dehydrogenase); the product is trapped by reacting with glutamate (glutamate–pyruvate transaminase) in order to displace the lactic acid–pyruvate equilibrium to the right. The rate of utilization of NAD^+ is used to measure lactic acid concentration. Sample preparation is generally as described for carboxylic acids above.

Hydrogen Peroxide

Spot tests for the presence of hydrogen peroxide in milk use either a solution of vanadium pentoxide in H_2SO_4 (pink or red color) or KI/starch (blue color).

Quantitative analysis is with peroxidase and a suitable substrate. The frequently recommended *o*-dianisidine is carcinogenic, and substrates such as guaiacol or 2,2′-azinobis (3-ethylbenzthiazolidine-6-sulfonic acid) are preferred. Assays on milk samples are carried out after precipitation of the protein by adjusting to pH 4.5 with HCl.

Nisin

The complexity of procedures for isolating and chemically quantifying nisin has led to the development of microbiological assays as normal analysis procedures. One international unit of nisin activity is the extent of inhibition of a test microorganism caused by approximately 25 ng of pure nisin. A suitable test microorganism is *Streptococcus agalactiae*. A particular assay procedure is an adaptation of the methylene blue reduction test; the delay in decolorization of the dye is proportional to nisin concentration over a 10-fold concentration range. A new method of analysis involves the enzyme-linked immunosorbent assay, which is much more straightforward than the microbiological assay and should become popular.

PRETERM INFANTS – NUTRITIONAL REQUIREMENTS AND MANAGEMENT

T F Fok, The Chinese University of Hong Kong, Shatin, NT, Hong Kong

Physiological Considerations

Recent advances in neonatal care have resulted in a significant improvement in the survival of infants who are born premature, notably the very low birthweight infants (birth weight < 1500 g). In the developed world, most infants with a birth weight over 1000 g are able to survive, and the survival rate of those weighing between 700 and 999 g is also showing progressive improvement. The nutritional needs of these infants pose a special challenge to scientists and clinicians: they have a high demand for calories and nutrients to cope with their rapid growth rate, while at the same time, the physiological and biochemical immaturity of their digestive systems and metabolic pathways render them inefficient in metabolizing and assimilating the nutrients.

Carbohydrate, protein, and fat comprise the major nutrients and sources of calories. Carbohydrate is available in human and formula milk in form of lactose. Lactose is hydrolyzed in the small intestine by the enzyme lactase present in the brush border at the villus tip. Preterm infants have a relatively low concentration of intestinal lactase, which is only about 70% of that of term infants. However, most preterm infants seem to be able to tolerate lactose in human milk or milk formulas, and only a small amount of lactose is excreted in the stools. In

formulas specially designed for preterm infants, the carbohydrate content is enriched by the addition of glucose polymers. Preterm infants are able to digest glucose polymers, apparently through the action of salivary amylase and mucosal α-glycosidase.

Protein is required for the formation of new tissues and is therefore essential for growth and repair. Because of the immaturity of the amino acid metabolic pathways, preterm infants are not able to completely metabolize several amino acids. Hence, excessive protein intake might lead to incomplete amino acid catabolism resulting in elevation of plasma concentration of amino acids, hydrogen ion, and ammonia. Also, because of the immature amino acid metabolism, preterm infants are not able to synthesize some amino acids that are nonessential in older subjects. These amino acids, notably cysteine, taurine, and glycine, must be provided in the diet.

The fat component of milk consists mainly of triglycerides. The digestion of fat begins in the intestinal lumen when the triglycerides are solubilized and hydrolyzed into fatty acids by the combined action of bile sat and lipase. In the preterm infants, pancreatic lipase and intraluminal bile salts are relatively deficient, and triglyceride hydrolysis is carried out mainly by the action of endogenous lingual lipase and gastric lipase, and also the lipase present in human milk. Infants with gestation less than 26 weeks might have impaired fat digestion owing to a deficiency of gastric lipase. The second phase of fat digestion takes place in the intestinal mucosa, where fatty acids are reesterified to form chylomicron, which is secreted into the lymphatics. Some of the fatty acids remain unesterified and are directly absorbed into the portal venous system.

Medium chain triglycerides (MCT) are incorporated into the intestinal mucosal cells without the need for intraluminal lipase or bile salt. In the intestinal mucosa, MCT are hydrolyzed by mucosal lipase, and absorbed directly into the portal venous system. Thus the addition of MCT to preterm infant formulas should theoretically enhance fat absorption. A number of studies showed that MCT increase energy absorption and better weight gain in preterm infants, but others failed to demonstrate any benefit of MCT in energy or nitrogen balance.

Besides being a concentrated source of calories, fat is also an important component of phospholipids, which are essential for cellular functions and the formation of a large variety of bioactive metabolites including surfactant and the prostaglandins. Some fatty acids, including linoeic acid and linolenic acid, cannot be synthesized by the body, and are known as essential fatty acids. Deficiency in these fatty acids in animal fetus has been associated with long-term impairment in learning and visual function. Linoleic acid and linolenic acid are metabolized to arachidonic acid and docosahexaenoic acid, respectively, both of which are essential for growth and development, especially of the central nervous system. In the preterms, the formation of arachidonic acid and docosahexaenoic acid is relatively insufficient, especially when the supply of calories is suboptimal.

Arachidonic acid (20:4*n*-6) and docosahexaenoic acid (22:6*n*-3) belong to the *n*-3 and *n*-6 long-chain polyunsaturated fatty acids (LCPUFA) with double bonds at the six and third position, respectively. LCPUFA are present in human milk but absent from formula milk. In a randomized control trial in 447 full-term infants, supplementation with *n*-3 and *n*-6 LCPUFA did not seem to have any beneficial or adverse effect. In another randomized control trial on 56 healthy full-term infants, supplementation of infant formulas with 0.35% DHA or with 0.36% DHA and 0.72% arachidonic acid results in an increase of 7 points on mental development index at 18 months of age.

Nutritional Requirements of Preterm Infants

Energy

Energy intake from food is required to maintain the resting metabolism, normal body temperature, and growth. A small amount of energy is excreted in the feces and urine. Normally, a very low birth-weight infant can retain up to 85–95% of the energy intake starting at 2–3 weeks of age. The resting metabolic rate of a preterm infant is around 40 kcal kg^{-1} day^{-1} in the first week, increasing to 50 kcal kg^{-1} day^{-1} by 2–3 weeks of age, and is higher in small for gestational age infants. The energy expenditure due to activity is highly variable, and the reported values range from 3.6 to 19 kcal kg^{-1} day^{-1}. Energy spent on thermoregulation should be negligible in infants being nursed in a thermal neutral environment. Published data on the energy of growth vary greatly as the amount of energy varies with the composition of the tissues synthesized. A reasonable estimate is approximately 3–4.5 kcal per gram weight gain, or an average of 10 kcal kg^{-1} day^{-1}. The total energy requirement, including that for the basal metabolic need, growth, stored energy, energy excreted, and energy stored, activity, is approximately 90–120 kcal kg^{-1} day^{-1}. Infants who have suffered from intrauterine growth retardation require a higher energy intake. Infants with medical or surgical complications also have significantly greater demands for energy.

Carbohydrate

Carbohydrate is an important and readily usable source of energy. An adequate supply of glucose also serves to prevent catabolism of body tissues. During the early days of life when the infant is sick from the complications of prematurity, glucose is often given via the intravenous route to maintain a normoglycemic state. Any shortage of exogenous glucose supply at this stage will result in hypoglycemia, which may cause injury to the brain and potentially other organs since glucose is the major, if not the only, source of energy for the metabolism of the nervous system, red blood cells, the renal medulla, and the retina. Excessive glucose supply, however, results in hyperglycemia, which causes glycosuria and osmotic diuresis, and stimulation of pancreatic islet cells resulting in rebound hypoglycemia when the glucose supply is interrupted. In most preterm infants, the glucose infusion rate should be 4–6 mg kg^{-1} min^{-1}. The extremely preterm infants may develop hyperglycemia, even at this rate of glucose infusion, because of inadequate insulin secretion, or peripheral insulin resistance. These infants may require a reduction of glucose intake or insulin therapy. When the infant becomes stable and is taking enteral milk feeding, carbohydrate should contribute to about 40–50% of the total caloric intake (10–14 g per kilogram of body weight), which is the proportion of carbohydrate content in human milk.

Protein

The estimation of protein requirement and the requirements of most other nutrients were based on the need of the growing fetus of the same gestation. Daily protein requirements appeared to be 2–4 g kg^{-1}. In extremely low birth-weight infants, the amount could be increased in stepwise fashion over a span of 2 weeks. This should be accompanied by a concomitant increase in calories intake, since protein synthesis requires energy. For each gram of protein deposited, the body spends about 10 kcal of energy. A deficient energy intake will result in the breakdown of endogenous protein and a negative nitrogen balance.

Fat

Fat provides a concentrated source of energy and is also required to provide the essential fatty acids. As recommended by the European Society of Paediatric Gastroenterology and Nutrition Committee on Nutrition, the fat intake of enterally fed preterm infants should be 40–55% of the total calories intake, or 4.4–6.0 g per 100 kcal. The Committee also recommended a linoleic acid content of 4.5–10.8% of the total energy content of infant formulas, and a linoleic acid: α-linolenic acid ratio of 5:1 to 15:1.

Carnitine facilitates the transport of long-chain fatty acids through the mitochondrial membrane and is therefore essential for the oxidation of fatty acids for energy production in the heart and skeletal muscle. The European Society of Paediatric Gastroenterology and Nutrition Committee on Nutrition recommended that infant formulas contain at least 7.5 μmol of carnitine per 100 kcal. This amount should be available in human milk. Carnitine is now added to some of the commercial parenteral nutrition fluid. There is, however, no clinical evidence that supplementation of carnitine to the parenteral lipid infusion has any physiological benefit.

Vitamins and Minerals

Vitamin A Vitamin A is important for the growth and differentiation of epithelial cells, and its deficiency results in pathological changes of the epithelium, including that of the airways and lungs. The vitamin is transferred to the fetus from the mother mainly during late gestation, and therefore the vitamin content is significantly lower in the preterm infants than in the term infants. Several studies have demonstrated a protective effect of vitamin A supplementation against bronchopulmonary dysplasia in preterm infants. Excessive vitamin A intake results in intoxication manifesting with increased intracranial pressure, bone and joint damage, mucocutaneous lesions, liver damage, and hematological changes.

The dietary intake of vitamin A, as recommended by the World Health Organization, is 333 IU kg^{-1} day^{-1}. This amount may not be sufficient for preterm infants, and a daily intake of 1500 IU kg^{-1}, 700–1500 IU kg^{-1}, and 700 IU kg^{-1} has been recommended for infants weighing less than 1000 g, 1000–1750 g, and 1751–2500 g, respectively. Infants at risk of developing BPD, namely the extremely preterm infants with respiratory distress requiring supplemental oxygen and mechanical ventilation, might be protected from BPD by additional vitamin A intake. It has been demonstrated that, in these infants, biochemical vitamin A deficiency could be corrected with intramuscular administration of 5000 IU of vitamin A given three times per week for 4 weeks, which was associated with a slight reduction in the risk of chronic lung disease.

Vitamin E Vitamin E is a biologic antioxidant important for the integrity of the lipid layers of cell membranes. Its deficiency in preterm infants has been associated with hemolytic anemia, and impaired phagocytosis. Clinical trials have been carried out to evaluate its protective effects

against bronchopulmonary dysplasia, retinopathy of prematurity, and intraventricular hemorrhage. However, there is no convincing evidence that vitamin E protects preterm infants from any of these conditions.

Because of the limited tissue store and poor dietary absorption of vitamin E, and the rapid growth of the preterm infants, The American Academy of Pediatrics Committee on Nutrition recommended that preterm infants should receive 5–25 IU supplemental oral vitamin E per day.

Vitamin K Vitamin K is a cofactor in the metabolic conversion of intracellular precursors of vitamin K-dependent clotting factors 2, 7, 9, and 10. Vitamin K deficiency results in hemorrhagic disease of newborn. Purely breast fed infants are particularly prone to develop vitamin K deficiency, since the concentration of the vitamin is very low in human milk. The current recommended daily intake of vitamin K for newborn infants is the same as that for children and adults, namely 1 mg kg^{-1} day^{-1}.

Vitamin D Vitamin D is obtained from the diet or produced endogenously in the skin after exposure to ultraviolet light. The vitamin is hydroxylated to 25-hydroxyvitamin in the liver, which is further hydroxylated to its most active ingredient, 1,25-dihydroxy vitamin D in the kidney. The process is stimulated by parathyroid hormone and deficiency in calcium and phosphate. Vitamin D increases intestinal calcium and phosphorus absorption; 1,25-dihdroxy vitamin D also maintains normal circulating calcium concentration by its direct action on mobilization of bone calcium and phosphorus to the extracellular fluid. The role of vitamin D in the cause of osteopenia and ricket of the newborn is not clear. It appears that mineral (calcium and phosphorus) intake is the most important factor affecting bone mineralization, since infants with low mineral intake developed ricket despite supplementation of vitamin D of up to 2000 IU day^{-1}, whereas ricket could be prevented by high mineral intake and moderate vitamin D (400 IU day^{-1}) supplementation. Thus, a daily enteral intake of vitamin D of 400 IU should be sufficient for the preterm infants. For infants on parenteral nutrition, a daily intake of 40–160 IU kg^{-1} has been recommended, with a maximum intake not exceeding 400 IU day^{-1}.

Water-soluble vitamins The water-soluble vitamins, vitamin C, vitamin B_1 (thiamin), vitamin B_2 (riboflavin), vitamin B_3 (niacin), vitamin B_6 (pyridoxine), pantothenic acid, and biotin, are cofactors for several important enzymatic reactions, and deficiencies can result in abnormal substrate utilization. The exact requirements for these vitamins by preterm infants are not clear. The vitamins are water-soluble, and therefore, excessive intake will be excreted in the urine. The current recommended dietary allowance (RDA) for the term neonate is: vitamin C 30 mg day^{-1}, vitamin B_1 300 μg day^{-1}, vitamin B_2 400 μg day^{-1}, vitamin B_6 300 μg day^{-1}, niacin 5 mg day^{-1}. The RDA of biotin and pantothenic acid has not been established, but doses of 10 μg day^{-1} and 2 μg day^{-1}μg have been suggested for biotin and pantothenic acid, respectively. For preterm infants, it has been suggested that those weighing > 1500 g should receive the RDA, whereas smaller infants can be supplemented with half the oral doses. Very low birth-weight infants on total parenteral nutrition should be supplemented with 25–30 mg of vitamin C per kilogram per day, 35 μg of vitamin B_1 per kilogram per day, 150–200 μg of vitamin B_2 per kilogram per day, 150–200 μg of vitamin B_6 per kilogram per day, 4–6 mg of niacin per kilogram per day, 5–8 μg of biotin per kilogram per day, and 1–2 mg of pantothenic acid per kilogram per day.

Folic acid is a water-soluble vitamin that is important for DNA synthesis and cell division, especially in tissues with high rates of cell multiplication, such as the bone marrow and intestine. Preterm infants are predisposed to folic acid deficiency because of limited intrauterine hepatic stores and because of their rapid postnatal growth. The American Academy of Paediatrics Committee on Nutrition for Preterm Infants recommended that preterm infants < 2000 g should receive 50 μg of folic acid daily, with a minimum intake of no less than 4 μg per 100 kcal, which is the same as that for term infants. Preterm infants on total parenteral nutrition should be given folic acid supplement at a dose of 56 μg kg^{-1} day^{-1} (140 μg kg^{-1} day^{-1} for full term) usually in the form of a multivitamin preparation.

Vitamin B_{12} is a water-soluble vitamin. Its deficiency may result in megaloblastic anemia and neurological changes during late infancy. The minimal dietary intake for preterm infants, as recommended by the American Academy of Pediatrics Committee on Nutrition, is 0.15 μg per 100 kcal, which is the same as that for term infants. Preterm infants on total parenteral nutrition should be given vitamin B_{12} supplement at a dose of 0.3 μg kg^{-1} day^{-1} (1 μg kg^{-1} day^{-1} for full term).

Minerals

Calcium, phosphorus, and magnesium Calcium and phosphorus are the major constituents of bone. Magnesium is also an important constituent of

bone, but a large amount is also found in the muscle and intracellular fluid. About 80% of these minerals accrue in the fetus from 25 weeks of gestation to term. The peak accretion rate occurs between 36 and 38 weeks of gestation. The amount of minerals present in human milk and ordinary infant formulas, especially that of calcium and phosphorus, is not sufficient to cope with this rate of mineral accumulation. Osteopenia and rickets are common among the extremely preterm infants, and the condition can be prevented by high calcium and phosphorus intake. The recommended daily intakes of calcium, phosphorus, and magnesium for preterm infants are $210\,mg\,kg^{-1}$ ($5.25\,mmol\,kg^{-1}$), $140\,mg\,kg^{-1}$ ($4.52\,mmol\,kg^{-1}$) and $10\,mg\,kg^{-1}$ ($0.42\,mmol\,kg^{-1}$), respectively.

Sodium and potassium Preterm infants, particularly those with a birth weight less than 1500 g, have significant urinary sodium loss during the first 10–14 days of life because of high fractional excretion rates of sodium. During this time when the infants are sick and unstable, serum sodium and potassium values are affected by a number of factors including the amount of fluid intake, the rate of evaporative fluid loss, which is affected by environmental temperature and humidity, and therapeutic interventions such as mechanical ventilation. These infants are normally given only parenteral fluid. Restriction of parenteral sodium intake during the first 2 days of life is a common practice in neonatal intensive care units and may prevent the development of hypernatremia. Additional potassium intake is also not necessary during this period. Subsequently, the daily requirement is 2–3 mmol kg^{-1} for each of sodium and potassium. The amount of supplementation has to be adjusted according to the serum sodium and potassium levels, which should be monitored frequently for as long as the infant is on intravenous feed. Preterm infants on enteral feeding also require 2–3 mmol of sodium per kilogram per day, which is greater than that required by term infants. The sodium content in term human milk and commercial infant formulas designed for the feeding of term infants is too low to meet the requirement of very low birth-weight preterm infants and may lead to hyponatremia when given to these infants as the sole source of sodium. Special formulas for preterm infants provide 2.5–3.5 mmol of sodium per kilogram per day at full feeding. During the stable and growing period, sodium requirements are usually met with a daily intake of $2–3\,mmol\,kg^{-1}\,day^{-1}$. The potassium requirement of preterm infants seem to be the same as that of term infants (2–3 mmol $kg^{-1}\,day^{-1}$).

Trace minerals Eight trace minerals are nutritionally essential for the human: iron, zinc, copper, selenium, chromium, molybdenum, manganese, and iodine.

Preterm infants have low iron stores because iron accumulation occurs mainly at the third trimester at a rate of $1.6–2.0\,mg\,kg^{-1}\,day^{-1}$. This, together with the rapid growth rate of preterm infants, and the frequent blood sampling during the early postnatal days, results in a high incidence of iron deficiency anemia after age 4 months. The incidence has been decreased with iron supplementation. At the same time, these infants are also often given multiple transfusions, which may restore the iron load and impair intestinal absorption of iron.

The American Academy of Pediatrics Committee on Nutrition recommended that iron should be started no later than 2 months of age in very low birth-weight preterm infants and should be continued for at least the remainder of the first year. The recommended dose is $2\,mg\,kg^{-1}\,day^{-1}$ up to a maximum of $15\,mg\,day^{-1}$. Others have suggested that iron should be started at 2 weeks of age or when the body weight doubles the birth weight. Iron supplementation is particularly important when the infant is being treated with erythropoietin because of increased erythropoiesis.

Zinc is important for protein metabolism and cell growth. Fetal accretion of zinc takes place mainly during the third trimester of pregnancy, and preterm infants have a lower total store at birth than term infants. The daily enteral intake of zinc, as recommended by the American Academy of Paediatrics and the European Society of Paediatric Gastroenterology and Nutrition, is $600\,\mu g\,kg^{-1}\,day^{-1}$ and $720–1400\,\mu g\,kg^{-1}\,day^{-1}$ respectively.

Copper is an essential component of many oxidative enzymes and is important for the integrity of cell membranes. Its deficiency presents clinically with anemia, neutropenia, osteoporosis, decreased pigmentation of the skin and hair, dermatitis, failure to thrive, diarrhea, hypotonia, and psychomotor retardation. The recommended daily enteral intake of copper for preterm infants is $100–150\,\mu g\,kg^{-1}$. For infants on long-term parenteral nutrition, the recommended daily intake is $20\,\mu g\,kg^{-1}$. Copper supplementation is not necessary for those on only short-term TPN. As copper is primarily metabolized in the liver, and reduced hepatic excretion may cause liver cirrhosis, it should be withheld from infants with cholestasis.

Iodine is essential for the manufacturing of thyroid hormones. Transient hypothyroidism has been reported in preterm infants taking $10–30\,\mu g\,kg^{-1}\,day^{-1}$ of iodine. Excessive intake of iodine, however,

also suppresses the thyroid gland. The recommended daily intake of iodine for stable growing preterm infants is 30–60 $\mu g\,kg^{-1}\,day^{-1}$. For infants on total parenteral nutrition (TPN), a daily intake of 1 $\mu g\,kg^{-1}$ is recommended.

Selenium is an essential constituent of the enzyme glutathione peroxidase. Its deficiency results in cardiomyopathy affecting children and adults. Clinical selenium deficiency has, however, not been reported in preterm infants. The recommended daily enteral intake of selenium for stable and growing preterm infants is 1.3–3 $\mu g\,kg^{-1}$. Infants on parenteral nutrition should be supplemented with selenium at a dose of 2 $\mu g\,kg^{-1}\,day^{-1}$.

Chromium is a cofactor involved in glucose homeostasis. Chromium deficiency has not been described in newborns. The daily recommended intake for stable and growing preterm infants is 0.1–0.5 $\mu g\,kg^{-1}$. The recommended daily parenteral intake for infants on TPN is 0.2 $\mu g\,kg^{-1}$.

Molybdenum is required for the function of certain enzymes, including xanthine oxidase. Its deficiency has not been described in the newborns. The recommended daily enteral intake for stable preterm infants is 0.3 $\mu g\ kg^{-1}$. The recommended intake for infants on total parenteral nutrition is 0.25 $\mu g\ kg^{-1}\,day^{-1}$.

Manganese is required for the function of pyruvate carboxylase, superoxide dismutase, and glycosyl transferase. Manganese deficiency has not been reported in the newborns. The recommended intake for stable growing preterms is 0.75–7.5 $\mu g\,kg^{-1}\,day^{-1}$. The recommended parenteral intake for infants on total parenteral nutrition is 1 $\mu g\,kg^{-1}\,day^{-1}$. Since manganese is metabolized in the liver, and its accumulation has been implicated as a cause of cholestasis and damage to the central nervous system, the element should be withheld from infants with cholestasis or impaired liver function.

Dietary Sources of Nutrients

Carbohydrate

The lactose content of mature human milk is 7.4–9.9 $g\,dl^{-1}$. The lactose content of preterm milk is 6.99 $g\,dl^{-1}$ after 26–31 weeks of gestation and 6.24 $g\,dl^{-1}$ after 32–36 weeks of gestation. In preterm formulas, the carbohydrate content is about 8.5 $g\,dl^{-1}$ and consists of lactose and glucose polymers in equal amounts. Compared with lactose, the addition of glucose polymers to formulas adds fewer osmotic particles per unit weight. Its use has allowed a substantial increase in the carbohydrate content of formulas without any significant increase in osmolality.

In infants receiving parenteral nutrition, carbohydrate is usually given in the form of intravenous glucose. As described above, the glucose infusion rate should be sufficient to maintain a normoglycemic state, and most preterm infants will require a glucose infusion rate of 4–6 mg $kg^{-1}\ min^{-1}$. The extremely preterm infants may not be able to tolerate glucose load and may require a reduction in the infusion rate or insulin therapy.

Protein

Mature human milk cannot provide sufficient protein for preterm infants since its protein content is only 1.2 $g\,dl^{-1}$. To obtain a daily amount of protein of 3 $g\ kg^{-1}$, the infant has to consume 250 ml of milk per kilogram per day. The milk produced by the preterm baby's own mother contains significantly more protein, especially during the first few weeks of life, and is more suitable for the infant. However, as the protein content of the preterm milk declines rapidly after delivery, and becomes quite similar to that of term milk after 2 weeks, it is now common practice to enrich the protein content of expressed breast milk with human milk fortifier. Such supplementation has resulted in a greater weight gain and nitrogen retention.

Formulas specially designed for preterm infants have a higher protein content than breast milk – ranging from 1.8 to 2.4 $g\,dl^{-1}$ and providing about 2.2–3.2 g of protein per 100 kcal.

Infants on parenteral nutrition are given protein in the form of amino acid mixture. Currently available amino acid mixtures provide up to 3 $g\,kg^{-1}\,day^{-1}$ of protein intake, and are able to meet the requirements for growth and nitrogen retention.

Fat

The fat content of mature expressed human milk is around 3.5–4.5 $g\,dl^{-1}$. The fat content of premature milk is lower, and its content and composition vary, depending on the mother's dietary fat intake. The fat content in the milk obtained by manual expression (expressed breast milk) is higher than drip breast milk. During tube feeding, substantial reduction in fat intake may result from the deposition of fat on the wall of the gastric tube.

Preterm formulas often contain 20–50% MCT. MCT are absorbed directly into the portal venous system without the need for intraluminal bile salts, which are relatively deficient in the preterms. The benefit of adding MCT oils to preterm formulas is controversial.

Several commercially available premature formulas are now supplemented with LCPUFAs.

Preterm infants on parenteral nutrition are given intravenous lipid, which contains about 45–55% linoleic acid and 6–9% linolenic acid. Normally, infusion of 0.5–1 g of lipid per kilogram per day of lipid will prevent essential fatty acid deficiency. More lipid can be given to provide more energy but should not exceed the rate of lipid clearance from the plasma. Most infants over 28 weeks of gestation can clear from the plasma up to 2 g of lipid per kilogram per day, and most infants more than 32 weeks of gestation can clear up to $3\,g\,kg^{-1}\,day^{-1}$. Infants less than 28 weeks of gestation are less able to clear lipid and have a high chance of hyperlipidemia when receiving intravenous lipid.

Intravenous lipid is hydrolyzed by endogenous lipoprotein lipase. The use of MCT in the lipid preparation results in more rapid clearance of lipid from the blood. There is, however, no clinical evidence that MCT preparation offers any physiological or metabolic advantage to the preterm infants.

Vitamins and minerals

Vitamin A The concentration of vitamin A in preterm milk is approximately $300\,IU\,dl^{-1}$, which is lower than that in term milk. The concentration is, however, variable. Preterm formulas are fortified with a vitamin A concentration of 250–1000 IU dl^{-1}. Multivitamin preparations usually contain about 1500 IU of vitamin A per milliliter.

Vitamin E The vitamin E content of preterm human milk is sufficient to satisfy the requirement of the preterm infant. The American Academy of Pediatrics Committee on Nutrition recommended that formulas designed for preterm infants should meet the minimum requirement of 0.7 IU per 100 kcal and 1.0 IU of linoleic acid per gram. The currently available preterm formulas are fortified with vitamin E well in excess of this amount. The requirement of vitamin E by preterm infants receiving parenteral nutrition is not clear. It has been recommended that infants weighting < 1000 g at birth should receive supplemental vitamin E of $3.5\,IU\,day^{-1}$, and those weighting 1000–1500 g should receive $4.7\,IU\,day^{-1}$.

Vitamin K The American Academy of Pediatrics recommended that in order to prevent hemorrhagic disease of newborns, vitamin K should be given to term infants at birth in the form of vitamin K_1 administered intramuscularly at a dose of 1 mg. Oral vitamin K can be used, but at a dose of 2 mg at birth, and should be repeated at 1–2 weeks and 4 weeks after birth. For preterm infants, an intramuscular dose of 0.3 mg is sufficient. It has been reported in one study that intramuscular vitamin K is associated with a higher incidence of childhood leukemia and suggested that it should be replaced by oral vitamin K. This recommendation was not supported, however, by other studies, and intramuscular injection remains the most certain way of vitamin K administration. Formulas designed for preterms are fortified with vitamin K well in excess of the daily requirement of the infants.

Preterm infants on TPN should be supplemented with vitamin K in the form of a multivitamin preparation. The amount provided usually exceeds the daily requirement of $10\,\mu g\,kg^{-1}$.

Vitamin D Preterm infants are often deficient in their mineral (calcium and phosphate) intake but the quantity of vitamin D in both human milk and formulas is sufficient. Infants on parenteral nutrition should be supplemented with vitamin D in form of a multivitamin preparation. Care is required to ensure that the dose is not excessive.

Water-soluble vitamins Human milk produced by healthy mothers on a balanced diet is a good source of the water-soluble vitamins vitamin C, vitamin B_1 (thiamin), vitamin B_2 (riboflavin), vitamin B_3 (niacin), vitamin B_6 (pyridoxine), pantothenic acid, biotin, folic acid, and vitamin B_{12}. Infant formulas are now all fortified with a sufficient quantity of these vitamins to meet the infant's requirements.

Minerals

Sodium and potassium Mature human milk contains 0.7–0.9 mmol per 100 ml, which is inadequate to meet the requirement of the preterm infants. Preterm milk has a higher sodium content during the first 3 weeks postpartum (1.3–1.7 mmol per 100 ml), which declines to 0.8 mmol per 100 ml by the 4th postpartum week. Formulas designed for preterm infants have a higher sodium content of 1.4 mmol per 100 ml and are able to provide 2.5–3.5 mmol of sodium per kilogram per day to infants receiving a full feed of $200\,ml\,kg^{-1}\,day^{-1}$. The potassium content in preterm formulas, and also in term and preterm human milk, contain is sufficient to meet the requirement of 2–3 $mmol\,kg^{-1}\,day^{-1}$ in preterm infants.

Calcium, phosphorus, and magnesium Preterm human milk contains only 40 mg of calcium per 100 kcal and 20 mg of phosphorus per 100 kcal, which are insufficient to satisfy the need of the preterm infants. The mineral content of the milk can be enriched by the addition of a human milk fortifier, the use of which has been associated with improved bone mineral content of the infants. Ordinary infant

formulas also cannot provide the necessary amount of calcium and phosphorus. Formulas designed for preterm infants contain 94–183 mg of calcium per 100 kcal and 50–70 mg of phosphorus per 100 kcal. Consumption of these formulas has been associated with improved bone mineral content of the preterm infants. The magnesium content of both human and formula milk is adequate for preterm infants.

Preterm infants, especially very low birth-weight infants, often have a transient period of hypocalcemia during the first few days of life, and require intravenous calcium supplement. In these infants, hypocalcemia can be prevented or treated with calcium infusion in the form of 10% calcium gluconate at a rate of 1.25–1.88 mmol (50–75 mg) of elemental calcium per kilogram per day in the first 2–3 days of life.

When the minerals are being delivered to infants on TPN, it is important that the concentrations of calcium and phosphorus do not exceed the solubility product, or else the minerals will precipitate. A calcium:phosphorus ratio of 1:1 to 1.3:1 by molar ratio, or 1.3:1 to 1.7:1 by weight, results in the highest calcium and phosphorus retention. It has been recommended that the TPN solution should contain 12.5–15 mmol (500–600 mg) of calcium per liter, 12.5–15 mmol (390–470 mg) of phosphorus per liter, and 1.5–2 mmol (36–48 mg) of magnesium per liter. This would provide the infant with 1.5–2.5 mmol (60–90 mg) of calcium per kilogram per day, 1.5–2.25 mmol (47–70 mg) of phosphorus per kilogram per day and 0.18–0.3 mmol (4.3–7.2 mg) of magnesium per kilogram per day.

Iron Human milk contains very little iron. Infants fed on breast milk should be supplemented with ferrous sulfate, which provides 2–4 mg of elemental iron per kilogram per day. Preterm formulas are fortified with 1.33 mg of iron per 100 ml or 1.67 mg of iron per 100 kcal, which should be sufficient for a fully fed infant.

For babies on prolonged TPN, 0.1–0.2 mg of parenteral iron per kilogram per day should be administered together with the TPN solution.

Trace minerals The zinc content in human milk declines rapidly during the first few postpartum months, and might not be sufficient to meet the need of the growing preterm infant. Preterm formulas contain sufficient zinc to provide the recommended daily intake in fully enterally fed infants. It has been suggested that preterm infants on human milk should be supplemented with $500\,\mu g\,kg^{-1}\,day^{-1}$ until 6 months of age. For infants on parenteral nutrition, it has been suggested that the TPN solution should be supplemented with 150 μg of zinc per kilogram per day during the transitional period after birth.

The copper content in human milk and preterm formulas is sufficient to meet the need of preterm infants. The iodine content of human milk varies with the dietary intake and geographic location of the mother. In most developed countries, human milk contains sufficient iodine to meet the need of the preterm infants. Preterm formulas are also fortified with an adequate amount of iodine. The amounts of other trace minerals (selenium, chromium, molybdenum, and manganese) in both human and formula milk are also adequate for the preterm infants.

PROBIOTICS

S E Gilliland, Oklahoma State University, Stillwater, OK, USA

Background

Probiotics may be defined as selected viable microorganisms that, following consumption in a food or feed, have potential for improving health or nutrition of man or animal. Bacteria in this group may be used to ferment food or are added to food as dietary supplements. Foods for human consumption containing these organisms are sometimes referred to as functional foods. A number of different bacterial species have been suggested as probiotics (**Table 1**). The major species that have been considered over the years, however, are *Lactobacillus acidophilus*, *Lactobacillus casei*, and *Bifidobacterium* species, and *Bifidobacterium longum*.

Table 1 Bacteria used as probiotics

Major bacteria
Lactobacillus acidophilus
Lactobacillus casei
Bifidobacterium longum
Bifidobacterium bifidum
Others
Lactobacillus ruterii
Lactobacillus johnsonii
Bifidobacterium lactis
Lactobacillus plantarum

Dairy products provide an excellent carrier for these probiotic bacteria especially *Lactobacillus acidophilus*, *Lactobacillus casei*, and *Bifidobacterium* species. Most of these can readily utilize lactose as an energy source for growth; thus, an important requirement for their growth in the intestinal tract is provided by the milk. Additionally, many of them have been used for centuries in the manufacture of cultured dairy products and thus are generally regarded as safe. This means that there should be no objection to their being used as dietary adjuncts in milk products. In the early 1900s, Eli Metchnikoff advocated that man should consume, on a daily basis, milk fermented by *Lactobacillus* species to displace microorganisms in the intestinal tract that produce toxic substances that could shorten man's life. Thus, he felt that consumption of such fermented milk would prolong life. This theory was the beginning of what we refer to today as foods containing probiotic bacteria.

Several dairy products containing probiotic bacteria are marketed today, and the most widely encountered product is yogurt. It is not uncommon to read on the label of a yogurt product that it was made with a culture including *Lactobacillus acidophilus* and/or *Bifidobacterium* species. These are not the bacteria that have traditionally been used to manufacture yogurt. The traditional yogurt starter cultures are *Streptococcus salivarius* ssp. *thermophilus* and *Lactobacillus delbrueckii* ssp. *bulgaricus*. Neither of these two organisms is traditionally listed as a probiotic, because they are not expected to survive and grow in the intestinal tract, whereas

probiotics do. In the USA, nonfermented milk products are available that contain added cells of *Lactobacillus acidophilus* and/or bifidobacteria. Following supplementation of the pasteurized milk with these two organisms, it is stored under refrigeration so that the probiotic bacteria do not grow in the milk. In this case, milk serves as a carrier for the organisms, and the product, of course, does not have the sour or tart taste normally associated with fermented dairy products. This provides a product containing the probiotics for those people who do not desire the taste and flavor associated with fermented products.

Potential Benefits

When Eli Metchnikoff proposed his theory to prolong life, the primary benefit he proposed from the consumption of the fermented milk product was to control the intestinal microflora. Since the interest in probiotics was renewed some 20–30 years ago, several other potential benefits have come to light (Table 2). While these potential health and nutritional benefits appear to be very important to mankind, most of them have not been thoroughly proven. In order to firmly establish whether or not the benefits can actually be produced, relatively large clinical trials will be required, especially in the case of humans. A large number of factors must be considered when undertaking such a monumental task. A very important aspect is the selection of the probiotic bacteria to be utilized. This will be discussed in a later section of this chapter. Most of the possible benefits listed in Table 2 have to do with human health and nutrition. However, with the pending ban on the use of subtherapeutic levels of antibiotics in livestock feed, there is tremendous interest in the role of probiotics as supplements for animal feed. The primary interest here focuses on controlling intestinal pathogens as well as improving nutrient utilization. The subtherapeutic antibiotics, which have been used for years as livestock feed supplements, have been shown in many cases to improve the growth and performance of livestock. While this may be due in part to control of undesirable microorganisms in the digestive tract, other mechanisms are also likely. Probiotic bacteria offer very good opportunities for use as livestock feed supplements to achieve these goals.

Table 2 Potential health and/or nutritional benefits from probiotics in the diet

- Control of intestinal pathogens
- Modulation of the immune system
- Control lactose maldigestion
- Hypocholesterolemic action
- Control of colon cancer
- Improved utilization of nutrients

Control of Intestinal Infections

In the literature, there are many studies on the use of *Lactobacillus* species to control intestinal infections. Unfortunately, many of these earlier studies were not well designed. In most cases, the probiotics, primarily *Lactobacillus* species, were used as a therapeutic rather than a preventative agent. In many cases, proper controls were not included in the studies, so valid observations as to the effectiveness of the probiotic could not be made. Additionally, in many of these studies, there was very little information concerning the particular culture of probiotic involved, especially with regard to origin or characteristics giving it the potential for producing the desired effect.

While it is possible that they may function in a therapeutic manner, it is more reasonable to consider probiotics as a prophylactic treatment for intestinal infections. This has been shown in a well-designed study involving germ-free chickens. In this study, germ-free chickens were fed a culture of *Lactobacillus acidophilus* and 2 days later were challenged with either *Salmonella typhimurium* or *Staphylococcus aureus*. In the same study, another series of germ-free chickens were fed the pathogenic organisms initially and then fed *Lactobacillus acidophilus* (as a therapeutic treatment). In the therapeutic experiments, the *Lactobacillus acidophilus* had minimal effect, but those animals fed the *Lactobacillus acidophilus* initially (prior to challenge with the pathogen) survived much better than did those animals that were challenged with the pathogen first. These results suggest that it is important to have the *Lactobacillus acidophilus* initially (i.e., as a prophylactic treatment) to ward off intestinal pathogens. The scientists conducting this study also indicated that it was desirable to provide the probiotic organism on a continuing basis in a diet for best control of the pathogens. Other studies involving animal models have confirmed these types of results. It is difficult to perform such studies in humans, since it is very difficult, if not impossible, in a university setting to obtain approval for doing challenge studies with intestinal pathogens using human test subjects. However, there have been some well-designed studies in which feeding products containing selected probiotic bacteria have been shown to be effective in helping control naturally occurring intestinal disorders brought on by intestinal pathogens, especially in young children. Based on what is known about the variation among strains and species of this group of bacteria, it is

Table 3 Suggested mechanisms through which probiotics might control intestinal infections

- Production of antimicrobial substances
- Competition for nutrients (not likely)
- Competitive exclusion
- Stimulation or modulation of the body's immune system

very important to properly select a strain or culture for use as a probiotic to control intestinal infections.

Several mechanisms have been suggested to be responsible for the control of intestinal pathogens by probiotic bacteria (Table 3). Probiotic bacteria can produce several types of antimicrobial agents, including acid, bacteriocins, and hydrogen peroxide. However, because of the proteolytic enzymes in the intestine, the role of bacteriocins (most of which are easily inactivated by proteolysis) may be very limited. Because of the low levels of oxygen, peroxide formation should be minimal. Acid (especially acetic acid) is likely the most involved of these antimicrobial agents. Some have suggested competition for nutrients as a mechanism, although this is unlikely. Competitive exclusion, where probiotic bacteria occupy the binding sights on the intestinal wall, thus preventing attachment of pathogenic organisms, may be a main factor in some cases. Stimulation or modulation of the body's immune system, which is discussed in the next section, appears to be a very likely mechanism.

Modulation of the Immune System

Stimulation or modulation of the body's immune system by probiotic bacteria can have health benefits. Probiotic bacteria can cause the body to secrete antimicrobial substances into the intestines. These antimicrobial substances then in turn inhibit the growth of undesirable microorganisms. This is a very interesting and challenging area of research and is currently receiving considerable attention throughout the world. While most of the research on modulation of the immune system has involved animal studies, several studies have focused on the influence of feeding cells of *Lactobacillus acidophilus* on the immune system of humans. In these studies, an increase in the secretion of substances, which are considered inhibitory for certain intestinal pathogens, into the intestine was observed. The ability to modulate the body's immune system through the consumption of probiotic bacteria provides a great opportunity to control intestinal pathogens as well as potentially to have other benefits for the consumer.

Lactose Maldigestion

A number of terms, including 'lactose malabsorption' and 'lactose intolerance,' have been used to describe the inability of a person to digest lactose adequately. 'Lactose maldigestion' seems to be a more accurate term to describe this condition in humans, since it refers to the inability of a person to digest lactose adequately. This is primarily due to the absence of sufficient amounts of the enzyme β-galactosidase in the small intestine.

Microorganisms in the intestinal tract can influence the ability to digest lactose. For instance, dietary lactose is highly toxic to germ-free chicks, whereas chicks with a normal intestinal flora, are able to digest the lactose. This difference has been attributed to the lactose-hydrolyzing enzymes provided by the microorganisms in the intestinal tract of conventional chicks.

Some cultured or culture-containing milk products have been shown to be beneficial. For instance, the consumption of milk containing cells of *Lactobacillus acidophilus* has been shown to improve the utilization of lactose by lactose maldigestors. A similar phenomenon can be observed by the consumption of cultured yogurt containing viable starter bacteria. The primary requirement for these probiotic and yogurt bacteria to provide this benefit is that they contain adequate levels of the enzyme β-galactosidase (Figure 1). The traditional bacteria used to manufacture yogurt, *Lactobacillus delbrueckii* ssp. *bulgaricus* and *Streptococcus salivarius* ssp. *thermophilus*, are not expected to survive and grow in the intestinal tract, because they lack bile tolerance. However, when they interact with bile in the intestinal tract, their permeability is altered, permitting lactose to enter the cells to be hydrolyzed. This results in the organisms being able to hydrolyze lactose at a more rapid rate than they would in milk in the absence of bile. Thus, without growing in the intestinal tract, these two species of bacteria can provide a benefit for those people unable to digest lactose adequately. Research has shown that, while the permeability of these cells was altered in the presence of bile, it was not sufficient to completely rupture the cells. The β-galactosidase remains in the cell having the increased permeability.

Bile has a similar effect on *Lactobacillus acidophilus* in that the permeability of the cells increases

Figure 1 Action required by probiotics to provide benefit for lactose maldigestion.

in the presence of bile enabling lactose to enter more freely and be hydrolyzed. Thus, the mechanism whereby cells of *Lactobacillus acidophilus* can alleviate the problems of lactose maldigestion is similar to that of yogurt. However, *Lactobacillus acidophilus* has the added advantage that it can grow in the presence of the bile, and so new cells can be produced during its growth in the intestine, providing even more of the enzyme necessary for hydrolyzing lactose. When preparing a product to which cells *Lactobacillus acidophilus* are added, it is important that the cells have been grown in a medium containing lactose as a sugar source to insure that cells contain adequate levels of the enzyme β-galactosidase. If not, the amount of enzyme probably will be too low to produce the desired benefit with regard to lactose maldigestion as rapidly as desired.

Hypocholesterolemic Actions

The risk of coronary heart disease in hypercholesterolemic persons can be significantly reduced by lowering serum cholesterol levels. Germ-free animals on an elevated cholesterol diet accumulate approximately twice as much cholesterol in the blood as conventional animals on a similar diet. This suggests the possibility that microorganisms in the intestinal tract can influence serum cholesterol levels. Consumption of organisms such as *Lactobacillus acidophilus* can aid in the control of serum cholesterol levels in humans. Two studies published in the 1970s showed this to occur. In one of the studies, infants fed a formula supplemented with *Lactobacillus acidophilus* exhibited reduced serum cholesterol levels associated with increased numbers of lactobacilli in the feces, compared with infants receiving the control formula. This suggests that the lactobacilli may be associated with the reduction of serum cholesterol levels. In another study, a group of men fed milk fermented by the natural flora in raw milk exhibited unexpected reduced serum cholesterol levels. The fermentation apparently included what was described as a culture of *Lactobacillus*, although the organism was not identified.

Because of these studies, considerable research has focused on the potential for *Lactobacillus acidophilus* or related bacteria to exert beneficial influences on serum cholesterol levels. *Lactobacillus acidophilus* growing in a laboratory medium supplemented with cholesterol and bile salts under anaerobic conditions will assimilate cholesterol. This ability to assimilate cholesterol varies tremendously among strains of this species of bacteria. Results from a feeding trial using pigs on a high-cholesterol diet as an animal model revealed that supplementation of the diet with a strain of *Lactobacillus acidophilus* that assimilated cholesterol during growth in a laboratory medium had a significant beneficial effect on serum cholesterol, whereas a strain that did not assimilate cholesterol during growth in a laboratory medium did not. This suggests the importance of screening cultures for use as a probiotic to produce a beneficial effect on serum cholesterol levels. In another feeding trial involving pigs with diet-induced hypercholesterolemia, animals receiving cells of *Lactobacillus acidophilus* exhibited a significant positive correlation between the reduction of serum cholesterol levels and the concentration of cholic acid in the serum. The decline in serum cholesterol was initiated more rapidly and reached a significantly lower level in the animals fed the lactobacilli than in those not fed the lactobacilli. Such data suggest the possibility that the lactobacilli interfered with the enterohepatic circulation of bile acids, which can be an important factor in reducing serum cholesterol levels. This also suggests another activity of the lactobacilli, which may be important in controlling serum cholesterol levels. *Lactobacillus acidophilus* has the ability to deconjugate bile acids through the action of bile salt hydrolase. Free bile acids being less well absorbed from the small intestine than conjugated acids are more likely to be excreted from the body. Replacement of these excreted bile acids involves the synthesis of new bile acids from cholesterol in the body. This has a tendency to lower the cholesterol pool in the body. This represents the major pathway for removing cholesterol from the human body. An additional advantage for the deconjugation is that free bile acids do not support the absorption of cholesterol for the intestinal tract as well as conjugated acids.

The mechanism whereby consumption of fermented milk products containing cells of *Lactobacillus acidophilus* or other probiotics may reduce levels of serum cholesterol appears to include their ability to assimilate cholesterol and/or deconjugate bile acids (Table 4). Some of the cholesterol assimilated by *Lactobacillus acidophilus* is incorporated in the cellular membranes of the organisms. *Bifidobacterium longum* also can incorporate some cholesterol into its membrane, but *Lactobacillus casei* does not. All three species have the ability to deconjugate bile salts.

Table 4 Activities of probiotic cultures important for imparting a hypocholesterolemic effect

- Assimilation of cholesterol
- Deconjugation of bile salts

Control of Colon Cancer

Some lactic acid bacteria can produce anticarcinogenic or antimutagenic compounds, which can result in the inhibition of some types of tumor cells in animals. For example, rats that had been implanted with ascites tumor cells and fed milk fermented with *Lactobacillus acidophilus* exhibited a lower proliferation of tumor cells than those in the control group. The conclusion was that the *Lactobacillus* species produced substances during growth in the intestine that was antagonistic toward the proliferation of these tumor cells.

Other studies have shown that certain fermented milks have a beneficial influence on the proliferation of colon tumor cells in rats. Feeding rats cells of *Lactobacillus* reduced the activity of three enzymes capable of converting procarcinogens into carcinogens in the intestinal tract. Similar results have been shown in human studies. These enzymes were β-glucuronidase, azoreductase, and nitroreductase. Reduction of the level of activity of these enzymes in the intestinal tract can reduce the chances of carcinogens being formed. The enzymes apparently are of microbial origin. Thus, the potential anticarcinogenic activity of feeding *Lactobacillus acidophilus* may, in this case, be related to the control of undesirable microorganisms in the intestinal tract. In other studies, the consumption of milk containing cells of *Lactobacillus casei* activated macrophages in mice. This observation was based on increases in enzyme activity associated with macrophages. This suggests another potential means, whereby the consumption of a selected probiotic culture may influence proliferation of tumor cells in the body.

Other Benefits

One of the main interests in the livestock industry in using probiotic bacteria as feed supplements is to improve nutrient utilization resulting in improved growth and/or feed efficiency of the livestock. While there is great interest in this area, there is very little evidence reported in the scientific literature to indicate how such benefits might occur. It is possible that such benefits can result from the action of certain enzymes associated with the probiotic bacteria. This could be similar, for instance, to the beneficial effect of yogurt bacteria and *Lactobacillus acidophilus* on lactose maldigestion in humans that results from β-galactosidase associated with the bacterial cells. Selection of a culture of *Lactobacillus acidophilus* with a high level of amylase activity for inclusion as a probiotic in the diet of young pigs can improve starch utilization in the young animal. In a feeding trial involving the use of such a culture, improved growth and feed efficiency of weaning aged pigs were observed as a result of including the selected culture in the diet. The benefit was attributed to the amylase activity of the culture. It is possible that other enzymes that could improve the digestion of other nutrients may be present in some bacteria used as probiotics that could result in improved growth and feed efficiency of the livestock. Of course, the improved growth may relate to the control of undesirable microorganisms in the animal's intestinal tract. There is also interest in the livestock and pet-food industries in using probiotics to help control intestinal infections in animals.

Selection of Probiotic Culture

While there are a number of potential benefits from the inclusion of a probiotic culture in the diet, it is essential that a culture be properly selected for such use. One culture, that is one strain of one species, should not be expected to provide all of the potential benefits that might be derived from probiotics. To help insure that the culture is successful and has a positive effect, certain requirements are to be met (Table 5). Since, in most cases, the sight of action of the probiotic organisms is the intestinal tract, it is generally accepted that the organism should be a normal inhabitant of the intestinal tract. There is strong evidence in the literature indicating that many of these probiotic bacteria exhibit host specificity; for example, a strain of *Lactobacillus acidophilus* originating in the intestinal tract of a calf should not be expected to function equally well in the intestinal tract of a pig or of a human. Thus, it is desirable to use a selected strain of bacteria that originated in the host species for which the product is to be used. If it is to be used as a probiotic for humans, it is highly desirable that the probiotic organism originated in the human intestines. In order to avoid problems with regulatory agencies, it is desirable that the organism of choice has a history of having been used for producing fermented food products.

Table 5 Important factors to consider in selection of a probiotic culture

- Normal inhabitant of intestine
- Host specificity
- Acid tolerance
- Bile tolerance
- Stability during production and delivery
- Production of desired health/nutritional benefit
- One strain would be unlikely to provide all possible benefits

The organism should be resistant to gastric acidity to survive passage through the stomach. The main organisms considered for use as probiotics (i.e., lactobacilli) are acid-tolerant. However, resistance to acidity varies among strains and species, so it must be considered. If the organism is expected to grow and function in the intestinal tract, it must have a certain degree of bile tolerance. The bile resistance based on the ability of the organism to grow in the presence of bile acids varies tremendously among strains of each species of probiotic bacteria. The minimum level of bile tolerance required is not known, but it is suggested that the most bile-resistant strain that will provide the desired benefit be selected. The probiotic culture must be stable during production and storage of the food or feed containing it. This is often the most challenging factor in providing a probiotic organism that has adequate levels of viability at the time of consumption. The most important characteristic of course is that the probiotic culture produce the desired effect. Therefore, it is desirable that some sort of laboratory screening test for the desired effect be implemented. This is not always easy. However, if the organism for instance is to be used for improving lactose utilization, it would be desirable to select one having a high level of β-galactosidase activity. If it is to be used for controlling serum cholesterol levels, it is desirable that the organism not only assimilate cholesterol but also have a high degree of ability to deconjugate bile acids. In order to develop useful screening tests, it is of course essential that we understand how the probiotic organism functions to provide the desirable benefit. In many cases, we simply do not know the answer to this mechanism at this point.

A major factor in selection of a specific organism for use as a probiotic is to remember that one strain should not be expected to provide all potential benefits. Far more is required in the selection process than to select a culture just because it is *Lactobacillus acidophilus*, for example. There is a great variation among strains of this bacterial species. Such variation also occurs among strains of other species of probiotic bacteria.

Dietary Delivery of the Probiotic

If the probiotic organism is expected to provide its benefit during growth and action in the intestinal tract, it is reasonable to assume that the organism must be viable at the time of consumption. It is also desirable and recommended that the probiotic be consumed on a continuing basis. The numbers of viable probiotic bacteria required in a food or feed product to provide the benefit are not known. The actual numbers required probably will vary with the organism and the expected function. Some have suggested, particularly with regard to milk products, that the probiotic should be present at a level of one to two million per milliliter; however, these numbers are not based on scientific data but are based more on an economic situation reflecting the cost of the organism. Research is needed to answer the question with regard to the optimum numbers required. It is essential that the organism be stable and that the desired characteristics be maintained during the production of the probiotic culture, during its storage, and delivery in the food or feed. This is often the greatest challenge in the use of probiotic bacteria. The stability of the organism during storage and delivery can be greatly influenced by the conditions under which the bacteria are grown. For instance, the growth of *Lactobacillus acidophilus* at pH 5 has resulted in cultures that are more stable during storage when added to refrigerated milk than the same cultures grown at a higher pH. The storage stability, especially during frozen and refrigerated storage, varies among strains of a given bacterial species used as a probiotic. Thus, this becomes a factor to consider in selecting the organism for use as a probiotic.

The use of probiotic bacteria such as *Lactobacillus acidophilus* in conjunction with yogurt can be accomplished by either including the probiotic as part of the starter culture or adding cells of the probiotic bacteria after the product has been manufactured. Of course, it would be desirable to use the probiotic as part of the inoculum (i.e., starter culture) used in the manufacture of yogurt in order to yield higher numbers of the probiotic bacteria during the incubation period for the fermentation. However, most of the probiotic bacteria do not grow well under such conditions, and very little increase in numbers is achieved during the incubation process involved in the manufacture of yogurt. Research is needed to provide means of increasing the numbers of probiotic bacteria that grow during the manufacture of a product such as yogurt when the organism is used as a part of the inoculum for manufacturing the fermented milk. In summary, once a desired probiotic culture has been selected, it is important to develop procedures for producing the culture, storing the culture, and delivering the culture in the food or feed without damaging the desired characteristics.

PROSTAGLANDINS AND LEUKOTRIENES

S Katayama, Saitama Medical School, Iruma-gun, Saitama, Japan
J B Lee, State University of New York, New York, USA

Background

Prostaglandins (PGs) were discovered in the 1930s and were first chemically isolated and identified in sheep seminal vesicles and renal medulla in the 1960s. Although together with thromboxanes (TXs) and leukotrienes (LTs), the PGs possess the most potent and most divergent biological activities of any naturally occurring compounds, their true physiological role in many instances remains unknown. From a pathophysiological viewpont, an absolute or relative deficiency of PGs relative to TXs has been implicated in the etiology of hypertension, thrombosis, and atherogenesis for many years. Since PGs and TXs are derived from essential fatty acids, the role of dietary intake of these fatty acids in PG and TX production, particularly in relation to cardiovascular system, will be examined. The possible role of dietary essential fatty acids on LT and PG production in relation to inflammation, the immune system, and gastric function will also be discussed.

Chemistry

In the 1930s, it was reported that fresh human semen causes rhythmic contractions of human endometrium. The active substance was called 'prostaglandin.' In the 1960s, PG was determined to be a mixture of biologically active compounds, which were isolated from sheep seminal vesicles and identified as PGE_{1-3} and PGF_{1-2}. These compounds were independently isolated from extracts of rabbit kidney

medulla and identified as PGA_2, PGE_2, and PGF_{2a}. Later, in 1975, the compound TXA_2, which is a potent vasoconstrictor and platelet aggregant, was isolated, and in 1976, prostacyclin (PGI_2) was discovered. Prostacyclin is synthesized mainly by endothelial cells, prevents platelet aggregation, and is vasodilatory. Studies of the slow-reacting substance of anaphylaxis (SRS-A) showed that it was composed of certain LTs, which are products of leucocyte membrane arachidonate.

The PGs are composed of a basic 20-carbon fatty acid chain containing a cyclopentane ring, the so-called hypothetical prostanoic acid. The carbons are numbered 1–20 from the carboxyl to the terminal group. The designations of PGE_1, PGE_2, and PEG_3 refer only to the number of double bonds in the aliphatic side-chains. The PG_2s are the most abundant naturally occurring class. For PG_1s, the precursor is 8,11,14-eicosatrienoic acid (dihomo-γ-linolenic acid), and for PG_2s, the precursor is 5,8,11,14-eicosatetraenoic acid (arachidonic acid). The PG_3s can be formed from 5,8,11,14,17-eicosapentaenoic acid (EPA).

The LTs were named because they were discovered in leucocytes and because the common structural feature is a conjugated triene. Various members of the group have been designated alphabetically, and the subscript denotes the number of double bonds.

Analysis of Prostaglandins and Leukotrienes

Prostaglandins and leukotrienes are present in many different biological samples, including plasma. However, eicosanoid quantification in the peripheral circulation does not accurately reflect *in vitro* biosynthesis and disposition because of rapid turnover, low concentration, metabolism by the lung and liver, and sample processing problems. For example, plasma concentrations of PGE_2 and TXB_2 determined by gas chromatography have been reported to be 12 and several picograms per milliliter, respectively. Urinary samples can be utilized to evaluate *in vivo* PGs or LTs for the kidneys, whereas pleural fluids or bronchial lavages can be used to evaluate pulmonary production. The most accurate reflection of local synthesis is obtained by incubations of slices or homogenates of specific cells and/or tissues with measurement of PG, TX, or LT production *in vitro*.

The most precise method to determine PGs and LTs is undoubtedly gas chromatography linked to mass spectrometry. However, this type of analysis is not widely available. Radioimmunoassay using a specific antibody against various PGs or LTs and ^{3}H- or ^{125}I-labeled tracer are available, highly specific, sensitive, and relatively inexpensive, and have been widely utilized for eicosanoid analysis.

Prior to radioimmunoassay, extraction of arachidonic acid metabolites from plasma, urine or tissue homogenates may be required. The most common method is to extract acidified aqueous solution with an oraganic solvent such as diethylether or ethyl acetate, followed by purification by column chromatography with a octadecylsilyl (ODS) silica (SEP-PAK C-18) cartridge, silicic acid or sometimes by high-performance liquid chromatography.

Biosynthesis of Prostaglandins and Leukotrienes

Arachidonic acid and its metabolite byproducuts (the arachidonic acid cascade) are important mediators of a number of physiological phenomena. As shown in Figure 1, the rate-limiting step in the formation of the metabolites of arachidonic acid seems to be the initial step, i.e., the release of free arachidonic acid from the cell membrane phospholipid pool mediated through activation of phospholipase A_2. Phospholipase C may play another role in arachidonic acid release through liberating a diglyceride, which is then hydrolyzed by another lipase to yield arachidonic acid. Following the release of arachidonic acid, enzymes are involved in its subsequent metabolism. Prostaglandin synthase, i.e., cyclooxygenase (COX), is a key enzyme in controlling the extent of prostanoid biosynthessis. It possesses two enzymatic activities: COX activity, the conversion of arachidonic acid (AA) to PGG_2 and peroxidase activity, the conversion of PGG_2 to PGH_2 catalyzing a two-electron reduction of PGG_2 to PGH_2. PGH_2 is the common precursor for a number of biologically important prostanoids, i.e., PGI_2, TXA_2, PGE_2, PGD_2, and $PGF_{2\alpha}$, the formation of which occurs through the action of the respective synthetase called PGI synthase, TXA synthase, PGE synthase, PGD synthase, and PGF synthase. COX is distributed in most mammalian tissues. Two isoforms of COX have been identified and cloned. COX-1, originally cloned from ram seminal vesicles and subsequently from mouse tissues and human endothelial cells and platelets, is considered to be constitutive, whereas COX-2, cloned from chicken embryonic fibroblasts and mouse 3T3 fibroblasts, is highly inducible. COX-1 activity is inactivated by aspirin through acetylation of the serine residue and inhibited by other nonsteroidal antiinflammatory drugs (NSAIDs), whereas COX-2 is inhibited by glucocorticoids. Various biological activities are due to binding of prostanoids to the receptors on the cell surface. With the advent of the molecular biology technique, eight prostanoid receptors have been

cloned so far; TP, IP, FP, DP and four classes of EPs (EP_1, EP_2, EP_3, and EP_4). Prostanoid receptors have seven transmembrene domains and are members of the superfamily of the rhodopsin receptor. These receptors are classified into three groups; IP, DP, EP_2, and EP_4 are the stimulatory receptors, which generate cAMP, resulting in vasodilatoion; TP, FP, and EP_1 are the G protein-linked receptors that increase intracellular Ca^{2+} concentration, resulting in vasoconstriction; and EP_3 is an inhibitory receptor, which inhibits the elevation of cAMP, resulting in vasodilation.

In the second pathway of arachidonic acid metabolism, 5-lipoxygenase forms a series of products named LTs, as illustrated in Figure 1. 5-Hydroperoxyeicosatetraenoicacid (5-HPETE) may be enzymatically dehydrated to LTA_4 (5(S)-*trans*-oxido-7, 9-*trans*-11, 14-*cis*-eicosa-tetraenoic acid). Subsequent enzymatic hydrolysis of LTA_4 results in LTB_4 (5(S)-12(*R*)-dihydroxy-6-*cis*-8, 10-*trans*-14-*cis*-eicosatetraenoic acid). LTA_4 also reacts with sulfydryl compounds by addition of gluthathione (Glu-Gys-Gly) by glutathione-(*S*)-transferase, yielding LTC_4 (5(*S*)-glutathionyl-7, 9-*trans*-11, 14-*cis*-eicosatetraenoic acid). LTD_4 can be then produced from LTC_4 through elimination of glutamyl residue by a γ-glutamyl transpeptidase. The remaining peptide bond in LTD_4 is hydrolyzed to give LTE_4 by a dipeptidase.

Physiological Action of PGs and LTs

The relative amounts of compound formed depend on the tissue or cell being studied. When platelets are activated by collagen or thrombin, unstable TXA_2 is predominant, resulting in a rapid and irreversible aggregation of platelets and contraction of vascular smooth muscle cells. However, vascular endothelial

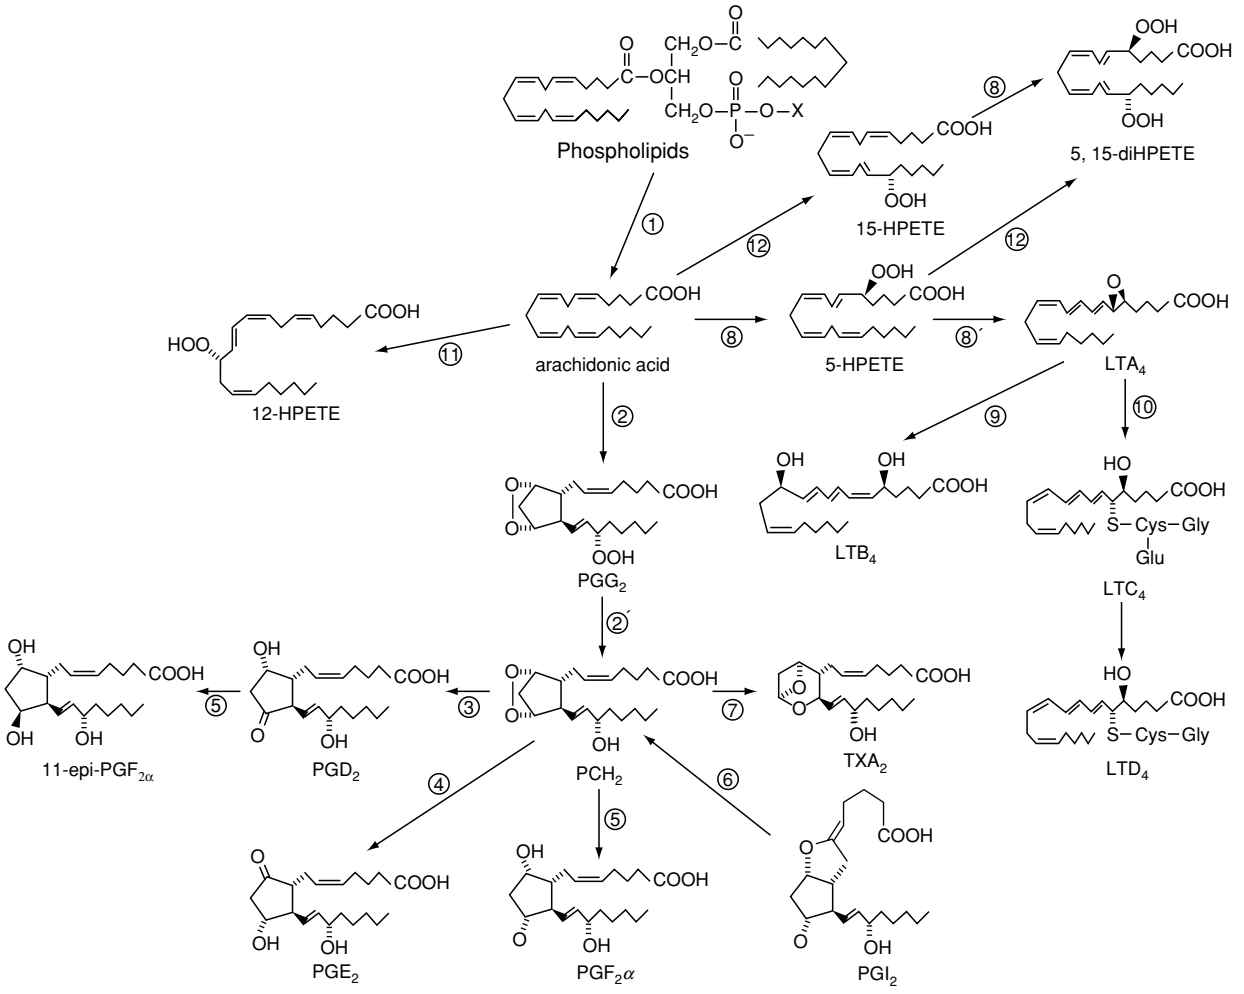

Figure 1 Metabolic pathways of prostaglandin (PG) and leukotriene (LT) from arachidonic acid. The name of enzyme that catalyzes each step is as follows: 1, phospholipase A_2; 2, cyclooxygenase; 3, PGD synthase; 4, PGE synthase; 5, PGF synthase; 6, PGI synthase; 7, TXA synthase; 8, 5-lipoxygenase; 8′, dehydrase; 9, hydolase; 10, glutathione-*S*-transferase; 11, 12-lipoxygenase; 12, 15-lipoxygenase.

cells form unstable PGI_2, which has a potent vasodilating and antiaggregatory action similar to stable PGE_2, Neutrophils as well as monocytes or macrophages produce PGE_2, whereas PGD_2 is formed in mast cells and basophils. In kidneys, renal interstitial cells and collecting duct cells synthesize PGE_2, collecting dust cells synthesize PGE_2, the renovasculature endothelia synthesize PGI_2, and glomerular mesangial endothelia from PGF_{2a}. In addition to PGE_2, other PGs are also produced in the gastrointestinal tract. PGE_1, PGE_2, and their analogs, administered exogenously, suppress gastric acid secretion and possess the property of protecting the gastric mucosa against necrotizing agents such as absolute ethanol or hydrochloric acid (cytoprotection). This is the reason why NSAIDs cause a variety of problems in the gastrointestinal tract including irritation and ulceration of the stomach. Since COX-1 appears to play a major role, treatment with COX-2 selective inhibitors appears to be associated with less gastrointestinal damage than conventional NSAIDs.

Prostaglandins play many physiological roles in human reproduction, e.g., menstrual regulation, pregnancy, and induction of labor. PGE_1, PGE_2, or their analogs are now widely used clinically for induction of labor or abortion. PGE_2 and PGI_2 produce or augment vasodilation and enhance bradykinin or serotonin-induced pain, resulting in redness, heat, swelling, and pain in the inflammatory processes. PGs such as PGE_2 and PGI_2 have also been shown to increase during pyrogen-induced fever. In fact, PGE_2 administered into the hypothalamus increases body temperature, whereas PGD_2 deceases body temperature, indicating a possible role of PGs in human thermoregulation. PGs, TXs, and some monohydroxy derivatives of arachidonic acid (hydroxyeicosatetraenoic acids) also have chemotactic effects on polymophonuclear leucocytes. LTB_4 is chemotactic not only for neutrophils and eosinophils but also for monocytic macrophages. These phenomena are considered to be the initial events of the inflammatory response. Polymorphonuclear leucocytes only survive for hours in the inflammatory area, whereas monocytes may stay for weeks and finally may be transformed to fibroblasts, initiating the repair process of the wounds. Furthermore, monocytes can present antigens to cells capable of producing antibodies and can synthesize all the members of the arachidonic acid cascade. Monocytes are also capable of forming interleukin, interferon, complement, and protease, all of which participate in tissue disruption. The lipoxygenase system is more important in subacute and chronic inflammation, whereas the COX system produces or modulates acute inflammation. The antiinflammatory action of aspirin, indomethacin, and other nonsteroidal antiinflammatory agents is produced almost entirely by PG synthesis inhibition, as shown by studies revealing inhibition of PG-cyclooxygenase with aspirin.

LTC_4, LTD_4, LTE_4, and their trans isomers do not have any effects on chemotaxis, enzyme release, or leucocyte aggregation. However, they possess potent biological activities, which were formerly attributed to SRS-A release from sensitized lungs treated with a specific antigen. These compounds may be important mediators in asthma and other acute hypersensitivity reactions. Contraction of guinea-pig ileum and other smooth muscle by LTs exhibits a slow onset and relaxation, which is the basis of the original designation as SRS-A. This distinguishes these substances from histamine, bradykinin, and PGF_{2a}. LTC_4 and LTD_4 are respectively about 200-fold and 20 000-fold more potent than histamine in promoting small airway contraction. In addition, these LTs cause rapid arteriolar contraction and promote plasma leakage in postcapillary venules. They also slow the rate of mucus clearance from the airways of patients with asthma after the inhalation of antigen and increase the amount of mucus glycoprotein synthesis in the airways.

With the advent of cloning of various prostanoid synthetases and their receptors, vast numbers of prostanoids analogs synthesized so far will be retested. Diverse physiological actions of various prostanoids will be shortly reevaluated and reclassified, based on their specific receptors using a specific agonist and antagonist. For example, inhibition of vasopressin-induced water reabsorption in kidney or histamine-induced gastric acid secretion can be explained by EP_3-mediated inhibition of adenylate cyclase. Furthermore, genetic engineering such as prostanoid receptor knockout mice may be able to clarify a specific physiological role of PGs and LTs.

Effects of Diet on PG Formation

Polyunsaturated Fatty Acids

It was first shown in 1974 that dietary deficiency of essential fatty acids in animals results in hypertension, which depends on a high sodium intake, thus being very similar to renoprival hypertension or experimental 'salt sensitive' hypertension. This was later confirmed in 1983, and the blood-pressure response was attributed to a dietary deficiency of linoleic acid. However, it would appear unlikely that this is a cause of human hypertension, since selective deficiency of essential fatty acids in the human diet is rare.

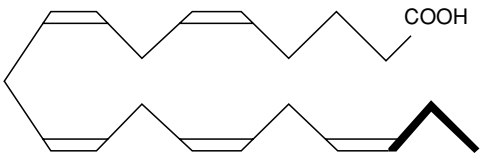

Figure 2 Eicosapentaenoic acid (EPA).

A low prevalence of atherosclerosis and a low mortality from myocardial infarction among Greenland Inuit, despite a diet high in fat and cholesterol, suggested that dietary fish may have some properties that could prevent coronary artery disease. The Inuit consume 5–10 g daily of the long-chain *n*-3 polyunsaturated fatty acids EPA (C20; 5*n*-3) (Figure 2) and docosahexaenoic acid (C22; 6*n*-3), which are present in fish oils. When *n*-3 fatty acids are included in the diet, EPA inhibits conversion of linoleic acid and competes with arachidonic acid for the 2-acyl position in membrane phospholipids, reducing plasma and cellular levels of arachidonic acid. In addition, EPA competes with arachidonic acid as the substrate for cyclooxygenase. The platelets produce biologically inactive TXA_3 instead of TXA_2. However, PGI_2 synthesis in endothelial cells is not markedly inhibited, and any newly synthesized PGI_3 has the same potency as PGI_2. Thus, a diet abundant in EPA may inhibit platelet aggregation and cause vascular dilatation, resulting in blood-pressure reduction. In fact, a metaanalysis including 1356 subjects from 31 placebo-controlled trials confirmed the blood-pressure-lowering effects of dietary fish oils. The hypotensive effect was dose-dependent; there was little change in blood pressure at doses lower than 3 g per day (corresponding to 250 g of salmon), but above this, a 0.66 mmHg fall in systolic blood pressure was demonstrated per 1.0-g increase in *n*-3 polyunsaturated fatty acid. The hypotensive effect appeared greater in patients with hypertension, hypercholesterolemia, or coronary heart disease. Mechanisms by which *n*-3 polyunsaturated fatty acids may act might be attributed to an attenuated constrictor responses to vasoactive agents, such as noradrenaline and angiotensin II, an attenuated sympatho-adrenal stimulation and/or modulated production or release of nitric oxide from vascular endothelial cells. However, the safety and long-term benefits of this treatment have been questioned because PGE_2 synthesis is inhibited and replaced by PEG_3 from EPA in the fish oils. Since renal blood flow is dependent on PGE_2 in renal disease and during volume contraction, any decrease in PGE_2 might result in more severely compromised renal function.

The other merit of dietary fish or fish oil supplements may be its lowering effect on plasma lipid. The principal effect has been found to be a reduced production of triacyglycerols and very-low-density lipoprotein (VLDL) in the liver. Because VLDL is a precursor of low-density lipoprotein (LDL), a secondary reduction in LDL cholesterol is also seen. Such conditions are considered to reduce the atherogenicity of lipoprotein particles. Futhermore, *n*-3 fatty acids have been reported to improve insulin sensitivity in skeletal muscle, possibly through a decrease in triacylglycerol accumulation. However, fish oil supplementation to diabetic patients resulted in no change in glycemic control in one study and an actual deterioration in glycemic control in another study.

Increased intake of polyunsaturated fatty acids has also been reported to result in reduced gastric acid secretion and an increase in gastric mucosal protection. Diets enriched in fish oil or dihomo-γ-linolenic acid also reduce LTB_4 formation in leucocytes or monocytes, suggesting a possible role for fish oil diets in suppressing inflammation in such disorders as rheumatoid arthritis or systemic lupus erythematosus.

Carbohydrate

The increase in urinary excretion of TXB2 associated with a decreased 6-keto-$PGF_{1\alpha}$ has been demonstrated in diabetic animals and humans. An overproduction of PGE_2 has also been considered to be one of the reasons for glomerular hyperfiltration. In fact, enhanced growth of mesangial cells under high-glucose conditions can be explained, at least in part, by a decreased cyclic adenosine monophosphate production via EP_4, which augments EP_1 function in conjunction with the overproduction of PGE_2. Diabetic pregnancy is associated with growth disturbances and malformations in the offspring. Embryonic dysmorphogenesis induced by high concentration of glucose is protected by addition of arachidonic acid or PGE_2. COX inhibitors such as indomethacin or aspirin yield embryonic dysmorphogensesis similar to that caused by glucose, indicating that this disturbance may be partly mediated via altered metabolism of arachidonic acid.

Proteins

Protein intake has profound effect on renal hemodynamics and excretory function. A high protein intake has been shown to have deleterious effects on the kidneys, especially in preexisting renal disease, indicating a rationale for dietary protein restriction to lessen renal parenchymal damage. However, not all proteins are equipotent in relation to their renal

effects. A lower glomerular filtration rate and renal plasma flow, as well as reduced excretion of albumin and some proteins, have been reported in vegan and lactovegetarian individuals compared with omnivorous subjects. In fact, acute (more than 80 g) or chronic loading (more than 1 g per kg of body weight per day) with animal proteins has resulted in an increase in renal plasma flow and glomerular filtration associated with a higher clearance of albumin than that on vegetable protein diets. Vasodilatory PGs such as PGI_2, which may be partly dependent on a rise in glucagon secretion from the pancreas, have been proposed as a possible mediator of such renal effects of animal proteins, since the administration of indomethacin was found to abolish the renal response to a meat meal.

Minerals

The isolation and identification of renal PGE_2 and PGA_2 between 1965 and 1967 provided biochemical support for the renal anitihypertensive-endocrine function. Numerous studies in humans and animals thereafter have shown that PGE_2 has a potent vasodilatory and natriuretic action and hence a pivotal role in sodium homeostasis. In fact, PGE_2 administration augments renal blood flow and urinary sodium excretion. In addition, PGE_2 stimulates renal renin secretion and inhibits vasopressin-mediated water reabsorption. During a low sodium intake, the renin–angiotensin axis is activated by volume depletion, resulting in antinatiuresis and vasoconstriction. Renal PGE_2 synthesis is stimulated by elevated circulating angiotensin II, which then counteracts the action of angiotensin II, leading to normalization of renal blood flow, blood pressure, and sodium excretion (Figure 3). This is the rationale for the beneficial effects of a low-sodium diet on these cardiovascular parameters. The same can be said for diuretic therapy, since the renomedullary synthesis of PGE_2 from arachidonic acid is directly stimulated by furosemide. The natriurietic and antihypertensiv effects of furosemide are mediated by this newly synthesized PGE_2, since both effects are inhibited by indomethacin. While COX-1 has long been recognized to be involved in normal kidney function, COX-2 is now seen to have a distinct role. COX-2 has been localized in both the macula densa and the interstitial cells of the medulla. Chronic sodium deprivation was found to increase COX-2 levels in the macula densa, and COX-2-generated prostanoids may be important mediators of renin production and tubuloglomerular feedback.

Dietary potassium deficiency leads to hypokalemia and impairment of maximal urinary concentrating ability. Since PGE_2 antagonizes vasopressin-induced water reabsorption, an increase in renomedullary PGE_2 production was postulated to underlie this concentrating defect. However, during chronic dietary potassium depletion secondary to dietary potassium deprivation in animals, PGE_2 synthesis by the renal medulla is markedly reduced, and thus current evidence does not support a role for PGs in hypokalemic polyuria.

Oral calcium supplementation has been reported to decrease blood pressure in some patients with essential hypertension and hypertensive rats. However, in other studies, calcium supplementation produced no effect on blood pressure in normotensive or hypertensive subjects, Although calcium supplementation has been shown to increase urinary PGE_2 excretion in normotensive women, there was no associated fall in blood pressure.

Spices

Spices have been consumed by many cultures for thousands of years. In fact, in classical Indian (Ayurvedism), Chinese, or Graeco-Arabic systems of medicine, some spice-containing plant materials were used to prevent or treat some diseases. Some spices have

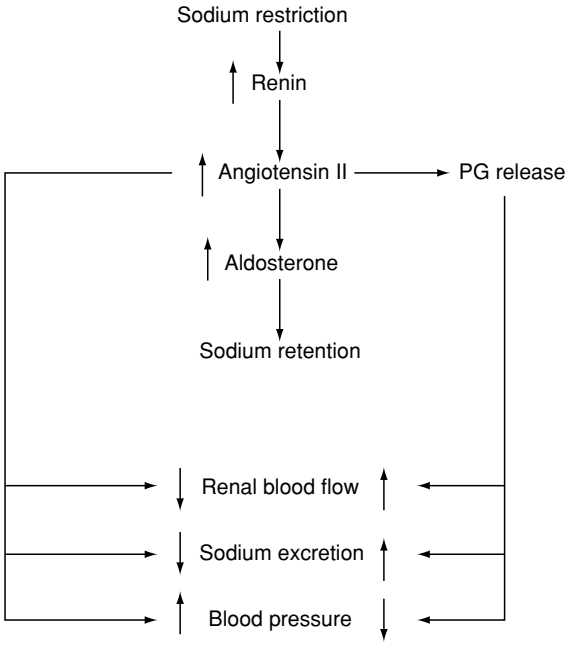

Figure 3 Scheme whereby volume depletion secondary to dietary sodium restriction leads to an increase in PG release from the renal medulla and resultant physiological actions of angiotensin II. From Lee JB (1980) Prostaglandins and the renin–angiotensin axis. *Clinical Nephrology* 14: 159–163, with permission.

been shown to inhibit platelet aggregation. These include onion, garlic, ginger, cloves, omum, cumin, and turmeric. Extracts from these spices were found to inhibit platelet COX, allowing less TXA_2 to be produced. As COX is inhibited, more substrate (arachidonic acid) becomes available to the lipoxygenase pathway, as shown by the observation that 12-HPETE increases in platelets treated with extracts from ginger, cloves, cumin, and turmeric. However, onion extracts have been demonstrated to inhibit the 5- or 12-lipoxygenase in platelets. This might at least partially explain the observation that crude ethanolic extracts of onion prevented allergen-induced bronchoconstriction in animals and humans. Ginger, which is demonstrated to have both antihistaminic and antioxidant action, also inhibits both the COX and 5-lipoxygenase pathway. Garlic extracts have also been demonstrated to inhibit COX activity and LTC4 formation.

Chemistry

J K P Weder and H-D Belitz[†], Technische Universität München, Garching, Germany

Background

Like peptides, proteins are formed from amino acids through amide linkages. Covalently bound hetero constituents can also be incorporated into proteins. For example, phosphoproteins such as milk casein or phosvitin of egg yolk contain phosphoric acid esters of serine and threonine residues. Glycoproteins, such as κ-casein, various components of egg white and egg yolk, collagen from connective tissue, and serum proteins of some species of fish contain one or more monosaccharide or oligosaccharide units bound *O*-glycosidically to serine, threonine, or δ-hydroxylysine or *N*-glycosidically to asparagine.

The structure of a protein is dependent on the amino acid sequence (the primary structure) which determines the molecular conformation (secondary and tertiary structures). Proteins sometimes occur as molecular aggregates which are arranged in an orderly geometric fashion (quaternary structure).

Amino Acid Sequence

Amino Acid Composition and Subunits

Sequence analysis can only be conducted on a pure protein. First, the amino acid composition is determined after acid hydrolysis. The procedure (separation on a single cation exchange resin column and color development with ninhydrin reagent) has been standardized and automated (amino acid analyzers). More recently, derivatization of amino acids to form fluorescent derivatives, e.g., with *o*-phthaldialdehyde (OPA) and 2-mercaptoethanol, followed by reversed-phase high-performance liquid chromatography (RP-HPLC) has been introduced (precolumn derivatization). The use of chiral thiols in this procedure allows the separation of amino acid enantiomers.

Selenocysteine has been detected as a relatively new protein amino acid in glutathione peroxidase (EC 1.11.1.9) in 1973, and later also in other oxidoreductases and other proteins (e.g., in selenoprotein P, 10 residues per molecule). The incorporation of selenocysteine occurs during ribosomal protein synthesis cotranslationally by a complex mechanism in which a specific $tRNA^{(ser)sec}$ is first loaded with serine, then transformed into selenocysteyl-$tRNA^{(ser)sec}$ with selenophosphate as the selenium donor and bound with its anticodon region to a UGA codon of the mRNA. Some selenocysteine, however, is also formed by posttranslational selenium–sulfur exchange, e.g., in selenoprotein P.

It is also necessary to know the molecular weight of the protein. This is determined by gel column chromatography, ultracentrifugation, sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) or mass spectrometry (matrix-assisted laser desorption/ionization time-of-flight mass spectrometry, MALDI-TOF-MS, or electrospray ionization mass spectrometry, ESI-MS). Furthermore, it is necessary to determine whether the protein is a single molecule or consists of a number of identical or different polypeptide chains (subunits) associated through disulfide bonds or noncovalent bonding.

[†] Deceased.

Dissociation into subunits can be accomplished by a change in pH, by chemical modification of the protein, such as by succinylation, or with denaturing agents (urea, guanidine hydrochloride, sodium dodecyl sulfate). Disulfide bonds, which are also found in proteins consisting of only one peptide chain, can be cleaved by oxidation of cystine to cysteic acid or by reduction to cysteine with subsequent alkylation of the thiol group to prevent reoxidation. Separation of subunits is achieved by chromatographic or electrophoretic methods.

Terminal Groups

N-Terminal amino acids can be determined by treating a protein with 2,4-dinitrofluorobenzene (DNFB, Sanger's reagent) or 5-(dimethylamino)naphthalene-1-sulfonyl chloride (dansyl chloride). Another possibility is the reaction with cyanate, followed by elimination of the *N*-terminal amino acid in the form of hydantoin, and separation and recovery of the amino acid by cleavage of hydantoin. The *N*-terminal amino acid (and the amino acid sequence close to the *N*-terminus) is accessible by hydrolysis with aminopeptidase M (EC 3.4.11.2), in which case it should be remembered that the hydrolysis rate is dependent on amino acid side chains and that proline residues are not cleaved. A special procedure is required when the *N*-terminal residue is acylated (*N*-formyl- or *N*-acetyl-amino acids, or pyroglutamic acid).

Determination of *C*-terminal amino acids is possible via the hydrazinolysis procedure. The *C*-terminal amino acid is separated from the amino acid hydrazides, e.g., by a cation exchange resin, and identified. The *C*-terminal amino acids can be removed enzymatically by carboxypeptidase A (EC 3.4.17.1), which preferentially cleaves amino acids with aromatic and large aliphatic side chains; carboxypeptidase B (EC 3.4.17.2), which preferentially cleaves lysine, arginine, and amino acids with neutral side chains; carboxypeptidase C (EC 3.4.16.1), which cleaves with less specificity and cleaves proline; carboxypeptidase P (EC 3.4. 16.1), hydrolyzing almost all amino acids (including proline, aspartic acid, and glutamic acid; release of serine and glycine is retarded); or carboxypeptidase Y (EC 3.4. 16.1), which shows high catalysis rate if the penultimate and/or terminal residue is an aromatic or aliphatic amino acid including proline (release of glycine and aspartic acid is considerably retarded).

Partial Hydrolysis

Longer peptide chains are usually fragmented. The fragments are then separated and analyzed individually for amino acid sequences. Selective enzymatic cleavage of peptide bonds is accomplished with trypsin (EC 3.4.21.4), which only cleaves Lys-X and Arg-X bonds; chymotrypsin (EC 3.4.21.1), which cleaves peptide bonds with less specificity (Tyr-X, Phe-X, Trp-X and Leu-X); and, more recently, with endoproteinase Arg-C (EC 3.4.22.8), hydrolyzing only Arg-X bonds; endoproteinase Asp-N (EC 3.4.24.33), hydrolyzing X-Asp and X-CySO_3H bonds; endoproteinase Glu-C (EC 3.4.21.19), hydrolyzing Glu-X or Glu-X and Asp-X bonds depending on pH and buffer; or endoproteinase Lys-C (EC 3.4.21.50), hydrolyzing only Lys-X bonds. The enzymatic attack can be influenced by modification of the protein.

The most important chemical method for selective cleavage uses cyanogen bromide (BrCN) to attack Met-X linkages. Separation of peptide fragments is achieved by gel and ion exchange column chromatography using a volatile buffer as the eluent (e.g., pyridine, morpholine acetate) which can be removed by freeze-drying of the fractions collected. Recently the separation of peptides and proteins by RP-HPLC has gained great importance, using volatile buffers mixed with organic, water-soluble solvents (e.g., acetonitrile) as the mobile phase.

The fragmentation of the protein is performed by different enzymatic and/or chemical techniques, at least by two enzymes of different specificity. The arrangement of the peptides obtained, in the same order as they occur in the intact protein, is accomplished with the aid of overlapping sequences.

Sequence Analysis

The Edman degradation is by far the most important method in sequence analysis. It involves stepwise degradation of peptides with phenyl isothiocyanate, starting at the *N*-terminus of the polypeptide. The resultant phenylthiohydantoin is either identified directly or the amino acid is recovered. The stepwise reactions are performed in solution or on peptide bound to a carrier, i.e., to a solid phase. Both approaches have been automated (sequencer). Carriers used include resins containing amino groups (e.g., aminopolystyrene) or glass beads treated with aminoalkylsiloxane. The peptides are then attached to the carrier by carboxyl groups (activation with carbodiimide or carbonyl diimidazole, as in peptide synthesis) or by amino groups. Nowadays, Edman degradation has been miniaturized and is performed on gas-phase or pulsed-liquid-phase sequencers, in which the peptide is adsorbed on a polybrene-treated glass-fiber disk and the reagents are applied either as vapors in a carrier gas stream or in small liquid doses separated by carrier gas bubbles.

Methods for C-terminal sequencing have also been reported. After activating the polypeptide at the α-carboxyl group with acetic anhydride, the activated polypeptide is reacted with thiocyanic acid (formed from ammonium thiocyanate with an acid) and the resulting thiohydantoin is cleaved with a base to give the thiohydantoin of the C-terminal amino acid and the polypeptide reduced by one amino acid residue. Another procedure uses diphenyl phosphoroisothiocyanatidate (DPP-ITC), pyridine for reaction and cyclization, and sodium trimethylsilanoate for cleavage. A modification of the first procedure has been automated including *S*-alkylation of the thiohydantoin with 2-(bromomethyl)-naphthalene and cleavage of the C-terminal amino acid derivative simultaneously with the formation of the next thiohydantoin by addition of ammonium thiocyanate plus trifluoroacetic acid. It should be mentioned that C-terminal sequencing procedures are by far less sensitive than Edman degradation and that only a few steps can be interpreted without doubt.

Methods other than chemical degradations can provide additional information. These include determination of terminal residues with amino- and carboxypeptidases, as already discussed, or mass spectrometry. Mass spectrometric sequencing can be done by MALDI-TOF-MS (peptide ladder sequencing and postsource decay (PSD)-MALDI) or ESI-MS (atmospheric pressure ionization collision-induced decay, API-CID; single or multiple fragmentation of selected ions, MS-MS or MS^n). Peptide ladder sequencing combines a modified Edman degradation (incomplete by the addition of 5% phenyl isocyanate) with the determination of the molecular masses of the resulting mixture consisting of phenylcarbamoyl derivatives of peptides stepwise reduced by one amino acid. Because of the small difference between the molecular mass of aspartic and glutamic acid and their amides, results can only be interpreted up to 5 kDa. The other two methods include fragmentation of the peptide chain, and unknown sequences can only be interpreted up to 2 kDa without doubts. The main area of mass spectrometric sequencing is the confirmation of already known sequences. None of the methods can differentiate between leucine and isoleucine.

Recently, amino acid sequences of proteins have increasingly been deduced from the nucleotide sequences of the corresponding genes. Examples of food proteins are gliadins and glutenins from wheat. If the gene responsible for the expression of a protein is known, the sequence analysis of the nucleic acid can be performed much easier than that of the protein itself.

Examples for amino acid sequences of food proteins are summarized in Tables 1–3 (legume 11S globulins, legume 7S globulins, wheat proteins). Further examples (milk proteins, collagen, monellin, and thaumatin) are presented in the first edition of this Encyclopedia.

Conformation

Information about conformation is available through X-ray crystallographic analysis of protein crystals and through the determination of the H–H distances by proton nuclear magnetic resonance (NMR) spectroscopy in solution. In principle, the conformation of the protein in crystalline form can be assumed to be similar to that of the protein in solution. In 1960 the structure of myoglobin (17.8 kDa) was elucidated with a resolution of 0.2 nm. Individual atoms are well revealed at 0.11 nm. Such a resolution has only been achieved with few proteins. Reliable localization of the C^{α} atoms of the peptide chain requires a resolution of less than 0.3 nm. Most protein conformations have been studied with a resolution between 0.2 and 0.3 nm and, more recently, between 0.15 and 0.2 nm.

Extended Peptide Chains

X-ray structural analysis and other physical measurements of a fully extended peptide chain reveal the lengths and angles of bonds. The peptide bonds have partial (40%) double-bond character with π-electrons shared between the C′–O and C′–N bonds. The resonance energy is about 83.6 kJ mol^{-1}. Normally the bond has a *trans* configuration, i.e., the oxygen of the carbonyl group and the hydrogen of the NH group are in the *trans* position; a *cis* configuration only occurs in exceptional cases (e.g., in small cyclic peptides or in proteins before proline residues). Because of the partial double-bond character, six atoms of the peptide bonds, C_i^{α}, C_i', O_i, N_{i+1}, H_{i+1} and C_{i+1}^{α}, lie in one plane. For a *trans* peptide bond, ω_i is 180°. The position of two neighboring planes is determined by the numerical value of the angles ψ_i (rotational bond between a carbonyl carbon and an α-carbon) and ϕ_i (rotational bond between an amide nitrogen and an α-carbon). For an extended peptide chain $\psi_i = 180°$ and $\phi_i = 180°$. The position of side chains can also be described by a series of angles χ_i^{1-n}.

Secondary Structure (Regular Structural Elements)

The primary structure gives the sequence of amino acids in a protein chain whereas the secondary and tertiary structure reveal the arrangement of the chain in space. The peptide chains are not in an extended or

Amino acids are given in the International Union of Pure and Applied Chemistry one-letter notation. The two polypeptides of glycinin and legumin are connected by a disulfide bond Cys(α84)-Cys(β7) and Cys(α89)-Cys(β7), respectively. The two remaining cysteine residues of the α subunits (10/43 and 13/46, respectively) probably form an intrachain disulfide bridge.
Data from Wright DJ (1987) The seed globulins. In: Hudson BJF (ed.) *Developments in Food Proteins*, vol. 5, pp. 81–157. London: Elsevier Applied Science.

unfolded form (ψ_i, $\phi_i \neq 180°$). It can be shown with models that ψ_i and ϕ_i, at a permissible minimum distance between atoms can assume only particular angles. It has been shown for many proteins empirically that they have values of ψ_i, ϕ_i pairs within the permissible range. When a multitude of equal ψ_i, ϕ_i pairs occurs consecutively in a peptide chain, the chain acquires regular repeating structural elements (secondary structure). Examples of some important secondary structures are shown in Figures 1–3.

β-Sheet Three regular structural elements (pleated-sheet structures) have values in the range of $\phi = -120°$ and $\psi = +120°$. The peptide chain is always lightly folded on the C_α atom, thus the R side chains extend perpendicularly to the extension axis of the chain, i.e., the side chains change their projections alternately from $+z$ to $-z$. Such a pleated structure is stabilized when more chains interact along the x axis by hydrogen bonding, thus providing the cross-linking required for stability. When adjacent chains run in the same direction, the peptide chains are parallel. This provides a stabilized, planar, parallel sheet structure (Figure 1). When the chains run in opposite directions, a planar, antiparallel sheet structure is stabilized (Figure 2). The lower free-energy, twisted sheet structures, in which the main axes of the neighboring chains are arranged at an angle of 25°, are more common than planar sheet structures.

The β-structures can also be regarded as special helical structures with a continuation of two residues per turn. With proline, the formation of a β-structure is not possible.

Helical structures There are three regular structural elements in the range $\phi = -60°$ and $\psi = -60°$, in which the peptide chains are coiled like a threaded screw. These structures are stabilized by intrachain hydrogen bridges which extend almost parallel to the helix axis, cross-linking the CO and NH groups, specifically the CO group of amino acid residue i with the NH group of residue $i+3$ (3_{10}-helix), $i+4$ (α-helix) or $i+5$ (π-helix). The α-helix, and for polypeptides from L-amino acids exclusively the right-handed α-helix, is the most common (Figure 3). The 3_{10}-helix is only observed at the ends of α-helices, whereas the existence of a π-helix is hypothetical. A helix is characterized by the angles ϕ and ψ, or by the

Data from Wright DJ (1988) The seed globulins – part II. In: Hudson BJF (ed.) *Developments in Food Proteins*, vol. 6, pp. 119–178. London: Elsevier Applied Science, and references therein.

parameters derived from these angles: n, the number of amino acid residues per turn; d, the rise along the main axis per amino acid residue; and r, the radius of the helix. Thus, the equation for the pitch, p, is $p = n \cdot d$.

Reverse turns An important conformational feature of globular proteins is the reverse turns, β-turns, or β-bends. They occur at 'hairpin' corners, where the peptide chain changes direction abruptly. Such corners involve four amino acids residues, among them frequently proline. Glycine is favored in the third position of β-bends on the basis of energy considerations. Different types of β-turns are known, for which different amino acids are allowed.

Super secondary structures Analysis of known structures has demonstrated that regular elements can exist in combined forms. Examples are the coiled-coil α-helix, chain segments with antiparallel β-structures (β-meander structure) and combinations of α-helix and β-structure (e.g., βαβα).

Tertiary and Quaternary Structure

Proteins can be divided into two large groups on the basis of conformation: (1) fibrillar (fibrous) or scleroproteins, and (2) folded or globular proteins.

Fibrous proteins The entire peptide chain is packed or arranged within a single regular structure for a variety of fibrous proteins. Examples are wool keratin (α-helix), silk fibroin (β-sheet), and collagen (a triple helix). Stabilization of these structures is achieved by intermolecular binding (electrostatic interaction and disulfide linkages, but primarily hydrogen bonds and hydrophobic interactions).

The high-molecular-weight (HMW) subunit (*x*-type) contains one intramolecular disulfide bond (Cys (10)-Cys (17)), whereas the remaining two cysteines (Cys (32) and Cys (758)) form intermolecular disulfide bonds probably with other HMW subunits. In HMW subunits (*y*-type), the two adjacent cysteines (Cys(43) and Cys(44)) form two intermolecular disulfide bonds with two adjacent cysteines of another *y*-type HMW subunit, Cys(513) forms an intermolecular disulfide bond with low-molecular-weight (LMW) subunits, whereas the linkage of the remaining four cysteines is still unknown (probably one intermolecular disulfide bond, Cys(10)-Cys(22)). The LMW subunit contains three intramolecular disulfide bonds (Cys(127)-Cys(162), Cys(135)-Cys(155) and Cys(163)-Cys(260)), whereas the remaining two cysteines (Cys(2) and Cys(210)) form intermolecular disulfide bonds with other LMW

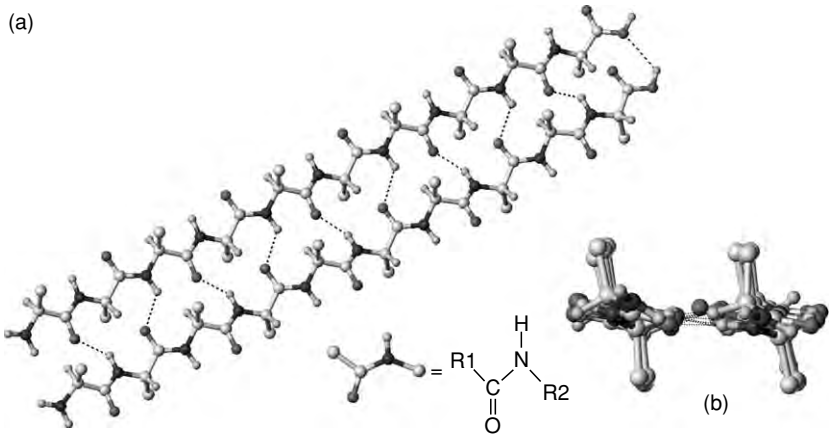

Figure 1 Parallel β-sheet ($\phi = -119°$, $\psi = +113°$, $n = 2.0$, $d = 0.32$ nm, $r = 0.11$ nm; see text). (a) Perspective view of two decapeptide chains consisting of 10 alanine residues each. The *N*-terminus of both chains is on the left; hydrogen atoms of the methyl groups have been omitted for clearness; hydrogen bridges are presented as broken lines. (b) View in the direction of the chain axis.

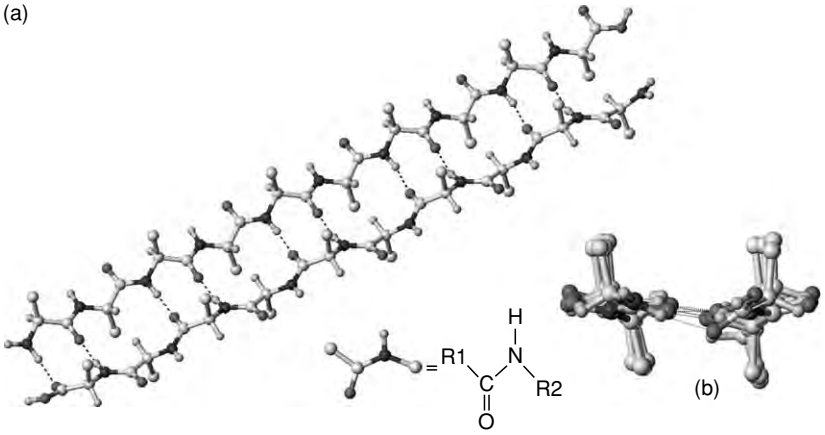

Figure 2 Antiparallel β-sheet ($\phi = -139°$, $\psi = +135°$, $n = 2.0$, $d = 0.34$ nm, $r = 0.09$ nm). (a), (b) Cf. **Figure 1**, but the *N*-terminus of the upper chain is on the left and that of the lower chain is on the right.

Globular proteins Regular structural elements are mixed with randomly extended chain segments (random-coiled structures) in globular proteins. The proportion of regular structural elements is highly variable: 20–30% in casein, 45% in lysozyme, and 75% in myoglobin. Five structural subgroups are known in this group of proteins: (1) α-helices occur only; (2) β-structures occur only; (3) α-helical and β-structural portions occur in separate segments on the peptide chain; (4) α-helices and β-structures alternate along the peptide chain; and (5) α-helices and β-structures do not exist. The process of peptide chain folding is not yet fully understood. It occurs spontaneously, probably arising from one center or from several centers of high stability in larger proteins. Folding of the peptide chain packs it densely, by formation of a large number of intramolecular noncovalent bonds. Data about the nature of the bonds involved are provided in Table 4.

subunits (head to head or head to tail), *y*-type HMW subunits or glutenin-bound γ-gliadins. In α-gliadins, three intramolecular disulfide bonds occur (Cys(120)-Cys(150), Cys(151)-Cys(241) and Cys(163)-Cys(249)). In γ-gliadins, four intramolecular disulfide bonds occur (Cys(157)-Cys(191), Cys(165)-Cys(184), Cys(192)-Cys(282) and Cys(204)-Cys(290)).

Data from Belitz H-D and Grosch W (1999) *Food Chemistry*, 2nd edn. Berlin: Springer–Verlag.

The hydrogen bonds formed between main chains, main and side chains, and side-side chains are of particular importance for folding. The portion of polar groups involved in hydrogen bond build-up in proteins of > 8.9 kDa appears to be fairly constant at about 50%. The hydrophobic interaction of the nonpolar regions of the peptide chains also plays an important role in protein folding. These interactions are responsible for the fact that nonpolar groups are folded to a great extent towards the interior of the protein globule. The surface areas accessible to water molecules have been calculated for both unfolded and native folded forms for a number of monomeric proteins with known conformations. The proportion of the accessible surface of a stretched state which tends to be fixed in the interior of the globule as a result of folding is a simple linear function of the molecular weight.

Proteins with disulfide bonds fold at a significantly slower rate than those without disulfide bonds. Folding is not limited by the reaction rate of disulfide formation. Therefore the folding process of disulfide-containing proteins seems to proceed in a different way. The reverse process, protein unfolding, is very much slowed down by the presence of disulfide bridges which generally impart great stability to globular proteins. This stability is particularly effective against denaturation. An example is the Bowman–Birk inhibitor from soya beans, which inhibits the activity of trypsin and chymotrypsin. Its tertiary structure is stabilized by seven disulfide bridges. The reactive sites of inhibition are Lys(16)-Ser(17) and Leu(43)-Ser(44), i.e., both sites are located in relatively small rings, each of which consists of nine amino acid residues held in ring form by a disulfide bridge. The thermal stability of this inhibitor is high (**Figure 4**).

Quaternary structures In addition to the free energy gain by folding of a single peptide chain, association of more than one peptide chain (subunit) can provide

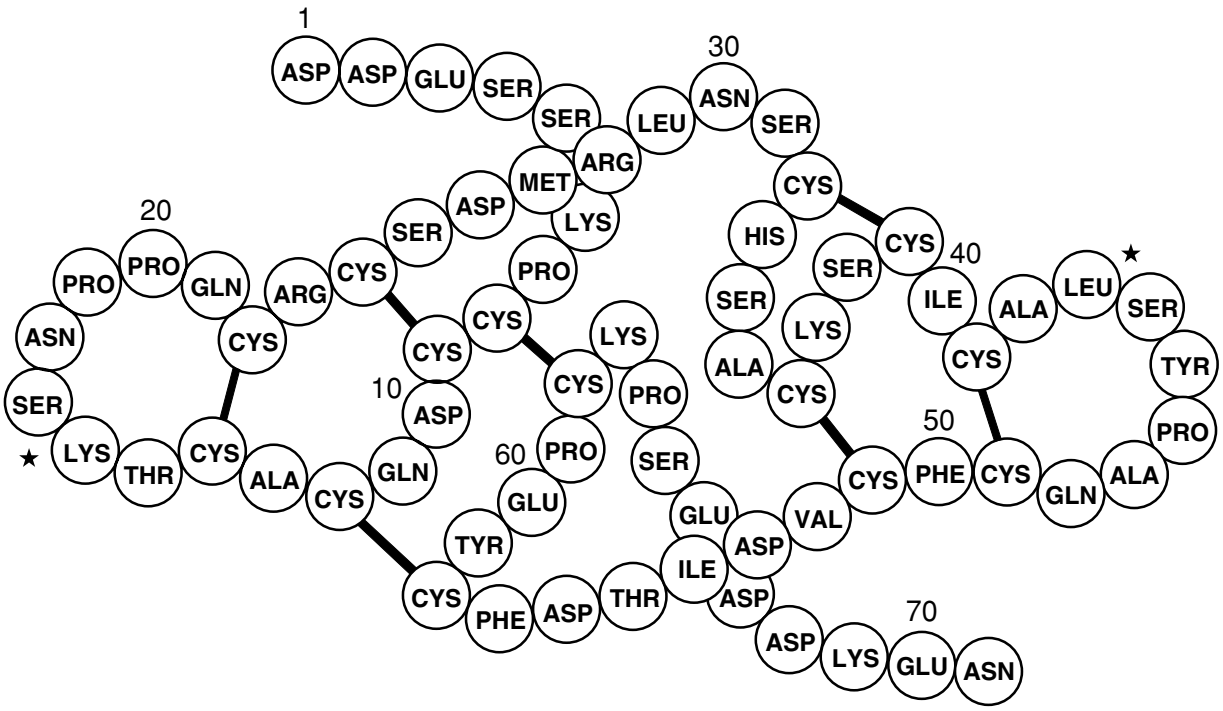

Figure 4 Bowman–Birk proteinase inhibitor from soya beans. Solid black lines, disulfide bridges between half-cystine residues; asterisks, trypsin (Lys-Ser) and chymotrypsin (Leu-Ser) reactive sites. Adapted from Ikenaka T, Odani S, and Koide T (1974) Chemical structure and inhibitory activities of soybean proteinase inhibitors. In: Fritz H, Tschesche H, Greene LJ and Truscheit E (eds) *Bayer-Symposium V Proteinase Inhibitors*, pp. 325–343. Berlin: Springer-Verlag, with permission.

further gains in free energy. For example, hemoglobin (four associated peptide chains) $\Delta G^\circ = -46\,\mathrm{kJ\,mol^{-1}}$ and the trypsin–trypsin inhibitor complex (association of two peptide chains) $\Delta G^\circ = -75.2\,\mathrm{kJ\,mol^{-1}}$. In principle, such associations correspond to the folding of a larger peptide chain around several structural domains without covalently binding the subunits.

Examples for protein conformations are given in Figure 5, which shows the sweet proteins monellin and thaumatin.

Denaturation

The term 'denaturation' denotes a reversible or irreversible change of native conformation (tertiary structure) without cleavage of covalent bonds (except for disulfide bridges). Denaturation is possible with any treatment that cleaves hydrogen bridges, or ionic or hydrophobic bonds. This can be accomplished by changing the temperature, adjusting the pH, increasing the interfacial area, or adding organic solvents, salts, urea, guanidine hydrochloride, or detergents such as sodium dodecyl sulfate. Denaturation is generally reversible when the peptide chain is stabilized in its unfolded state by the denaturing agent and the native conformation can be reestablished after removal of the agent. Irreversible denaturation occurs when the unfolded peptide chain is stabilized by interaction with other chains (as occurs for instance with egg proteins during boiling). During unfolding, reactive groups, such as thiol groups, that were buried or blocked may be exposed. Their participation in the formation of disulfide bonds may also cause an irreversible denaturation. Denaturation of biologically active proteins is usually associated with loss of activity. The fact that denatured proteins are more readily digested by proteolytic enzymes is also of interest.

Physical Properties

Dissociation

Proteins, like amino acids, are amphoteric. Depending on pH, they can exist as polyvalent cations, anions, or zwitterions. Since α-carboxyl and α-amino groups are linked together by peptide bonds, the uptake or release of protons is limited to free terminal groups, and mostly to side chains. In contrast to free amino acids, the pK_a values fluctuate greatly for proteins since the dissociation is influenced by neighboring groups in the macromolecule. For example, in lysozyme the γ-carboxyl group of Glu(35) has a pK_a of 6–6.5,

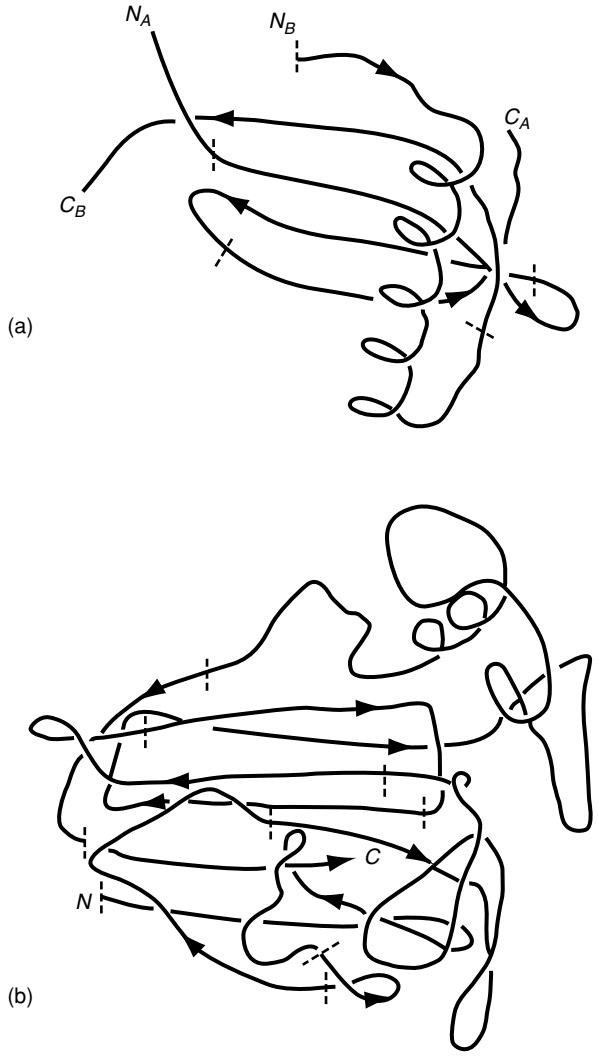

Figure 5 Conformation of the peptide chains of the sweet proteins (a) monellin and (b) thaumatin. β-sheet, |→; α-helix, ෆ; β-turn, ⊃; N_A, N_B, C_A, C_B denote the *N*- and *C*-termini of the *A* and *B* chains. Adapted from Ogata C, Hatada M, Tomlinson G, Shin WC and Kim S-H (1987) Crystal structure of the intensely sweet protein monellin. *Nature* 328: 739–742, with permission.

while the pK_a of the β-carboxyl group of Asp(66) is 1.5–2, of Asp(52) is 3–4.6, and of Asp(101) is 4.2–4.7. The total charge of a protein, which is the absolute sum of all positive and negative charges, is differentiated from the so-called net charge which, depending on the pH, may be positive, zero, or negative. By definition the net charge is zero and the total charge in general is maximal at the isoelectric point. Lowering or raising the pH tends to increase the net charge toward its maximum, whereas the total charge becomes less than at the isolectric point.

Since proteins interact not only with protons but also with other ions, there is a further differentiation between an isoionic and an isoelectric point. The isoionic point is defined as the pH of a protein solution at infinite dilution, with no other ions present except for H^+ and OH^-. Such a protein solution can be acquired by extensive dialysis (or, better, electrodialysis) against distilled water. The isoionic point is constant for a given substance whereas the isoelectric point is variable, depending on the ions present and their concentration. In the presence of salts, e.g., when binding of anions is stronger than that of cations, the isoelectric point is lower than the isoionic point. The reverse is true when cation binding is dominant. In most cases the shift in pH is consistently positive, i.e., the protein binds more anions than cations. At its isoelectric point a protein is the least soluble and the most likely to precipitate (isoelectric precipitation) and it is at its maximal crystallization capacity. The viscosity of solubilized proteins and the swelling power of insoluble proteins are at a minimum at the isoelectric point.

Optical Activity

The optical activity of proteins is due not only to asymmetry of amino acids but also to the chirality resulting from the arrangement of the peptide chain. Information on the conformation of proteins can be obtained from recording the optical rotatory dispersion (ORD) or the circular dichroism (CD), especially in the range of peptide bond absorption wavelengths (190–200 nm). The Cotton effect occurs in this range and reveals quantitative information on secondary structure. An α-helix or a β-structure gives a negative Cotton effect, with absorption maxima at 199 and 205 nm, respectively, whereas a random-coiled conformation shifts the maximum to shorter wavelengths, i.e., results in a positive Cotton effect.

Solubility, Hydration, and Swelling Power

Protein solubility is variable and is influenced by the number of polar and apolar groups and their arrangement along the molecule. Generally, proteins are soluble only in strongly polar solvents such as water, glycerol, formamide, dimethylformamide, or formic acid. In a less polar solvent such as ethanol, few proteins have appreciable solubility (e.g., prolamins). The solubility in water is dependent on pH and on salt concentration. At low ionic strength, the solubility rises with increase in ionic strength and the solubility minimum (isoelectric point) is shifted to a somewhat lower pH. This shift is due to preferential binding of anions to the protein. As a rule, neutral salts have a twofold effect on protein solubility. At low concentrations they increase the solubility ('salting-in' effect) by suppressing the electrostatic protein–protein interaction (binding forces).

The logarithm of the solubility (S) is proportional to the ionic strength (μ) at low concentrations: $\log_{10}S = k{\cdot}\mu$.

Protein solubility is decreased ('salting-out' effect) at higher salt concentrations due to the ion hydration tendency of the salts. The following relationship applies (S_0, solubility at $\mu = 0$; K, salting-out constant): $\log_{10}S = \log_{10}S_0 - K{\cdot}\mu$. Cations and anions in the presence of the same counter ion can be arranged in the following orders (Hofmeister series) based on their salting-out effects: $K^+ > Rb^+ > Na^+ > Cs^+ > Li^+ > NH_4^+$; SO_4^{2-} > citrate^{2-} > tartrate^{2-} > acetate$^-$ > $Cl^- > NO_3^- > Br^- > I^- > SCN^-$. Multivalent anions are more effective than monovalent anions, whereas divalent cations are less effective than monovalent cations.

Since proteins are polar substances, they are hydrated in water. The degree of hydration (grams of water of hydration per gram protein) is variable. It is 0.22 for ovalbumin (in ammonium sulfate), 0.06 for edestin (in ammonium sulfate), 0.8 for β-lactoglobulin, and 0.3 for hemoglobin.

The swelling of insoluble proteins corresponds to the hydration of soluble proteins in that insertion of water between the peptide chains results in an increase in volume and other changes in the physical properties of the protein. The amount of water taken up during swelling can exceed the dry weight of the protein by several times. For example, muscle tissue contains 3.5–3.6 g of water per gram of protein (dry matter).

Chemical Reactions

The chemical modification of proteins is of importance for a number of reasons. It provides derivatives suitable for sequence analysis, identifies the reactive groups in catalytically active sites of an enzyme, enables the binding of protein to a carrier (protein immobilization), and provides changes in protein properties which are important in food processing. In contrast to free amino acids, except for the relatively small number of functional groups of the terminal amino acids, only the functional groups in protein side chains are available for chemical reactions.

Lysine Residue

Reactions involving the lysine residue can be divided into several groups: (1) reactions leading to a positively charged derivative; (2) reactions eliminating the positive charge; (3) derivatizations introducing a negative charge; and (4) reversible reactions. The last are of particular importance.

Reactions which retain the positive charge Alkylation of the free amino group of lysines with aldehydes and ketones is possible, with a simultaneous reduction step. A dimethyl derivative (Prot-N$(CH_3)_2$) can be obtained with formaldehyde.

Guanidination can be accomplished by using *O*-methylisourea as a reactant. α-Amino groups react at a much slower rate than ε-amino groups. This reaction is used analytically to assess the amount of biologically available ε-amino groups.

Derivatization with imido esters to amidines is also possible. The reactant is readily accessible from the corresponding nitrile. Proteins can be cross-linked with the use of a bifunctional imido ester.

Treatment of the amino acid residue with amino acid carboxyanhydrides yields a polycondensation reaction product, made up of the protein as main chain and peptide side chains. The length of the side chains depends on reaction conditions. The carboxyanhydrides are readily accessible through interaction of the amino acid with phosgene.

Reactions resulting in a loss of positive charge Acetic anhydride reacts with lysine, cysteine, histidine, serine, threonine, and tyrosine residues. Subsequent treatment of the protein with hydroxylamine leaves only the acetylated amino groups intact. Acylation is possible with *N*-hydroxysuccinimidyl acetate, succinimidyl 3-(*p*-hydroxphenyl)propionate (after radioiodination for radioactive labeling, Bolton–Hunter reagent) or *S*-ethylthiotrifluoroacetate. A photocleavable amine-protecting group can be introduced by reaction with 6-nitroveratryl chloroformate.

Sulfonylation occurs with dansyl chloride (5-(dimethylamino)-naphthalene-1-sulfonyl chloride), which also reacts with cysteine, histidine, and tyrosine. Carbamoylation with cyanate attacks α- and ε-amino groups as well as cysteine and tyrosine residues. However, their derivatization is reversible under alkaline conditions. Thiocarbamoylation with fluorescein isothiocyanate (FITC) or tetramethylrhodamine isothiocyanate (TRITC) is used for fluorescent labeling of proteins.

Arylation is possible with DNFB (2,4-dinitrofluorobenzene) and 2,4,6-trinitrobenzenesufonic acid (TNBS). DNFB also reacts with cysteine, histidine, and tyrosine. 7-Chloro-4-nitrobenz-2-oxa-1,3-diazole, which also reacts with cysteine, and 4-fluoro-3-nitrobenzenesulfonic acid, a reactant which has good solubility in water, are also of interest for derivatization of proteins.

Deamination can be accomplished with nitrous acid. This reaction involves α-and ε-amino groups as well as tryptophan, tyrosine, cysteine, and methionine residues.

Reactions resulting in a negative charge Acylation with dicarboxylic acid anhydrides, e.g., succinic anhydride, introduces additional carboxyl groups into the protein. Introduction of a fluorescent acid group is possible by interaction of the protein with pyridoxal 5-phosphate, followed by reduction of an intermediate Schiff base, or with fluorescamine.

Reversible reactions *N*-Maleyl derivatives of proteins are obtained at alkaline pH by reaction with maleic anhydride. The acylated product is cleaved at pH < 5, regenerating the protein. The half-life (τ) of ε-*N*-maleyl lysine is 11 h at pH 3.5 and 37 °C. More rapid cleavage is observed with the 2-methylmaleyl derivative (τ < 3 min at pH 3.5 and 20 °C) and the 2,2,3,3-tetrafluorosuccinyl derivative (τ very low at pH 9.5 and 0 °C). Cysteine binds maleic anhydride through an addition reaction. The *S*-succinyl derivative is quite stable. This side reaction is, however, avoided when protein derivatization is carried out with *exo-cis*-3,6-endoxo-1,2,3,6-tetrahydrophthalic acid anhydride.

Acetoacetyl derivatives are obtained with diketene. This type of reaction also occurs with cysteine and tyrosine residues. The acyl group is readily split from tyrosine at pH 9.5. Complete release of protein from its derivatized form is possible by treatment with phenylhydrazine or hydroxylamine at pH 7.

Arginine Residue

The arginine residue of proteins reacts with α- or β-dicarbonyl compounds, e.g., with glyoxal, phenylglyoxal hydrate, 2,3-butanedione (diacetyl) or nitromalondialdehyde, to form cyclic derivatives. The nitropyrimidine resulting with nitromalondialdehyde absorbs at 335 nm. The arginyl bond of this derivative is not cleaved by trypsin but it is cleaved in its tetrahydro form, obtained by reduction with sodium borohydride. In the reaction with benzil, an iminooxo-imidazolidine derivative is obtained after a benzilic acid rearrangement. Reaction of the arginine residue with 1,2-cyclohexanedione is highly selective and proceeds under mild conditions. Regeneration of the arginine residue is again possible with hydroxylamine.

Glutamic and Aspartic Acid Residues

These amino acid residues are usually esterified with methanolic hydrochloric acid. There can be side reactions, such as methanolysis of amide derivatives or *N,O*-acyl migration in serine or threonine residues. Diazoacetamide reacts with a carboxyl group and also with the cysteine residue to carboxamidomethyl derivatives.

Amino acid esters or other similar nucleophilic compounds can be attached to a carboxyl group of a protein with the help of a carbodiimide. Amidation is also possible by activating the carboxyl group with an isoxazolium salt (Woodward reagent) to an enolester and its conversion with an amine.

Cystine Residue

Reductive cleavage of cystine occurs with sodium borohydride and with thiols. Thiols used to reduce cystine to cysteine include 2-mercaptoethanol and, more effectively, dithiothreitol (DTT, Cleland's reagent) or dithioerythritol (DTE). More recently, bis(2-mercaptoethyl)sulfone and tris(2-carboxyethyl)phosphine have been introduced, which are both water-soluble and very effective, and also tri-*n*-butylphosphine, which is less water-soluble. The phosphines have the advantage that the excess used for reduction does not react with thiol reagents used for subsequent thiol modification.

Cleavage of cystine is also possible by a nucleophilic attack. The nucleophilic reactivity of the reagents decreases in the following series: arsenite and phosphite > alkanethiol > aminoalkanethiol > thiophenol and cyanide > sulfite > OH^- > *p*-nitrophenol > thiosulfate > thiocyanate. Complete cleavage with sulfite requires that oxidative agents (e.g., Cu^{2+}) are present and that the pH is higher than 7. The resultant *S*-sulfo derivative is quite stable in neutral and acidic media and is fairly soluble in water. The *S*-sulfo group can be eliminated with an excess of thiol reagent. Cleavage of cystine residues with cyanides (nitriles) is of interest since the thiocyanate formed in the reaction is cyclized into a 2-iminothiazolidine under cleavage of the *N*-acyl bond. This reaction can be utilized for the selective cleavage of peptide chains. Initially, all the disulfide bridges are reduced with DTT, and are then converted to mixed disulfides through reaction with 5,5′-dithio-bis(2-nitrobenzoic acid). These mixed disulfides are then cleaved by cyanide at pH 7.

Electrophilic cleavage occurs with Ag^+ and Hg^+ or Hg^{2+}. Electrophilic cleavage with H^+ is possible only in strong acids (e.g., 10 mol l^{-1} hydrochloric acid). The sulfenium cation which is formed can catalyze a disulfide exchange reaction. In neutral and alkaline solutions a disulfide exchange reaction is catalyzed by the thiolate anion.

Cysteine Residue

A number of alkylating agents, e.g., iodoacetic acid, iodoacetamide, ethylenimine, and 4-vinylpyridine, yield derivatives which are stable under the conditions for acid hydrolysis of protein. The reaction with ethylenimine gives an *S*-(2-aminoethyl) derivative

and, hence, an additional linkage position in the protein for hydrolysis by trypsin. Iodoacetic acid, depending on the pH, can react with cysteine, methionine, lysine, and histidine residues. Maleic anhydride, 2-nitrobenzyl bromide, 2-nitrohydroxybenzyl bromide, and methyl *p*-nitrobenzenesulfonate are also alkylating agents. A number of reagents make it possible to measure thiol group content spectrophotometrically (azobenzene-2-sulfenyl bromide, 5,5′-dithio-bis(2-nitrobenzoic acid) (DTNB, Ellman's reagent), *p*-hydroxymercuribenzoate, *N*-ethylmaleimide, *N*-phenylmaleimide). Especially suitable for the specific and very sensitive labeling of cysteine-containing peptides prior to isolation are *N*-[4-(4′-dimethylaminoazobenzene)]maleimide (DABM), N-(7-dimethylamino-4-methyl-3-coumarinyl)maleimide (DACM), *N*-(1-pyrenyl)maleimide, and 4-aminosulfonyl-7-fluoro-2,1,3-benzoxdiazol (ABDF).

Cysteine is readily converted to the corresponding disulfide, cystine, even under mild oxidative conditions, such as treatment with iodine or potassium hexacyanoferrate(III). Stronger oxidation of cysteine, and also of cystine, e.g., with performic acid, yields the corresponding sulfonic acid, cysteic acid.

Methionine Residue

Methionine residues are oxidized to methionine sulfoxide with hydrogen peroxide. The sulfoxide can be reduced, regenerating methionine, using an excess of thiol reagent. With performic acid, methionine sulfone is formed.

α-Halogen carboxylic acids, β-propiolactone, and alkyl halides convert methionine into sulfonium derivatives, from which methionine can be regenerated in an alkaline medium with an excess of thiol reagent. Reaction with cyanogen bromide, which splits the peptide bond on the carboxyl side of the methionine molecule, is used for selective cleavage of proteins.

Histidine Residue

Diethyl pyrocarbonate reacts with histidine to form *N*-(ethoxycarbonyl)histidine. With iodoacetamide, *N*-1-(carboxamidomethyl)-, *N*-3-(carboxamidomethyl)-, or *N*-1,*N*-3-di(carboxamidomethyl)histidine are formed.

Selective modification of histidine residues present on active sites of serine proteinases is possible. Substrate analogs such as halogenated methyl ketones inactivate such enzymes (e.g., 1-chloro-3-tosylamido-7-amino-2-heptanone inactivates trypsin and 1-chloro-3-tosylamido-4-phenyl-2-butanone inactivates chymotrypsin) by *N*-alkylation of the histidine residue.

Tryptophan Residue

N-Bromosuccinimide oxidizes the tryptophan side chain and also tyrosine, histidine, and cysteine. The reaction is used for the selective cleavage of peptide chains at the carboxyl group of tryptophan residues and the spectrophotometric determination of tryptophan. Other oxidative cleaving reagents are *o*-iodosobenzoic acid and 3-bromo-3-methyl-2-(2-nitrophenylmercapto)-3H-indole. Selective modification of histidine is possible with 2-hydroxy-5-nitrobenzyl bromide (Koshland reagent I) and 2-nitrophenylsulfenyl chloride.

Tyrosine Residue

Selective acylation of tyrosine can occur with 1-acetylimidazole as a reagent. Diazotized *p*-arsanilic acid reacts with tyrosine (*ortho* substitution) and with histidine, lysine, tryptophan, and arginine. Tetranitromethane introduces a nitro group into the *ortho* position. Radioactive labeling of tyrosine is possible with $Na^{125}I$ and chloramine T (*ortho* mono- and di-iodo derivatives).

Bifunctional Reagents

Bifunctional reagents enable intra-and intermolecular cross-linking of proteins. Examples are bifunctional imidoester, maleimides, fluoronitrobenzene, and isocyanate derivatives.

Food Sources

J K P Weder and H-D Belitz[†], Technische Universität München, Garching, Germany

Protein

Amino acids, peptides, and proteins are important constituents of food. They supply the required building blocks for protein biosynthesis. In addition, they directly contribute to the flavor of food and are precursors for aroma compounds and colors formed during thermal or enzymatic reactions in production, processing, and storage of food. Other food constituents, e.g., carbohydrates, take part in such reactions. Proteins also contribute significantly to the physical properties of food through their ability to stabilize gels, foams, doughs, emulsions, and fibrillar structures.

Table 1 World-wide annual protein production ($\times 10^6$ tonnes)

Source	*1993*	*1994*	*1995*	*1996*	*1997*	*1998*

[a]Excluding fish and aquatic animals.
Data from FAO (1999) *FAO Year book Production*, vol. 52, 1998. FAO Statistics Series No. 148. Rome: Food and Agriculture Organization and by courtesy of Dr. Rehbein (Federal Research Centre for Fisheries, Hamburg, Germany, for fish and aquatic animals), protein calculated from production with data from Scherz H and Senser F (eds) (2000) *Food Composition and Nutrition Tables*, 6th edn. Boca Raton, FL: CRC Press.

Table 1 shows the most important protein sources and their contribution to world-wide production of protein. Cereals contribute to protein production by more than half, followed by oil seeds and meat. Besides plants and animals, algae (*Chlorella*, *Scenedesmus*, and *Spirulina* spp.), yeasts and bacteria may be used for protein production (single-cell protein (SCP)). Common carbon sources are glucose, molasses, starch, waste water, higher *n*-alkanes, and methanol. Yeasts of the genus *Candida* can be grown, for example, on paraffins, and they deliver about 0.75 t of protein per tonne of alkane. Bacteria of the genus *Pseudomonas* deliver about 0.3 t of protein per tonne of alcohol in aqueous methanol. Because of the high nucleic acid content of yeasts and bacteria (6–17% of dry mass), isolation of the protein from biomass is necessary. The importance of SCP in the future will depend on the total protein market, especially on prices and functional properties of individual proteins.

Table 2 provides data on the average protein content and the nutrient density – the ratio between the amount of protein (g) and the total energy value (MJ) of the digestible constituents – of selected foodstuffs. The protein content varies as follows: >20%

[†]Deceased.

Table 2 Protein content (%) of selected foodstuffs

No.[a]	Foodstuff	Average protein content		Nutrient density ($g\,MJ^{-1}$)
		Raw product	Edible portion	
Milk and dairy products				
1	Human milk	1.13	1.13	3.92
2	Cow's milk	3.33	3.33	12.05
3	Buffalo milk	4.01	4.01	8.94

[a]Numbering as in **Table 2**; units are grams of amino acid per 100 g of edible portion.
Data from Scherz H and Senser F (eds) 2000 *Food Composition and Nutrition Tables*, 6th edn. Boca Raton, FL: CRC Press.

(cheeses, meat, legumes, oil seeds); 10–20% (fish, eggs); 5–10% (cereals); and < 5% (milk, roots, tubers, vegetables, fruits, mushrooms).

A considerable number of proteins have been isolated from various foods and characterized by physical and chemical properties. Cereals and cereal products are amongst the most important staple foods of mankind. Proteins provided by bread consumption in industrial countries meet about one-third of the daily requirement. The major cereals are wheat, maize, rice, barley, sorghum, oats, millet, and rye. Wheat and rye have a special role since only they are suitable for bread-making. With the example of wheat, the cereal proteins have been separated by Osborne, on the basis of their solubility, into four fractions: the water-soluble albumins, the salt-soluble globulins, the 70% aqueous ethanol-soluble prolamins, and the remaining glutelins. In the literature, Osborne fractions derived from different cereals are often designated by special names, e.g., gliadin and glutenin for wheat prolamins and glutelins, respectively. The levels of Osborne fractions differ amongst cereals with albumins amounting to 4–44%, globulins 3–12%, prolamins 2–48%, and glutelins 24–77% of the whole protein fraction. Each of the Osborne fractions consists of a larger number of proteins. Albumins and globulins contain the enzymes, whereas prolamins and glutelins are storage proteins. The glutelins can be separated into two subfractions after reduction of the disulfide bonds: the low-molecular-weight (LMW) subunits and the high-molecular-weight (HMW) subunits. Wheat prolamins and glutelins, both fractions together also designated wheat gluten, are responsible for the characteristic rheological properties of wheat dough. Wheat prolamins consist of ω-, α-, and γ-gliadins, designated according to their electrophoretic mobility. In addition, the LMW subunit fraction of wheat glutelins also contains some gliadins (ω5-, ω1,2-, and γ-gliadins). The amino acid sequences of some gluten proteins from wheat are shown in the article '**Protein: Chemistry**' (HMW subunit of glutenin, x-type and y-type; LMW subunit of glutenin; α-gliadin; γ-gliadin).

Meat and meat products are other important staple foods, in particular in industrial countries. The main meat-producing warm-blooded animals are pig, cattle, poultry, sheep, goats, and buffalo. Meat proteins, i.e., the proteins of the muscle, are divided into three groups: proteins of the contractile apparatus (myofibrillar proteins), soluble proteins (sarcoplasma proteins), and insoluble proteins (connective tissue and membrane proteins). The myofibrillar proteins of a typical mammalian muscle amount to about 60% of total muscle protein, with myosin (29%) and actin (13%) as their predominating components and about 20 minor components including connectin, tropomyosins, troponins, and actinins. The sarcoplasma proteins form about 30% of total protein. They contain most of the enzymes, in particular those of glycolysis and the pentosephosphate cycle, but also considerable amounts of creatine kinase (2.7% of total protein), myoglobin, and some hemoglobin. The insoluble proteins contain collagen as the main component, besides elastin, insoluble enzymes, and cytochrome *c*. In connective tissue, collagen forms a triple-stranded helix composed of α-helices.

Covalent cross-links are formed between the fibers of collagen during maturation and aging, thus improving its mechanical strength. When heated, collagen fibers shrink or are converted into gelatine, depending on the temperature. The structure of the gelatine obtained after cooling depends on the gelatine concentration and temperature gradient. Collagen contains two unusual amino acids, 4-hydroxyproline and 5-hydroxylysine. Since the occurrence of the former is confined to connective tissue, its determination provides data on the extent of connective tissue content of a meat product. The primary structure of bovine skin collagen is given in the first edition of this encyclopedia (Belitz H-D (1993) Protein-Chemistry. In: Macrae R, Robinson RK and Sadler MJ (eds) *Encyclopaedia of Food Science, Food Technology, and Nutrition,* pp. 3781–3791. London: Academic Press) showing the characteristic three-amino-acid repeats with glycine in the first position, often followed by proline and hydroxyproline.

Milk and dairy products form a further important group of staple foods. Milk generally means cow's milk, but milk from buffalo, goats, and sheep is of importance in some regions. Milk proteins, in particular the caseins, play an important role in processing to yield dairy products such as cheese and sour milk products. The caseins, first isolated by Hammarsten in 1877, make up about 80% of total milk proteins. They have been separated later into different fractions: α_{s1}-, α_{s2}-, κ-, β-, and γ-caseins, constituting 34, 8, 9, 25, and 4% of total protein, respectively. Each of these fractions occurs in the form of different genetic variants, designated A, B, C, etc., depending on the breed from which they have been isolated. In cheese-making, the specific cleavage of κ-casein by chymosin (EC 3.4.23.4) into para-κ-casein and a glycopeptide (so-called, though not always containing a sugar moiety) reduces the solubility of the casein complexes and casein micelles, thus leading to their aggregation followed by gel formation (curd formation). The whey proteins (about 20% of total protein) consist of β-lactoglobulins, α-lactalbumins (both in different genetic variants), serum albumin, immunoglobulins, and proteose-peptone. Also, more than 40 enzymes occur in the whey protein fraction, but in much lower quantities than the other components. Whey proteins can be incorporated into the curd using several new processing methods of cheese-making in order to increase the yield and also to reduce waste water or whey treatment costs. The primary structures of some proteins from bovine milk are shown in the first edition of this encyclopedia (Belitz H-D (1993) see above) (α_{s1}-, α_{s2}-, β-, and κ-casein; α-lactalbumin; β-lactoglobulin).

Legumes (pulses) are very important staple foods in some parts of the world, e.g., soya beans in South-east Asia and common beans in Latin America. Other legumes, some of greater regional importance, include peas, peanuts, chick peas, broad beans, and lentils. Legume proteins, when fractionated, according to Osborne, in a similar way to cereal proteins, yield three fractions: albumins, globulins, and glutelins. The portion of the fractions varies, depending on the legume species, but globulins always predominate. The globulins are subdivided, initially according to sedimentation during ultracentrifugation, into 11S and 7S globulins (legumins and vicilins, respectively). Again, the subfractions derived from different legumes are sometimes designated by special names, e.g., glycinin and arachin for soya bean and peanut legumin, as well as β-conglycinin and phaseolin for soya bean and common bean vicilin, respectively. Soya protein isolates, produced by diluted alkali extraction of defatted soya bean flakes followed by acid precipitation, are texturized and flavored for use as meat substitutes or are added to foods to raise their protein level and improve their processing qualities such as the water-binding capacity or emulsion stability. The isolates contain about 95% protein and consist of 11S and 7S globulins. The similarity between the caseins from bovine milk and the globulins from soya beans is reflected by the production of some typical Asian foods such as soy milk, soy curd (tofu), and soy cheese (sufu). The primary structures of some legume proteins are shown in the article '**Protein**: Chemistry' (glycinin, pea legumin; β-conglycinin, pea vicilin, phaseolin.)

Eggs are used as a food not only because of their excellent nutritional quality but also because of their functional properties. Eggs generally means chicken eggs; those of other birds (geese, ducks, plovers, seagulls, quail) are less important. Egg proteins are divided into those of egg white and those of egg yolk. Egg white proteins (about 10% of total egg white) are ovalbumin, conalbumin (ovotransferrin), ovomucoid, ovomucin, lysozyme, ovoglobulin G_2, ovoglobulin G_3, and some minor components (54, 12, 11, 3.5, 3.4, 4, 4, and 2.5% of total egg white protein, respectively). Ovalbumin, conalbumin, ovomucin, and the ovoglobulins G contribute to foam formation and foam stability. Yolk proteins (about 17% of total yolk) are phosvitin, the livetins, and the protein moieties of high-density lipoproteins (HDL) and low-density (LDL) lipoproteins (13, 31, 36, and 20% of total yolk protein, respectively). Apart from phospholipids, LDL and proteins are responsible for the emulsifying effect of whole eggs or egg yolk alone. Owing to the ability of all egg proteins, except ovomucoid and phosvitin, to coagulate

Table 4 Daily requirement of essential amino acids (milligrams per kilogram of bodyweight)

Amino acid	*Infants (3–4 months)*	*Children (2 years)*	*Schoolboys (10–12 years)*	*Adults*

[a]Evidence is accumulating that histidine is essential even for adults.
SAA, sulfur amino acids (methionine+cystine).
AAA, aromatic amino acids (phenylalanine+tyrosine).
Data from WHO (1985) *Energy and Protein Requirements: Report of a Joint FAO/WHO/UNU Expert Consultation*. WHO Technical Report Series 724. Geneva: World Health Organization.

when heated, egg products are important food-binding agents.

The amino acid compositions of selected foodstuffs are shown in Table 3. The nutritional quality of a food protein depends on the absolute content of essential amino acids, the relative proportions of essential amino acids, and their ratios to nonessential amino acids. In addition, the digestibility of the food protein, the influence by other food components such as dietary fibers, polyphenols, or proteinase inhibitors, and also the total food energy intake are of importance. (*See* '**Protein**: Requirements'; **Protein**: Quality.) The daily requirements of humans at different ages for essential amino acids are compiled in Table 4. During pregnancy and lactation, the first 6 months, and after 6 months, the daily requirement increases by 13, 24, and 18%, respectively. The biological value of a protein is generally limited by the following amino acids:

- lysine: deficient in proteins of cereals and other plants;
- methionine: deficient in proteins of bovine milk and meat;
- threonine: deficient in wheat and rye;
- tryptophan: deficient in casein, corn and rice.

The biological values of some important food proteins are given in the article '**Protein**: Quality'. The highest value observed so far is for a blend of 35% egg and 65% potato proteins (one chicken egg and 500 g of potatoes).

Determination and Characterization

D Otter, New Zealand Dairy Research Institute, Palmerston North, New Zealand

Background

The nutritional and functional value of proteins in food have resulted in considerable research efforts devoted to their analysis. This work has been

undertaken on a number of different levels, i.e., total protein content, defining and quantifying the individual protein components, and characterization of protein biological activity (direct or indirect) and functional properties.

Food Matrix

Food manifests itself in a wide variety of guises from the basic, raw material such as fruit through to highly refined processed foods. Food contains a large number of other components, as well as proteins, such as carbohydrates, fats, and minerals/salts. These components all interact to form the food matrix. It is usually necessary to separate the protein fraction from the other nonprotein material before any meaningful analysis of the individual proteins can be undertaken. The effect of the other components in the food matrix must be considered, however, when characterizing the protein biological activity and functional properties.

Total Protein Content

The gross analysis of protein in food is often required prior to the characterization of the individual protein components. The amount of protein is also necessary during the purification of the individual proteins to determine their relative purity. The three principal protein analysis methods are total nitrogen, UV adsorption, and chemical or dye-binding reactions.

The Kjeldahl method, in which the sample is digested with acid, a boiling aid, and a catalyst to produce an ammonium salt that is then reacted with alkali, and the resulting free ammonia is determined either titrimetrically or photometrically, results in an approximate protein level. Interference by nonprotein nitrogen-containing material and inaccuracies caused by differences in the nitrogen content of various proteins must be considered.

UV adsorption at either 280 nm (aromatic band of tyrosine and tryptophan) or 205–220 nm (peptide band) provides a rapid, nondestructive, and sensitive estimate of protein content. This is subject to interference from nucleic acids and other compounds and can be used to quantify purified proteins if their extinction coefficients are known.

A number of chromophore or dye-binding assays are available, including the Biuret, Lowry, and bicinchoninic acid reagents and the Coomassie Blue dye. The methods differ in their sensitivity and require a prepurified calibrating protein for quantitative results.

Individual Protein Characterization

Electrophoresis

Electrophoresis encompasses a wide range of techniques used for the separation and analysis of complex mixtures of proteins and peptides, and for the purification of small amounts of these different compounds. Separation is based on the differential movement of charged particles under the influence of an electric field where the overall motion is the product of the charge on the particles and the field strength, and where this movement is balanced by the frictional resistance of the medium. Four parameters, viz. differences in molecular size, charge or hydrophobicity, and specific interactions with other molecules, can be used to optimize the separation of molecules from each other, thus making electrophoresis a very powerful analytical technique. In the separation of proteins and peptides, the charged amino acids and carboxyl and amino terminal groups contribute to the overall charge on the protein and result in migration to either the anode or the cathode when an electric field is applied.

There are presently two methods commonly used for the electrophoretic separation of proteins and peptides. Gel electrophoresis utilizes a 'solid,' immobilized matrix to retard the movement of the sample through the aqueous phase. Initially, cellulose acetate strips and starch gels provided this matrix, although they have generally been superseded by polyacrylamide. Capillary electrophoresis (CE) occurs in free solution in very narrow bore capillary tubes and with high separation voltages, and is the electrophoretic analog of high-performance liquid chromatography (HPLC). Narrow capillary tubes allow rapid separation through their excellent heat dissipation, thus minimizing convective mixing and diffusion spreading of the separated zones.

Polyacrylamide gel electrophoresis Polyacrylamide gels are three-dimensional networks of acrylamide reacted with the bifunctional reagent *N,N′*-methylene-bis-acrylamide (abbreviated as Bis) via a free-radical initiated vinyl polymerization mechanism. The pore size of the gel is very reproducible and is directly related to the ratio of acrylamide to Bis. The resulting gels are described in terms of %T, the concentration (w/v) of acrylamide and Bis, and %C, the weight percentage of the cross-linker in T. For proteins, %T values of 5–10% result in gels with relative molecular mass (M_r) ranges of 20 000–200 000 Da. Separation of proteins in complex samples based on size, net charge, and hydrophobicity is possible using different polyacrylamide gel electrophoresis (PAGE) formats.

Sodium dodecyl sulfate–polyacrylamide gel electrophoresis This technique separates proteins according to their subunit size. The natural charge of the protein is masked by saturation with the anionic detergent sodium dodecyl sulfate (SDS), which also denatures the protein degrading the secondary, tertiary, and quaternary protein structure and aiding solubilization. The inclusion of a reducing agent such as 2-mercaptoethanol breaks any disulfide bonds, resulting in rod-like protein monomers containing one SDS molecule for every two amino acid residues. In an electric field, the protein–SDS complexes therefore migrate towards the anode at a rate dependent on the number of SDS molecules (or the M_r of the protein) and the pore size of the gel.

The M_r of the sample proteins can be determined by direct correlation of their migration distance with proteins of known M_r. Resolution of the protein bands in SDS–polyacrylamide gel electrophoresis (SDS–PAGE) can be improved by using a discontinuous gel system, where a stacking gel is used to concentrate the protein sample into sharp bands before the main separation gel. Differences in pH and ionic strength between the stacking gel and the electrophoresis buffer (isotachophoresis) are used to achieve this. When a sample contains proteins with a wide range of M_r values, a gradient polyacrylamide gel (e.g., 5–20% acrylamide) can be used.

The determination of M_r of glycoproteins and lipoproteins by SDS–PAGE can often result in erroneous M_r estimates due to the different binding characteristics of SDS to carbohydrate and lipid moieties.

Native gel electrophoresis This electrophoretic technique is generally used when the biological activity of the sample to be detected is required. It is generally considered to be a 'gentle' method with a lower resolving power than SDS–PAGE. Separation is based on the native charge, size, and shape of the sample molecules and on the properties of the separating gel. Homogeneous or gradient gels can be used, and the sample must be soluble, as any aggregated or precipitated material will not enter the gel matrix. Identification of individual proteins within these gels can be difficult due to the complex separation mechanisms.

Urea gel electrophoresis Urea gel electrophoresis is similar to SDS–PAGE in that it uses a detergent, 6–8 M urea, and a reducing agent, usually 2-mercaptoethanol, to ensure sample solubilization and disulfide bond disruption. In this method, however, the urea does not impart any charge on to the individual proteins, and separation is due to both charge and subunit size. In food analysis, the method is particularly useful for the separation of the individual casein proteins from the casein micelles in milk.

Isoelectric focusing Isoelectric focusing (IEF) is a high-resolution technique where proteins are separated according to their isoelectric points within a continuous pH gradient. The high resolving power allows the separation of compounds differing by only 0.01 pH units in p*I*. Separation is achieved by initially establishing a pH gradient along the gel using a mixture of low-M_r carrier ampholytes such as amino acids or small peptides. The sample components then travel through the pH gradient under an electric field until their individual charges reach zero, i.e., when they attain the pH corresponding to their isoelectric point. For this technique, a low polyacrylamide or agarose gel is used as it is only a stabilizing medium and does not participate in the sample separation. As urea carries no charge, samples can be run under either native or denaturing conditions (8 M urea).

Two-dimensional electrophoresis With the advent of proteomics, two-dimensional gel electrophoresis has become an indispensable tool with which to tease apart the individual proteins in cell systems. Proteins in a sample are initially separated according to their p*I* by isoelectric focusing (often in 8 M urea), and then a sample strip is applied at right angles along the edge of a SDS gel. Electrophoresis in the second direction is therefore according to subunit size, and the resulting pattern provides a unique 'fingerprint' of the sample.

Protein/peptide fixing and detection Proteins are immobilized in the gels after separation by fixing, usually with trichloroacetic, methanolic acetic or sulfosalicylic acid. Dyes such as Coomassie brilliant blue R-250, silver nitrate or Sypro Orange or Red are then used to visualize the protein bands.

Capillary Electrophoresis

Capillary electrophoresis (CE) includes a range of methods where samples are analyzed electrophoretically in capillary tubes. The capillaries may contain buffers, sieving gels, or more classic HPLC porous beads. As in HPLC, the numerous separation mechanisms available contribute to the versatility of CE with the different modes generally accessible simply by altering the buffer composition. Separation is based on differences in component migration in an electric field where the migration is a sum of the electric force on the component and the frictional drag through the medium. This is often highly dependent on the pH and composition of the running

buffer and is also affected by the electroosmotic flow (or bulk flow) of liquid in the capillary.

Capillary zone electrophoresis Fundamentally, capillary zone electrophoresis (CZE or free zone electrophoresis (FZE)) is the simplest CE format, principally because the capillary is only filled with buffer. Separation of both anionic and cationic components in a sample occurs when they migrate in discrete zones at different velocities due to electroosmotic flow. The selectivity of the separation can be altered using additives or coatings that alter the charge and hydrophobicity of the capillary wall.

CZE has a diverse range of applications for protein analysis such as purity validation, screening protein variants, and contaminants, and in conformational studies. It is also well suited for analysis of posttranslational modifications such as N- or C-terminal modifications, phosphorylations, carboxylations or N-glycosylations, and qualitative peptide mapping to detect subtle differences in proteins.

Micellar electrokinetic chromatography Micellar electrokinetic chromatography (MEKC) is a hybrid of electrophoresis and chromatography which uses surfactants in the running buffer, thus making the separation of neutral species possible. The surfactant molecules form micelles above their critical micelle concentration that can then interact with the neutral components. MEKC can be used for charged, uncharged, hydrophilic, and hydrophobic compounds such as peptides and amino acids.

Capillary gel electrophoresis The size-based separation of macromolecules such as proteins and nucleic acids is affected in capillary gel electrophoresis (CGE) by the electrophoresis of the compounds through a polymer network that acts as 'molecular sieve.' It is directly comparable to PAGE and uses polymer matrices such as acrylamide, dextran, and agarose.

For protein chemistry applications, the separation of native and SDS-complexed proteins in either the reduced (by 2-mercaptoethanol) or nonreduced state has been achieved using either cross-linked polyacrylamide or linear dextran polymers.

Capillary isoelectric focusing Capillary isoelectric focusing (CIEF) is similar to IEF–PAGE and separates proteins and peptides according to their p*I* values. It is a 'high-resolution' technique with a resolution of 0.005 p*I* units and less. Ampholytes are used to form a pH gradient within the capillary, and the proteins to be separated migrate (or are focused) through the ampholyte medium until they become uncharged at their p*I* values.

The p*I* values of proteins can be determined using protein standards with known p*I* values. Protein isoforms, proteins whose separation by other methods can be problematic, such as immunoglobulins and hemoglobins, and dilute biological solutions have all been successfully analyzed by CIEF.

Capillary isotachophoresis This is a 'moving boundary' electrophoretic technique where the separated zones move at the same velocity sandwiched between two buffer systems (called the leading and terminating electrolytes). The method creates very sharp boundaries between the zones and is mainly used to separate anions or cations.

Whilst it has not been used extensively for proteins, it has great potential for separating components of very similar mobility such as removing small amounts of impurity in recombinant proteins.

Capillary electrochromatography Capillary electrochromatography (CEC) is a true hybrid of electrophoresis and chromatography. It uses capillaries packed with chromatographic material, and the separation is based on electrophoresis and the chromatographic distribution of the various components between the stationary solid phase and the liquid mobile phase. It can also be compounded by interactions between the sample components and the capillary walls.

In theory, CEC has similar applications to CZE and MEKC. In practice, however, macromolecules such as proteins have an increased surface adsorption to both the capillary wall and the chromatographic matrix that restricts its usefulness. The problems should not be as severe with peptides.

Liquid Chromatography

Liquid chromatography (LC) consists of a family of methods in which two phases are used to separate structurally different analytes in a mixture. For the separation and purification of proteins, a variant of LC, HPLC, is now routinely used. This method uses small-diameter, wide-pore, solid-phase packings, and several techniques are available based on differences in the protein properties of size, charge, and hydrophobicity. The methods all use a stationary solid phase immobilized in a column and a liquid mobile phase. The protein mixture is introduced on to the column via the mobile phase, separation occurs via interaction with the stationary phase, and the individual components are detected usually at 214 or 280 nm using the UV-absorptive properties of proteins.

Reversed-phase chromatography Separation of proteins by reversed-phase chromatography (RPC)

depends on the reversible adsorption/desorption of the proteins, which have varying degrees of hydrophobicity, to a hydrophobic stationary matrix. The nature of the hydrophobic binding interaction is thought to be the result of a favorable entropy effect in areas adjacent to the hydrophobic regions where there is a higher degree of organized water structure, although the actual mechanism has yet to be fully elucidated. The matrices are generally silica-based or synthetic organic polymers and contain covalently bound alkyl chains of different lengths such as *n*-octadecyl (C18), *n*-butyl (C4), or phenyl groups. The strength of the hydrophobic interaction increases as the alkyl chain size increases.

Proteins are initially introduced on to the chromatographic matrix in conditions that promote binding, e.g., 5% organic modifier (acetonitrile) containing a weak hydrophobic ion-pairing reagent such as trifluoroacetic acid (0.1%, pH $\sim$ 2), and then eluted with an aqueous gradient of the organic modifier (5–60% v/v). The resulting separations are generally quick, and the proteins are usually highly resolved.

RPC has only recently become the method of choice for the separation and characterization of proteins/peptides. This is because of concerns that the organic solvents, e.g., acetonitrile, routinely used for the mobile phase can lead to protein denaturation and loss of biological activity. Strategies such as using short columns of short alkyl chain length, e.g., C4, organic modifiers such as ethanol or isopropanol, and omitting trifluoroacetic acid have been developed to allay these apprehensions.

Hydrophobic interaction chromatography Separation of proteins by hydrophobic interaction chromatography (HIC) is similar to RPC and utilizes hydrophobic interactions between the proteins in a mixture and the hydrophobic ligands (usually butyl, octyl, or phenyl groups) attached to an immobile matrix. HIC is different to RPC, however, in its use of aqueous mobile phases of high ionic strength and neutral pH that do not denature proteins. The ligands in HIC are also less hydrophobic and less densely bound to the solid matrix than in RPC matrices.

Proteins are bound to the column in a mobile phase that contains a high salt concentration, e.g., 1–3 M ammonium sulfate, and then eluted with a descending salt gradient that resolvates the proteins and makes binding thermodynamically unfavorable. This differs from RPC, where an organic solvent gradient is used to neutralize hydrophobic binding interactions. The protein-binding selectivity and strength can be manipulated by the mobile-phase pH and temperature, and elution of strongly adsorbed hydrophobic proteins can be achieved using ethylene glycol to lower the polarity of the mobile phase.

Affinity chromatography Affinity chromatography uses unique aspects of the biological or individual chemical structure of a protein to affect its purification. By selecting an interacting ligand which has a high natural specificity to the target protein, highly selective separations can be achieved. The protein to be purified or quantified is specifically and reversibly adsorbed by the complementary ligand immobilized on an insoluble matrix. Purification factors of up to several thousand can be achieved, together with further concentration during the elution step and high recoveries of the initial active protein.

Whilst the method is now routinely used for the purification of monoclonal antibodies and their corresponding antigens, receptor proteins, DNA-binding proteins, and 'tagged' recombinant proteins, its use in protein analysis is less prevalent.

Immobilized metal affinity chromatography Immobilized metal affinity chromatography (IMAC) is a specialized variant of affinity chromatography where the proteins or peptides are separated according to their affinity for metal ions that have been immobilized by chelation to an insoluble matrix. At pH values around neutral, the amino acids histidine, tryptophan, and cysteine form complexes with the chelated metal ions (e.g., Zn^{2+}, Cu^{2+}, Cd^{2+}, Hg^{2+}, Co^{2+}, Ni^{2+}, and Fe^{2+}). They can then be eluted by reducing the pH, increasing the mobile phase ionic strength, or adding ethylenediaminetetraacetic acid (0.05 M) to the mobile phase. This technique is especially suited for purifying recombinant proteins as poly-histidine fusions and for membrane proteins and protein aggregates where detergents or high-ionic-strength buffers are required.

Size-exclusion chromatography Size exclusion (or gel filtration) chromatography (SEC or GFC) separates proteins in solution according to differences in their size and shape as they travel through a solid phase (gel) matrix. As most proteins are spherical, their shape, or radius of gyration, will approximate to their M_r. The gel matrices are usually cross-linked three-dimensional polymers of dextran, agarose, or silica that contain pores of controlled size ranges to allow free transfer of the liquid phase and limited diffusion of the proteins to be separated. By using matrices with pores of carefully controlled sizes, different M_r ranges of proteins can be separated.

Separation of a mixture of proteins occurs when the passage of the smaller proteins, peptides, and

other molecules through the column is retarded by their diffusion into the pores of the gel beads. In comparison, the large proteins do not diffuse into the pores, effectively only 'see' a smaller volume of the mobile phase, and are said to elute with the 'solvent front.' Hence, the proteins are eluted from the column according to their size, with the large proteins eluting earlier. The M_r of the eluting proteins can be calculated by using suitable reference proteins.

The gel matrix and buffer systems are designed to minimize any adsorption of the protein to the gel matrix (e.g., 20 mM sodium phosphate, pH 7 or 50–100 mM NaCl for silica matrices). Denaturants such as 0.1% SDS or 6 M guanidine hydrochloride can also be added to the mobile phase to disrupt aggregates, promote the formation of uniform, rod-like conformations, and reduce interactions between the sample and the column matrix.

Ion-exchange chromatography Separation of proteins by ion-exchange chromatography (IEXC) is based on the interaction between proteins containing different charged groups and the oppositely charged moieties covalently linked to a chromatographic matrix. Thus, negatively charged proteins (i.e., in a mobile phase with a pH greater than the isoelectric point of the proteins) will separate on a positively charged solid phase (such as diethylaminoethyl groups) using anion exchange. The converse situation occurs for positively charged proteins usually using a negatively charged carboxymethyl ion exchanger and a pH 5–6 buffer. The technique is very powerful and can separate two proteins differing by only one charged amino acid.

Proteins are initially introduced on to the column under conditions that encourage binding. They are then sequentially eluted from the matrix usually by increasing the ionic strength of the eluting buffer by including a salt gradient or by changing the pH of the eluting buffer. Separation is due to different proteins having different degrees of interaction with the ion exchanger because of differences in their charges, charge densities, and distribution of charges on their surfaces.

Immunoassays

Immunochemical techniques require an antibody (or immunoglobulin) to recognize and bind to a three-dimensional site on an antigen giving rise to a measurable secondary effect. This reaction is of necessity very specific for the given antigen and can be monitored by a number of detection systems, including precipitation of the antibody–antigen complex, agglutination, or the use of labels, e.g., radioactive, enzymatic, or fluorescent.

Marker-free immunoassays These techniques rely on the ability to measure the antigen–antibody complex 'physically' and include turbidity, nephelometry, and immunodiffusion. The first two methods rely on differences in the light-scattering properties of the antigen–antibody complex and are not generally considered to be as sensitive or accurate as other immunoassays. This may change with the introduction of surface plasmon resonance that detects changes in the refractive index of the reaction solution close to a sensor surface and is sensitive down to the picomole level.

Immunodiffusion covers a number of formats where antigen and an excess of antibody are allowed to react as they diffuse through a permeable gel. The end product of the reaction is an immunoprecipitate that is 'trapped' in the gel.

In single radial immunodiffusion (RID), the antigen is added to a well in the gel and diffuses radially through the gel that contains the antibody. Initially, the antigen is in excess of the antibody, resulting in soluble complexes. The antigen diffuses further until the antibody concentration is greater than the antigen, and a precipitation ring forms.

In the double diffusion (Ouchterlony) immunoassay, the antigen and antibody are applied to separate wells and diffuse towards each other until a precipitation line is formed. This method can be used to compare the specificity of an antibody for different antigens.

Immunoelectrophoresis combines electrophoresis, initially to separate the antigens (proteins), and then gel immunodiffusion, to visualize them by precipitation with specific antibodies. A variation of this method, rocket immunoelectrophoresis, permits quantification of the antigen by performing the electrophoesis in a gel that contains antibody. A precipitation line in the shape of a 'rocket' is formed whose peak height depends on the concentration of the antigen.

Labeled-reagent immunoassays Immunoassay sensitivity can be increased by several orders of magnitude by using labeled reagents instead of marker-free immunoassays. The label can be an enzyme, a radioactive antigen or antibody, or a fluorescent chromogen. There are a large number of methods available based on either competitive or noncompetitive formats. In competitive assays, free antigen competes with labeled or solid-phase bound antigen for a limited amount of antibody. In noncompetitive methods, the amount of antigen is limited and is

bound by specific labeled antibodies. Various formats such as microtiter plates, dipsticks, immunodots, and immunofiltration devices can be used.

Other Technologies

Protein bioassays When proteins or peptides have specific functions, e.g., enzymes, folate-binding protein, or biologically active peptides, individual bioassays are often used to determine their bioactivity. These assays are often more informative to the researcher than the more physical data. For proteins (and enzymes), this activity is usually also indicative of the conformational state of the protein with protein denaturation correlating to loss of activity.

Mass spectrometry Recent developments in mass spectrometry, such as electrospray ionization and matrix-assisted laser desorption ionization, have made it possible to determine the M_r of proteins and peptides that weigh in excess of 100 000 Da and to analyze minute amounts of these compounds down to the femtomole level. This has resulted in mass spectrometry becoming a common adjunct to the UV adsorption detector for the detection and characterization of proteins and peptides by HPLC and CE.

Requirements

A E Bender[†], Fetcham, Leatherhead, Surrey, UK

Introduction

The protein requirement is defined as the lowest level of dietary protein that will balance the losses of nitrogen (N) in persons maintaining energy balance. The body proteins are constantly undergoing breakdown and resynthesis at rates that vary from tissue to tissue. The amino acids released by tissue breakdown are mostly reused for synthesis but there is some loss – the obligatory nitrogen loss – by oxidative catabolism.

It is necessary to specify that the subject is in energy balance because utilization of dietary protein is influenced by energy intake. It has been shown that at any given level of dietary protein, the addition of energy improves nitrogen balance until it reaches a plateau, which represents the limitation imposed by protein. Any change above or below the energy needs of the subject is likely to influence nitrogen balance. This is why the current international recommendations consider energy and protein requirements together. (*See* **Energy:** Measurement of Food Energy; Energy Expenditure and Energy Balance.)

If more protein is consumed than is physiologically required, the excess is metabolized as a source of energy. However, there has been some concern that excessive protein intakes may contribute to demineralization of bone and deterioration of renal function in patients with renal disease; it is therefore suggested that the upper limit should be 1.5 g of protein per kg of body weight per day.

Earlier Recommendations

According to the perceived wisdom of the day, figures for requirements for protein have varied enormously (**Table 1**). In the early days such figures were effectively pronouncements by leading physiologists and it was not until the discussions of the Food and Agriculture Organization (FAO) of the United Nations that figures were based on scientific evidence. At intervals of about 10 years, namely 1957, 1965, 1973 and 1985, revised FAO recommendations have been made in the light of increasing knowledge.

The first of these reports, in 1957, emphasized the proportions of the various amino acids required and

[†] Deceased.

Table 1 History of recommended protein intakes (adult man)

Author	*Recommended intake*
Playfair (1865)	57–184 g (observed)
Voit (1881)	118 g (recommended)
Chittenden (1905)	50–55 g (observed and recommended)
Sherman (1920)	33–40 g at 70 kg body weight (0.59 g per kg)
League of Nations (1936)	1 g per kg body weight
FAO (1957)	0.35 g kg^{-1}
FAO (1965)	0.71 g kg^{-1}
FAO (1973)	0.57 g kg^{-1}
FAO (1985)	0.86 g kg^{-1}

FAO, Food and Agriculture Organization.

they quantified dietary protein requirements in terms of a theoretical reference protein of perfect amino acid composition, i.e., satisfying the experimentally determined needs for each amino acid. The reason for terming this a theoretical protein is that dietary protein is most effectively assimilated only at low levels of intake (as used in the laboratory assessment of protein quality) and efficiency falls off as the level rises. The efficiency of utilization of the theoretical protein is constant at all levels of intake.

National Recommended Dietary Allowances (RDAs)

While the FAO reports represent the conclusions of expert committees, each national authority has compiled its own figures based on the opinions of the committee involved and taking national habits into account. This has led to different figures in different countries. Thus, the RDA for protein for adult males is 81 g day^{-1} in France, 64 g day^{-1} in Germany, 70 g day^{-1} in the Netherlands, and 54 g day^{-1} in Spain. In practical food terms, the amount of protein one would recommend in the diet must depend on the total food (energy) intake; otherwise, heavy work would apparently call for provision of the extra energy from pure carbohydrate and fat. Two examples of the practical food approach that obviate this difficulty are the figure of 10–15% of the total energy intake as protein recommended by the Scandinavian countries, and 10% (69 g of protein on average) in the 1979 UK tables.

The 1991 UK revision (Table 2) adopted the FAO/World Health Organization (WHO)/United Nations University (UNU) figures. For adult males aged 19–50 years this is listed as 42.6 g of protein for males weighing 74 kg as the estimated average requirement, with 55.5 g as the reference nutrient intake – the term introduced in the 1991 revision and which is equivalent to RDA. For women weighing 60 kg, the corresponding figures are 36 and 45 g day^{-1}. The figures are based on milk or egg protein which are taken as completely digestible. For diets based on unrefined cereal grains and vegetables, a correction factor for digestibility of 85% is applied; for diets based on refined cereals, the correction factor is 95%. (*See* **Dietary Reference Values**.)

Table 2 UK dietary reference values for protein

Age	*Weight (kg)*	*Estimated average requirement (g day^{-1})*	*Reference intake (g day^{-1})*
0–3 months	5.9		12.5
4–6 months	7.7	10.6	12.7
7–9 months	8.8	11.0	13.7
10–12 months	9.7	11.2	14.9
1–3 years	12.5	11.7	14.5
4–6 years	17.8	14.8	19.7
7–10 years	28.3	22.8	28.3
Males			
11–14 years	43.0	33.8	42.1
15–18 years	64.5	46.1	55.2
19–50 years	74.0	44.4	55.5
50+ years	71.0	42.6	53.3
Females			
11–14 years	43.8	33.1	41.2
15–18 years	55.5	37.1	45.4
19–50 years	60.0	36.0	45.0
50+ years	62.0	37.2	46.5
Pregnancy			+6
Lactation			
0–6 months			+11
6+ months			+8

Methods of Assessment of Needs

There are two methods of determining nitrogen requirements. The one used until the 1985 FAO report was the factorial method in which the losses of nitrogen from the body are measured to establish the amount that is required. The second method, adopted in the 1985 report, measures the intake of nitrogen needed to maintain nitrogen equilibrium.

Factorial Method

On a diet free from protein the body loses nitrogen in the urine as urea, creatinine, uric acid, and ammonium salts, together with small amounts of other compounds; this is termed the endogenous loss. There are also losses in the feces from bacteria, mucosal cells shed from the lining of the intestine, and residues of digestive juices that have not been reabsorbed; this is termed metabolic loss.

In addition, there are small losses from skin cells, hair, finger nails, and body fluids.

These obligatory losses are measured on subjects fed a diet free from protein. On such a diet the urinary output of nitrogen does not attain a constant level but falls sharply for 4–6 days and then very slowly. The levels reached are 2–3 g day^{-1} or 30–45 mg per kg of body weight. Forty-five milligrams of nitrogen approximates to 2 mg of nitrogen per basal kcal. The two phases of this decline are taken to indicate two processes. The first rapid fall is loss from organs with a rapid protein turnover and is called labile body protein. The second is largely from muscles and skin. The obligatory nitrogen loss is taken as the figure at the end of the rapid fall. This relative inexactitude is one of the disadvantages of the factorial method.

The 1965 report took the figures of 46 mg nitrogen per kg (2 mg per basal kcal) for urine loss, 20 mg kg^{-1} for fecal loss, and 20 mg for other losses. In the light of better evidence, the 1973 report changed these findings to 37, 12, and 5 mg respectively. This accounts for the marked reduction in protein recommendations between 1965 (0.71 g kg^{-1}) and 1973 (0.57 g kg^{-1}). At first consideration, obligatory losses should be balanced by an intake of the same amount. This was assumed in the 1965 report but it was later realized that when an individual is supplied with the same amount of nitrogen as his or her obligatory loss, he or she remains in negative nitrogen balance. It was found necessary to increase that figure by 30% to achieve nitrogen equilibrium. An additional 30% was added to allow for individual variation. All measurements are made as nitrogen and then converted into protein by multiplying by the factor 6.25.

While the basic data show a small difference for nitrogen losses between males and females, figures are not sufficiently firm to allow any distinction. The difference between final protein figures is due to the different standard body weights used for males and females; in the 1973 report this was 0.71 g of protein per kg of body weight per day, which is 39 g for females and 46 g for males. This was called the practical allowance and based on full utilization of the protein in the diet, i.e., high-quality protein, termed reference protein.

An extra allowance is made for protein of lower quality, i.e., protein with net protein utilization (NPU) values of 70–80 in developed countries and 60–70 in less developed countries (with values as low as 50–60 in special conditions); this is stated in the 1973 report.

Apart from the difficulty of deciding the level of the endogenous loss (since there is no clear sharp break in the curve), most workers did not measure the cutaneous losses because of the difficulty of doing so, and they accepted published values which were derived from only a limited number of experiments.

Nitrogen Balance Method

Nitrogen balance is the difference between nitrogen excreted from the body and nitrogen ingested in the diet (of which the greater part by far is protein). During growth, pregnancy, lactation, and recovery from convalescence, the body is in positive nitrogen balance since it is retaining nitrogen for the purpose of synthesizing new protein tissues. During dietary deprivation, most illnesses, and certain types of stress, the body loses nitrogen and is in negative balance. The healthy adult is in nitrogen equilibrium. The basis of this method of determining nitrogen requirements is to feed the subjects a series of diets with different levels of protein while measuring nitrogen excretion, then to interpolate to nitrogen equilibrium (zero nitrogen balance).

In early studies the diets included very low levels of protein and a zero level but since the nitrogen balance response is not linear throughout the entire submaintenance range, recent studies use levels around the expected range of requirements. An allowance has to be made for the variable losses of nitrogen in sweat, which are considerable in heavy work in a hot climate.

It takes some time at a given level of dietary protein to achieve a steady state, i.e., adjustments in urine output do not immediately follow changes in nitrogen intake, so that diets are fed for periods of 1–3 weeks at each intake level. These short-term nitrogen balance determinations do not take account of adaptation to low levels of dietary protein as experienced in developing countries. Long-term studies require several months, but these are usually limited to a single level of protein intake which would provide evidence that a particular diet is adequate.

It must be borne in mind that in these detailed consultations about protein (and energy) requirements and recommendations, the FAO is largely concerned with the adequacy of diets in poorly fed populations of developing countries. In the well-fed western world there is never a problem of protein shortage in healthy people as long as enough food is consumed to satisfy hunger. The fundamental physiological considerations, of course, still apply.

Direct nitrogen balance studies are the currently accepted method of determining protein requirements but they suffer from the lack of long-term balance studies, the absence of independent validation of an optimal state of protein nutrition, and lack of knowledge of the functional significance of

the size of the total nitrogen pool and rate of turnover of tissue proteins. There are no functional indicators of protein inadequacy at a stage before clinically detectable changes occur.

The limitations of the data are indicated by the small numbers of studies at the time of the 1985 report – nine short-term studies of single protein sources on a total of 93 subjects, eight short-term studies on the typical mixed diets of eight countries on a total of 73 subjects, and six long-term studies, 24–89 days, five on egg and one on milk, on a total of 34 subjects.

The short-term studies provide an estimate of a mean daily requirement of 0.63 g of highly digestible good-quality protein – a figure slightly higher than the 1973 'safe level.' The long-term studies suggest that 0.58 g kg^{-1} is a reasonable estimate.

From all the available results it is suggested that 0.6 g per kg of body weight per day is the average requirement for good-quality proteins such as meat, milk, egg, and fish.

The coefficient of variation was 12.5%, i.e., 2 SD equals 25%. This provides the currently accepted figure of 0.75 g of protein per kg of body weight per day as the safe level of intake for an adult.

Table 4 Safe level of protein intake (good-quality protein)

Age	*g per kg body weight*	*g per day*
3–6 months	1.85	13
9–12 months	1.50	14
1–2 years	1.2	13.5
2–3 years	1.15	15.5
3–5 years	1.10	17.5
5–7 years	1.0	21
7–10 years	1.0	27
10–12 years		
Male	1.0	34
Female	1.0	36
12–14 years		
Male	1.0	43
Female	0.95	44
14–16 years		
Male	0.95	52
Female	0.9	46
16–18 years		
Male	0.9	56
Female	0.8	42
Adult		
Male	0.75	49 (65 kg body weight)
Female	0.75	41 (55 kg body weight)
Pregnancy		+6
Lactation		+17.5

Table 5 Protein losses related to surgery

Time of loss	*Protein loss (g)*
Before surgery	
Bleeding peptic ulcer	90 (over 5 days)
Long-bone fracture	140–190 (over 10 weeks)
Limb burn	Up to 1000
During surgery (blood loss)	
Gastric surgery	9–18
Pneumonectomy	20–60
Thyroidectomy	3–12
Catabolic response after surgery	
Herniorrhaphy	18 (over 10 days)
Gastric resection	50–175 (5–10 days)
Appendectomy	50 (10 days)
Bed rest (inactivity), 3–4 weeks	300

Quality and Digestibility

Earlier recommendations for protein requirements were based on 'good-quality' protein or reference proteins such as eggs or milk, i.e., proteins with NPU close to 1.0 (100 in the older nonmenclature). Thus, the recommendation of 0.75 g protein per kg of body weight is for protein of this high quality and the amount has to be increased proportionately to compensate for lower quality. For example, 0.75 g of NPU

Table 6 Approximate protein loss (g) during first 10 days following injury or operation

	Loss of tissue	*Hemorrhage or exudate*	*Catabolic phase*	*Total*
Simple fracture of femur		200	700	900–1100
Muscle wound	500–750	150–400	750	1350–1900
35% Burn	500	150–400	750	1400–1650
Gastrectomy	(20–180)	20–100	625–750	645–850
Untreated typhoid fever			675	675

1.0 is equivalent to 1.07 g of quality 0.7, or 1.25 g of NPU 0.6.

In practice, the quality of the mixture of dietary proteins in underdeveloped countries (which rely very largely on a single staple food, usually a cereal), is about 0.7, and the addition of protein-rich foods such as meat and milk – cereals, meat, and milk are the major sources of dietary protein in the developed countries – increases this to only 0.8. Consequently, the 1985 report lays less emphasis on the quality of the protein because the figure recommended is higher than the 1973 figure and digestibility correction alone is adequate. Digestibility was not mentioned at that time.

Only four amino acids are likely to limit the protein quality of mixed diets: they are lysine, the sulfur amino acids, threonine, and tryptophan, and diets in developing countries generally meet the adult requirement for these amino acids. Quality can be taken care of by calculating the proportion of the most limiting amino acid compared with that in the requirement pattern and then increasing the protein figure in that ratio. (*See* **Amino Acids**: Metabolism.)

Differences in digestibility arise from the nature of the cell walls of the food, the presence of dietary fiber and polyphenols, and from chemical reactions that alter the release of amino acids during digestion. Adjustments are therefore made to the amount of food protein to be ingested by comparing the digestibility of the protein food with that of reference proteins (Table 3).

The digestibility of a complete diet can be calculated by using the values for individual sources of protein and multiplying by the proportion of those foods in the diet.

Diets based on coarse, whole-grain cereals and vegetables are generally about 85% digested, while those based on refined cereals are 95% digested; meat, milk, and eggs are 100% digested.

Extra Allowances

Figures for protein requirements are based on measurements made on young adults with corrections for age, sex, and body weight. They apply to healthy adults in nitrogen equilibrium. There are obviously greater needs for growing children, pregnant women, and lactating mothers, and these are shown in Table 4 (the UK figure for lactation, in Table 2, has been modified). The extra needs for growth are small compared with the nitrogen required to maintain the tissues, even in young children, except for babies under 1 year of age. For example, the average requirement for growth of boys 4–5 years of age is 0.36 g of protein per day, while for maintenance it is 12.6 g. It is accepted that different amounts of protein may be laid down from day to day as part of the normal process of growth. The body has very limited capacity for storing amino acids; it is therefore necessary to provide enough protein every day for possible extra demands of higher rates of growth. For this reason the extra demands for growth were estimated at 50% greater than the theoretical growth rate. (*See* **Children**: Nutritional Requirements; **Lactation**: Human Milk: Composition and Nutritional Value; Physiology; **Pregnancy**: Safe Diet.)

Trauma

Protein requirements for healthy adults take into account the 'normal stresses of everyday life' but there are increased losses of nitrogen from the body in pain, anxiety, and psychological stresses, with very large losses in trauma, chronic disorders, and parasitic infections. Clearly, these will vary enormously with the severity and duration of the condition. Tables 5 and 6 show some examples of these losses which must be made good during convalescence.

Functional Properties

J K P Weder and H-D Belitz†, Technische Universität München, Garching, Germany

Introduction

Standardization of food properties, in order to meet nutritional, physiological and toxicological demands, and requirements of food-processing operations, is a perennial endeavor. Food production is similar to a standard industrial fabrication process: on the one hand is the food commodity with all its required properties; on the other hand are the components of the product, each of which supplies a distinct part of the required properties. Such considerations have prompted investigations into the relationship in food between macroscopic physical and chemical properties and the structure and reactions at the molecular level. Reliable understanding of such relationships is a fundamental prerequisite for the design and operation of a process, either to optimize the process or to modify the food components to meet the desired properties of the product.

Functional Properties

In common with other food constituents, proteins contribute significantly to the physical properties of foodstuffs, especially through their ability to build or stabilize gels, foams, doughs, emulsions and fibrillar structures. **Table 1** shows some typical examples of functional properties of proteins in relation to important food systems. Foaming, gelling, and emulsifying properties will be discussed in more detail.

† Deceased.

Foaming Properties

Proteins act as foam-forming and foam-stabilizing agents in various foodstuffs, e.g., in baked products, sweets, desserts, and beer. The properties of various proteins are different: serum albumin foams very well, whereas ovalbumin does not. Mixtures of proteins, e.g., egg white, can be particularly effective. In that case, the globulins start the formation of foam; ovomucin is important for its stabilization, and ovalbumin and conalbumin are responsible for the heat-setting properties.

Foams are dispersions of gases in liquids. Proteins stabilize such systems by forming flexible, cohesive films around the surface of the gas bubbles. During whipping, the protein is adsorbed at the interface via hydrophobic areas, followed by partial unfolding (surface denaturation). The decrease of the surface tension, caused by protein adsorption, facilitates the formation of new interfaces and further gas bubbles. The partially unfolded proteins associate under film formation.

The foamability of a protein molecule depends on its diffusion rate and the ease with which it is denatured. These parameters in turn depend on the molecular mass, the surface hydrophobicity, and the stability of the conformation.

Foams collapse because large gas bubbles grow at the expense of smaller ones ('*disproportionation*'). Therefore, the stability of a foam depends on the stability of the protein film and its permeability for gases. The stability of the film in turn depends on the amount of adsorbed protein and on the ability of the adsorbed protein to associate. Generally, surface denaturation exposes additional amino acid side-chains that can participate in intermolecular interactions. The stronger the cross-linking, the more stable is the film. The pH of the system should be near the isoelectric points of the involved proteins because the association is promoted by a small net charge.

In summary, the ideal foam-forming and foam-stabilizing protein is characterized by a low molecular mass, high surface hydrophobicity, good solubility, a small net charge at the pH of the food, and easy denaturability.

Foams are destroyed by lipids and organic solvents such as higher alcohols, which, because of their hydrophobicity, displace proteins from the surface of the gas bubbles without being able to form stable films. Egg yolk, for example, prevents the whipping of egg white, even at low concentrations. The disturbance of protein association by the lecithins is responsible for that effect.

The foaming properties of proteins can be improved by chemical and physical modification. Partial

Table 1 Typical functional properties caused by proteins in food systems

Functional property	*Mode of action*	*Food system*
Solubility	Protein solvation, pH-dependent	Beverages
Water absorption and binding	Hydrogen bonding of water, entrapment of water (no drip)	Meat, sausages, bread, cakes
Viscosity	Thickening, water binding	Soups, gravies
Gelation	Protein matrix formation and setting	Meat, curds, cheese
Cohesion–adhesion	Protein acts as adhesive material	Meat, sausages, baked goods, pasta products
Elasticity	Hydrophobic bonding in gluten, disulfide bridges in gels (deformable)	Meat, bakery
Emulsification	Formation and stabilization of fat emulsions	Sausages (e.g., Bologna), soup, cakes
Fat adsorption	Binding of free fat	Meat, sausages, doughnuts
Flavor binding	Adsorption, entrapment, release	Simulated meat, bakery, etc.
Foaming	Formation of stable films to entrap gas	Whipped toppings, chiffon desserts, angel cakes

Modified from Kinsella and Srinivasan (alias Damodaran S) (1981).

enzymatic hydrolysis produces smaller molecules of a higher diffusion rate, better solubility, and higher surface hydrophobicity. The disadvantages are the lower film stability and the loss of heat coagulability. The introduction of charged or neutral groups or a partial thermal denaturation (e.g., of whey proteins) can also improve the desired properties. Recently, the addition of strongly basic proteins (e.g., clupeines) has been tested, which obviously increases the protein association within the films and allows the foaming of lipid-containing systems.

Emulsifying Properties

Emulsions are disperse systems of two or more immiscible liquids. They are stabilized by emulsifiers, compounds that form interfacial films and prevent the dispersed phase from coalescing. Proteins are able to stabilize emulsions (e.g., milk) due to their amphipathic nature. The emulsifying properties of a protein depend on the rate at which it diffuses into the interface, on its adsorbability there, and on the deformability of its conformation through interfacial tension (surface denaturation). The diffusion rate depends on the temperature and the molecular mass of the protein, which in turn can be influenced by the pH and the ionic strength. The adsorbability depends on the exposure of hydrophilic and hydrophobic groups, and thus on the amino acid composition, as well as on the pH, ionic strength, and temperature. The stability of the conformation depends on the molecular mass, amino acid profile and number of intramolecular disulfide bonds of the protein.

Thus, a protein with ideal qualities as an emulsifier for oil-in-water emulsions would have a relatively low molecular mass, a balanced amino acid composition in terms of charged, polar and apolar side-chains, good solubility in water, marked surface hydrophobicity, and a relatively stable conformation.

Gel Formation

Gels are disperse systems of at least two components in which a solid phase (dispersed phase) forms a cohesive network in a liquid phase (continuous phase). Gels are characterized by their lack of fluidity and their elastic deformability. They are placed between solutions with repulsive forces between molecules of the dispersed phase predominating, and precipitates with strong intermolecular forces predominating. A differentiation is made between two types of gels, the '*polymeric networks*' and the '*aggregated dispersions*.' Intermediate forms are also known.

Examples of *polymeric networks* are the gels formed by gelatin or by polysaccharides such as agarose or carrageenan. The formation of a three-dimensional network takes place by aggregation of unordered fibrous molecules via limited ordered structures, e.g., double helices. Gels of this type are characterized by a low concentration of polymer (*c*. 1%), transparency and fine texture. Gel formation is started by adjusting to a suitable pH, by adding suitable ions, or by heating followed by cooling. Since the aggregation takes place mainly via hydrogen bonds, which are easily solved when heated, polymeric networks are '*thermo-reversible*,' i.e., they are formed when a solution is cooled, and they melt again when they are heated.

Examples of *aggregated dispersions* are the gels formed by globular proteins after denaturation by heat. The thermal unfolding of the protein exposes amino acid side-chains, which can take part in intermolecular interactions. The subsequent association leads to small spherical aggregates, which combine into linear strands whose interaction results in the three-dimensional gel network. Because of the unordered type of aggregation, gel formation requires a relatively high protein concentration (5–10%). To

avoid the formation of coarse and fairly unstructured gels, in particular in the area of the isoelectric point, the aggregation rate should be slower than the unfolding rate. The degree of unfolding necessary to start aggregation seems to depend on the particular protein. Since partial denaturation exposes mainly hydrophobic groups, the aggregation takes place predominantly via intermolecular hydrophobic bonds, and '*thermoplastic*' *(thermo-irreversible)* gels are formed. This type of gel does not liquefy when heated, but can soften or shrink. Besides hydrophobic bonds, disulfide bonds formed from exposed thiol groups can also contribute to cross-linking, as can electrostatic bonds between proteins with different isoelectric points in heterogeneous systems (e.g., egg white).

Addition of salts improves the gel formation. The moderate increase in ionic strength promotes interaction between charged macromolecules or molecule aggregates through charge shielding without precipitation. An example is the improvement of thermal gelling of soya globulins in soya milk by calcium ions (soya curd, tofu).

Modification of Functional Properties

Modification of proteins is still far from being a common method in food processing, but it is increasingly being recognized as essential, for two main reasons. First, proteins fulfill many functions in food, and some of these can be served better by modified than by native proteins. Second, persistent nutritional problems the world over necessitate the utilization of new raw materials. Modifying reactions can insure that such new raw materials (e.g., proteins of plant or microbial origin) meet stringent standards of food safety, palatability, and acceptable biological value. This review includes several protein modification reactions that are being used or are being considered for use. They involve chemical or enzymatic reactions or a combination of both. Examples have been selected to emphasize existing trends. Modification of the properties of proteins is possible by changing the amino acid composition or the size of the molecule, or by removing or inserting hetero constituents. Such changes can be accomplished by chemical and/or enzymatic reactions.

From a food processing point of view, the aims of protein modification are:

- blocking the reactions involved in deterioration of food (e.g., the *Maillard* reaction);
- improving some physical properties of proteins (e.g., texture, foam stability, whippability, solubility);
- improving the nutritional value (increasing the extent of digestibility, inactivation of toxic or other undesirable constituents, introducing essential ingredients such as some amino acids).

Chemical Modification

A selection of chemical reactions of proteins that are pertinent to, and of current importance in, food processing is shown in Table 2.

Acylation Treatment with succinic anhydride generally improves the solubility of a protein. For example, succinylated wheat gluten is quite soluble at pH 5. This effect is related to disaggregation of high-molecular-weight gluten fractions. In the case of succinylated casein, the modification shifts the isoelectric point of the protein (and thereby the solubility minimum) to a lower pH. Succinylation of leaf proteins improves the solubility as well as the flavor and the emulsifying properties. Succinylated yeast protein not only has an increased solubility in the pH range of 4–6 but is also more heat-stable above pH 5. It has better emulsifying properties, surpassing many other proteins, and has an increased whippability.

Table 2 Chemical reactions of proteins significant in food

Reactive group	*Reaction*	*Product*
—NH_2	Acylation	—NH—CO—R
—NH_2	Reductive alkylation with HCHO	— $N(CH_3)_2$
—NH_2	Reductive glycosylation	—NH—CH_2—$(CHOH)_n$—CH_2OH
—$CONH_2$	Hydrolysis	—COOH
—COOH	Esterification	—COOR
—COOH	Amidation ('glycosylation')	—CO—NH—CH(CHO)—$(CHOH)_n$H
—OH	Esterification	—O—CO—R
—SH	Oxidation	—S—S—
—SH	Alkylation	—S—R
—S—S—	Reduction	—SH
—CO—NH—	Hydrolysis	—COOH + H_2N—

Introduction of aminoacyl groups into protein can be achieved by reactions involving amino acid carboxy anhydrides, amino acids and carbodiimides, or by *t*-butyloxycarbonyl (BOC)-amino acid *N*-hydroxysuccinimide esters with subsequent removal of the amino-protecting group (BOC). Feeding tests with casein with attached methionine, as produced by this method, have demonstrated a satisfactory availability of methionine. Such covalent attachment of essential amino acids to a protein may avoid the problems associated with food supplementation with free amino acids: losses during processing, development of undesired aroma due to methional, etc. With β-casein as an example, it was shown that the association of a protein is significantly affected by its acylation with fatty acids of various chain lengths.

Alkylation Modification of proteins by reductive methylation of amino groups with formaldehyde and sodium borohydride ($NaBH_4$) retards *Maillard* reactions. The resultant methyl derivative, depending on the degree of methylation, is less accessible to proteolysis. Hence, its value from a nutritional and physiological point of view is still an open question.

Sugars such as glucose, fructose, maltose, or lactose can be bound to the amino groups of proteins (casein, legumin, β-lactoglobulin) by reductive glycosylation with sodium cyanoborohydride. Whereas neutral sugars favor foaming capacity and foam stability, charged carbohydrates improve emulsifying properties. Amino sugars can also be bound to the carboxyl group of proteins through an amide bond by the carbodiimide method.

Reactions involving cysteine and cystine Disulfide bonds exert a strong influence on the properties of proteins. Wheat gluten can be modified by reduction of its disulfide bonds to sulfhydryl groups and subsequent reoxidation of these groups under various conditions. Reoxidation of a diluted suspension in the presence of urea results in a weak, soluble, adhesive product (gluten A), whereas reoxidation of a concentrated suspension in the presence of a higher concentration of urea yields an insoluble, stiff, cohesive product (gluten C). Additional viscosity data have shown that the disulfide bridges in gluten A are mostly intramolecular, whereas those in gluten C are predominantly intermolecular.

Disulfide cleavage in soya protein by 0.1 M sodium sulfite produces an adhesive with an acceptable viscosity and improved adhesive strength and hydrophobicity compared with unmodified soya protein when spray-dried, but a very low viscosity when freeze-dried.

Enzymatic Modification

Of the great number of possible enzymatic reactions with protein as a substrate, only a small number have been found so far to be suitable for use in food processing.

Dephosphorylation With β-casein as an example, it was shown that the solubility of a phosphoprotein in the presence of calcium ions is greatly improved by enzymatic dephosphorylation.

Plastein reaction The enzyme-catalyzed formation of larger polypeptides (about 3 kDa) from peptide fragments of a hydrolysate, i.e., the formation of peptide bonds, is called the '*plastein* reaction.' Amino acid esters that are added to the hydrolysate are incorporated into the resulting products, which are called '*plasteins*.' Incorporation of amino acid esters into the polypeptide is affected by the nature of the amino acid side-chain and by the length of the alkyl chain of the ester. Amino acids with hydrophobic side-chains and long-chain alkyl esters are preferred. Thus, an amino acid with a short side-chain should be applied as an ester of a long-chain alcohol. The plastein reaction can help to improve the biological value of a protein. An example is the plastein enrichment of zein with tryptophan, threonine, and lysine.

Enrichment of a protein with selected amino acids can be achieved with the corresponding amino acid esters or, equally well, by using suitable partial hydrolysates of another protein. For example, the enrichment of soya protein with sulfur-containing amino acids is possible through '*adulteration*' with the partial hydrolysate of wool keratin. The protein efficiency ratio (PER) value of such a plastein is significantly improved. In this way, the production of plasteins with an amino acid profile very close to that recommended by the Food and Agriculture Organization and the World Health Organization (FAO/WHO) can be achieved from very diverse proteins, e.g., from leaf, bacterial and algal proteins.

The plastein reaction also makes it possible to improve the solubility of a protein, e.g., by increasing the content of glutamic acid. Soya protein (24% glutamic acid) yields a plastein with 25% glutamic acid and a Glu-plastein with 42% glutamic acid. Soya protein has a pronounced solubility minimum in the pH range of 3–6. The minimum is much less pronounced in the case of the plastein, and the glutamic acid-enriched Glu-plastein has a satisfactory solubility over the whole pH range and is also resistant to thermal coagulation. Proteins with an increased content of glutamic acid show an interesting sensory

effect: partial hydrolysates of such plasteins do not taste bitter, but exhibit a pronounced 'meat broth' flavor.

Elimination of the bitter taste from a protein hydrolysate is also possible without incorporation of hydrophilic amino acids. Bitter-tasting peptides, such as leucyl-phenylalanine, which are released by partial hydrolysis of proteins, react preferentially in the subsequent plastein reaction and are incorporated into higher-molecular-weight peptides with a neutral taste.

The versatility of the plastein reaction is also demonstrated by examples wherein undesired amino acids are removed from a protein. A phenylalanine-free diet, which can be prepared by mixing amino acids, is recommended for certain metabolic defects. However, the use of higher-molecular-weight phenylalanine-free peptides is more advantageous from a sensory and osmotic point of view. Such peptides can be prepared from proteins by the plastein reaction. First, the protein is partially hydrolysed with pepsin (pepsin A, EC 3.4.23.1). Then, treatment with pronase (mycolysin, EC 3.4.24.31) under suitable conditions preferentially releases amino acids with long hydrophobic side-chains such as phenylalanine. The remaining peptides are separated by gel chromatography and subjected to the plastein reaction in the presence of added tyrosine and tryptophan ethyl esters. This yields a plastein that is practically phenylalanine-free and has a predetermined ratio of other amino acids, including tyrosine. The plastein reaction can also be carried out as a one-step process, thus putting these reactions to economic, industrial-scale use.

Associations involving cross-linking Cross-linking between protein molecules is achieved with peroxidase (EC 1.11.1.7). The cross-linking occurs between tyrosine residues when a protein is incubated with a mixture of peroxidase and hydrogen peroxide (H_2O_2). Incubation of a protein with a mixture of peroxidase, H_2O_2, and catechol also results in cross-linking. In this case, oxidative deamination of lysine residues takes place, followed by aldol and aldimine condensations, i.e., reactions analogous to those catalyzed by lysyl oxidase in connective tissue.

Texturized Proteins

The world protein production for nutrition is currently about 22% from animal sources and 78% from plant sources. The plant proteins are primarily from cereals (53%) and oilseed meal (18%). Some nonconventional sources of protein (single cell proteins, leaves) have also acquired some importance. Proteins are responsible for the distinct physical structure of a number of foods, e.g., the fibrous structure of muscle tissue (meat, fish), the porous structure of bread, and the gel structure of some dairy and soya products.

Many plant proteins have a globular structure and, although available in large amounts, are used to only a limited extent in food processing. In an attempt to broaden the use of such proteins, a number of processes were developed in the mid-1950s that confer a fiber-like structure to globular proteins. Suitable processes yield products with cooking strength and a meat-like structure. They are marketed as meat extenders and meat analogs and can be used whenever a lumpy structure is desired.

Starting material The following protein sources are suitable for the production of texturized products: soya; casein; wheat gluten; oilseed meals such as from cottonseed, groundnut, sesame, sunflower, safflower or rapeseed; zein (corn protein); yeast; whey; blood plasma; or packing plant offal such as lungs or stomach tissue. The required protein content of the starting material varies and depends on the process used for texturization. The starting material is often a mixture such as soya protein with lactalbumin, or protein plus acidic polysaccharide (alginate, carrageenan, or pectin).

The suitability of proteins for texturization varies, but the molecular weight should be in the range of 10–50 kDa. Proteins of less than 10 kDa are weak fiber builders, whereas those higher than 50 kDa are disadvantageous due to their high viscosity and their tendency to gel in the alkaline pH range. The proportion of amino acid residues with polar side-chains should be high in order to enhance intermolecular chain binding. Bulky side-chains hinder such interactions, so that the proportions of amino acids with these structures should be low.

Texturization The globular proteins are unfolded during texturization by solving the intramolecular bonds. The resultant extended protein chains are stabilized through interactions with neighboring chains. In practice, texturization is achieved in one of two ways:

- The starting protein is dissolved, and the resultant viscous solution is pressed through a spinning nozzle into a coagulating bath ('*spin process*').
- The starting protein is moistened slightly, and then, at high temperature and pressure, the molten protein is extruded with shear force through the orifice of a die ('*extrusion process*').

In the *spin process*, the starting material (protein content >90%, e.g., soya protein isolate) is suspended in water and dissolved by the addition of alkali. The 20% solution is then aged at pH 11 through constant stirring. The viscosity increases during this step as the protein unfolds. The solution is then pressed through the orifices of a nozzle (5000–15 000 orifices, each with a diameter of 0.01–0.08 mm) into a coagulating bath of pH 2–3. The bath contains an acid (citric, acetic, phosphoric, lactic, or hydrochloric) and, usually, 10% sodium chloride. Spinning solutions of protein–acidic polysaccharide mixtures also contain earth alkali salts. The resulting protein filaments are extended further (to about two to four times the original length) in a 'winding up' step, and are bundled into thicker fibers with diameters of 10–20 mm. The molecular interactions are enhanced during stretching of the fibers, thus increasing the mechanical strength of the fiber bundles.

The adherent coagulation solvent is then removed by pressing the fibers between rollers, followed by passing a neutralizing bath (sodium bicarbonate plus sodium chloride) of pH 5.5–6 and, occasionally, also a hardening bath (concentrated sodium chloride). The fiber bundles may be combined into thicker cords with diameters of 7–10 cm. Additional treatment involves passage of the bundles through a bath containing a binder (a protein that coagulates when heated, such as egg protein) and other additives such as modified starch or other polysaccharides, aroma compounds or lipids. This treatment produces bundles with improved thermal stability and aroma. A typical bath for fibers that are processed to produce a meat analog might consist of 51% water, 15% ovalbumin, 10% wheat gluten, 8% soya flour, 7% onion powder, 2% protein hydrolysate, 1% sodium chloride, 0.15% monosodium glutamate, and 0.5% pigments. Finally, the soaked fiber bundles are heated and chopped.

In the *extrusion process*, the moisture content of the starting material (protein content about 50%, e.g., soya concentrate) is adjusted to 30–40%, and additives (sodium chloride, buffers, aroma compounds, pigments) are incorporated. Aroma compounds are added in fat as a carrier, when necessary, after the extrusion step to compensate for aroma losses. The protein mixture is fed into the extruder (a thermostatically controlled cylinder or conical body that contains a polished, rotating screw with a gradually decreasing pitch) that is heated to 120–180 °C and develops a pressure of $3–4 \times 10^6$ Pa. Under these conditions, the mixture is transformed into a plastic, viscous state in which solids are dispersed in the molten protein. Hydration of the protein takes place after partial unfolding of the globular molecules and stretching and rearrangement of the protein strands along the direction of mass transfer. The process is affected by the rotation rate and shape of the screw, and by the heat transfer and viscosity of the extruded material and its residence time in the extruder. As the molten material exits from the extruder through a die of 4 mm diameter, the water vaporizes, leaving behind vacuoles in the ramified protein strands.

The extrusion process is more economical than the spin process. However, it yields fiber-like particles rather than well-defined fibers. A great number and variety of extruders are now in operation. As with other food processes, there is a trend toward developing and utilizing high-temperature/short-time (HTST) extrusion cooking.

Interactions and Reactions Involved in Food Processing

J K P Weder and H-D Belitz†, Technische Universität München, Garching, Germany

Introduction

The nature and extent of the chemical changes induced in proteins by food processing depend on a number of parameters, for example, food composition and processing conditions, such as temperature, pH, or the presence of oxygen. The consequences of such reactions may be desirable or undesirable. For example, the biological value of proteins may be decreased by destruction of essential amino acids, conversion of essential amino acids into derivatives that are not metabolized, or reduced digestibility of protein as a result of intra- or interchain cross-linking. The formation of toxic degradation products is also possible. The nutritional/physiological and toxicological assessment of changes induced by processing of foods is a subject of some controversy and opposing opinions.

Reactions with Carbohydrates

Many foodstuffs contain reducing sugars and amino compounds such as proteins, peptides, amino acids, and amines. Reactions between these components are usually classed under the term '*Maillard reaction*' or 'nonenzymatic browning.' They occur especially at a higher temperature, low water activity and during longer storage. Reactive sugars are glucose, fructose, maltose, lactose, and, to a smaller extent, reducing pentoses. On the side of the amino components, primary amines are more important than secondary amines because their concentration in foods is usually higher. Exceptions are, for example, malt and corn products, which have a high proline content. In the case of proteins, the ε-amino groups of their lysine residues react predominantly, but guanidino groups of arginine residues can also react. These reactions result in:

- Brown pigments, known as '*melanoidins*,' which contain nitrogen in variable amounts, and have varying molecular masses and solubilities in water. Little is known about their structure. Browning is desired in baking and roasting, but not in foods which are only slightly colored or have a distinct color (condensed milk, faintly colored dried soups, tomato soup).
- Volatile compounds, which often contribute to the aroma. Aroma formation through the Maillard reaction is desired in cooking, baking, roasting, and frying. However, the generation of off-flavors in food during storage, especially in the dehydrated state, or during pasteurization, sterilization, or roasting is not desired.
- Bitter substances, which are partially desired (coffee), but can also cause an off-flavor, e.g., in grilled meat or fish.
- Reductones, which have highly reductive properties and contribute to the stabilization of foods against oxidative deterioration.
- Losses of essential amino acids (e.g., lysine, methionine).
- Mutagenic compounds.
- Cross-linking of proteins.

The Maillard reaction of the ε-amino group of lysine prevails in the presence of reducing sugars, for example, lactose or glucose, which yield the protein-bound Amadori compounds, ε-*N*-deoxylactulosyl-1-lysine or ε-*N*-deoxyfructosyl-1-lysine, respectively. Lysine is not biologically available in these forms.

† Deceased.

Acid hydrolysis of such primary reaction products yields lysine as well as the degradation products furosine and pyridosine in a constant ratio. A nonreducing sugar (e.g., sucrose) can also cause a loss of lysine when conditions for sugar hydrolysis are favorable, leading to the formation of the reactive sugars glucose and fructose.

Very recently, two intensely red-colored compounds were isolated from brown–orange melanoidins with mass > 10 000 Da obtained by thermal treatment of an aqueous solution of casein and furan-2-carboxaldehyde (furfural), a well-known product of the Maillard reaction. These compounds were identified as the so-far unknown chromophoric amino acids (*S*)-2-amino-6-{4-[(*E*)-1-formyl-2-(2-furyl)ethenyl]-5-(2-furyl)-2-[(*E*)-(2-furyl)methylidene]-2,3-dihydro-3-oxo-1*H*-pyrrol-1-yl}hexanoic acid and its 2-[(*Z*)-(2-furyl)methylidene] isomer.

In the late 1970s, it was shown that charred surface portions of grilled fish and meat, as well as the smoke condensates, isolated during grilling, exhibit highly mutagenic effects in microbial tests (Ames test with *Salmonella typhimurium* mutant strain TA 98). Model experiments showed that pyrolysates of amino acids and proteins are responsible for those effects. Table 1 lists several mutagenic compounds (pyridoindoles, pyridoimidazoles, pyridocarbazoles, and tetraazafluoranthenes) that were isolated from such pyrolysates.

Mutagenic compounds can also be formed at lower temperatures from amino acids and proteins. The compounds listed in Table 2 were isolated from meat extract, deep-fried meat, grilled fish, and heated model mixtures of creatinine, an amino acid (glycine, alanine, or threonine), and glucose. The compounds, mainly imidazoquinolines and imidazoquinoxalines, are formed from creatinine, subsequent products of the Maillard reaction (pyridines, pyrazines), and amino acids. Their toxicity is based on the heteroaromatic amino function.

Pentosidine (N^5-[*N*-(5-amino-5-carboxy-1-pentyl)-pyrido[4,5-*b*]imidazol-2-yl]-2,5-diaminopentanoic acid), a cross-linked amino acid in which one arginine and one lysine residue are linked together by a pentose, was recently detected in foods. The low levels found in commercial thermally processed food samples (up to 4 mg kg^{-1} protein in milk products, up to 40 mg kg^{-1} protein in roasted coffee beans and bakery products) indicate that pentosidine does not contribute significantly to food protein cross-linking.

CROSSPY (1,4-bis-(5-amino-5-carboxy-1-pentyl)-pyrazinium radical cation), a cross-linked amino acid in which two lysine residues are linked together through reaction with two molecules of glycolaldehyde, a Maillard reaction product, was more recently isolated from heated aqueous solutions of bovine serum albumin and glycolaldehyde and detected also in toasted wheat bread crust and dark brown roasted cacao as well as coffee beans by ESR (electron spin resonance) spectroscopy.

Reactions with Lipid Oxidation Products

Products Formed from Hydroperoxides

Fatty acid hydroperoxides formed thermally or enzymatically in food are usually degraded further. This degradation can also be of nonenzymatic nature. In nonspecific reactions involving heavy metal ions, heme(in) compounds or proteins, hydroperoxides are transformed into oxo, epoxy, mono-, di-and trihydroxy carboxylic acids. Unlike hydroperoxides, i.e., the primary products of autoxidation, some of these derivatives have a bitter taste. Such compounds are detected in legumes and cereals. They may play a role in other foods rich in unsaturated fatty acids and proteins, such as fish and fish products.

Lipid–Protein Complexes

Studies related to the interaction of hydroperoxides with proteins have shown that, in the absence of oxygen, linoleic acid 13-hydroperoxide reacts with *N*-acetylcysteine, yielding an adduct that consists of

several isomers. However, in the presence of oxygen, covalently bound amino acid–fatty acid adduct formation is significantly suppressed; instead, oxidized fatty acids are formed.

The difference in reaction products is explained by different reaction pathways. The thiyl radical, derived from cysteine by abstraction of a hydrogen atom, is added to the epoxyallyl radical only in the absence of oxygen. In the presence of oxygen, oxidation of cysteine and fatty acids to their oxidized forms occurs with a higher reaction rate than in the previous reaction. As a consequence, a large portion of the oxidized lipid from a protein-containing food stored in air does not have lipid–protein covalent bonds and, hence, is readily extracted with a lipid solvent such as chloroform/methanol (2:1, v/v).

Protein Changes

Some properties of proteins change when they react with hydroperoxides or their degradation products. This is reflected by changes in food texture, decreases in protein solubility (formation of cross-linked proteins), changes in color (browning), and changes in nutritive value (loss of essential amino acids).

The radicals generated from hydroperoxides can abstract hydrogen atoms from proteins, preferentially from the amino acids tryptophan, histidine, lysine, arginine, cysteine and tyrosine, wherein the nitrogen-, sulfur- or phenolic hydroxyl-containing group reacts. Protein radicals combine with each other, resulting in the formation of a protein network.

Malonaldehyde is generated under certain conditions during lipid peroxidation. As a bifunctional reagent, malonaldehyde can cross-link proteins through a Schiff base reaction with the ε-amino groups of two lysine residues. The Schiff base product is a conjugated fluorochrome that has distinct spectral properties (λ_{max} excitation $\sim$350 nm; λ_{max} emission $\sim$450 nm). Hence, it can be used to detect lipid peroxidation and the reactions derived from it with the proteins present.

Table 4 Products formed from amino acids exposed to peroxidizing lipids

Reaction system		*Compounds formed from amino acids*
Amino acid	*Lipid*	
Histidine	Methyl linoleate	3-(Imidazol-4-yl)lactic acid, 3-(imidazol-4-yl)acetic acid; histamine, valine, aspartic acid, ethylamine
Cysteine	Ethyl arachidonate	Cystine, hydrogen sulfide, alanine
	Linoleic acid	Cystine, cysteic acid, cystine disulfoxide
Methionine	Methyl linoleate	Methionine sulfoxide
Lysine	Methyl linoleate	Diaminopentane, aspartic acid, glycine, alanine, α-aminoadipic acid, pipecolinic acid, 1,10-diamino-1,10-dicarboxydecane

Modified from Gardner HW (1979) Lipid hydroperoxide reactivity with proteins and amino acids: a review. *Journal of Agricultural and Food Chemistry* 27: 220–229.

Table 5 Formation of unusual amino acids by alkali treatment of proteins

Name	*Formula*
3-N^6-Lysinoalanine (R═H) 3-N^6-Lysino-3-methylalanine (R═CH_3)	3-N^5-Ornithinoalanine (R═H) 3-N^5-Ornithino-3-methylalanine (R═CH_3)	Lanthionine (R═H) 3-Methyllanthionine (R═CH_3)	3-Aminoalanine (R═H) 2,3-Diaminobutyric acid (R═CH_3)	3-N^{π}-Histidinoalanine	3-N^{τ}-Histidinoalanine	
Reactions resulting in the formation of a protein network like that outlined above have practical implications; for example, they are responsible for the decrease in solubility of fish protein during frozen storage. Also, the monocarbonyl compounds derived from autoxidation of unsaturated fatty acids readily condense with free amino groups of the proteins, thus forming Schiff bases that can provide brown polymers by repeated aldol condensations. The brown polymers are often nitrogen-free since the amino compound can be readily eliminated by hydrolysis. When hydrolysis occurs in the early stages of aldol condensations (after the first or second condensation) and the released aldehyde, which has a powerful odor, does not re-enter the reaction, the condensation process results not only in discoloration (browning) but also in a change in aroma.

Decomposition of Amino Acids

Studies of model systems have revealed that protein cleavage and degradation of side-chains, rather than the formation of protein networks, are the preferred reactions when the water content of protein–lipid mixtures decreases. Examples for the extent of losses in amino acids in a protein in the presence of an oxidized lipid are presented in Table 3. The strong dependence of this loss on the nature of the protein and on reaction conditions is obvious. Degradation products obtained in model systems of pure amino acids and oxidizing lipids are listed in Table 4.

Reactions Under Alkaline Conditions

Losses of available lysine, cystine, serine, threonine, arginine, and some other amino acids occur at high pH values. Hydrolysates of alkali-treated proteins often contain some unusual compounds, such as ornithine, β-aminoalanine, lysinoalanine, ornithinoalanine, lanthionine, methyllanthionine and D-*allo*-isoleucine, as well as other D-amino acids. The formation of these compounds is based on the following reactions: 1,2-eliminations in the case of hydroxy amino acids and thio amino acids

Table 6 Lysinoalanine content of various foods

Food	*Origin/treatment*	*Lysinoalanine (mg kg^{-1} protein)*

Data from Sternberg M and Kim CY (1977) Lysinoalanine formation in protein food ingredients. *Advances in Experimental Medicine and Biology* 86B: 73–84 and Haagsma N and Slump P (1978) Evaluation of lysinoalanine determinations in food proteins. *Zeitschrift für Lebensmittel-Untersuchung und -Forschung* 167: 238–240.

result in 2-aminoacrylic acid (dehydroalanine) or 2-aminocrotonic acid (dehydroaminobutyric acid). In the case of cystine, the eliminated thiolcysteine can form a second dehydroalanine residue. Alternatively, cleavage of the cystine disulfide bond can occur by nucleophilic attack on sulfur, yielding dehydroalanine residues through thiol and sulfinate intermediates. Intra- and interchain cross-linking of proteins can occur through addition of amino and thiol groups containing amino acid side-chains to dehydroalanine residues. Ammonia may also react via an addition reaction. Acid hydrolysis of such a cross-linked protein yields the unusual amino acids listed in Table 5. Ornithine is formed by cleavage of arginine.

Reaction of the imidazole ring of protein-bound histidine with dehydroalanine residues results in two histidinoalanine isomers, depending on the nitrogen that reacts. The two isomers, 3-N^{τ}- and 3-N^{π}-histidinoalanine, are formed in a constant ratio of about 8:1. The histidinoalanine content of commercial foods containing milk protein (50–1800 mg kg^{-1} protein) is comparable with their lysinoalanine content.

Histidinomethylalanine and lysinomethylalanine do not contribute significantly to protein cross-linking. Their demonstration failed in numerous acid hydrolysates of various milk products. Model studies showed that β-elimination of threonine takes place much more slowly than that of serine and that the reactivity of the resulting dehydroaminobutyric acid towards nucleophiles is also much lower.

The formation of D-amino acids occurs through abstraction and subsequent back addition of a proton via the C^{α} carbanion. For example, the extent of D-amino acid formation is 30.1, 24.9, 18.8, 15.8, 8.0, 6.6, and 5.7% for aspartic acid, phenylalanine, glutamic acid, alanine, leucine, valine, and proline, respectively, when soya protein is exposed to 0.1 N sodium hydroxide (pH $\sim$ 12.5) at 65 °C for 3 h. The reaction with L-isoleucine is particularly interesting. L-Isoleucine is isomerized to D-*allo*-isoleucine, which, unlike other D-amino acids, is a diastereomer and thus has a retention time different from L-isoleucine,

making its direct determination by amino acid analysis possible.

Heating proteins in a dry state at neutral pH results in the formation of isopeptide bonds between the ε-amino groups of lysine residues and the β- or γ-carboxamide groups of asparagine or glutamine residues. These isopeptide bonds are cleaved during acid hydrolysis of protein and, therefore, do not contribute to the occurrence of unusual amino acids. But their formation reduces protein digestibility. A more drastic heat treatment of proteins in the presence of water leads to more pronounced degradation. Alkaline treatment of a protein isolate of sunflower seeds shows that serine, threonine, arginine, and isoleucine concentrations are markedly decreased with increasing concentrations of sodium hydroxide. New amino acids (ornithine and *allo*-isoleucine) are formed. Initially, the lysine concentration decreases but increases at higher concentrations of alkali. Lysinoalanine behaves in the opposite manner. The formation of lysinoalanine is influenced not only by pH but also by the protein source. A pronounced reaction occurs in casein, even at pH 5.0, due to the presence of phosphorylated serine residues, whereas noticeable reactions occur in gluten from wheat or in zein from corn only in the pH range of 8–11. Table 6 lists the content of lysinoalanine in food products processed industrially or prepared under 'usual household conditions.' The lysinoalanine content is obviously affected by the food type and by the processing conditions.

Reactions Under Oxidative Conditions

Oxidative changes in proteins primarily involve methionine, which forms methionine sulfoxide relatively readily. After *in vivo* reduction to methionine, protein-bound methionine sulfoxide is apparently biologically available.

Quality

G S Gilani and N Lee, Bureau of Nutritional Sciences, Health Canada, Ottawa, Ontario, Canada

Background

The quality of a dietary protein is determined by the pattern and concentration of indispensable or essential amino acids, the digestibility of the protein, and the bioavailability of its amino acids. To satisfy the protein requirements of the body, the diet must supply both enough of the indispensable amino acids (IAA) in required proportions and enough of the total amino nitrogen for synthesis of dispensable or nonessential amino acids. These are needed to support the synthesis of body protein and the production of other nitrogen-containing compounds such as hormones and neurotransmitters involved in a range of physiological functions.

An IAA is defined as an amino acid that cannot be synthesized in the body, or at least not in adequate amounts. Nine amino acids – histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine – are not synthesized in adequate amounts by mammals and are, therefore, IAA for humans. Dispensable amino acids (alanine, arginine, aspartic acid, cyst(e)ine, glutamic acid, glycine, hydroxyproline, proline, serine, and tyrosine) are not essential in the diet, as they can be synthesized from IAA and amino nitrogen. Since cystine can replace part of the requirement for methionine, and tyrosine a part of the requirement for phenylalanine, cystine and tyrosine are also included when considering IAA contents of diets, and these pairs are then expressed as total sulfur amino acids (methionine + cystine) and total aromatic amino acids (phenylalanine + tyrosine). Most dietary proteins contain a mixture of all 20 common amino acids in varying proportions.

The reported quality of a protein may vary depending on the function measured, for instance growth versus maintenance, because these differ in the amount and pattern of IAA they require. In all cases, however, the quality of a protein source is limited by the IAA available in least amounts (the first limiting amino acid) relative to requirements. Occasionally, a protein source may be colimiting in more than one IAA. There are several different ways that have been developed to assess how well a protein could be expected to meet human protein and amino acid requirements.

Methods of Assessing Protein Quality of Foods

The only true measurement of protein quality for human use is an evaluation, in humans, of growth, nitrogen balance, or metabolic balance or some other appropriate test, preferably performed with suitable subjects from the target population of interest. Such evaluations directly reflect how well the food or food product meets human needs and this is a function of the proportion and content of IAA, the digestibility of the protein, and the bioavailability of amino acids in the food or food product.

Conventional or 'long-term' nitrogen-balance experiments which measure dietary nitrogen retained in the body (nitrogen intake − fecal nitrogen output − urinary nitrogen output) in humans are often considered to be the standard or reference method for assessing protein quality of foods. Nitrogen balance is used as a surrogate for protein balance and is assumed to reflect how well protein intake is maintaining body protein homeostasis and organ function. Nitrogen balance can be expressed in two ways: one relates nitrogen intake to nitrogen retained, as measured by the net protein utilization (NPU) method, and the second relates nitrogen absorbed to nitrogen retained, as measured by the biological value (BV) (see **Table 1**).

Nitrogen-balance studies are used to determine the minimum intake of a test or food protein that will maintain nitrogen balance. The amount of a protein required to maintain nitrogen balance is a measure of its quality. Therefore, the accepted nitrogen balance technique to measure protein quality in humans is to feed graded levels of a test protein for 10–21 days. Shorter-term human nitrogen balance assays or those based on single test levels can provide useful information, but at this time, it is not clear without further validation and critical evaluation whether these methods have the capacity to predict, in quantitative terms, the nutritional value of a source of protein.

More recently, some research has focused on protein and nitrogen metabolism during different periods

Table 1 Comparison of features of rat assays for protein quality evaluation

	Credits protein used in both growth and maintenance	*Description/equation*	*Comments*
Growth methods			
PER (standardized) (protein efficiency ratio)	No, growth only; no protein-free diet group included	Weight gain of rats on test or casein control diets per gram of protein consumed, standardized to casein PER of 2.5	Simple but relatively costly and lacking other attributes including proportionality to protein quality, accuracy, precision, and reproducibility
NPR (net protein ratio)	Yes, protein-free diet group included	Weight gain on test or control diet plus weight loss on nonprotein diet per gram of protein consumed	Overcomes the major weakness of PER, but the assumption is that the quality of protein required to prevent weight loss is equivalent to that needed for maintenance; usually conducted in 2 weeks, half the time required for standardized PER; comparable to NPU (below) except estimated from body weight change, not nitrogen balance
RNPR (relative net protein ratio)	Yes, protein-free diet group included	NPR for test protein divided by NPR for reference protein expressed as a fraction of 100	Values are proportional with respect to protein quality within reasonable limits; more accurate and reproducible and cheaper than PER
NU (nitrogen utilization)	Yes, no protein-free diet group included; factor of maintenance calculated	Body weight gain + 0.1 (initial + final body weight) divided by nitrogen consumed	Factor of maintenance is calculated instead of measured
RNU (relative nitrogen utilization)	Yes, no protein-free diet group included; factor of maintenance calculated	100 × NU (test protein)/NU(reference protein)	RNU gives almost the same results as RNPR
Nitrogen balance methods			
NPU (net protein utilization)	Yes, protein-free diet group included	The proportion of ingested protein (N×6.25) that is retained for maintenance and/or growth Equation: 100 × (N retained on protein diet − N retained on protein-free diet/g N ingested on protein diet) Note: N retained = N intake − fecal N output − urinary N output	Relates N intake to N retained; this index includes the factor of digestibility; nitrogen retained can be measured either by the balance method or by carcass analysis; nitrogen balance is used as a surrogate for protein balance and is assumed to reflect how well protein intake is maintaining body protein homeostasis and organ function; NPU is the product of BV and TPD
BV (biological value)	Yes, protein-free diet group included	The proportion of nitrogen absorbed that is retained for maintenance and/or growth purposes Equation: 100 × (N retained on protein diet − N retained on protein-free diet)/N ingested − (fecal N on protein diet − fecal N on protein-free diet)	Relates N absorbed to N retained; thus, as an index, it excludes the factor of digestibility
TPD (true protein digestibility coefficient)	Yes, protein-free diet group included	The proportion of ingested protein (N×6.25) that is absorbed Equation: 100 × (N ingested on protein diet − (fecal N on protein diet − fecal N on nitrogen-free diet))/N ingested on protein diet	This is not a measure of protein quality, only digestibility; it is needed for calculating protein digestibility-corrected amino acid score; this test requires an adaptation period of 4 days and a fecal collection period of 5 days

of the day in relation to eating and fasting. The metabolic fate and retention of dietary nitrogen during the postprandial phase may be of particular importance in determining the quality of a given protein. An experimental approach, termed 'net postprandial protein utilization,' measures the efficiency of postprandial nitrogen retention in humans after the ingestion of different protein sources and appears to be able to differentiate between proteins of similar high quality. Postprandial nitrogen retention may offer a sensitive *in-vivo* method to discriminate between protein sources of differing quality. It is too early, however, to say whether this will become a routine method of protein-quality evaluation.

Although they are the gold standard, human studies cannot be carried out on a routine basis for reasons of cost and ethics. Therefore, *in-vitro* and animal assay techniques have been developed that correlate well with data from human experimentation for each food product.

Routine Protein-quality Evaluation Methods

Criteria for a valid and useful assay for routine protein-quality evaluation include accuracy, precision, reproducibility, proportionality to protein quality, and low cost. The ability of assays to accurately measure protein quality depends on a number of factors including whether they account for protein requirements for growth alone or for growth plus maintenance.

Chemical and Microbiological Assays

The chemical assays are the amino acid scoring methods which involve chemical analysis of the amino acid composition of the protein of interest and comparison of its IAA profile to that of a reference profile. As a routine assay, this method has been standardized as the protein digestibility-corrected amino acid score (PDCAAS), which will be discussed later. Microbiological, or *in-vitro*, assays use microorganisms that require the same amino acids as humans. The most successful of these uses the protozoans, *Tetrahymena pyriformis* or *T. thermophila*, which require the same 10 IAA as the growing rat and human. The use of this method is limited mainly by the fact that the growth of *T. pyriformis* can be inhibited by factors in the food unrelated to protein quality, including several food additives and spices.

Rat Assays

The rat is the most common species used in a protein-quality bioassay. Rat assays are based on the measurement of either growth or nitrogen balance in young animals in response to feeding defined amounts of one or more test proteins or a control protein (see also Table 1).

The protein efficiency ratio (PER) was the first method adopted for routine assessment of protein quality of foods. The PER is a standardized method in which a test diet and a casein control diet, both containing 10% protein ($N \times 6.25$) are fed to weanling rats for a period of 4 weeks. The PER values are calculated by dividing the weight gain of the rats by the amount of protein consumed over this period. To compare PER values of diets determined by different laboratories, the PER values are corrected to an assumed value of 2.5 for casein control. It has been recognized that the PER method, although simple, does not meet any other criteria of a valid bioassay, as noted above. The failure of the PER assay to properly credit protein used for maintenance purposes is the chief criticism of the method. The poorer the quality of dietary protein, the larger is the error that is introduced because of this failure to make allowance for maintenance. For this reason, PER values are not proportional to protein quality, i.e., a PER of 2.0 is not twice as good as a PER of 1.0.

The net protein ratio (NPR) method overcomes the major weakness in the PER assay by adding the weight loss of a group of rats fed a zero-protein diet to the weight gain of the rats fed the test protein. However, it has to be assumed that the protein required to prevent weight loss of rats fed the nonprotein diet is equivalent to the protein needed for maintenance. As normally carried out, NPR values are uncorrected to any standard. However, relative NPR (RNPR), where the NPR of a test protein is expressed relative to a value of 100 for the NPR of a reference protein, is expressed on a scale of 1–100. NPU and BV, two nitrogen-balance methods mentioned earlier, are also expressed on a scale of 1–100.

The relative net protein ratio (RNPR) method at 2 weeks is shorter than the standard PER method (4 weeks) and therefore is less expensive. Also, RNPR values (unlike PER values) are proportional to each other in protein quality within reasonable limits. RNPR is more accurate and reproducible than PER.

The nitrogen utilization (NU) method is a modification of NPR, the factor of maintenance being calculated instead of measured:

$$\begin{aligned} \text{NU} = {} & \text{body weight gain of test group} \\ & + 0.1\ (\text{initial} + \text{final body weight}) \\ & / \text{nitrogen consumed by test group.} \end{aligned}$$

The factor, 0.1, derives from experimental observations of the growth of rats on protein-free diets. The relative NU (NU of test protein/NU of reference protein × 100) gives essentially the same values as RNPR. For example: lactalbumin, RNPR of 87 vs. RNU of 87; for egg white, RNPR of 97 vs. RNU of 97; for wheat gluten, RNPR of 32 vs. RNU of 31; for wheat gluten + soy protein, RNPR of 64 vs. RNU of 64. The RNU method eliminates the feeding of a 'zero' protein diet to a group of rats; thus, less labor is required for the RNU procedure than for the RNPR procedure.

Limitations of Rat Assays

It is well known that the requirements of rats for sulfur amino acids are much larger than those of humans. Thus, a limitation of any rat growth assay is that it will underestimate the protein quality of any protein limiting in sulfur amino acids such as soybean protein, peanuts, and other legumes or pulses. (*See* **Protein**: Sources of Food-grade Protein.)

Protein Digestibility-corrected Amino Acid Score (PDCAAS) Method

A method based on a comparison of the amino acid content of food with human requirements (amino acid scoring system) is considered internationally to be the most suitable approach for routine assessment of the protein quality of foods. The amino acid score should be corrected for incomplete digestibility of protein, and for the unavailability of individual amino acids, especially those that are susceptible to damage by processing treatments.

The FAO/WHO has recommended the PDCAAS as the preferred method for routine prediction of protein quality of properly processed and highly digestible food products for human nutrition. In other words, the foods should contain minimal amounts of residual antinutritional factors, and the digestibility of the protein should be a good approximation of the bioavailability of individual amino acids.

Analyses Required for the Determination of PDCAAS

Proximate composition Levels of moisture, total nitrogen, fat, and crude protein are determined according to standardized AOAC methods. Total protein is then calculated by using a nitrogen-to-protein conversion factor of 6.25. When the true nitrogen-to-protein conversion factor is known for a given protein, this should be used.

Amino acid profile Amino acids in foods have commonly been analyzed by ion-exchange chromatography of protein hydrolysates. Hydrolysis with 6 M HCl at 110°C for 24 h is routinely used for all amino acids except tryptophan and sulfur amino acids. Since sulfur amino acids and tryptophan are destroyed to varying degrees by 6 M HCl hydrolysis, a performic acid followed by the HCl hydrolysis and an alkaline (4.2 M NaOH) hydrolysis are widely used for the accurate determination of sulfur amino acids (methionine as methionine sulfone and cysteine/cystine as cysteic acid) and tryptophan, respectively. Amino acids may also be determined accurately and more rapidly by high-performance liquid chromatography methods using precolumn phenylisothiocyanate-derivatized amino acids. Amino acids should be expressed on the basis of mg per gram of protein.

Amino acid score Amino acid ratios (milligrams of an IAA in 1.0 g of test protein per milligram of the same IAA in 1.0 g of reference protein × 100) for nine IAA are calculated by using the FAO/WHO's suggested pattern of amino acid requirements as the reference protein for all ages except for infants. This pattern contains, in milligrams per gram of protein: histidine, 19; isoleucine, 28; leucine, 66; lysine, 58; methionine + cystine, 25; phenylalanine + tyrosine, 63; threonine, 34; tryptophan, 11; and valine, 35. For infants under 1 year of age, the amino acid composition of human milk is used as the basis for scoring: (milligrams per gram of protein): histidine, 26; isoleucine, 46; leucine, 93; lysine, 66; methionine + cystine, 42; phenylalanine + tyrosine, 72; threonine, 43; tryptophan, 17; and valine, 55. The lowest amino acid ratio is termed the amino acid score.

Protein digestibility The classic method for determining the digestibility of proteins and amino acids has been the balance method, in which the protein or amino acid excreted in the feces is subtracted from the amount ingested and the value expressed as a percentage of protein intake. This calculation gives an apparent digestibility value. To determine true digestibility, it is necessary to correct for the amount of fecal protein or amino acid excreted when the subject or animal is consuming either a protein-free diet or a diet with just enough of a highly digestible protein to prevent excessive loss of body protein. Therefore, the true digestibility of protein and amino acids can be calculated by the following equations:

$$\text{True protein digestibility} = [\text{PI} - (\text{FP} - \text{MFP})/\text{PI}] \times 100,$$

where PI is the protein intake, FP is fecal protein, and MFP is metabolic fecal protein.

$$\text{True amino acid digestibility} = [\text{AAI} - (\text{FAA} - \text{MFAA})/\text{AAI}] \times 100,$$

where AAI is the amino acid intake, FAA is fecal amino acid, and MFAA is metabolic fecal amino acid.

The amounts of protein and amino acids in the feces of rats fed the protein-free diet are used as the estimates for MFP and MFAA, respectively.

Since true digestibility measurements take into account the fecal protein or amino acids which are not of dietary origin, the true digestibility of a protein or amino is always higher than the apparent digestibility. Unlike apparent digestibility, the true protein digestibility of a food is not affected by the dietary conditions under which the food is fed to the animal such as the protein content of the test diet. It is a more accurate measure of amino acids that are absorbed from the gut and therefore gives a better representation of protein quality than apparent digestibility.

Protein/amino acid digestibility is most frequently determined using rats. The rat balance method is well established, and the procedure for the determination of true protein digestibility has been standardized. It has been recommended by the FAO/WHO that when human balance studies cannot be used, the standardized rat fecal-balance method should be used. The true digestibility of protein is considered to be a reasonable approximation of the true digestibility of most amino acids (as determined by the rat balance method) in mixed diets. Therefore, the FAO/WHO has recommended that amino acid scores be corrected only for true digestibility of protein.

Protein Digestibility-corrected Amino Acid Score (PDCAAS)

The PDCAAS of a test food is calculated as follows:

$$\text{True protein digestibility coefficient} \times \text{amino acid score}.$$

PDCAAS above 100 are considered as 100.

Protein Digestibility of Some Diets and Common Foods

Values for the true digestibility of protein in diets from India (54–75%), Guatemala (77%), and Brazil (78%) are markedly lower than the values in North American diets, including vegetarian diets, 88–94%, suggesting that protein digestibility is of greater concern in diets of some developing countries. The poor digestibility of protein in the diets of some developing countries is due to the use of less-refined cereals and pulses (such as beans and lentils). Low true digestibility values (63–65%) have also been reported in studies with children fed millet and ragi-based diets in India.

A comparison of the true digestibility of protein in some common foods for human adults has indicated that animal protein sources (meat, fish, poultry, eggs, properly processed milk protein products) and flours and breads made from low-fiber wheats, wheat gluten, farina, peanuts, and soy-protein isolates have high true protein digestibilities of 94–99%. Whole corn (except high amylose containing opaque-2) and flour or bread of high-fiber wheat, polished rice, oatmeal, triticale, cottonseed, soy flour, and sunflower have intermediate true protein digestibilities of over 85%. Ready-to-eat cereals (corn, wheat, rice, or oat) have lower true protein digestibilities of 70–77%, probably due to the high heat involved in their processing. Various types of dry beans (*Phaseolus vulgaris*) and millet also have low true protein digestibilities of 75–79%.

PDCAAS for Some Common Foods or Food Products

The availability of amino acid composition and protein digestibility data for a number of foods has made it possible to calculate their PDCAAS. Animal protein products such as egg white powder, casein, ground beef, beef salami, skim milk powder, tuna and chicken frankfurters have high PDCAAS of about 100 (97–100). Soybean protein products also have high PDCAAS (89–99) and are marginally deficient in sulfur amino acids in some cases. The scores for various types of beans, lentils, and peas range from 47 to 71, and these products are first limiting in sulfur amino acids for human nutrition. Wheat gluten and sunflower-protein isolate are severely limiting in lysine and have PDCAAS of 25 and 37, respectively.

Effects of Supplementation and Complementation on Protein Quality

The low protein quality of a vegetable protein source can be improved by the addition of supplementary protein or a limiting amino acid, or by protein complementation. Protein supplementation means to increase the protein quality of a food having a low-quality protein by the addition of a moderate amount of another food having a high content of the indispensable amino acid which is limiting in the low-quality protein. For example, egg, milk, meat, and fish proteins are rich in lysine and sulfur amino acids, and so they would be supplementary for lysine deficient proteins such as cereals, and for proteins deficient in sulfur amino acids such as beans, peas, and lentils. These animal proteins can also fully satisfy all indispensable amino acid requirements for adults when ingested as the sole protein source at a level of 0.7 g per kilogram of body weight per day.

Protein complementation means that the quality of two proteins is higher than either of the two components. Proteins which complement each other have different limiting amino acids. When blended in the right proportions, cereals and legumes (beans and peas) complement each other because cereals are limiting in lysine, and legumes are deficient in sulfur amino acids. As an example, the BV of pea flour is 43% and is limited by methionine, with a surplus of lysine. Maize meal protein with a BV of 35% is limited by lysine but with a surplus of sulfur amino acids. The average of the BV of these two protein sources is 39%. In practice, however, the BV of an equal mixture of these two proteins sources is found to be 70% due to the complementary effects. In the same way, traditional combinations of vegetable proteins consumed in some countries, such as rice–chick peas in Asia, wheat–bean in the Near East, and maize–bean in the Americas, have a good protein quality.

Applications of Protein-quality Measurement

There are two distinct purposes for measuring protein quality: to determine whether a food or diet will meet human amino acid needs, and for regulatory purposes to ensure that foods are of the appropriate protein quality for the intended use and that protein claims are valid.

Protein-quality Measurement of Mixed Diets

It is recognized that the consumption of mixed diets in the developed world poses no problem of inadequacy in protein content and quality. However, the food supply is undergoing many changes, which may significantly alter the types and quality of protein available. Many new foods are being produced for various purposes through genetic modification. Increasing numbers of foods consumed in the West are processed, and new methods of processing are constantly being developed. Products of the plant and animal world that have not been previously used as human food are being developed for that purpose. These situations point to a continuing need for surveillance of potential effects on protein quality of foods in the diet, if not the diet as a whole.

Some subgroups in developed countries consume protein from a single source, rely on a small variety of foods, or eat foods with proteins of inferior quality. To the extent that these people do not have control over the source of the proteins in their foods because they may be relying on commercially formulated products, they must be considered at risk, and the quality of their dietary proteins must be known. Examples of such groups are infants and young children relying on commercial formulas; people using formulated products to lower their energy/food intake, generally for weight reduction; people changing their eating patterns to become vegetarian, for example, and possibly relying on prepackaged substitute foods of lower protein quantity and quality; and individuals with various illnesses requiring therapeutic formulated diets. There are also subpopulations who, for economic or other sociocultural reasons, might become at risk because of their decreased ability to procure high-quality proteins or because of making uninformed dietary choices. These might include the poor, the elderly, teenagers who are undergoing rapid growth and often eating unbalanced diets, and pregnant and lactating women, especially the growing number of teenage mothers. Depending on the issue of concern, either protein-quality assessment or protein-status assessment will have an application.

Regulatory Use of Protein-quality Assessment of Foods for Human Nutrition

Methods currently used by regulatory bodies Since the adoption of the PDCAAS method by the FAO/WHO, this method has been widely accepted. For example, in the USA, PDCAAS has replaced PER as the official method of protein-quality assessment, including for protein declaration in nutritional labeling of all foods except infant formulas. However, PER remains the official regulatory biological method for protein-quality assessment of infant formulas sold in USA. PER also remains the official method for evaluating protein claims for foods sold in Canada. The chemical index (amino acid score using human breast milk as reference protein) is used for assessing the protein quality of infant formulas in the UK. The Codex Alimentarius Commission requires that the quality of protein in an infant formula not be less than 85% of that of casein as determined by the PER method. The EC requires that, for an equal energy value, an infant formula must contain an available quantity of each essential and semiessential amino acid at least equal to that contained in the reference protein (breast milk), but for calculation purposes, the concentrations of methionine and cystine may be added together. For infant formulas based on partial protein hydrolysates, the EC has an additional requirement, specifying that the PER and the NPU must be at least equal to those of casein.

Limitations of the PDCAAS As adopted by the FAO/WHO, the PDCAAS method is truncated in that it requires the adjustment of all values that

exceed 100 down to 100. This means that, unlike biological assays such as PER, the PDCAAS does not recognize the additional value of high-quality animal proteins (*see* **Protein**: Sources of Food-grade Protein) and their potential for acting as supplements to low-quality proteins.

Since the PDCAAS method was adopted, it has been found that there are differences in the metabolic fate and retention of dietary nitrogen from different protein sources when measured acutely during the postprandial period in humans. One method, called 'net postprandial protein utilization,' is designed to measure the efficiency of postprandial nitrogen retention following consumption of various dietary proteins. Results obtained so far have placed several food protein sources in the order: milk > soy > pea > wheat, with values of 120 (sulfur amino acids), 99 (sulfur amino acids), 73 (sulfur amino acids), and 36 (lysine), respectively. This order is the same as that of the nontruncated PDCAAS values for these sources, suggesting that there may be valid reasons to use the nontruncated PDCAAS values. The official PDCAAS method puts both milk and soy at 100.

PDCAAS includes a rat-feeding study, but this only measures protein digestibility. Thus, it may not adequately reflect the adverse effect on the bioavailability and utilization of amino acids caused by naturally occurring growth-depressing factors such as glucosinolates and isothiocyanate in mustard flour, trypsin inhibitors, and hemagglutinins in soy protein and beans (*Phaseolus* spp.), or antinutritional factors formed during processing such as lysinoalanine in alkaline-/heat-processed lactalbumin and soy protein. As a result, the PDCAAS method would overestimate the protein quality of such sources. In the absence of upper safe limits for these antinutritional factors, the use of the PDCAAS method may be inappropriate for predicting the protein quality of such protein products and any foods where these products may be the sole source of protein, such as infant formulas and enteral nutritionals.

The PDCAAS method assumes complete biological efficiency of supplemental amino acids in improving protein quality which may not be true, especially in the case of low-quality proteins. Markedly lower relative protein efficiency ratio or RNPR values have been seen with amino acid-supplemented zein (3–44%) compared to the PDCAAS value (71%), which suggests incomplete biological efficiency of the supplemental amino acids and overestimation of protein quality by the PDCAAS method. The crystalline amino acid added to a low-quality protein that also has poor digestibility may be absorbed more quickly than the amino acids from the protein, so protein synthesis does not take place.

The PDCAAS method does not accurately predict the quality of proteins colimiting in more than one IAA such as soy when used in infant formulas. The amino acid requirements for infants are not the same as the FAO/WHO's suggested pattern of amino acid requirements used in PDCAAS. Since the identification of the true first limiting amino acid would be difficult in cases where the protein is colimiting in more than one IAA, an improvement in protein quality with supplementary amino acid(s) should not be assumed without biological testing.

Recommended method for regulatory purposes The PDCAAS is the most appropriate routine method for properly processed food where protein digestibility is a good approximation of bioavailability of the amino acids and where there is known to be no or only low levels of antinutrient factors. Where these conditions do not apply, a biological method should be used, whether this is PER, RNPR, or relative nitrogen utilization (RNU). Probably the least expensive and yet still valid and reliable method, and one that gives results that are proportional across a range of protein qualities, is the RNU method. The RNU method gives essentially the same values as the better known RNPR rat assay for routine protein-quality assessment of foods except that, as described in the section Rat Assays, it replaces measurement of protein needed for maintenance with a factor for maintenance. The elimination of the need for feeding a 'zero' protein diet to a group of rats makes the RNU method less costly than the RNPR method.

Digestion and Absorption of Protein and Nitrogen Balance

P W Emery, King's College London, London, UK

Background

The assimilation of protein into the body has classically been viewed as involving digestion of protein to amino acids in the gut, absorption of these amino acids through the gut mucosa, and transport of amino acids in the plasma for subsequent metabolism, including protein synthesis, in other tissues. However, it is now clear that substantial quantities of peptides containing up to five amino acid residues can also be absorbed into the intestinal mucosa. Here they are largely hydrolyzed to free amino acids before being released into the circulation, so that the circulating concentration of peptides is normally very low, although many other tissues are capable of taking up and utilizing peptides. There is also growing evidence that very small but detectable amounts of whole proteins can be absorbed. It should also be noted that the bacterial flora of the colon can play a significant part in the supply of nitrogenous molecules to the body.

Digestion

The digestion of protein is a series of hydrolytic reactions which split the α-peptide bonds between adjacent amino acid residues in the primary sequence of the polypeptide chain. Peptide bonds involving the side chains of amino acids (the γ- and β-carboxyl groups of glutamate and aspartate and the ε-amino group of lysine) are not hydrolyzed by human enzymes and are thus not biologically available.

Protein digestion begins in the stomach with the action of pepsins, which are hydrolytic enzymes which preferentially cleave peptide bonds adjacent to phenylalanine, tyrosine or leucine residues. The human stomach secretes at least three distinct pepsins with different pH optima ranging from almost neutral, corresponding to the condition of the stomach contents immediately after a meal, to pH 1.2, as would be found several hours later.

Further digestion then takes place in the small intestine, under the influence of enzymes which originate in the acinar cells of the exocrine pancreas. These are mainly endopeptidases which hydrolyze particular classes of peptide bonds within the polypeptide chain (see **Table 1** for their specificity) to produce a large number of small-peptide fragments.

Table 1 Digestive proteolytic enzymes

Enzyme	*Proenzyme*	*Source*	*Substrate*	*Specificity*
Endopeptidases				
Pepsin A	Pepsinogen A	Stomach	Polypeptides	Hydrophobic/aromatic amino acids
Pepsin B (parapepsin)	Pepsinogen B	Stomach	Gelatin	
Pepsin C (gastricin)	Pepsinogen C	Stomach	Polypeptides	Tyrosine residues
Trypsin	Trypsinogen	Pancreas	Polypeptides	Arginine, lysine residues
Chymotrypsin	Chymotrypsinogen	Pancreas	Polypeptides	Tyrosine, phenylalanine, tryptophan, leucine residues
Elastase	Proelastase	Pancreas	Elastin and similar proteins	Alanine residues
Elastase II	Proelastase II	Pancreas	Elastin and similar proteins	Leucine, phenylalanine, methionine residues
Enteropeptidase		Small intestine	Trypsinogen	$Lysine^{6}$-isoleucine
Exopeptidases				
Carboxypeptidase A	Procarboxypeptidase A	Pancreas	Peptides	C-terminal except aspartate, glutamate, arginine, lysine, proline
Carboxypeptidase B	Procarboxypeptidase B	Pancreas	Peptides	C-terminal arginine, lysine
Aminopeptidase		Small intestine	Peptides	N-terminal except arginine, lysine
Tripeptidases		Small intestine	Tripeptides	Mainly N-terminal
Dipeptidases		Small intestine	Dipeptides	Various

The final stage of protein digestion is accomplished by a wide array of aminopeptidases and di- and tripeptidases manufactured in the absorptive cells of the intestinal epithelium. Some of these act in the lumen of the gut, but most of the activity is located within the brush-border membrane or within the cytoplasm of the cells. These are mainly exopeptidases, which remove single amino acids from the N-terminal (aminopeptidases) or the C-terminal (carboxypeptidases).

Both pepsin and the pancreatic proteolytic enzymes are synthesized in the form of inactive proenzymes (also termed zymogens) containing one or more terminal peptide regions which prevent the formation of the three-dimensional structure that confers catalytic activity. The terminal peptide of pepsinogen (containing 42 amino acids) is hydrolyzed by hydrochloric acid in the stomach. Trypsinogen is activated by the removal of a hexapeptide from the amino-terminal by enteropeptidase (formerly known as enterokinase), an enzyme secreted by the small intestine. Trypsin in turn activates all the pancreatic proenzymes, including itself. Hence the presence of trypsin inhibitors in some legumes plays a crucial role in reducing the digestibility of these otherwise valuable sources of protein.

Absorption

Absorption of the products of digestion involves active transport into the enterocyte, metabolism within the cell, and diffusion down a concentration gradient into the portal circulation. Absorption occurs throughout the length of the small intestine, but is confined to the cells in the top third of the villus.

Amino acids and peptides are transported into cells by a number of active transport systems, most of which are linked to the simultaneous entry of sodium ions. Sodium enters the cell down a chemical concentration gradient; this is maintained by the membrane 'pump' which exchanges sodium for potassium ions and is fueled by the hydrolysis of adenosine triphosphate (ATP). The specificity of the amino acid transport systems in the gut is broadly similar to that of the systems which are found in other tissues, particularly the brush border of the kidney tubule, and this is summarized in Table 2. Evidence from *in vitro* studies suggests that small peptides may be transported more rapidly than free amino acids, but these studies often have not been carried out under the conditions which occur *in vivo* after a normal meal.

After transport across the intestinal wall, amino acids can be degraded, metabolized to other compounds, including other amino acids, incorporated into proteins, or released unaltered into the circulation. The rate of protein synthesis in the small intestinal mucosa is amongst the highest of any tissue in the body. This is no doubt related to the high rate of cell turnover and the requirement for secretion of digestive enzymes. These cells also utilize energy at a high rate, and the amino acid glutamine, supplied both from the lumen of the gut and from the circulation, is a major fuel. Some of the ammonia which is formed during the utilization of glutamine is released into the gut, from where it may subsequently be reabsorbed and transported to other tissues to be used for the synthesis of nonessential amino acids.

Most of the peptides which are absorbed into the mucosal cells are hydrolyzed to single amino acids before being released into the portal circulation. However, some intact peptides have also been observed to enter the portal circulation, and this has raised some interest because of the possibility of peptides with hormonal activity being absorbed intact.

Table 2 Intestinal amino acid transport systems

System	*Sodium dependence*	*Preferred amino acids*
A	Yes	Alanine, serine, glycine, methionine, proline
L	No	Leucine, isoleucine, valine, methionine, phenylalanine, tyrosine, tryptophan, histidine
ASCP	Yes	Alanine, serine, cysteine, proline
Ly	Yes	Lysine, histidine, arginine, ornithine
x^-_A	Yes	Aspartate
x^-_G	Yes	Glutamate
x^-_C	No	Aspartate, glutamate, cystine
y^+	Yes	Lysine, arginine, histidine
β	Yes	β-alanine, taurine
$b^{0,+}$	No	Lysine, leucine
Gly	Yes	Glycine, sarcosine
N	Yes	Histidine, glutamine, asparagine
imino	Yes	Proline

The circulating concentration of peptides is normally very low. This may suggest that only small quantities of peptides are released into the portal circulation. However, it has also been observed that when peptides are infused directly into the circulation they are rapidly metabolized, probably extracellularly, since the plasma concentration of the free amino acid constituents of the peptides rises almost immediately. This means that glutamine, an amino acid which is notoriously unstable during storage in solution, and sparingly soluble amino acids such as tyrosine can be supplied in parenteral nutrition mixtures in the form of stable and soluble peptides which are readily available to the tissues.

Very small quantities of whole proteins can also be absorbed directly from the intestinal lumen, possibly by diffusion through tight junctions between cells. There may also be some endocytosis of food proteins by immunologically active cells within the intestinal epithelium, particularly in the areas known as Peyer's patches, and these proteins may subsequently be transported by lymphocytes to distant sites. The absorption of intact proteins from maternal milk makes an important contribution to the development of passive immunity by neonates. Where it persists into later life it is likely to be a major factor in the development of food allergies.

It is now known that some small molecules can be absorbed from the colon as well as the small intestine, so that the products of bacterial metabolism can be an important source of nutrients. In the case of nitrogenous compounds the main process appears to be secretion of urea into the colon, bacterial hydrolysis of this urea to ammonia, and subsequent absorption of the ammonia into the body. The ammonia may then be used for the synthesis of amino acids by transamination. This process is referred to as urea salvage, since it results in rather less urea being excreted in the urine than has been produced by the liver. This may make an important contribution to the maintenance of nitrogen balance when protein intake is low. There is also some evidence that essential amino acids synthesized by colonic bacteria may also be absorbed into the body, but the quantitative significance of this observation is not clear.

Amino Acid Pools

Amino acids are transported in the plasma and are taken up into tissues by mechanisms similar to the systems referred to in Table 2. Amino acids are also present in blood cells, but the interaction of these amino acids with other tissues may be quite different from that of plasma amino acids. For example, the plasma amino acid concentration increases as blood traverses the gastrointestinal tract after a meal, whereas the amino acid content of blood cells decreases.

The intracellular free amino acid content varies between different tissues, and is affected by hormonal and nutritional influences. However, the intracellular concentration is greater than the plasma concentration for most amino acids in most tissues. The distribution ratio (intracellular concentration divided by plasma concentration) is close to unity for many of the essential amino acids, particularly in muscle, but is severalfold higher for some of the nonessential acids, with a value as high as 70 having been reported for aspartic acid in liver. The interpretation of changes in amino acid concentrations in particular situations is complex. Changes in concentration may result from changes in outflow to or inflow from other tissues, or pools of other metabolites in the same or different tissues, including utilization for protein synthesis and supply from protein degradation.

Only about 2% of the amino acids in the body are present as free amino acids, the rest being present as protein. Again there is considerable variation between different amino acids and different tissues in the ratio of the free to protein-bound amino acids, with much lower values generally being found for essential than nonessential amino acids. Given the currently accepted values for rates of protein synthesis, it can be shown that in some tissues the entire free pool of some essential amino acids is incorporated into protein within seconds, emphasizing the rapidity with which free amino acids must be resupplied.

Nitrogen Balance

The state of protein metabolism in the body as a whole may be assessed by measuring nitrogen balance. This is because almost all the nitrogen in the body is in the form of protein, and the nitrogen content of a wide range of proteins is relatively constant, at around 16%. Thus, if the body is in positive nitrogen balance, it must be laying down new protein, and this is normally associated with growth in children or recovery from illness. Conversely, if the body is in negative nitrogen balance, it must be losing tissue protein, either because the diet is inadequate or because of a pathological response to injury or illness. Nitrogen balance in an individual will fluctuate from day to day by a few grams either side of zero, but over a period of weeks a nongrowing adult will normally be in zero nitrogen balance.

Every protein in the body has a specific functional role. These roles include the catalytic function of enzymes, the contractile function of muscle proteins, the structural role of connective tissue proteins, roles

in transport, immunological recognition, hormone receptors, and many others. There is no inert store of protein to be drawn on in times of need, as exists for fat (adipose tissue triacylglycerol) and carbohydrate (glycogen); any sustained period of negative nitrogen balance is likely to have functional consequences. Nevertheless, different tissues do lose proteins at different rates when the body goes into negative nitrogen balance, with muscle protein (including the smooth muscle of the gut) being lost in the early stages while the liver and the heart are relatively protected.

Measurement of Nitrogen Balance

Nitrogen balance is defined as the difference between intake and output, and may be formally represented by the following equation:

$$\text{Balance} = I - (U + F + M)$$

where I is nitrogen intake, U is urinary nitrogen excretion, F is fecal nitrogen excretion, and M is the sum of all the other routes by which nitrogen is lost from the body.

Nitrogen intake is mainly in the form of protein and can conveniently be measured by the Kjeldahl method, which measures virtually all nitrogen except that bonded to oxygen (e.g., nitrates and nitrites). The same method is thus also appropriate for measurement of the various components of nitrogen excretion. Accurate determination of nitrogen balance requires direct analysis of duplicate portions of diet, although a reasonable approximation can be made using a weighed-food record and tables of food composition. An alternative approach is to feed the subjects a constant amount of a diet which has been specially formulated using known quantities of ingredients.

The urine is the major route for excretion of nitrogen, so that urinary nitrogen is the major determinant of nitrogen balance and reliable collection of 24-h urine specimens is required for measuring nitrogen balance. Most of the nitrogen in urine is in the form of urea, which is the end product of amino acid oxidation. Other nitrogenous compounds in the urine include ammonia, creatinine, and uric acid, as well as small quantities of peptides, amino acids, and other small molecules. The amount of ammonia depends on the body's acid–base status and the amount of uric acid varies with nucleic acid intake. The amount of creatinine is fairly constant from day to day within a healthy individual, and shows a good correlation with muscle mass. When protein intake is low, the proportion of urea in the urine will decrease, so that urinary urea content is not a reliable indicator of total urinary nitrogen.

Fecal nitrogen is mainly composed of bacterial cells from the large intestine, together with mucosal cells which have been sloughed off from the intestinal wall, and some remnants of undigested food proteins. On a normal mixed diet fecal nitrogen amounts to a fairly constant 8% of nitrogen intake, although on very-high-fiber diets and particularly those containing large quantities of legumes this proportion may increase. In the measurement of nitrogen balance it is conventional to use a nonabsorbable marker to mark the beginning and end of the fecal collection, or to use a continuous fecal marker.

The other routes by which nitrogen is lost from the body include the shedding of hair, nails and dead skin cells, sweat, saliva, semen, blood lost during menstruation or removed for clinical testing, and the ammonia exhaled in the breath. Dermal losses vary with the rate of sweating and with protein intake. Many of these losses are small and hard to measure, so that a single figure of 0.5 g of nitrogen per day may be taken to approximate the sum of these miscellaneous routes.

The most important use of nitrogen balance is in evaluating the adequacy of dietary intake. It is the major criterion which is used to assess quantitative protein requirements. Such studies have demonstrated that energy intake is also a major determinant of nitrogen balance. Measurement of nitrogen balance is also the basis of many biological methods for measuring protein quality.

Amino Acid Imbalance and Antagonism

It is normally the case that once the minimum requirements for total nitrogen and for each essential amino acid have been met, any surplus protein intake has no deleterious effect on nitrogen balance. However, there are reports of the addition of a very large quantity of a single essential amino acid causing a reduction in the biological value of an otherwise adequate protein. This has been called amino acid imbalance and appears to occur only when protein intake is marginally adequate. It can thus be overcome by increasing the intake of either total protein or of the limiting amino acid.

The related phenomenon of amino acid antagonism refers to a situation in which the addition of one amino acid affects the efficiency of utilization of another related amino acid. For example, the addition of one of the branched-chain amino acids (leucine, isoleucine, or valine) will impair the utilization of dietary protein, and this can be overcome by adding the other two branched-chain amino acids. It is tempting to speculate that this is because of competition for membrane transport, or because of increased activity of the common pathway by which these

amino acids are oxidized, but no such mechanism has yet been confirmed.

Synthesis and Turnover

P W Emery, King's College London, London, UK

Background

It is self-evident that growth must involve the synthesis of new protein. Equally, there are situations, usually associated with illness or undernutrition, when the organism loses protein, indicating that a mechanism must also exist for degrading tissue proteins. However, not until the 1940s was there direct evidence that the processes of protein synthesis and degradation continue to occur in healthy nongrowing adult animals which are neither gaining nor losing weight. The amino acid tyrosine, labeled with the stable isotope ^{15}N, was fed to an adult rat, and after 10 days only half the isotope had been excreted in the urine while most of the rest had been incorporated into tissue proteins. Protein turnover includes both the synthesis of protein from amino acids and the breakdown of protein to amino acids. Much experimental work over the last 40 years has been devoted to measuring the rates at which these two processes occur and identifying the factors which modulate them. It is now clear that both processes occur continuously and simultaneously, and it is estimated that an adult man synthesizes and degrades about 300 g of protein each day, which is three or four times as much as is consumed in the diet.

Mechanism of Protein Synthesis

The major biochemical pathways by which protein is synthesized in cells are now well established. Information specifying the primary structure is carried in the sequence of base pairs in the DNA molecules in the nucleus. This information is transcribed by the formation of short-lived molecules of messenger ribonucleic acid (mRNA) with base sequences complementary to those of the deoxyribonucleic acid (DNA). The mRNA moves out of the nucleus into the cytosol, where it associates with ribosomes to allow translation of the message as a sequence of amino acids. Every three bases on the mRNA specify a single amino acid which then binds to the ribosome in association with a specific molecule of transfer RNA (tRNA). A peptide bond is formed to join the new amino acid to the growing polypeptide chain, and the deacylated tRNA is released from the ribosome.

Even when the completed polypeptide has been released from the ribosome it may undergo considerable posttranslational modification. Some amino acid residues may be hydroxylated or methylated, while others may form covalent links with other parts of the molecule as the protein adopts a stable three-dimensional structure. Nonprotein molecules, particularly carbohydrates, may be added. Finally, parts of the protein may be removed altogether, possibly after being transported to a different compartment of the cell, to allow activation of an inactive precursor or to facilitate secretion of export proteins.

Regulation of the rate of protein synthesis within a given cell occurs at two levels. There is specific control of the types of protein synthesized, which occurs mainly by controlling the transcription of particular genes. There is also general control of the total amount of protein synthesized, which occurs mainly at the level of translation. This includes regulation of the number of ribosomes present in the cell, and hence its capacity for protein synthesis, as well as regulation of the efficiency of translation, which

appears to be achieved largely by changes in the rate of initiation of peptide synthesis, although elongation and termination may also be modulated under some circumstances.

Protein Degradation

The mechanisms by which proteins are broken down are much less well understood. A large number of proteolytic enzymes have been identified, with differing substrate specificities and conditions for optimal function. This may reflect the complexity and variety of the substrates on which they operate, and may also indicate a degree of cooperative activity, since once a protein is committed to degradation it appears to be broken down to its constituent amino acids very rapidly.

Many of the proteolytic enzymes appear to operate within a specific organelle, the lysosome. This provides the acidic environment in which enzymes such as the cathepsins are optimally active. Lysosomes can engulf and degrade large structures such as whole mitochondria, but individual soluble proteins can also enter the lysosome from the cytosol.

Lysosomes are believed to be responsible for the majority of protein degradation, particularly in tissues such as the liver where the overall rate of protein turnover is high. However, there are also a number of proteinases which operate in the cytosol, and are active at neutral or even alkaline pH. These include the following: the calpains, which are activated by calcium ions and may be particularly active in muscle; a large multicatalytic proteinase sometimes called a proteosome; and a series of enzymes which commit proteins to degradation by binding them to a 76-amino-acid polypeptide called ubiquitin.

There also exist extracellular proteinases which degrade specific extracellular proteins such as collagen.

The control of protein degradation may be exercised at both a general and a specific level, as with protein synthesis. Some of the factors that affect the rate of protein degradation are intrinsic to the protein substrate itself, for example, increasing size and acidic nature favor more rapid degradation. At least some protein degradation appears to require energy. There also appears to be a requirement for continuing protein synthesis, although this may simply reflect the fact that the enzymes which degrade proteins are, of course, proteins themselves. However, this association may at least partly explain the observation that rates of protein synthesis and degradation often change in the same direction in response to external influences.

Measurement of Protein Synthesis and Breakdown

Having identified the pathways by which proteins are synthesized and degraded it is desirable to measure the rates at which these processes occur. Such measurements can be made *in vivo*, in humans or experimental animals, or *in vitro*, in perfused or incubated tissues or organs, cell cultures, or cell-free systems. Unfortunately there are quantitative differences between the results obtained from different systems, which limits the usefulness of *in vitro* measurements. For example, rates of protein synthesis measured in incubated muscle preparations tend to be lower, and rates of protein breakdown are always considerably higher than those observed *in vivo*. This occurs despite careful attention being paid to factors which are known to affect the viability of the model such as tissue oxygenation, muscle integrity, stretch and electrical stimulation, as well as nutrient supply and hormonal environment. Hence such preparations are always in net negative protein balance, whereas *in vivo* muscle switches between negative balance, in the postabsorptive state, and positive balance after a meal.

The ultimate aim is to be able to measure the turnover rates of individual proteins. This can be done *in vitro*, and it may soon be possible to make such measurements *in vivo* as well. However, for technical reasons the methods that are currently available for use *in vivo* are only able to give reliable data for turnover rates in whole tissues or even the whole body. Nevertheless, such data do provide a useful insight into the mechanisms by which nutritionally significant quantities of protein are gained or lost, and such measurements are being made increasingly frequently in both clinical and agricultural research.

Measurement of Whole-Body Protein Turnover

The measurement of protein turnover necessitates a model which is simple enough to analyze fully but can be reasonably interpreted in terms of what happens in a living animal or person. The model used most commonly is the two-pool model, shown in Figure 1. All the protein in the body is represented by one pool, while the other pool represents the total amount of one particular free amino acid (both intracellular and extracellular). The flux of that amino acid (Q) is defined as the sum of all the processes by which the amino acid leaves the free pool:

$$Q = O + S + M$$

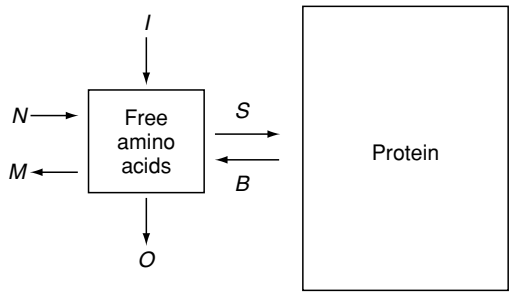

Figure 1 Two-pool model for investigating whole-body protein turnover. *I*, intake of amino acid from dietary protein; *S*, protein synthesis; *B*, protein degradation; *O*, amino acid oxidation; *N*, synthesis of amino acid; *M*, metabolism to other compounds.

In this equation O is the rate at which the amino acid is oxidized, S is the rate at which it is incorporated into protein, and M is the rate at which it is metabolized to other compounds. Measurements are normally made in a steady state, when the amino acid pool is neither expanding nor contracting, so that flux is also equal to the sum of all the processes by which the amino acid enters the pool:

$$Q = I + B + N$$

where I is the intake of the amino acid from dietary protein, B is the rate at which it is released by protein breakdown, and N is the rate at which it is synthesized. Judicious choice of amino acid allows these equations to be simplified: for essential amino acids, $N = 0$, and several of the amino acids have no metabolic fates other than oxidation, so that $M = 0$. Dietary intake can be controlled during the period of measurement, and is often set to zero. Thus, if the rates of flux and oxidation can be measured, the rates of incorporation of amino acid into protein (i.e., protein synthesis) and release from protein (i.e., protein degradation) can be calculated. Knowledge of the proportion of this amino acid in tissue proteins then allows the overall rates of protein synthesis and degradation to be calculated.

There are two commonly used methods for measuring amino acid flux. One involves the administration of a single dose (d) of an amino acid (often glycine) labeled with ^{15}N and measurement of the cumulative urinary excretion of label in an end product of amino acid metabolism, usually either urea or ammonia, over a period of up to 60 h. The flux is calculated from the following equation:

$$Q = d(E/et)$$

In this equation e is the cumulative excretion of the labeled end product and E is the total excretion rate of that end product. Oxidation rate can be estimated from the rate of excretion of urea nitrogen expressed as a proportion of the nitrogen flux. This method is noninvasive and therefore particularly suitable for certain clinical situations. However, from a theoretical point of view it has major disadvantages in that the long period necessary to obtain a representative collection of labeled end product allows some isotope to reenter the free amino acid pool after incorporation into rapidly turning over proteins, leading to an underestimate of flux. In addition, the fact that very different values for flux are obtained using different end products even in the same experiment suggests that the end products may not actually be derived from the same pool as the precursors for protein synthesis. This therefore casts doubt on the validity of the method, particularly when comparing different clinical and metabolic conditions.

The other method for measuring protein turnover is to give a constant infusion of labeled amino acid (at a rate i) and to measure the isotopic enrichment of the amino acid in the plasma when this reaches a steady-state value (L_{max}), at which time isotope is entering and leaving the plasma pool at the same rate. The flux is then calculated from

$$Q = i/L_{max}$$

L_{max} is expressed as the ratio of plasma enrichment to infusate enrichment. The most commonly used amino acid is leucine labeled with ^{13}C in the carboxyl group so that the oxidation rate can be obtained by measuring the rate at which ^{13}C-labeled carbon dioxide ($^{13}CO_2$) is excreted in the breath. By giving priming doses of labeled amino acid and bicarbonate, steady-state labeling of both plasma leucine and breath CO_2 can be reached very quickly and the whole procedure can be completed in 4 h, although the need to take repeated blood samples is considered a practical disadvantage. The major theoretical limitation is that the enrichment of free amino acids in the plasma may not be the same as that at the site of protein synthesis, which is likely to be intracellular and will thus vary between different tissues anyway. The enrichment of the intracellular amino acid pool will be lower than that of the plasma pool, so that this method tends to underestimate the true flux rate. When ^{13}C-leucine is being used as the tracer the enrichment of its transmination product, α-ketoisocaproic acid, in plasma is often taken as an estimate of the enrichment of intracellular free leucine.

Measurement of Protein Synthesis in Individual Tissues

The rate of protein synthesis in an individual tissue can be measured directly by administering a labeled amino acid and measuring the amount of the

labeled amino acid that has been incorporated into the proteins within the tissue after a given time. The enrichment of the precursor pool for protein synthesis during the incorporation time must also be measured in order to calculate the rate of protein synthesis. This can be problematical since the enrichment of the free amino acid pool following administration of a tracer dose of labeled amino acid follows rather complex kinetics, and erroneous conclusions have been drawn from experiments in which the enrichment of the precursor pool was not measured.

One way of overcoming this problem is again to give a constant infusion of the labeled amino acid, so that the free amino acid enrichment remains constant for a period of several hours. Since the practical approach is similar this can conveniently be combined with measuring whole-body protein turnover. The major limitation of this technique is again that the enrichment of free amino acids reaches different steady-state values in the plasma and within the cells. It is not clear which value best reflects the precursor pool for protein synthesis, since there is some evidence that extracellular amino acids may be incorporated directly into proteins. Furthermore, in some tissues which contain proteins that turn over very rapidly, there is the possibility of some reentry of label from protein after several hours of infusion.

A method which largely overcomes these problems involves giving a very large single dose of labeled amino acid. This effectively floods all the free amino acid pools, so that they reach virtually the same level of isotopic enrichment, and this value remains constant, or declines slowly and linearly for an adequate period, after which the tissue sample is taken. This period is usually 10 min in rats or mice and 90 min in humans.

The practical drawback to both these methods for measuring protein synthesis in tissues is the need to take a sample of the tissue. This can be achieved in animals which can be killed at the end of the experiment, but studies in humans are restricted to those tissues which can safely be sampled by percutaneous biopsy (such as muscle) or those which can be sampled during scheduled surgical operations.

An alternative approach which obviates the need for tissue sampling involves sampling arterial and venous blood simultaneously during a constant infusion of a labeled amino acid. The decrease in amino acid enrichment between arterial and venous blood samples reflects the rate at which free amino acid is being produced in the tissue, and at steady state, for an amino acid that is not synthesized in that tissue, this is assumed to equate with the rate of release by protein degradation. This value can then be subtracted from the net difference in amino acid concentration across the tissue to calculate the rate of amino acid incorporation into tissue protein, so long as the amino acid has no other metabolic fate within that tissue. This method has been used to measure protein synthesis and degradation in muscle using deuterated or tritiated phenylalanine as the tracer. However there are practical limitations, including the difficulty of measuring small differences in isotopic enrichment, measuring blood flow accurately, and reliably sampling venous blood from a single tissue.

Measurement of Protein Degradation

The method outlined above produces values for the rate of protein degradation as well as protein synthesis. This is important since there are no other methods for measuring protein degradation in single tissues directly. Other methods based on isotopic labeling are limited by the problem of reutilization of amino acids after release from protein. Thus many workers have concluded that the most reliable estimate of protein breakdown is obtained from the difference between protein synthesis and the net rate of change of the protein mass of the tissue. This involves sequentially killing closely matched groups of animals over a period of days, and thus cannot give any information about short-term fluctuations in protein degradation.

One approach to estimating protein degradation specifically in skeletal muscle involves 3-methylhistidine. This amino acid is formed by post translational modification of certain histidine residues in the myofibrillar proteins actin and myosin, and once it is released from degraded protein it cannot be reutilized for protein synthesis. 3-Methylhistidine is not metabolized, except for *N*-acetylation in certain species, including the rat; assessment of its production rate, from measurement of urinary excretion, should therefore indicate the rate of myofibrillar protein breakdown. Unfortunately, it is now known that many other tissues, including smooth muscle and skin, contain significant quantities of actin, and can make appreciable contributions to 3-methylhistidine excretion, and this has led to erroneous conclusions about muscle protein degradation in certain circumstances such as fasting. Some useful data have been derived from measurements of arteriovenous differences in 3-methylhistidine across muscles, but results based solely on measurement of urinary excretion of 3-methylhistidine should be interpreted with extreme caution.

Rates of Protein Synthesis

Whole-body protein turnover has been measured in a number of species. Values (per kg of body weight per

day) reported for mature animals range from 40 g in the mouse to 3 g in the cow and 4–5 g in humans (Table 1). Both synthesis and degradation are considerably increased in young growing animals, with values of 12 g kg^{-1} day^{-1} being reported for premature infants, falling to 7 g kg^{-1} day^{-1} in 1-year-old children.

Whole-body protein turnover represents the sum of the contributions from many different tissues. The contribution of each tissue depends on the fractional rate of protein synthesis in the tissue and on the proportion of the body's protein mass present in that tissue. Table 2 shows representative data for a number of tissues in the rat; isolated values are available for several other species, including humans but these do not yet form a comprehensive picture.

It should be noted that protein turnover in different tissues is controlled independently. Thus a simple measurement of whole-body protein turnover may fail to detect changes in opposite directions in two different tissues, such as muscle and liver.

Regulation of Protein Synthesis and Degradation

The rates of both protein synthesis and degradation change in response to nutritional and other environmental influences. For example, muscle protein synthesis increases rapidly after a meal, as the tissue goes temporarily into positive balance, then subsequently declines as amino acids are mobilized during the postabsorptive phase. There is a similar cycle of positive and negative balance with feeding and fasting at the level of the whole body, although the changes in protein synthesis and degradation are more equivocal. Whole-body protein degradation is suppressed by feeding, but the rate of whole-body protein synthesis does not always increase. The magnitude of the changes in protein balance is affected by the habitual diet, so that people who are habituated to a high-protein diet lose more protein during the postabsorptive period. This has important implications for the estimation of protein requirements, which will appear to be higher in people who are accustomed to a high protein intake.

It is possible that the concentrations of free amino acids within the cell have an influence on the rate of protein synthesis, but this view is hard to reconcile with the observation that the Michaelis constants (K_m) of the amino acyl tRNA ligases are generally well below the intracellular amino acid concentrations, so that the tRNAs are normally fully charged. Moreover, intracellular amino acid concentrations have been observed to increase in starvation, when the rate of protein synthesis is known to go down. Thus it is likely that other factors such as hormones play a more important role in regulating protein synthesis.

However, it is still possible that the concentration of one or another amino acid may affect protein turnover. Tryptophan is the amino acid which is generally present in the lowest concentrations in intracellular free amino acid pools, at least in mammalian tissues, and there is evidence from *in vitro* studies using rat liver cells that changes in tryptophan supply can affect the rate of protein synthesis by affecting the aggregation of ribosomes into polysomes (the form in which they are active). However, the circumstances in which such large changes in tryptophan concentration would occur *in vivo* are not clear.

In vitro studies have also suggested that the branched-chain amino acids, or leucine alone, may regulate protein synthesis in skeletal muscle, and that the deaminated metabolite of leucine, α-ketoisocaproic acid, may regulate protein degradation. However, injection of a large quantity of leucine has been

Table 1 Representative values for whole-body protein turnover (i.e., synthesis or degradation) rates in adult animals

Species	*Protein turnover (g kg^{-1} body weight day^{-1})*
Mouse	40
Rat	20
Rabbit	10
Sheep	6
Human	4–5
Cow	3

Table 2 Contributions of tissues to whole-body protein synthesis (average values for 100 g rats)

Tissue	*Protein content (% of whole body)*	*Fractional synthetic rate (% per day)*	*Absolute synthesis (% of whole body)*
Whole body	100	34	100
Muscle	45	17	23
Skin	10	64	19
Liver	4	90	12
Gut	4	100	11
Bone	3	90	8
Remainder	34	26	27

shown to have no effect on muscle protein synthesis *in vivo*.

Recent evidence has indicated that the rate of protein synthesis in muscle correlates with the intracellular concentration of glutamine, particularly in circumstances where both are reduced, including injury and infection. However, increasing muscle glutamine concentration has not been shown to alter the balance between protein synthesis and degradation.

Of the many hormones that are known to affect protein turnover, insulin has perhaps received the most attention. Studies in rats show that insulin increases protein synthesis, and this may be the major mechanism by which food intake affects protein metabolism. In contrast, insulin's main action in humans appears to be to decrease protein degradation. Glucocorticoids depress muscle protein synthesis, and thyroid hormones increase protein breakdown. Testosterone and its synthetic derivatives appear to exert their anabolic effects either by increasing protein synthesis or by decreasing protein degradation, depending on concentration.

The rate of protein synthesis in muscle is affected by physical activity. Exercise causes muscles to hypertrophy by increasing the rate of protein synthesis. During normal growth an increase in the length of long bones tends to stretch the muscles which are attached to them, and this stimulates muscle protein synthesis, resulting in the growth of the muscle.

Factors that Depress Protein Synthesis

One of the major reasons for studying protein turnover in relation to nutrition is to investigate the mechanisms by which growth rate is reduced or by which lean body mass is lost in situations of undernutrition or disease. It is perhaps not surprising that retardation or even cessation of growth is associated with a reduction in the rate of protein synthesis. There is now considerable evidence that the net loss of lean body mass in adults suffering from chronic diseases such as cancer as well as primary muscle-wasting diseases is also caused by a decrease in protein synthesis. Protein breakdown appears not to be increased, and may even be decreased in many tissues as a secondary response to decreased protein synthesis. This has major implications for therapy, which should be directed towards augmenting protein synthesis rather than suppressing protein breakdown.

Several factors appear to be involved in the depression of protein synthesis. Patients with chronic diseases often have inadequate intakes of protein and energy, and this is likely to depress protein turnover. Lack of physical activity, particularly in bedridden patients, is another important factor. Changes in conventional hormones are likely to be involved, as are cytokines such as the interleukins and tumor necrosis factor. These are peptides produced by the cells of the immune system in response to infection and injury which, apart from their immediate local action, also appear to have systemic effects, including suppressing muscle protein synthesis. This presumably evolved as an adaptive response to acute injury or infection, when it would be more important to insure the supply of substrates for such processes as gluconeogenesis and acute-phase protein synthesis than to synthesize muscle proteins. However, this now appears as a maladaptive response to chronic disease, since prolonged or severe muscle wasting is associated with considerable morbidity and mortality. At the cellular level there is some evidence that these cytokines, and indeed some conventional hormones, may act by modulating the production of eicosanoids. In this context prostaglandin $F_{2\alpha}$ appears to increase the rate of protein synthesis while prostaglandin E_2 promotes protein breakdown.

Deficiency

C Leitzmann, Justus-Liebig University, Giessen, Germany

Background

Protein deficiency indicates a lack of body protein or a relative deficiency of one or several essential amino acids. Thus, protein deficiency is synonymous with a negative nitrogen balance. The deficiency can result from a protein-deficient diet or other events, such as diseases, and it must be distinguished from the multifactorial syndrome of kwashiorkor. However, the clinical features and physiological effects are generally similar to those of kwashiorkor.

In this article the causes and groups at risk of protein deficiency are described. Its clinical features, physiological effects and treatment are explained. The adaptation to low-protein intake and protein reserves of the body are discussed.

Causes and Groups at Risk

Causes

Although the main cause of protein deficiency is a protein-deficient diet, seen in children in developing countries, it can also occur in patients suffering from various diseases. In this sense, protein deficiency (as well as other nutritional deficiencies) is a secondary consequence of the particular disease. (*See* **Malnutrition**: The Problem of Malnutrition.)

Secondary protein deficiencies can be ascribed to six causes:

1. Irregular food habits, e.g., in the case of chronic alcoholics. The diet of alcoholics can be severely deficient in protein.
2. Inability to digest and absorb the protein that is consumed; this occurs in patients with chronic gastrointestinal disorders, such as celiac disease or enteritis. (*See* **Celiac (Coeliac) Disease**.)
3. A disturbed protein metabolism, which may exist in patients with cirrhosis of the liver but also in patients with hormonal disorders or in some cases of diabetes.
4. A continuous loss of protein; this predominates in patients with diseases such as chronic renal disease, bleeding or exudative gastroenteropathy. High losses of albumin into the urine are indicators of the nephrotic syndrome. (*See* **Renal Function and Disorders**: Kidney: Structure and Function.)
5. An increased protein turnover, which is characteristic in cases of infection, fever, or gastroenteritis.
6. Enhanced catabolism of protein, with increased nitrogen losses, seen in patients with severe injuries, especially burns, or in postoperative stress. (*See* **Burns Patients – Nutritional Management**.)

Protein losses after operations depend on the kind of surgery (Table 1). If patients are unable to eat normally, insufficient food intake worsens the protein deficiency.

Groups at Risk

The groups at risk can be classified according to the causes of protein deficiency (see above) or better according to socioeconomic parameters. According to socioeconomic parameters, by far the largest group is the poor population in developing countries, primarily children in the second year of life. This group is at risk from primary protein deficiency because of a protein-deficient diet, caused by economic, ecological, and political factors. In developed societies, groups at risk are those who adhere to extreme diets or suffer from anorexia nervosa or bulimia nervosa. (*See* **Anorexia Nervosa**; **Bulimia Nervosa**.)

Clinical Features

Fatty Liver

Protein deficiency contributes to fatty infiltration of the liver and results in hepatomegaly. This can be seen in healthy subjects receiving a low-protein diet as well as in protein-deficient animals fed adequate quantities of other nutrients. Because of a decreased synthesis of β-lipoproteins needed for the transport of triglycerides, the fat accumulates in small droplets within the cells, first accumulating in the periphery of the lobules and then spreading to the center of the

lobules. In spite of this, the liver functions are well maintained. (*See* **Fats**: Digestion, Absorption, and Transport.)

Muscle Wasting

Because of increased protein catabolism, skeletal muscle is often wasted, and subjects limit their physical activity. In many cases, the parallel prevailing edema conceals the wasting.

Edema

Edema is a frequent sign in protein deficiency. It generally causes swelling of the tissues but usually appears in the feet and lower legs. The etiology of edema has not been completely clarified. Protein deficiency or, rather, hypoalbuminemia is only one of the factors.

Other common features of protein deficiency are changes in the hair; it becomes easily plucked, and there are changes in texture and color. Also common are skin changes, with areas of desquamation and hypo- and hyperpigmentation. Protein deficiency also leads to mental changes, lethargy, fatigue, anorexia, and some degree of anemia, and is frequently associated with infections. In children, severe protein deficiency leads to growth retardation.

Physiological Effects

Organs and systems can be changed in protein deficiency, and this may alter their physiological functions.

Cardiovascular System

Muscle wasting in the heart leads to reduced cardiac output and poor circulation. As a result, the pulse rate of many patients is low and even impalpable, and the extremities are cold and pale.

Renal Function

Structural abnormalities of the kidney have not been observed, but the glomerular filtration rate may be diminished. The concentrating power can also be impaired, which may be attributable to a low blood urea concentration or an accompanying potassium deficiency.

Pancreas

Atrophic changes and fibrosis of the pancreas have been observed both in children dying of protein malnutrition and in animals fed low-protein diets. The atrophy affects the acinar cells, responsible for exocrine secretion, but not the islets, responsible for hormone (glucagon and insulin) production. A reduced number of secretory granules have also been observed. These changes result in impaired pancreatic function with a diminished secretion of pancreatic enzymes into the intestine. Glucagon and insulin secretion are also lowered in severe cases of protein deficiency.

In another abnormality of the pancreas in protein-deficient animals, the protein content and phospholipid levels are reduced, and triglyceride and cholesteryl ester levels are increased. This altered pancreatic lipid composition in protein-deficient animals may lead to changes in the integrity of pancreatic membranes and can predispose to injury.

Gastrointestinal Tract

The mucosal epithelial cells of the small intestine make up the tissue with the highest turnover rate and are therefore very vulnerable to protein deficiency. The intestine wall becomes thin, the mucous membrane is smooth and atrophic, and the villi are frequently flattened. The enzyme-secreting cells and the pancreatic acinar cells may be affected in a similar way. As a result, the production of digestive enzymes, primarily the disaccharidases, is reduced, and the absorptive and digestive capacity of nutrients is impaired.

A feature seen in biopsis after protein deficiency is the intense cellular infiltration in the mucosa and submucosa, especially with lymphocytes and plasma cells. The colon can be less affected, but the muscle coats may also be atrophic, and the surface epithelium may show infiltration of plasma cells.

Endocrine System

The pituitary gland responds effectively to the stimulus of protein deficiency; thus, the secretion of human growth hormone is normal or, possibly, supranormal, and the thyroid-stimulating hormone is elevated. (*See* **Hormones**: Thyroid Hormones; Pituitary Hormones.)

The thyroid may be atrophic, with reduced colloid tissue, and the vascular cells are flattened and inactive. The thyroid function appears to be normal, but there are data suggesting a reduced function of the thyroid gland. The concentrations of thyroxine-binding proteins and of thyroxine are reduced.

The adrenal gland appears atrophic, but nevertheless, plasma cortisol levels are elevated and may lead to metabolic disturbances. A reduced insulin secretion, as seen after glucose tolerance tests, can also be predominant in protein deficiency. (*See* **Glucose**: Glucose Tolerance and the Glycemic (Glycaemic) Index; **Hormones**: Adrenal Hormones.)

Immunological System

In protein deficiency, the lymphoid tissue – primarily the thymus gland, but also lymph nodes and spleen – is

atrophic. First, the production of thymus-dependent lymphocytes (T cells) is reduced and is responsible for the diminished cell-mediated immunity to infectious agents, as demonstrated in specific tuberculin skin tests. Second, the phagocytic activity of neutrophils and antibody formation are reduced. The body therefore becomes more susceptible to infections which can be fatal. (*See* **Immunology of Food**.)

Treatment

The dietary treatment of protein deficiency depends on the cause of the deficiency. In patients with nephrotic syndrome, characterized by massive losses of albumin into urine, the intake of protein should be increased to 90–120 g per day for adults when hepatic synthesis of albumin can compensate in part the urinary losses. (*See* **Kwashiorkor; Marasmus**.)

In cases of acute renal failure, the protein intake should be only 20 g per day. This reduces protein metabolism and the production of urea. In patients with liver cirrhosis, the protein intake should also be reduced because a high-protein diet can precipitate hepatic encephalopathy.

Special Feeding Methods

Protein deficiency can be treated by tube feeding, intravenous feeding or supplementary feeding. Tube feeding is indicated in patients with severe malnutrition who are unable to eat. Parenteral nutrition is essential when the small intestine is unable to digest and absorb nutrients, or after severe injuries such as burns.

In mild protein deficiencies, an increased oral intake of protein is sufficient to meet dietary needs. Several special preparations containing high levels of protein are available on the market.

Complications

Since protein deficiency is frequently accompanied by infections, dehydration, and deprivation of vitamins and electrolytes, these conditions need special attention. In most cases of severe protein deficiency, therefore, treatment has to start with fluid replacement and, if indicated, with antibiotic therapy.

Adaptation to Low-protein Intakes

Waterlow (1986) described two possibilities of nutritional adaptation, which he called the first and second line of defense. The first line of defense is the ability to achieve nitrogen balance at various levels of protein intake. The second line of defense is necessary after the capacity to economize nitrogen is exhausted, resulting in a reduced lean body mass or reduced growth rate in children. In this section, only the first line of defense is discussed.

Nitrogen Balance

Nitrogen equilibrium is a state in which, for a given intake of nitrogen, an equivalent amount of nitrogen is lost from the body via urine, feces, skin, sweat, etc. When protein intake is low, dietary protein is used more efficiently; this is exemplified by the excretion of nitrogen, particularly in the form of urea, which is reduced and so contributes to the restoration of nitrogen balance. In this situation, the pathways of amino acid synthesis predominate.

The liver plays an important role in the adaptive process, since it is the only organ which can transform the nitrogen from amino acids into urea. The alterations in the nitrogen pathway are mainly brought about by changes in the activity of liver enzymes. Experiments with animals have shown that in protein deficiency, urea cycle enzymes, such as argininosuccinase, are low, and the amino-acid-activating enzymes are high. Table 2 shows this finding in children with severe protein malnutrition, soon after admission to hospital and after recovery.

The metabolic activity of the gastrointestinal tract is important in the adaptive process. Normally, one-third of the urea produced is passed into the bowel and can be hydrolyzed by the gut microflora. Thus, urea nitrogen becomes available for metabolic interaction, e.g., for the synthesis of nonessential and essential amino acids. However, the necessary carbon skeletons can be the limiting factor in adaptation. In protein deficiency, a greater proportion of urea is retained by the body. (*See* **Microflora of the Intestine: Role and Effects**.)

Recent investigations have shown that the colon is permeable to urea and amino acids, thus supporting the view that hydrolysis of urea plays an important nutritional role.

Table 2 Enzymatic activity of the livers of children with malnutrition

	Amino-acid-activating enzymes	*Argininosuccinase*
Soon after admission	1.44	1.06
1–2 months later	0.91	1.46

The figures for the amino-acid-activating enzymes are the means of 18 measurements and are expressed in micromoles of phosphorus exchanged per milligram of protein; for argininosuccinase, the figures are the mean of 11 measurements and expressed in micromoles of urea per milligram of protein. The changes on recovery are statistically significant. From Passmore R and Eastwood MA (1986) *Human Nutrition and Dietetics*, 8th edn., p. 52. Edinburgh: Churchill Livingstone.

Table 3 Relative losses of protein in different organs and tissues from rats over 7 days

Organ or tissue	*Loss (percentage of primary content)*
Liver	40
Prostate gland	29
Seminal vesicle	29
Gastrointestinal tract	28
Kidney	20
Blood plasma	20
Heart	18

Adrenal gland	0

From Kraut H (ed.) (1981) *Der Nahrungsbedarf des Menschen: 1 – Stoffwechsel, Ernährung und Nahrungsbedarf, Energiebedarf, Proteinbedarf*, p. 148. Darmstadt: Steinkopff Verlag.

Plasma Albumin

Plasma albumin reacts very sensitively to a reduced protein intake. Although the albumin turnover is reduced by about 36% in studies with adults, the plasma albumin concentration is reduced by only about 7%. This maintenance of intravascular circulating albumin mass is attributable to a reduced breakdown and a shift of albumin from the extravascular to the intravascular compartment.

Factors Affecting Adaptation

Among the factors that can affect the adaptation to low protein intake are infections, diarrheal diseases, and injuries. In infections, protein from muscle and skin is needed for the immune response, and this leads to a negative nitrogen balance. In diarrheal diseases, the malabsorption has a negative influence on the adaptive process; in patients with injury, the severe losses of nitrogen have the same effect.

Energy balance is also essential for nitrogen balance because of its nitrogen-sparing effect. Thus, if protein deficiency is accompanied by energy deficiency, the adaptation to a low protein intake cannot be achieved completely.

Protein Reserves

The body of a human adult (65 kg) contains 12 kg of protein, about 50% of which is found in muscles. The amount of body protein depends on, among other things, the dietary protein and carbohydrate intake; if carbohydrate is lacking, the amino acids are utilized for gluconeogenesis. (*See* **Glucose**: Function and Metabolism.)

Protein reserves are not comparable to special fat depots, and not all body proteins can serve as protein reserve. Reserves are primarily organs which contain labile body protein such as liver, plasma (with proteins such as albumin and enzymes) and the gastrointestinal tract, which has an assessed protein content of about 700–800 g. Although the protein turnover rate in muscle is very slow, this tissue is a very important protein reserve owing to its large mass.

In protein deficiency, the labile body proteins are metabolized first; when deficiency is long-term, all organs are affected to various extents (Table 3). The well-fed human adult can lose about 3 kg of protein without any disturbances to his or her health.

Heat Treatment for Food Proteins

L Mauer, Purdue University, West Lafayette, IN, USA

Background

Amino acid composition and sequence determine the native structure, functionality, and nutritional quality of a protein in a set environment. During food processing, heat is often added to the protein's environment, and this addition of energy can change any or all of the structural, functional, and nutritional characteristics of the native protein. Foods are complex systems, and it is important to recognize that pH, water activity, food composition, and interactions of these with temperature also affect protein properties to varying extents. Common heat treatments used in processing food proteins, effects of heat on protein structure and function, effects of heat on protein interactions with carbohydrates and lipids, and nutritional effects of heating proteins are discussed.

Common Heat Treatments on Food Proteins

At home or on an industrial scale, the purposes of common heat treatments of foods containing proteins are similar: to change texture or function, improve safety and quality, and control enzymes by altering physical, chemical, and biological protein properties. Foods are baked to change texture and improve safety, vegetables are blanched to inactivate enzymes, canning temperatures used for low acid foods are designed to prevent toxin production by pathogenic microorganisms, pasteurization and sterilization are designed to kill pathogens and inactivate enzymes, and extrusion modifies the texture of protein-containing foods. Mild heat treatments, such as incubation, generally do not cause the same extent of change as higher heat treatments and may be used to promote enzyme activity instead of destroying it. It is worthwhile to note that proteins usually are most stable to heat at their isoelectric points.

Dry-heat Food Preparation

Dry-heat food preparation methods at temperatures ranging from 160 to 230 °C include baking, roasting, grilling, and frying. In addition to microbial destruction, dry-heat methods alter the texture of protein foods by heat gelation of proteins, denature enzymes and pigments, and with extensive heat may form thermally induced mutagens. When meats are heated, myofibrillar proteins denature, then form a gel matrix, enzymes such as myosin and actomyosin are inactivated, and oxidation of denatured myoglobin pigments turns cooked meats brown. On baking, the elastic wheat gluten network in bread dough expands to contain leavening gases until the temperature is high enough to gelatinize starch, around 65 °C. Gluten protein denaturation and gelation occur at higher temperatures than starch gelatinization, beginning around 74 °C, and continuing for the remaining baking time. The Maillard reaction between proteins and carbohydrates produces the browning of bread crusts during baking.

Moist-heat Food Preparation

Moist-heat food preparation methods at temperatures ranging from 65 to 100 °C include blanching, boiling, steaming, scalding, and poaching. Pressure canning foods can reach temperatures in excess of 116 °C. Blanching is a process to inactivate enzymes by dipping foods, usually vegetables, into boiling water for a short time period. This enzyme inactivation prevents quality loss by color, texture, or flavor changes during frozen storage. Blanching also decreases initial microbial load on foods as well as wilts products such as spinach for tighter packing. Boiling occurs at or near 100 °C, depending on elevation, and functions to inactivate enzymes, denature proteins, change texture, and potentially destroy toxins.

Higher temperatures achieved under pressure, such as for pressure canning, inactivate enzymes, destroy pathogenic and many spoilage microorganisms, and prevent toxin formation during storage. Poaching eggs leads to denaturation and coagulation of egg white proteins. Steaming fish causes texture changes as a result of denaturation and gelation of proteins. Scalding milk may initiate unfolding of whey proteins and improve select functional properties desirable in preparing bakery foods.

Microwaving

Microwaving combines properties of dry- and moist-heat food preparations with the advantage of reducing food cooking times. Heat produced by friction of rotating food molecules, most notably water, in response to magnetron-generated microwaves denatures and coagulates food proteins as do other heating methods. However, foods cooked in a microwave do not brown as they would in dry-heating methods. The crust of microwaved bread dough does not brown, because the air in the microwave does not

reach high enough temperatures, and the steam generated does not allow the surface to dry sufficiently for nonenzymatic browning to occur.

Pasteurization

The pasteurization process is designed to destroy any pathogenic microorganisms that might be present in the food product. Temperatures used for pasteurization also reduce the total microbial load, thereby increasing shelf-life, and may inactivate select enzymes that lead to quality loss during storage. Pasteurization of milk, designed to destroy the pathogen *Coxiella burnetti*, is accomplished by a time/temperature integrated process. Lower temperatures take longer times (63 °C for 30 min, 71.5 °C for 15 s), whereas higher temperatures require much shorter process times to accomplish the same result (88.5 °C for 1 s). At temperatures above 78 °C, esterase, a lipase that may cause hydrolytic rancidity of milk products, is inactivated. Pasteurization of milk also may denature whey proteins, and higher temperatures (ultrahigh temperature processing) or longer process times (such as vat pasteurization) may cause cooked and heated flavors primarily from the volatile sulfur compounds released by β-elimination of disulfide bonds in denatured whey proteins. The high temperatures used for sterilization of aseptic products lead to microbial safety but do not inactivate all enzymes. During extended storage, these enzymes may cause age gelation of aseptically processed milk products. Pasteurization of liquid eggs is a low-temperature, long-time process, either 60 °C for 3.5 min or 64 °C for 2.5 min, designed to destroy pathogenic microorganisms, specifically *Salmonella*, without coagulating the egg proteins.

Extrusion

Extrusion is a high-temperature/high-pressure/high-shear process used to convert soy proteins to textured vegetable protein meat analogs. The texture changes during extrusion cooking result from orientation and denaturation of proteins followed by cross-linking into a network of fiber-like proteins. The extruded vegetable protein network mimics the fibrous texture of meat products. Pressure and shear individually can denature proteins, and lower temperatures may be used in combination with these forces to achieve the same level of denaturation as higher temperatures alone.

Incubation

Temperature is the most important factor affecting the rate of enzyme-catalyzed reactions and also influences the stability of the enzymes. As temperature is increased, reaction rates increase until a temperature at which the enzyme loses activity is passed, often around 50 °C. In the range of 10–40 °C, every 10 °C rise in temperature is accompanied by a 1.8 increase in reaction rate for the enzyme chymosin. The enzyme calf rennet (chymosin) is added to milk in the cheese-making process to cleave κ-casein from the casein micelle and induce micelle aggregation. The maximum rate of aggregation is achieved at 40 °C, and no aggregation occurs below 18 °C or above 60 °C. At temperatures above 50 °C, denaturation of the enzyme causes it to lose activity. Therefore, incubation at 40 °C will maximize chymosin activity, and increasing temperatures above 50–60 °C can be used to stop the enzyme. Temperatures used for cheese ripening also are controlled to maximize desirable enzyme activity for flavor development.

Heat-induced Changes in Protein Structure

Common changes in protein structure as a result of thermal processing include denaturation, aggregation, and thermal degradation. Elevated temperatures also increase rates of deleterious chemical reactions in proteins that lead to oxidation, isomerization, Maillard browning, deamidation, desulphuration, and other β-elimination reactions; however, many of these reactions may occur at temperatures as low as 0 °C as well.

Denaturation

Heat denaturation of proteins involves configurational changes in the thermodynamically stable native structure of the protein via unfolding or alteration of the quaternary, tertiary, or secondary structure as a response to heat exposure. Denaturation may disrupt hydrogen and disulfide bonds, hydrophobic interactions, and salt bridges, but peptide bonds remain intact. The primary structure, or amino acid sequence, of the protein remains unchanged, as does the molecular weight. A loss of ordered structure generally occurs in the entropy-driven transition from a native to a denatured protein. Temperatures at which denaturation occurs vary greatly with protein source and type. Some proteins unfold a few degrees above temperatures at which they function, whereas others, such as wheat gluten and milk β-casein, require much higher temperatures for denaturation. Globular dairy whey proteins denature at much lower temperatures than casein proteins that have more random coil native structures.

Functional properties affected by heat denaturation include solubility, emulsifying capacity, gelation

capacity, foaming properties, and enzyme or biological activity. After mild (or insufficient) heat treatments, protein denaturation may be reversible. For enzymes, this reversible unfolding always occurs prior to irreversible inactivation. If a thermal process does not irreversibly inactivate target enzymes, the enzymes may be able to refold and potentially cause quality issues in food products during storage. Residual enzyme activity in aseptically processed foods can lead to problems such as thinning of puddings due to amylase activity, age gelation in ultra-high-temperature processed milks, and separations in orange juice caused by pectin methylesterase activity.

Aggregation

Denaturation, or at least a partial denaturation, of a protein is usually required prior to its ability to aggregate and form a gel or a precipitate. Unfolding of a protein exposes reactive groups that may then form intermolecular cross-links via covalent, hydrogen, ionic, or other bonding. Gels are formed when the cross-linked protein network is extensive enough to form a continuous phase and trap water. Precipitates are formed when the aggregated proteins become insoluble and settle out of a solution.

Gelation The cross-linking of proteins and entrapment of water during gelation may be either reversible or irreversible. The polymeric networks formed by hydrogen bonding of gelatin molecules are thermoreversible. On cooling, the gelatin bonds to form a gel, and on reheating, the hydrogen bonds break, and gelatin returns to the dispersed phase in the solution. Conversely, denatured globular proteins form thermoirreversible gels. Whey, soy, and egg white proteins first denature and then interact via disulfide, hydrophobic, and ionic bonds to form gels when exposed to heat. These gels are heat-set and may stiffen, instead of liquefy, when exposed to additional heat. The term 'coagulation' is often applied to irreversible heat-setting of proteins.

Precipitation Precipitation of food proteins often is controlled by pH, enzymes, or salt concentration adjustments for food ingredient isolation and applications; however, heat also may destabilize proteins, causing them to precipitate. Solubility and hydrophobicity, which are affected by temperature, also influence protein precipitation. As temperatures increase, the likelihood of protein precipitation increases as hydrophobicity increases and solubility decreases. Denaturation of whey proteins in milk causes them to precipitate, adhere to the cooking vessel, and possibly scorch with continued heating.

Thermal Degradation

Thermal degradation of proteins occurs at temperatures higher than those for denaturation, and as with denaturation reactions, temperatures for thermal degradation vary greatly with protein type. In addition to the quaternary, tertiary, and secondary structure disruption in denaturation, thermal degradation also disrupts the primary structure and peptide bonds of proteins. Effects of thermal degradation on functionality of proteins are more severe than the effects of denaturation. Types of protein thermal degradation include hydrolysis, racemization, and pyrolysis.

Hydrolysis Hydrolysis of proteins for use as functional or flavor ingredients often is accomplished using acid and enzyme techniques; however, high temperatures also may be used to hydrolyze proteins into peptides, especially at high or low pH. Hydrolysis of caseins may occur at 140 °C, and heat-induced hydrolysis of meat connective tissue proteins may increase their solubility. Partially hydrolyzed proteins may be more digestible than native proteins due to the unfolding of the protein structure.

Racemization Racemization, or isomerization, of amino acid residues from L-isomers to D-isomers occurs when heating proteins either above 200 °C or at alkaline pH. This may reduce protein digestibility, because D-amino acids are less absorbed and hydrolyzed than L-amino acids in the digestive tract. Isomerase or racemase enzymes also contribute to these conversions.

Pyrolysis Pyrolysis is a high temperature degradation of organic materials in nonoxidative conditions. Amino acid pyrolysis products are formed at temperatures above 250–300 °C. Free radicals formed during pyrolysis may attach to other amino acids, thereby forming new heterocyclic compounds. Some of these compounds are thermally induced mutagens.

Functional Changes in Heat-treated Proteins

Research indicates that protein structure is optimized for function as opposed to stability. As a result, when addition of heat destabilizes protein structure and stability, functionality also is affected. Effects of heat on protein functionality can be positive or negative, and the degree of heat treatment on a specific protein often differentiates between an increase or decrease in the desired functionality. Addition of some heat may slightly unfold a protein, thereby

increasing emulsifying, gelation, and foaming properties. In designing functional and nutritional foods, the extent of protein denaturation is controlled to attain desired functional characteristics, such as whey proteins designed for use as fat replacers. Higher heat treatments, especially those leading to thermal degradation, may in turn decrease these functional properties as the protein unfolds more or loses primary structure. Water–protein interactions dominate protein functionality in food structure; therefore, effects of heat on hydrophobicity, solubility, emulsifying and gelation capacities, foaming properties, and enzyme activity are important.

Hydrophobicity

The surface hydrophobicity of proteins may either increase or decrease as a result of heat treatments. A thermally induced unfolding of protein molecules exposes hydrophobic sites, thereby increasing hydrophobicity. Conversely, protein aggregation in response to heat results in decreased exposure of hydrophobic sites, thereby decreasing the surface hydrophobicity of aggregated proteins.

Solubility

The solubility of proteins depends on the nature of the protein surfaces in contact with the environment (usually water). To generalize, a protein with a hydrophilic surface will be more soluble in water than a protein with a more hydrophobic surface. As temperatures rise from 0 to 40 °C, most proteins exhibit increasing solubility; however, hydrophobic proteins such as β-casein show the opposite solubility trend in this temperature range and may be most soluble around 4 °C. As temperatures rise above 40 °C and proteins unfold, more hydrophobic sites are exposed, and the solubility of the proteins will decrease. These temperature-dependent changes in solubility will influence emulsifying, gelation, and foaming properties, since solubility influences the amount of protein available for reactions.

Emulsifying Capacity

The emulsifying capacity of proteins results from amphipathic structure and is measured as the volume of oil that can be emulsified per gram of protein in an oil-in-water system. The protein must be somewhat soluble in water in order to act as an emulsifier, and the increase in surface hydrophobicity that occurs with partial denaturation of most proteins will increase their emulsifying capacities. When higher temperatures have caused extensive denaturation and decreased protein solubility, the emulsifying capacity also will decrease.

Gelation Capacity

The gelation capacity of proteins is measured as the amount of water that can be bound or trapped per gram of protein. The effects of heat on gelation capacity are similar to those on emulsifying capacity. Partial denaturation may increase gelation capacity, whereas extensive denaturation will decrease it.

Foaming Properties

The foaming capacity of a protein is measured as the amount of interfacial area that can be created by whipping the protein. Foam stability is measured as the time required to lose either 50% of the liquid or 50% of the volume from the foam. Generally, heating a globular protein to achieve partial denaturation will increase foaming properties. As the structure unfolds and exposes hydrophobic sites, it may be able to adsorb more quickly to air–water interfaces and lower interfacial tension, thereby trapping more air and increasing the foaming capacity. Extensive heat denaturation of proteins will decrease their ability to form foams.

Enzyme Activity

Temperature controls the rate of enzyme-catalyzed reactions and influences enzyme stability. As discussed in the incubation section, moderate temperatures can optimize the rate of enzyme-catalyzed reactions, and higher temperatures may denature (unfold) the enzymes, thereby causing them to lose activity. The temperatures at which enzymes denature vary with the type of enzyme. Chymosin, added to milk for cheese-making, loses activity above 50 °C, whereas pectinmethylesterase present in orange juice is stable to much higher heat treatments.

Heat-induced Protein–Carbohydrate Interactions

Perhaps the most notable protein interaction with other food ingredients is the browning produced in the Maillard reaction between proteins and carbohydrates. At high temperatures, low water activity, and/or extended storage times, proteins may react with reducing sugars to form brown pigments in the Maillard reaction (nonenzymatic browning). Reactive groups in proteins for the Maillard reaction are primary amines, usually the ε-amino groups of lysine residues. Examples of reducing sugars are glucose, fructose, lactose, and maltose. When the free ε-amino group of lysine reacts with a reducing sugar, the lysine is no longer nutritionally available. Lysine is often the limiting amino acid in protein quality of grain products, and a decrease in the available lysine due to the Maillard reaction decreases the overall

protein quality of the food. Nonenzymatic browning is desirable in bakery products such as breads, cooked meats, and caramels for which browning contributes to color and flavor development. However, too much browning produces burnt or off-flavors in these products. Nonenzymatic browning also is undesirable in dried milk powders, infant formula, dehydrated potatoes, dried fruits, and white wine.

Heat Effects on Protein–Lipid Interactions

Heat treatments may affect protein–lipid interactions in terms of free-radical formation, changes in emulsifying capacity, and alteration of conjugated lipoprotein structure. Lipid–protein free radicals may be formed when free radicals produced by oxidation of unsaturated lipids react with proteins. High temperatures greatly increase the rate of oxidation of sulfur-containing amino acids via reactions with oxidized lipids. Cysteine and histidine free-radicals may then cross-link and induce aggregation of proteins. As discussed in the emulsifying capacity section, partial denaturation of globular proteins may expose hydrophobic sites and increase emulsifying capacity, thereby increasing the ability of proteins to interact with lipids; however, higher heat treatments will decrease this ability. Heat also will denature proteins in conjugated lipoprotein structures and affect the functionality of these, especially in membrane systems.

Nutritional Changes in Heat-treated Proteins

Heat-induced changes in protein structure can exhibit both advantageous and negative effects from a nutritional standpoint. Heat denaturation of globular proteins, such as dairy whey proteins, often leads to increased digestibility and sometimes increased nutritional value as the structure is unfolded and therefore more susceptible to proteolytic attack by digestive enzymes. Proteinaceous antinutritional factors, commonly found in legume and oilseed proteins as well as milk and egg proteins, can be inactivated with sufficient heat, usually moderate heat treatments, thereby increasing the biological availability and digestibility of select proteins. Heat inactivation of trypsin and chymotrypsin inhibitors present in legumes and oilseeds also may protect the pancreas. Once heat denatured, the lectins (phytohemagglutinins) present in legumes and oilseeds no longer bind to intestinal cells, causing malabsorption of nutrients. Heat inactivation of ovomucoid and ovoinhibitor in eggs and plasmin and plasminogen activator inhibitors in milk prevent their protease inhibitory activities. Once denatured by heat, egg avidin no longer inhibits biotin absorption. Toxic proteins, including *Clostridium botulinum* neurotoxin and *Staphylococcus aureus* enterotoxin, also are inactivated by heat, although toxin destruction usually requires higher heat treatments than inactivation of antinutritional factors.

Although heat improves safety and some nutritional aspects of food, heating foods also may detract from nutritional quality, especially during high heat or long time processes such as charcoal grilling. Protein cross-linking can decrease proteolysis, thereby decreasing digestibility. The D-amino acid residues formed in racemization are less digestible than the original L-amino acids. As a result of Maillard browning, there is a loss of available lysine and consequent decrease in protein quality. Melanoidins and heterocyclic amines produced in this reaction and during pyrolysis have been shown to be mutagenic or carcinogenic and classified as thermally induced mutagens or carcinogens. Consumption of small amounts of these compounds over extended periods of time may lead to serious health problems.

Sources of Food-grade Protein

G S Gilani and N Lee, Bureau of Nutritional Sciences, Health Canada, Ottawa, Ontario, Canada

Background

Comparison of data from different countries has indicated that countries with low gross national products also tend to have a low food energy availability. In addition, there are major differences in the pattern of foods in the diet in such countries compared with wealthier countries. In particular, the availability of animal-protein foods is significantly lower in poor countries. Compared to the developed world, a greater proportion of the protein consumed by people in developing countries is derived from low-quality protein sources such as cereals. Moreover, the patterns of indispensable amino acid (IAA) composition in the proteins are such that there is a significant difference between the diets of rich and poor people with respect to lysine. Standard tables of amino acid composition show that the values for cereals range from 26 to 38 mg of lysine per gram of protein, while the values for animal foods range from 70 to 100 mg of lysine per gram of protein. A recent analysis of the world's balance of dietary IAA demonstrated that average lysine intakes were low in poor, developing countries. This would indicate a considerable risk of inadequate levels of intake, especially in vulnerable subgroups such as children and pregnant or lactating women. Strategies to alleviate the possible global problems of a low lysine supply could include increasing dietary diversity as well as either supplementing cereal-based foods with food-grade proteins high in lysine or fortifying cereals with lysine.

Food-grade Proteins

In this chapter, sources of food-grade protein are defined as products made by processing certain food ingredients in a manner that significantly increases their protein content. They are often referred to as protein flours, protein concentrates, and protein isolates. Some examples are milk-protein isolate, whey-protein concentrate, casein, lactalbumin, egg-white solids, gelatin, soybean-protein flours, concentrates, and isolates, pea-protein concentrate, canola-protein concentrate, mycoprotein, cottonseed protein, and wheat gluten.

These protein sources could be used to improve the protein nutriture of populations by increasing the protein content of the diet, increasing the quality of the proteins in the diet, or a combination of both. It should be noted that increasing the protein quantity and/or quality of a diet is ineffective if energy requirements are not met.

Animal-protein Products

Most animal sources of food-grade protein (except gelatin) are excellent sources of all the IAA (Table 1) and have a high protein digestibility (*See* **Protein: Quality**). High-protein-quality animal products include egg proteins, casein, milk protein isolate, lactalbumin, whey-protein concentrate, beef, tuna, and chicken meat products. These products are especially high in key IAA such as lysine, methionine+cystine, threonine, and tryptophan, which are limiting in poor-quality vegetable-protein products. Among the animal-protein products, egg white contains the highest amount of methionine+cystine, and lactalbumin and whey-protein concentrate contain the highest amounts of lysine and tryptophan, while egg white, tuna, beef, and chicken meat products contain the highest amounts of threonine. Therefore, these animal-protein products could serve as supplements to low-quality proteins limiting in one or more of these IAA.

The protein efficiency ratio (PER) values of most high-quality animal-protein products are higher than that of the standard for the method, which is casein (Table 2). In contrast, proteins with protein digestibility-corrected amino acid scores (PDCAAS) exceeding 100% are truncated to 100%, implying that values exceeding 100% do not contribute any additional benefit in humans. This is not true, especially when these proteins are used as supplements to poor-quality proteins. Therefore, there is an urgent need to revise the PDCAAS method to permit the use of untruncated PDCAAS values for high-quality animal-protein products so that their supplementary value, when combined with lower-quality protein sources, can be identified by their PDCAAS values.

Gelatin is a unique animal protein product which is devoid of tryptophan and is also limiting in all other IAA. This complete lack of nutritional value has not stopped some individuals from using it as the basis for weight-loss drinks. After several illnesses and deaths were associated with the use of these products in very-low-calorie diets, Canada introduced a requirement that any product containing gelatin or collagen or hydrolyzed gelatin or collagen must carry a cautionary statement advising people not to use it as a sole source of nutrition.

Vegetable-protein Products

The Codex Committee on Vegetable Proteins (CCVP) has developed an international general standard for vegetable protein products (VPP). This standard applies to VPP intended for use in foods and prepared by various separation and extraction processes from proteins of vegetable sources except single-cell proteins. The VPP are intended for use in foods requiring further preparation and for use by the food-processing industry. The VPP standard applies to food products produced by the reduction or removal from vegetable materials of the major constituents (water, oil, starch, and other carbohydrates) in a manner to achieve a protein (N × 6.25) content of 40% or more. CCVP has also developed international standards for soy-protein products (flour, concentrate, and isolate) and for wheat gluten. These VPP are extensively used in international trade.

Soybean-protein Products

Soybeans are dehulled and solvent-extracted to remove the oil. The residual solvent is then removed and the flakes dried, resulting in defatted soy flakes. Soybean-protein products are mostly made from the defatted flakes. They are not consumed directly but instead find wide application as versatile ingredients in various food systems, including bakery, breakfast cereals, beverages, infant formulas, enteral nutritionals, dairy, meat, and dairy and meat analogs. They not only boost protein content in these food systems but also provide many functional properties, including gelling, emulsifying, water-holding, and fat-absorbing properties. There are four major types of soybean protein products, including flour, concentrates, isolates and textured soybean protein. The Codex Alimentarius Commission has established international compositional standards for soybean protein flours, concentrates, and isolates.

Soybean flour comes in many types including full-fat, low-fat and defatted, as well as toasted and textured. Defatted soybean flour, the most common type, is produced by grinding the defatted flakes. It has a protein content of about 50% (N × 6.25). The soybean-protein flour is mainly used as an ingredient in bakery products. However, full-fat soybean flour has been gaining popularity in recent years as newer technology has enabled it to be used as a starting material for the production of soy milk and tofu and as an ingredient in many other food systems.

Soybean protein concentrate is traditionally made by aqueous alcohol extraction of defatted soy flakes. The resulting product has a protein content of about 70% (N × 6.25), with the remaining portion being mainly insoluble carbohydrates. The protein

concentrate can be further processed by thermal processing and homogenization for a better functionality. Alternatively, soybean protein concentrate can be made by an acid-leach method to retain isoflavones and other beneficial phytochemicals, and to prevent protein denaturation. Soybean protein concentrate is widely used in the meat industry to bind water and emulsify fat, and as a key ingredient for many meat alternatives. It is also used for protein fortification of various types of food.

Soybean-protein isolate is produced by alkaline extraction of the defatted flour, followed by precipitation at acid pH. As a result, both soluble and insoluble carbohydrates are removed. The resulting product has a protein content of about 90% ($N \times 6.25$), and is light in color and bland in flavor. Soybean protein isolate is the most refined soybean protein product and possesses many functional properties, including gelation and emulsification. Consequently, it may be used in a wide variety of food systems, including processed meat, meat analogs, soup and sauce bases, nutritional beverages, sole-source foods such as infant formulas and enteral nutritionals, and dairy analogs.

Textured soybean proteins are produced by thermoplastic extrusion of soybean protein flour or concentrate under moist heat and high pressure to impart a fibrous texture. The textured products, which come in many sizes, shapes, colors, and flavors, are mainly used in processed meats and snack foods, and as meat alternatives.

Soybean protein products contain a number of antinutritional and bioactive components such as trypsin inhibitors (causing potential adverse effects on pancreatic function and growth in animal models), phytates (causing potential adverse effects on mineral status), phytohemagglutinins (with the unique property of being able to agglutinate red blood cells), and isoflavones (causing potential hormonal and goitrogenic effects). However, residual levels of these naturally occurring bioactive components, and of those formed during alkaline/heat processing such as lysinoalanine (an unnatural amino acid derivative) would be expected to be minimal in properly processed soybean protein products.

Adverse nutritional effects following consumption of uncooked and lightly heat-treated soybean protein have been attributed to the presence of endogenous inhibitors of digestive enzymes (about 56–64 mg per gram of protein of trypsin inhibitor activity) and saponins (0–10 μg per gram of protein) and to poor digestibility. To improve the nutritional quality of soy foods, inhibitors and saponins are generally inactivated by heat treatment or eliminated by fractionation during food processing. Soybean protein products also contain about 1–2% of phytic acid, which has long been recognized to interfere with the absorption of minerals, especially zinc. Phytic acid is stable to cooking and probably is not degraded during texturization by extrusion. Although long considered to be antinutritional factors, because of their estrogenic properties, soybean isoflavones are now of great interest because of their possible role in preventing many chronic diseases. Soy-protein flour has an isoflavone profile approximating that of soybeans (4028–4808 μg per gram of protein). Protein isolates contain reduced levels of isoflavones (690–1096 μg per gram of protein) compared to flours as a result of aqueous processing during manufacture. A concentrate made by aqueous alcohol extraction is very low in isoflavones (73 μg per gram of protein) because the isoflavones are especially soluble in aqueous alcohol and are thus largely removed during processing.

Soybean protein flours, concentrates, and isolates are good sources of all IAA, but some products could be marginally deficient in sulfur amino acids (Table 3). Although the addition of methionine to properly processed soybean protein products consumed by adults has no significant effect on the nutritional value when nitrogen intake is adequate, the addition of methionine to soy milk preparations increases the nitrogen retention by malnourished children and improves the protein quality of soy-based formulas for infants. The PER value of the methionine-supplemented soybean protein products is equivalent to that of casein. Because soybean-protein products have high levels of lysine, they can be used to fortify cereal proteins, which are limiting in lysine.

Wheat Gluten

According to the CCVP specifications, wheat gluten is a food product prepared by the wet extraction from wheat or wheat flours of certain nonprotein constituents (starch and other carbohydrates), in a manner to achieve a protein content of 80% or more ($N \times 6.25$) on a dry-weight basis. Although high in protein digestibility, wheat gluten is drastically limiting in lysine, with a PDCAAS of 36% (Table 4). Therefore, this protein source should not be used as the sole source of protein nutrition. However, the low protein quality of gluten can be improved by the addition of supplementary protein high in lysine, by supplementary lysine, or by protein complementation. (*See* **Protein**: Quality.)

Other Vegetable-protein Products

Besides soy protein products and wheat gluten, processing technology has also been developed for the

Table 3 Protein (on a percentage dry weight basis), IAA compositions, protein quality expressed as PDCAAS, and contents of minor bioactive components in soybean protein products

PDCAAS (%)	36	37	73	50	90

[a]FAO/WHO (1991) Recommended Amino Acid Scoring Pattern (containing, in milligrams per gram of protein included: histidine, 19; isoleucine, 28; leucine, 66; lysine, 58; methionine + cystine, 25; phenylalanine + tyrosine, 63; threonine, 34; tryptophan, 11; and valine, 35.).

preparation of a number of other VPP such as pea-protein concentrate, cottonseed-protein products, sunflower-protein isolate, peanut flour and canola (rapeseed)-protein concentrate (Table 4). However, among these protein products, only the pea-protein concentrate is distributed and used internationally. Pea-protein concentrate is a highly functional and nutritious protein concentrate derived from field peas. Careful processing to prevent protein denaturation has resulted in a wide range of useful functional properties. Moreover, due to its high lysine content, it can be used to greatly improve the nutritional quality of cereal proteins. Pea-protein concentrate has a protein digestibility of about 92% and a PDCAAS of 73%, with tryptophan and sulfur amino acids being the limiting IAA.

Like cereal proteins, sunflower-protein isolate and peanut flour are first limiting in lysine (Table 4). Sunflower-protein isolate has a high protein digestibility of 94%, and peanut flour has a somewhat lower protein digestibility of 91%. The PDCAAS values for sunflower-protein isolate and peanut flour are about 37 and 50%, respectively, because of the low lysine concentration.

In contrast to peanut and sunflower, canola (rapeseed) protein concentrate is one of the more balanced sources of IAA among VPP (Table 4). It is marginally limiting in lysine, and, along with its moderately low

protein digestibility of 92%, this gives it a PDCAAS of about 90%.

The properly processed defatted cottonseed flours (about 60% protein, N × 6.25) (glandless or deglanded (liquid cyclone process)) have a PER equivalent to that of casein. Heat and moisture introduced after removal of lipids significantly decrease the PER. Fractionation of the various types of cellular proteins during isolate preparation also produces both favorable and unfavorable effects. Storage protein isolates (99–100% protein) are low in lysine and the sulfur amino acids, and low in protein quality, but the nonstorage protein isolates (76–85% protein) are high in all IAA and in protein quality (PER > 2.5). The degree of fractionation of the seed proteins and, consequently, the nutritive value of the isolates are dependent upon the extraction characteristics of the flour and on the isolation process. The quality of defatted cottonseed products also depends upon the level of physiologically active or 'free' gossypol. Gossypol is a binaphthyl, dialdehyde, polyhydroxyl pigment which is highly reactive and deleterious to monogastric animals, including humans. All of the gossypol in the seed is in discrete extracellular glands. During processing, the glands usually are ruptured, and consequently, gossypol is either removed with the oil or converted to a physiologically inactive form through interaction with other cellular constituents. Glandless cultivars of cotton seed have also been developed. Edible cottonseed protein products, approved by the US FDA, have a maximum of 0.045% 'free' gossypol. IAA data and PER values of cottonseed-protein isolates are listed in Table 5. The protein quality of the minor, nonstorage-protein isolate is higher than that of the major storage-protein isolate, while the protein quality of the classical protein isolate is intermediate between the nonstorage and storage-protein isolates.

Table 5 Protein (on a percentage dry weight basis), IAA compositions and protein quality expressed as PER of cottonseed-protein isolates

Nutritional parameter	*Nonstorage protein*	*Storage protein*	*Classical*
Protein (%, N × 6.25)	76–86	99–100	92
IAA: expressed as a percentage of the respective IAA in the FAO/WHO (1991) scoring pattern[a]			
Isoleucine	146	121	135
Leucine	120	95	110
Lysine	109	55	82
Methionine + cystine	145	76	100
Phenylalanine + tyrosine	140	152	150
Threonine	114	85	99
Tryptophan	134	109	120
Valine	149	143	145
PER	2.7–3.2	1.3–1.7	2.0–2.2

[a]FAO/WHO (1991) Recommended Amino Acid Scoring Pattern (containing, in milligrams per gram of protein included: histidine, 19; isoleucine, 28; leucine, 66; lysine, 58; methionine + cystine, 25; phenylalanine + tyrosine, 63; threonine, 34; tryptophan, 11; and valine, 35.).

Table 6 PER and PDCAAS values for some properly processed vegetable-protein sources

Product	*PER (casein = 2.5)*	*PER as a percentage of casein*	*PDCAAS (%)*
Rapeseed-protein concentrate	2.6	104	96
Rapeseed-protein isolate	2.4	96	86
Soy-protein isolate	1.7	68	99
Pea-protein concentrate	1.2	48	68
Kidney beans	1.1	44	68
Pinto beans	0.5	20	63
Lentils	0.3	12	52
Peanut butter	1.7	68	52
Sunflower-protein isolate	1.1	44	37
Rolled oats	1.8	72	63
Wheat cereal	1.4	56	40
Wheat gluten	0.9	36	25

As can be seen from Table 6, the PER method of protein-quality determination gives a lower score than PDCAAS for proteins that are low in sulfur amino acids such as soy protein products, beans, and peas. This is because of the higher requirements for methionine and cysteine by rats compared to humans. In contrast, those first limiting in lysine, such as sunflower-protein isolate, have a PER that corresponds closely to PDCAAS.

Addition of beef to vegetable protein sources improves significantly the protein quality of soy, pea, peanut, sunflower and wheat-gluten-protein sources but only marginally improves that of rapeseed (Table 7).

Mycoprotein Products

Mycoprotein is the ingredient name for a food-grade protein source that has been available for food use only since 1985. As the name suggests, this protein is made from a type of fungus, *Fusarium venenatum* (PTA 2684), that was found in the wild and developed specifically for the production of food-grade protein. Mycoprotein production follows a series of steps. The organism is first grown in an aerobic, axenic, continuous fermentation system using food-grade carbohydrate substrates and other components needed for growth. The mycelium of the fungus is then heat-treated to reduce the ribonucleic acid content to safe levels. Single-cell protein sources tend to be high in nucleic acids, which can lead to excessive blood uric acid levels, a problem for people prone to gout. Once

the RNA level is reduced, the suspended solids are centrifuged and recovered in the form of a paste with 75% water content. This is the mycoprotein.

The vegetative growth of fungi, the mycelium, is in the form of hyphae – thread-like cells that permeate the growing medium. In the case of *F. venenatum* (PTA 2684), these hyphae, after the heat treatment, become insoluble and are of a length and diameter that make them suitable for creating products that mimic meats. To do this, binders, flavorings, and other ingredients are added and the mixture further processed to achieve the desired organoleptic and physical properties.

The introduction of this product onto the market required considerable toxicity and nutritional testing because it was a novel food not previously used for human consumption. As part of these tests, the protein quality was evaluated. Based on both PDCAAS and animal and human studies, it was determined that the protein quality of this mycoprotein is similar to that of soybeans. It has now been on the market under the brand name, Quorn™, in the UK and Europe for some 10–15 years and has secured considerable consumer acceptance. It has recently been introduced to the USA.

Mycoprotein is typically 12% water, 3% fat, 3% available carbohydrates, 6% fiber, and 2% ash. B complex vitamins and mineral nutrients are also present in small amounts. The amino acid profile and protein-quality indices are shown in Table 8.

A number of other features make mycoprotein of interest beyond being simply a protein source. It can be modified so as to function as either a fat replacer or a cereal replacer. Clinical studies have found that it can help control blood lipids and blood glucose as well as appetite, effects that may relate to its dietary fiber content.

Leaf-protein Concentrate

Green leaves are protein factories producing good-quality protein. Because of the low concentration, high fiber content, and palatability problems, however, potential sources are rarely exploited for human food use. When leaves are used as food, they are not generally considered important protein sources but rather as vegetables, such as lettuce, spinach, and cabbage. However, some green forage crops produce several times more protein per unit area than grain crops, and there may be circumstances where extracting the protein for direct human use has economic and ecological advantages over feeding it to domestic animals.

Consideration of the possible suitability of this protein for use as human food goes back at least to the 1940s and research to develop a potential product was conducted in the 1960s and 1970s in many parts of the world. In brief, it has been found that leaf-protein concentrate (LPC) can be obtained from harvested leaves by first pressing out the juice. The soluble protein in the juice is then heat-coagulated, the serum drained away, and the solid material dried and powdered. This produces 'whole' leaf protein concentrate (WLPC), which is about 45–60% crude protein, or 34–45% true protein. There are different types of protein in leaves that can be separated by coagulating at different temperatures. The green

[a]FAO/WHO (1991) Recommended Amino Acid Scoring Pattern (containing, in milligrams per gram of protein included: histidine, 19; isoleucine, 28; leucine, 66; lysine, 58; methionine + cystine, 25; phenylalanine + tyrosine, 63; threonine, 34; tryptophan, 11; and valine, 35.).

fraction is dominated by proteins from the chloroplasts, while the white-protein fraction is largely from the cell cytoplasm. The nature of these fractions is such that the white protein appears to be more suitable for incorporation into foods for humans since it is bland-tasting, white or off-white in color, and of a higher protein quality.

Any plant whose leaves can be eaten safely by humans is a potential source of LPC, which can also be used for animal feed. Some of these sources may currently be largely waste material or may be used as animal feed such as cassava leaves, or may be weeds such as dandelions and water hyacinth. Candidates should not have any toxic or antinutritional factors or unpalatable flavors, and preferably should provide high protein yields per unit area, be readily available, and be easy to harvest and process.

Investigations have shown that the amino acid profile of whole-leaf protein is very similar from one plant species to another. Taking alfalfa as an example, the protein digestibility of the WLPC is about 88%, and the amino acid score is 107, giving a PDCAAS of 95. Lysine is the limiting amino acid. The white-protein fraction has a PDCAAS of 100 (109) (see **Table 9**). The WLPC also contains significant amounts of vitamin A precursors, iron, and other nutrients which may be reduced in the white-protein fraction.

While an industrial process for producing WLPC has been developed, there appears to be little, if any, commercialization of this material for human use at present. Efforts have been made to set up facilities in developing countries as a way of converting this underutilized protein and nutrient source to useful, nutritious food and feed.

Microbial-biomass Protein

The original term for protein derived from yeast and bacteria was 'single cell protein.' The term 'microbial-biomass protein' was coined to permit the inclusion of protein from multicellular fungi, such as the mycoprotein described above. The interest in microbial-biomass protein was prompted by the same concerns of global protein shortages that brought about the development of LPC. It was also considered to be a possible way to produce useful food while reducing waste products and surplus raw materials resulting from some types of industrial and agricultural activities such as pulp mill waste liquor. The former Soviet bloc countries had, in the 1980s at least, about 100 plants producing microbial biomass protein, but very few existed elsewhere. The further development of these potential protein sources would seem to depend on the economical availability of a suitable substrate, the assurance that safe food materials are being produced, the lack of other more familiar or accessible alternatives, and the technology and facilities to produce attractive food products.

PULSES

D D Dalgetty, B-K Baik and B G Swanson,
Washington State University, Pullman, WA, USA

Introduction

Of all the plants utilized by man, only grasses are more important than legumes. The term legume comes from the Latin word 'legumen,' which means seeds harvested in pods. *Leguminosae* is the Latin name of the third largest family of flowering plants. Of the 18 000 different species within the family *Leguminosae*, humans consume only a mere 24 species as food. A common name used to identify the food legumes is pulses. Pulse is a word most commonly used in the UK to denote edible legumes that store their energy in the form of starch. Other terms for pulses include beans or starchy legumes. Notable members of the pulses include peas (*Pisum sativum*), chickpeas (*Cicer arietinum*), and the common bean (*Phaseolus vulgaris*). Table 1 gives a list of these and other common pulses with their Latin designations.

Another very important category of food legumes are the oilseeds. As the name implies, these legumes store their energy in the form of lipid rather than starch. The two most common oilseeds are soybeans (*Glycine max*) and peanuts (*Arachis hypogaea*).

Food legumes can be further partitioned into separate classifications based on their growing climates as cool- and warm-season legumes. The four main species of cool-season food legumes are peas,

Table 1 Food legumes Latin and common names

Latin name	*Common name*
Arachis hypogaea L.	Groundnut, peanut
Cajanus cajan (L.) Millsp.	Pigeonpea, red gram, Congo pea, Arhar, Tur, Gongo pea
Cicer arietinum L.	Chickpea, Bengal gram, garbanzo gram
Glycine max (L.) Merr.	Soybean, soya
Lablab purpureus (L.) Sweet	Hyacinth bean, Egyptian bean, Val
Lathyrus sativus L.	Khesari, chickling vetch, grasspea
Lens culinaris Medik.	Lentil, Masur
Lupinus albus L.	White lupine
Lupinus angustifolius L.	Blue lupine, New Zealand blue lupine
Lupinus luteus L.	European yellow lupine
Macrotyloma uniflorum (Lam.) Verdc.	Horse gram, Madras gram, Kulthi
Phaseolus lunatus L.	Lima bean, butter bean
Phaseolus vulgaris L.	Bean, common bean, Franch bean, field bean, haricot bean, pinto bean, navy bean, dry bean
Pisum sativum L.	Common or garden pea, dry pea
Psophocarpus tetragonolobus (L.) DC.	Winged bean, Goa bean, four-angled bean, Manila bean, princess pea
Vicia faba L.	Broad bean, faba bean, horse bean
Vigna aconitifolia (Jacq.) Marechal	Moth bean, mat bean
Vigna mungo (L.) Hopper	Urd, black gram, mung bean
Vigna radiata (L.) Wilczek	Green gram, golden gram, mung bean
Vigna umbellata (Thumb.) Owhi & Ohashi	Rice bean, mambi bean
Vigna unguiculta (L.) Walp. ssp. unguiculata	Cowpea, black-eyed pea, crowder pea
Voandzeia subterranea (L.) Thouars	Bambarra groundnut

chickpeas, lentils, and faba beans. Cool-season legumes are very widespread geographically, with production concentration in temperate and subtropical climates. Some production occurs in the tropics at high altitudes. Cool-season legumes make up nearly 60% of the world pulse production and occupy around 40% of the world area. However, the distribution of each species over this area is very uneven. In developing countries, chickpeas and lentils are dominant in production and are a very common staple of the diet. The other two crops, peas and faba beans, are typically produced in more developed countries. Yields of these crops are much higher than for chickpeas and lentils.

The warm-season food legumes include the common beans and other tropical pulses such as cowpeas, lupines, and pigeonpeas. Aside from the common bean, most warm-season food legumes are produced in small amounts in specific regions. Warm-season legumes are well adapted to harsh conditions such as those in Africa where beans are an essential crop. These species are also very common in the Asian and Mediterranean regions.

Table 2 World production of major food crops (production in thousand metric tons)

Legume	*Total production*	*Developed nations*	*Developing nations*
Soybeans	92,982	64,401	28,581
Groundnuts	18,580	1,801	16,740
Dry beans	14,195	2,116	12,079
Peas	9,807	6,552	3,225
Chickpeas	6,158	346	5,812
Broad beans	4,224	464	5,759
Lentils	1,292	231	1,061

Distribution and Use of Edible Food Legumes

Among the cultivated legumes, soybeans, peanuts, dry beans, peas, broad beans, chickpeas, and lentils are the major crops produced worldwide. The other legumes are produced in more local settings in some countries depending on the climate needed to support the growth and food habits of the population. Table 2 shows the production (in tonnes) of the major food legumes in developed and developing nations. The breakdown of total production of food legumes into regions and countries of the world is illustrated in Tables 3 and 4. In many developed countries, the lack of pulse production is caused by low yields, uncertain harvests, slow maturation, and sensitivity of legumes to growing conditions at all periods of development and loss due to pest damage. Another reason for low production is cost in energy to prepare legumes with ensured digestibility.

Soybeans

Soybeans (*Glycine max* (L.) Merr.) are grown primarily throughout the world as a food crop. Nearly 46% of the world soybean production is in the USA. Other soybean-producing countries include Brazil, Argentina, China, Japan, Korea, India, Indonesia, Thailand, and the Philippines. The highest yields per hectare of soybeans have been achieved in the USA. (*See* **Soy (Soya) Beans**: The Crop.)

Groundnuts or Peanuts

The peanut (*Arachis hypogaea* L.) makes up a large part of the economy in many developing nations where most of its production occurs. The major peanut-producing nations are India, China, and the USA, of which India contributes 30% of the total world production. Peanuts are also produced in

Table 3 Regional food legume production (production in thousand metric tons)

Table 4 Food legume production by nation (production in thousand metric tons)

Nation	*Soybeans*	*Peanuts*	*Other legumes*
World	92,982	18,580	44,701
China	7,477	3,873	6,858
India	650	5,700	11,107
Russia	460	–	6,508
US	61,970	1,561	–
Brazil	12,810	–	3,011
Mexico	672	–	1,430
Ethiopia	–	–	1,002
Trinidad and Tobago	–	–	1,356

most African countries. The highest peanut yields are in Europe, where only small amounts of peanuts are actually produced.

French Beans

French Beans (*Phaseolus vulgaris* L.) are widely cultivated in semitropical regions of the world. The leading producer of beans is Brazil, followed by India, China, the USA, and Mexico. Nearly 50% of the world production occurs in Asia with over 14 000 cultivars.

Peas

Peas (*Pisum sativum* L.) are produced mainly in cool areas. China and Russia contribute about 80% of the world production. *P. sativum* has been divided into the subspecies: *hortense, syracium, absyssinicum, jomardi, elatius*, and *arvense*. Garden peas have been separated into two types: smooth and wrinkled seeded. The wrinkled seeded peas tend to be sweeter than the smooth peas. (*See* **Peas and Lentils**.)

Chickpeas

One of the most important legumes in the developing world is the chickpea (*Cicer arietinum* L.). Among developing nations, India produces nearly 80% of the world production, with other major producers being Pakistan, Turkey, and Myanmar. World chickpea production has seen a decrease in recent years due to reductions in yield. Chickpeas are subgrouped into *Kabuli* and *Desi*. *Kabuli* chickpeas are very large creamy seeds and grow well under irrigated conditions. *Desi* chickpeas are much smaller and produce the best yields.

Pigeonpeas

Pigeonpeas (*Cajanus cajan* (L.) Millsp.) are a very important crop in Asia, Africa, and South America, ranking sixth in total world production of the food legumes, with more than 90% produced in India.

Lentils

The lentil (*Lens culinaris* Medik) is an important crop in developing nations, accounting for only 2% of total world pulse production with 75% of their production in Asia. Several lentil cultivars exist, with differences based on flower color and shape. Lentils are grouped into small and large seeded subgroups. The large seeded lentils are grouped into the subspecies *macrosperma* Baroulina, and the small seeds are grouped into *microsperma* Baroulina. Lentils are grown as a cold-season crop throughout the subtropics of India, North Africa, Central America, and South America. (*See* **Peas and Lentils**.)

Cowpeas

Cowpeas (*Vigna unguiculata* L.) are cultivated for their pods and seeds. The seeds are used as a vegetable and sometimes roasted like peanuts, while the roots are consumed in South Africa. Cowpeas are grouped into 'crowder peas,' 'brown crowders,' and 'black-eyed,' depending on the color of the seed and its arrangement in the seedpod. Cowpeas are produced in Asia, Africa, and the Mediterranean.

Consumption of Food Legumes

Food legumes are distributed throughout the whole world, with different species being popular in different regions. Legume preference for different areas of the world is due to the availability of the food in those areas. Availability results directly from environmental conditions favoring their growth. For people in developing countries of the world, where standards of living are limited due to a lack of buying power, legumes are a crucial part of the diet. Since the prices of other food commodities are unmanageable for the average family, pulses receive an enhanced level of consumption. Although legumes constitute a major portion of the diet in many developing nations, their most prominent use is in the form of feed for animals. In developed nations, where yields are significantly higher, the low market value of legumes provides an inexpensive source of animal feed. The popularity of processed cereal crops and knowledge of the antinutritional effects of legumes in these countries also inhibit the consumption of food legumes.

Africa

Cowpeas and groundnuts are the primary legume crops of West Africa, where consumption of 10–17 g per day per person is not unusual. In the humid, high-altitude regions of Central and East Africa, legume consumption is unusually high. Broad beans, chickpeas, and lentils are staples, with hyacinth beans,

lupines, lathyrus beans, and peas having local importance.

Asia

The leading consumer of legumes in Asia is India, whose average pulse consumption is around 34 g per person per day, with some variation between individual states. The most popular legume of the Indian nation is the chickpea, but pigeonpeas, black gram, mung beans, horse gram, and pea are also very important. In western Asia, popular legumes include beans, chickpeas, lentils, and peas. The haricot bean from America has also been successfully introduced into western Asia. South-east Asians do not consume large amounts of legumes, but a variety are grown for their use as vegetables. In the eastern Asian nations of China, Japan, Korea, and Indonesia, the dominant legume crop is the soybean. Soybeans are the basis of many traditional food products of eastern Asia. Groundnuts and pulses, along with the soybean, are very important foods in Indonesia.

In Asian countries, the consumption of pulses tends to increase with income level. This is primarily due to the predominance of soybeans in eastern Asia, which are of a higher value than most pulses. Typically, legume consumption tends to increase with decreasing income level, but because of the importance of the soybean in so many Asian dishes, the opposite is true. Higher income levels also show an increase in the consumption of animal products, but this does not change the consumption level of soybeans.

Latin America

By far the most predominant food crop of Central America and Mexico is maize, followed closely by the haricot bean. Although many pulses have been introduced into this region, their consumption and production are low. An important commercial crop of this region is the groundnut, which is also consumed in small amounts as a snack.

Pulse consumption in the islands of the Caribbean is much higher than in Central America and Mexico. Pulses such as cowpeas, kidney beans, and pigeonpeas are popular when mixed with cereals in main dishes. Most of the pulse consumption in the Mediterranean is in lower-income families, where as much as 50 g per person is consumed daily.

In most South American countries, legumes are a traditional part of the diet, except in the beef-producing countries of Argentina, Bolivia, and Uruguay. The main pulse crop of South America is the haricot bean, which is indigenous to this region of the world. Other important crops include lima beans and lupines. Chickpeas, lentils, peas, broad beans, and pigeonpeas have been introduced to South America and are quite successful. Another indigenous legume crop of South America is the groundnut, which is grown primarily for oil extraction, but some are consumed whole as food.

Europe

Legume consumption in Europe is rather high in England and in the poor Mediterranean countries (about 5 kg per year or 13–14 g per day) of southern and eastern Europe. The summers in southern and eastern Europe are hot and dry, enabling legume seeds to grow well and at a relatively low cost. Consumption of legumes is substantially lower in central and eastern European countries (about 2 kg per year or 5–6 g per day). However, in France, the average daily consumption of pulses and nuts is around 10 g.

North America

Large quantities of groundnuts are consumed in both the USA and Canada. Most pulses are consumed in the warmer, poorer areas of the southern USA. The highest USA consumption of 24 g per day is in rural nonfarm families of very low income, with the lowest consumption rates in high-income families.

Nature and Composition of Food Legumes

Seed Structure

The seeds of all legumes are generally very similar in structure, with major differences being in the method of energy storage. Pulses store their energy in the form of carbohydrate, and oilseeds store energy in the form of lipid. The major components of mature legume seeds are the seed coat (8%), the cotyledons (90%), and the embryo (2%). Like cereals, legumes do have an endosperm at the early stages of development, but as the seed matures, the energy is stored in cotyledons. The seed coat is the only source of protection for mature legume seeds. Therefore, legume seeds are unusually vulnerable to breakage, which can lead to damage to the cotyledons.

The seed coat and the cotyledons of legume seeds are very tightly attached to one another, which can make hull removal very difficult. The cotyledons of legume seeds, much like the endosperms of cereals, are made up of starch and protein. Within the cotyledon, the most abundant component is starch, which is surrounded near the outside of the cotyledons by protein bodies. The ability to remove the hull from the cotyledons is very important when trying to recover these fractions.

The outsides of legume seeds are typically characterized by three structures, which include the hilum,

the micropyle, and the rhape. The hilum is the point at which the seed breaks away from the stalk and looks like a large oval scar. The micropyle, which is next to the hilum, is a small opening in the seed coat where the pollen tube enters the valve. The raphe is a ridge opposite the micropyle and represents the base of the stalk. The hilum and the micropyle are very important to permeability and water absorption of the seed coat of legume seeds. Both vary in appearance, depending on the size and shape of the seed.

Legume seeds are very similar, but they do differ from each other in color, shape, size, and seed coat thickness. In general, the thickness of the seed coat is directly proportional to the lipid content of the seed. Oilseeds have much thicker seed coats than the pulses, which are starch-rich.

Chemical Composition

With the exception of peanuts, chickpeas, and soybeans, legumes can be described as containing approximately 10% moisture, 21–25% protein, 0.8–1.5% lipid, 60–65% total carbohydrates, and 2.2–4.0% ash. Table 5 illustrates the proximate composition of some commonly consumed food legumes. The energy provided by legumes falls in the range of 345–350 kcal per 100 g. The exceptions which all contain higher amounts of lipid are consequently of a higher caloric value. Along with a high fat content, soybeans contain the highest amount of crude protein of all food legumes. Due to the high protein and fat content of soybeans and peanuts, the total carbohydrate content of these legumes is much lower than in other legume species.

Carbohydrates Carbohydrates of legumes, much like the carbohydrates of other grains, can be divided into water-soluble components, such as sugars and pectin, and insoluble components, such as starch and cellulose. Within both the soluble and insoluble fractions of legume carbohydrates are components that can be used as sources of energy and those that cannot be utilized because they are resistant to human digestive enzymes. (*See* **Carbohydrates**: Classification and Properties.)

The most dominant carbohydrate in most legumes is starch, but some seeds such as winged beans, soybeans, and those seeds containing gum tend to lack starch. Legume starch is located in the cotyledon as granules embedded in a very thick protein matrix. The average size of legume starch granules ranges from 25 to 28 μm, varying between species. The two primary constituents of starch are amylose and amylopectin, which are glucose homopolymers. Starch is the primary storage carbohydrate in legumes, but other carbohydrates such as mono-, di-, and oligosaccharides as well as cyclitols and sugar alcohols have received attention because of their association with flatulence.

The mono- and disaccharide content of legumes is generally less than 4%. Soybeans have been reported to contain as much as 7% sucrose. Among the oligosaccharides found in legumes are raffinose, stachyose, and verbascose. These compounds are galactosides of sucrose containing one, two, and three molecules of galactose, respectively. The human digestive system does not contain the enzyme α-galactosidase, which is required for the digestion of such oligosaccharides. Without the ability to digest these compounds, they are subject to occasional anaerobic fermentation. This results in gas production or flatulence, which can be very discomforting.

The other carbohydrate fraction of legumes is dietary fiber, which is composed primarily of cellulose, hemicelluloses, and lignin. Legumes contain a wide range of unusual storage dietary fibers with unique properties. The water-soluble gums making up the dietary fiber of legumes have the ability to form gels in water, which provides unique cooking characteristics. Both the soluble and insoluble fractions of dietary fiber are very beneficial nutritionally as they play key roles in laxation, blood-glucose attenuation, and blood-cholesterol attenuation.

Protein The protein of legume seeds is located primarily within the cotyledon, with only a small portion present in the seed coat. Quantitatively, legumes are an excellent source of protein, but qualitatively, they have many problems. Probably the most notable problem with legume protein is the lack of sulfur-containing amino acids. Another major problem is the presence of proteinase inhibitors, which lower the digestibility of legume proteins considerably. (*See* **Protein**: Food Sources.)

The amino acid composition of legumes has been widely studied and has shown that lysine levels are very high, while cysteine and other sulfur amino acid

Table 5 Proximate composition of common food legumes

Legume	*Protein (%)*	*Lipid (%)*	*Crude fiber (%)*	*Ash (%)*	*Starch (%)*

contents are quite low. This property makes legumes a natural complement to cereal products, which contain high levels of sulfur amino acids and relatively low levels of the essential amino acid lysine. In general, legumes exhibit a large variation in amino acid content, depending mainly on the environmental conditions.

Legume protein has often been categorized as poor and of low biological value. This has mainly been attributed to the low concentration of sulfur amino acids and poor digestibility. Besides proteinase inhibitors, the poor digestibility of legumes is caused by trypsin inhibitors, lectin, tannins, and phytates. Trypsin inhibitors not only reduce the digestibility of legume protein but also remove a significant fraction of cysteine, which is already low. Lectin is a phytohemagglutinin that combines with cells lining the intestinal wall and causes nonspecific interference with absorption of nutrients. Tannins are known to form complexes with proteins, which decrease the digestibility and amino acid availability. Phytic acid interacts with protein to form phytate–protein complexes that are insoluble. The most efficient way to improve the digestibility of legume protein is through heat processing. By heating in the presence of water, proteins can easily denature and become subject to proteolytic enzymes to aid digestibility. (*See* **Protein**: Quality.)

Lipids In general, food legumes tend to have higher lipid contents than cereals. The lipid content of pulses ranges from 1 to 7%, while soybeans and peanuts contain 20–45% lipids. Due to their high lipid content, soybeans and peanuts are very good sources of edible oil. The fatty acid composition of legumes varies, with the predominant fraction being the unsaturated oleic and linoleic acids. Oils from temperate-zone legumes tend to have more unsaturated fatty acid components than those of the tropic regions. Some legumes also contain considerable amounts of linolenic acid. (*See* **Fats**: Occurrence.)

Vitamins and minerals The vitamin content and availability in legumes vary as a result of both genetic and environmental factors. Legumes are very good sources of B vitamins. The thiamin contents of legumes are usually equivalent to, or higher than, those of cereal grains. Legumes contain small amounts of riboflavin but tend to be a good source of nicotinic acid. The pantothenic acid content of legumes is less than that of cereal grains, but in comparison with most common foods, legumes are good sources of folic acid. In general, legumes contain very small amounts of vitamins.

The mineral content of legumes is in the range of 2.5–4.2%. The most predominant mineral found in legumes is phosphorus, averaging around 300 mg per 100 g. The calcium and iron contents of legumes are variable, but in general, legumes are good sources. Minerals are more concentrated in the seed coat of legumes than in the cotyledons, but because of the size of the cotyledon, most of the total mineral content is found in this fraction.

Antinutritional factors The most prevalent antinutritional factors in legumes are those dealing with protein, but there are also a number of other factors that decrease the nutritional value of food legumes. One such factor is the presence of goitrogens in oilseeds. Goitrogens are thioglycosides or glucosinolates that react with iodine and lead to the formation of goiter in humans. This effect can be counteracted in soybeans by heating, but not in peanuts. Another problem with legumes is the presence of mineral chelating agents such as phytic and oxalic acid. This can lead to a decrease in the availability of certain trace minerals, thus causing anemia. (*See* **Plant Antinutritional Factors**: Characteristics.)

Cyanogenic glycosides that are naturally present in legumes can be cleaved by the action of the β-glucosidase enzyme producing cyanide, which is a toxicant. Other antinutritional compounds in legumes include α-amylase inhibitors, saponins, allergens, and toxic amino acids that have been known to exhibit antivitamin and antihormonal activity.

Processing and Food Use of Legumes

Storage of Food Legumes

Food legumes are stored at all levels from farmer to trader in various types of storage units until the next season's harvest. Farmers generally retain a portion of their harvest for family consumption, for seed, and for animal feed. In developing nations, legume storage is done at the trader and government levels as insurance against future crops of low yield or poor quality and against fluctuation in price and market demand. Losses of legume seeds due to storage are quite high in comparison to other crops. These losses are the result of physical, biological, and engineering factors. Physical factors causing loss are temperature, moisture, and oxygen concentration. Biological causes of loss are birds, rodents, insects, mites, bacteria, and yeast. Engineering factors resulting in loss are storage structures and process handling equipment.

Food Uses of Legumes

Typically, the leaves, stalks, and seed coats of legumes are used as animal feed in many underdeveloped

countries of the world. These parts of the plant are generally not used as human food at a household level but may find use in some bulk products. Humans usually consume legumes in the form of whole seeds in a variety of ways. One of the most common ways in which legume seeds are consumed by humans is in the form of a dhal. A dhal is a legume seed that has been physically or mechanically separated at the cotyledon, resulting in dehusked, split cotyledons that are then soaked in water and cooked. Cooked dhals are seasoned appropriately and consumed with cereal-based products such as bread or cooked rice. Seasoning for legume seeds varies considerably by region, with common seasonings being onion, garlic, cilantro, green chilies, ginger root, black mustard seeds, cumin seeds, anise seeds, coriander, and turmeric. To prepare these dishes, the seeds and seasonings are heated separately and then mixed and boiled, resulting in a soup-like product. In addition to this common method of consumption, a variety of different products are prepared from food legumes.

Soaking legumes in water is often the first step to prepare the seeds for consumption or processing. Seeds are usually soaked for up to 24 h to loosen the hulls and help remove antinutrients such as tannins, oligosaccharides, and β-glysosides. In many cases, food legumes are germinated to form sprouts. Legume sprouts are a very important part of the diet in the Far East. By germinating legumes, the flavor and nutritional properties of the seeds are improved through the breakdown of antinutrients and phytic acid, which leads to flatulence.

Another legume process traditionally used in Africa and Asia is milling or removal of the outer portion of the seed. Milling occurs at all levels from the home kitchen to large-scale commercial operations. Prior to milling, legume seeds are often pretreated using wet and dry methods to aid in hull removal. The wet method involves mixing legume seeds with small amounts of water, followed by draining and sun drying. The dry method, commonly used in India, involves sun drying legume seeds that have been treated with oil and a very small amount of water. Both methods cause shrinkage of the endosperm, thus loosening the seed coat for easy removal by milling. The resulting legume flour is used to make a variety of breads and pastries.

One of the oldest methods of food processing that is often used with food legumes is fermentation. In many parts of the world, fermented legume products serve a very important function in the diet. Most fermented legume products are widely used in Asia and India but are rapidly gaining popularity in the western hemisphere. Legume-based fermented products are popular because of their texture and organoleptic characteristics. By fermenting legumes, it is possible to eliminate undesirable flavor, improve digestibility, prolong shelf-life, and increase the safety of the food. Popular legume-based fermented products include soy sauce, shoyu, miso, sufu, natto, and tempeh. Food legumes are also very popular in the canning industry. Most of this is the increased popularity of refried beans, soups, and other ready-to-eat dishes.

Byproduct Processing

Whole legumes, although produced and used widely throughout the world, have a low market value in comparison to other food commodities. To increase the value of legumes, some processors isolate functional byproducts from whole seeds. By far the most popular legume byproduct, due to its high availability, is protein. Legume protein concentrates and isolates are prepared by air classification and solvent solubilization. Air classification is a physical method in which legume flour is separated by density into a protein concentrate and a starch-rich fraction. In solvent solubilization techniques, soluble protein is removed from insoluble material by centrifugation, followed by an acid precipitation. Other byproducts of food legumes include starch and dietary fiber, which can be used to fortify and increase the functionality of various food products.

QUALITY ASSURANCE AND QUALITY CONTROL

P J Molnar, Central Food Research Institute, Budapest, Hungary

Background

A principal factor in the performance of a food enterprise is the quality of its products. There is a worldwide trend towards more stringent customer expectations with regard to food quality and safety. Accompanying this trend has been a growing realization that continual improvements in quality are often necessary to achieve and sustain good economic performance.

Today, every customer demands quality from their supplier. In particular, the last customer in the chain of suppliers and customers – the consumer – has increasingly placed vociferous demands on quality in the sense that (1) the future of the world will not be endangered by harm to the environment resulting from food production and (2) the consumer will suffer no economic damage or injury to health as a result of the consumption of food components.

Definition and Description of Food Quality and Safety

The quality of food can be defined as a composite of characteristics which affect the ability of foods to satisfy definite requirements and which determine its fitness for consumption.

Quality in this sense can be discussed under three headings:

1. Sensory quality, the basic characteristics of which are the product's color, appearance, texture, tenderness, juiciness, taste, and smell; these characteristics, being easily perceptible, are the basis of evaluation and preference on the part of consumers. (*See* **Sensory Evaluation**: Sensory Characteristics of Human Foods.)
2. Nutritive value, which determines the content and level of essential nutrients (biological value), some microbial components (e.g., desirable lactic bacteria), energy content, dietary value, digestibility, and availability. (*See* **Bioavailability of Nutrients**.)
3. Convenience and technological quality, characterizing the easy handling and functionality of a food product, to manufacturers and tradesmen and then to consumers; these qualities are based on characteristics such as shelf-life, processing level, good price–quality relation, durability, ease of storage and transportation, dimensions, functionality, and usefulness in the production of definite food products. (*See* **Storage Stability**: Mechanisms of Degradation; Parameters Affecting Storage Stability; Shelf-life Testing.)

Wholesomeness, also called food safety or food hygiene, may be defined as the result of all conditions and measures that are necessary during the production, processing, storage, distribution, and preparation of food to ensure that it is safe, sound, wholesome, and fit for human consumption. The aim of all these conditions and measures is to protect the health of people as consumers and to ensure fair practice in the food trade.

The wholesomeness of food determines its fitness for consumption, the classification of which should be based on specified sanitary criteria. The bases of these criteria are the assumptions that a food product must not (1) be harmful to human health, (2) have undergone deterioration (spoilage), (3) have been adulterated, and (4) have been produced, distributed, or stored under improper sanitary or physical conditions.

Factors harmful to food consumers include the following:

1. Pathogenic microorganisms and their toxins.
2. Pathogenic parasites and products of their metabolism.
3. Foreign substances, or their degradation products, with toxicity to humans. (*See* **Parasites**: Occurrence and Detection; **Spoilage**: Bacterial Spoilage; Molds in Spoilage; Yeasts in Spoilage.)

In relation to pathogenic microorganisms and parasites, there is an obligatory sanitory rule, which states that they must not occur in foods owing to their decisively negative influence on human health. Foreign substances may be differentiated as follows:

1. Food additives introduced intentionally to foods to improve their utilization quality, and
2. Technical and accidental contaminations present in food as residues resulting from technological processes or environmental pollution. These include toxic metals, pesticides, medicines, fodder supplements (premix), and growth stimulants. (*See* **Contamination of Food**; **Food Additives**: Safety.)

The main components of food quality and safety are shown in Figure 1.

Role of Quality Assurance and Quality Control

Quality assurance can be characterized by the quality loop for processed food (Figure 2). Quality assurance is consistent only if the origins of lack of quality are eliminated, or the emergence of faults is excluded from the beginning: problems result in, rather than originate from, exceeded limits of contamination, adulteration, etc. The quality-assurance system is based on the following:

1. Product planning and development, including the results of marketing and market research.
2. Education and training for management and quality staff as well as for each counterpart.

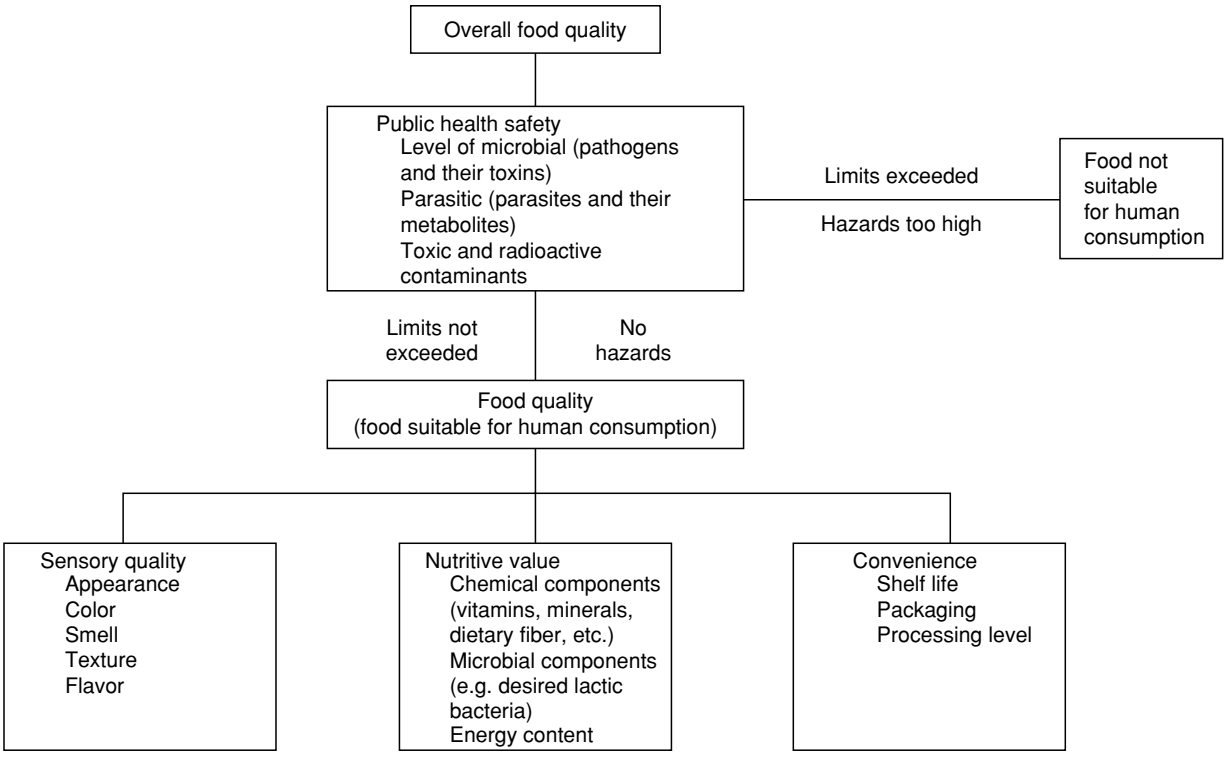

Figure 1 Main components of food quality and safety.

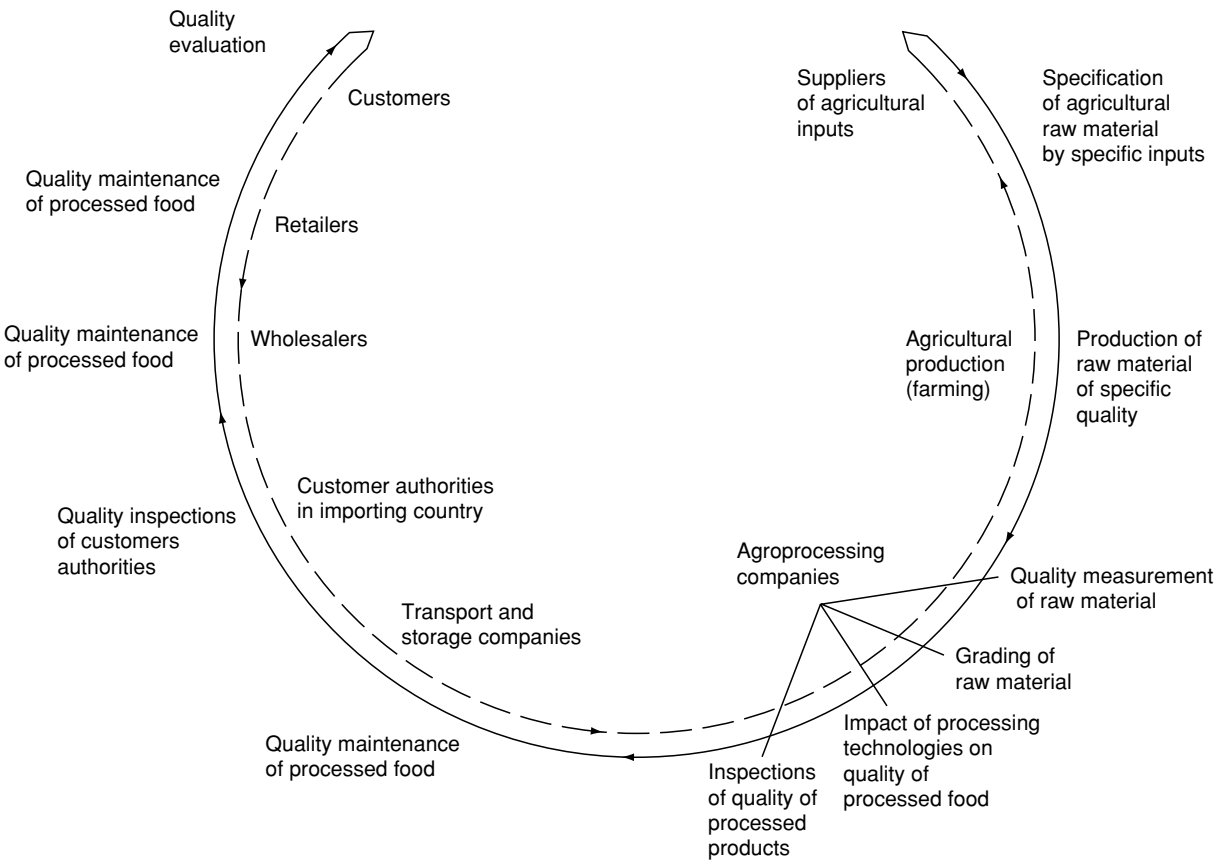

Figure 2 Quality loop for processed food: flow of products and flow of information on quality requirements. ———, main food chain; — — background information flow.

3. Application of a statistical control method and sampling inspection plan in process control and for final inspection.
4. Responsibility for the quality in each step of the quality loop.
5. Use of an information and motivation system on product quality.

Assisted by the internal quality system of a company and with additional commitment from the external quality partners (suppliers and customers), the product-oriented quality-assurance system is structured in the following steps:

1. Definition of requirements and responsibilities with regard to the quality of individual activities, processes, and materials.
2. Definition of the desired properties and required parameters of the product.
3. Definition of materials, technologies, packagings, storage conditions, number and qualification of personnel, etc.
4. Analysis of possible sources of faults and factors affecting quality.
5. Definition of the quality-assurance actions: information, education, training, motivation, parameters of investigations, methods of analysis and sampling documentation, etc.
6. Risk assessment and hazard analysis critical control point (HACCP).
7. Definition of responsibilities for certain quality-assurance actions.

Appropriate quality-control procedures should be part of the process to ensure product safety and quality and hence part of the company quality assurance system. Figure 3 shows the quality control of food manufacturing, including inspection and laboratory investigation, in a general flow chart.

All plant operations should be controlled by written procedures and records of performance data. The range and complexity of procedures vary, depending upon the size and scope of the operation. However, management personnel of even the smallest operation should be aware of the need for quality control consistent with the type of food products being manufactured, stored, or distributed. In larger, more complex operations, the inspector should determine whether

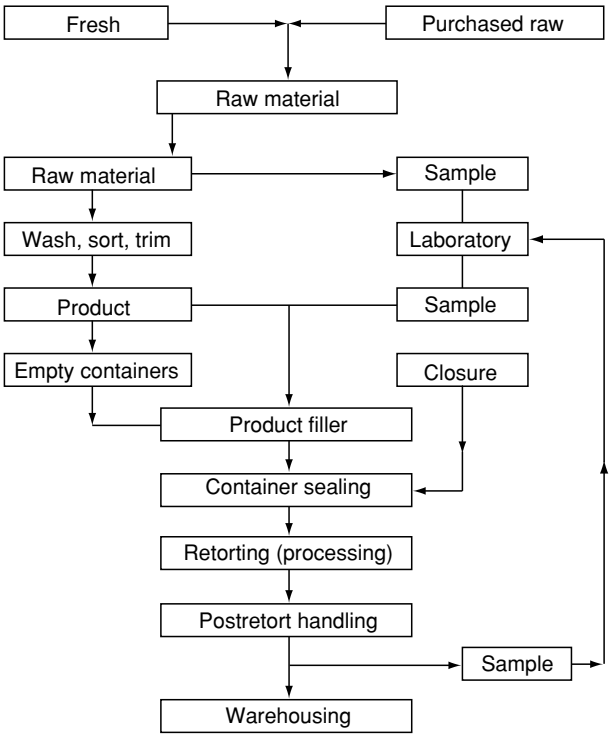

Figure 3 General flow chart including quality control.

written control procedures exist and should review records detailing results of quality-control testing relating to product safety or other factors where regulatory requirements exist.

The quality-control department analyses any planned production changes. Final approval for production should not be given until all quality-control records have been reviewed and properly endorsed by the quality-control management team.

Laboratory personnel and equipment must be evaluated to determine whether or not they are able to carry out all their responsibilities under the firm'sspecifications and existing regulations. Laboratory inspection should include spot checks of in-process controls made by personnel on the production lines.

Implementation in Food Production (Good Manufacturing Practice)

The guidelines on good manufacturing practice (GMP), elaborated and published initially for drugs, were later modified for human foods and oriented mainly to food safety. The formulated criteria apply in determining whether or not the facilities, methods, practices, and controls used in the manufacture, processing, packing, or holding of food conform with, or are operated or administered in line with, GMP to ensure that food for human consumption is safe and has been prepared, packed, and held under sanitary conditions.

More recently, systematic, rule-based approaches to quality assurance have been widely applied, most notably that based on the HACCP program. Such techniques provide ways of applying our current knowledge of microbial ecology of food in a systematic manner to ensure that nothing is overlooked and that the risk of microbiological food contamination is minimized. (*See* **Hazard Analysis Critical Control Point**.)

The HACCP program includes an assessment of potential microbiological, chemical, and physical hazards, prescribes the elimination of avoidable hazards, and sets tolerances for the hazards that cannot be eliminated in the processing of food. It defines the appropriate control measures, the tests to be carried out, and the criteria for product acceptance. It gives a rational systematic documented procedure which can be used for organizing and implementing the entire quality-assurance program.

However, GMP includes not only food safety, but also, as a part of the quality-assurance system, the application of product specifications. The specification for a product is usually the description of the requirements with which the product has to comply. These can have a regulatory, commercial, or in-house basis. Specifications are an integral part of product development, manufacture, marketing, and sales. From primary producer to the retail trade, each industry has its own specific requirements in the description of the following characteristics of their products:

- name;
- product description;
- specific properties;
- sensory attributes;
- chemical parameters;
- physical data;
- microbiological parameters;
- shelf-life;
- storage conditions;
- packaging and labeling;
- handling;
- proper sampling and test methods.

From a company viewpoint, specifications can have an internal and external function. The internal function comprises purchasing criteria, incoming goods control, and recording of knowledge and information in a systematic and accessible way. The external function includes sales criteria, sampling procedures, and quality control of finished products. It simplifies

functional contacts between companies and can serve as a base for product comparisons. This has led to the development of quality system standards and guidelines that complement relevant product requirements given in the technical specifications.

The International Standards Organization (ISO) 9000 series of standards set by the ISO embodies a rationalization of the many and various national approaches in this sphere which must be applied in adequate form under the circumstances of the food industry. According to this standard, an increasing number of food companies have a quality-assurance handbook or quality manual covering the following main topics:

1. General quality policy.
2. Description of the quality system and the responsibilities and interrelationships of all operating and staff functions.
3. General description of quality planning requirements, with specific details for each product category where appropriate.
4. Policy requirements for specific elements of the system (relating to GMP) and procedures which implement these policies.

The quality manual is of direct benefit not only to the producer (e.g., cost reduction, help in product liability cases, or improved competitively), but also to the consumer, who will perceive its effect as a high level of quality that will be produced and maintained by the application of an integrated and documented quality-assurance system.

Food-quality and safety programs in many countries are currently in a period of reevaluation and change. Risks to consumers resulting from hazards in food largely depend on the means available to prevent, eliminate, or reduce the risks to acceptable levels through the food chain. Management of foodborne risks in these terms is a complex independent activity, and risk-management strategies must include consideration of all options, including general approaches such as adherence to GMP, good agricultural practice, good veterinary practice, consumer education, and labeling.

Total quality management (TQM) is a modern term to describe how firms are becoming more successful today. The results of TQM are significant in productivity gains, unit cost reduction, elimination of most consumer complaints, and winning consumers by always giving them what they expect. TQM based on GMP and HACCP includes quality assurance and quality control as well as problem-solving by team work, and by the quality tools, risk management, cost of quality and rewards.

Implementation in the Food Laboratory (Good Laboratory Practice)

Whereas quality assurance of the work performed by laboratories was formerly based largely on confidence in the individual laboratory and in individual members of staff, a more formalized requirement has recently been developed for factual documentation of quality in the results of the investigations presented. In this respect, the work has proceeded largely along international lines where, for example, the ISO has been extremely active.

Incorrect results from a laboratory may have serious health or economic consequences as a result of an unsuitable food incorrectly being assessed as suitable, or by unnecessary rejection of an acceptable food. To ensure reliable analytical results and avoid mistakes, the laboratories must continuously check and improve the quality of analytical work.

The quality manual, which consists of general advice for 'quality assurance,' should be supplemented with more detailed regulations for individual laboratories. Consequently, it is recommended that each laboratory prepare its own quality-assurance directives in a quality manual as a supplement to the general principles. A quality manual is individual and therefore differs from laboratory to laboratory, and so each laboratory needs to prepare its own manual. However, the following information is necessary in almost every case:

1. Requirements placed on the laboratory: staff (management, experts, chemists, physicists, microbiologists, etc.); premises (type and extent of the activities); apparatus (equipment, instruments, etc.); glassware and plastic equipment; chemicals, gases, and solvents.
2. Sampling (sampling and sampling staff do not necessarily belong to the laboratory).
3. Sample reception at the laboratory: marking and keeping records; storage of samples before and after analysis.
4. Sample preparation.
5. Selection of methodology.
   - *Defining method* (type I) is one which determines a value that can only be arrived at in terms of the method *per se* and serves for calibration purposes.
   - *Reference method* (type II) is designated where type I methods do not apply. It should be selected from type III methods and should be recommended for use in cases of dispute and for calibration purposes.
   - *Alternative approved method* (type III) is one which meets the criteria required by the Codex

Committee on Methods of Analysis and Sampling for methods that may be used for control, inspection, or regulatory purposes.

- *Tentative method* (type IV) is one which has been used traditionally or else has been recently introduced but for which the criteria required for acceptance by the Codex Committee on Methods of Analysis and Sampling have not yet been determined.

6. Documentation and reporting: registration; laboratory register; analytical documentation; use of computers and electronic data processing; method description.
7. Quality assurance of analytical results: acceptance criteria for an evaluation of analytical results; standard substances, recovery tests, and reference materials; repeated determinations; intercalibration and collaborative tests; control chart.

The intention with a quality manual is to provide a general survey of the factors that influence analytical reliability at the food laboratories. The implementation of good laboratory practice and the guidelines should be of value to all the staff working within the laboratory and should inspire the creation of efficiently operating quality-assurance systems for laboratory work within the food companies. (*See* **Analysis of Food**.)

QUINOA

S A Valencia-Chamorro, Escuela Politécnica Nacional, Quito, Ecuador

Introduction

Quinoa is a typical crop of the Andean region. It has been cultivated since ancient times, and was a staple food of the Inca empire. However, production of quinoa was almost completely reduced after the Spanish conquest; foreign grains were widely produced instead.

During the 1970s, initial interest in the crop was increased. At the same time, higher plantation areas for cultivation of quinoa in South America and new markets for the grain in the USA and Europe were developed. Thus, quinoa is now of great interest to the scientific world, and it may become a food for the future.

The origin of quinoa and its distribution in the Andean region have been reviewed, as well as its actual distribution in North and South America and Europe. It is important to mention the strong and dedicated interest in cultivating this grain outside the borders of the former Inca empire. Classification of the grain, cultivation practices, and morphology of the plant have been described.

Quinoa has been recognized as an extremely nutritious grain all over the world thanks to both the high quantity and good quality of its protein content as regards its essential amino acid content. Thus, an extensive review of the chemical composition and nutritional value of quinoa has been made, including its main nutritionally disadvantageous factors.

Finally, several traditional and new forms of using quinoa have been described. Some future perspectives with regard to the germplasm collection, agronomic and agricultural practices, postharvest and industrial uses of this promising grain, which has been called the 'mother grain,' have been included.

Origin and Distribution

Quinoa (*Chenopodium quinoa*, Willd) is an indigenous crop of the Andean region of South America. It is one of the oldest crops of the American continent. Archeological findings in northern Chile showed that quinoa was used prior to 3000 BC. In Ayacucho, Peru, evidence has been shown that quinoa was cultivated before 5000 BC.

The quinoa plant was widely cultivated in the entire Andean region, in Colombia, Ecuador, Peru, Bolivia, and Chile, before the Spanish conquest. However, habits and traditional foods of natives were substituted by foreign crops such as wheat and barley. Therefore, quinoa was cultivated either in small plantations in rural areas for domestic consumption or as borders for other crops such as potatoes or maize. For that reason it was classed as food for poor people.

Quinoa is grown in the highlands from 5°N in southern Colombia to 30°S in north-eastern Argentina. At sea level, it is cultivated between 36 and 40°S, in central Chile.

In the late 1970s the main production areas of quinoa were widely described in Colombia, Chile, the Andean valleys in Peru, Altiplano in Bolivia and Peru, and the highlands of Ecuador. In Peru and Bolivia, this crop has been of great importance. It is cultivated not only for domestic consumption but also for export. Common efforts made by governments and research institutes have contributed to increase the production of quinoa in Andean countries. The cultivation of quinoa has now spread from the Andean region to several countries in the world. In the 1980s, in the USA, quinoa was cultivated in the Colorado Rockies. Nowadays, it has became a commercial crop. In the UK, in 1989 quinoa was grown commercially. In Manitoba, Canada, quinoa was grown for domestic consumption; farmers expected to have a viable crop for Canada. Quinoa was introduced to Denmark in 1984. Further improvements in the crop could make quinoa a promising new crop for European agriculture.

In order to promote the regional interchange of the excellent genetic material of quinoa among research institutes and universities, an American and European trial of quinoa was undertaken in the late 1990s. In the project, sponsored by the Food and Agriculture Organization (FAO: regional office for Latin America and the Caribbean), 25 cultivars selected from 10 different countries were tested: eight from Peru, four from Bolivia, two from Ecuador, the UK, Denmark, and Chile respectively, and one each from Argentina, Brazil, Colombia, and The Netherlands. The best cultivar from each country taking part in the experiment was used as a local control. Therefore, it is expected to be able to identify, evaluate, and select promissory genotypes of quinoa with high yield, and to provide the technological knowledge of cultivation practices and production of

quinoa suitable for the agroecological and food requirements of the producer and national consumer.

Classification

Quinoa belongs to the Chenopodiceae family, genus *Chenopodium*. Its botanical name is *Chenopodium quinoa*, Willd. Common names used in the Andean region are: quinua, kiuna, parca (Ecuador, Peru, Bolivia); supha, jopa, jupha, jiura, aara, ccallapi, vocali (Bolivia); quinhua (Chile); and suba, pasca (Colombia).

The classification of quinoa was first made from the color of the plant and fruits. Subsequently it was based on the morphological types of the plant. Despite the wide variation observed, quinoa is considered to be one single species. For practical reasons, quinoa, like maize, was classified as a race.

The most extensive collection of different races of quinoa belongs to Peru and Bolivia; each has over 2000 ecotype samples. However, other collections do exist in Argentina, Colombia, Chile, Ecuador, England, the USA, and the Former Soviet Union.

Quinoa collected in Ecuador, Peru and Bolivia has been classified into 17 races; however, more races may exist. Two types of inflorescence are described:

1. Glomerulates – small groups of flowers (glomeruli) originate from tertiary axes
2. Amaranthiformes have glomeruli originating mainly from secondary axes

According to this, the races of quinoa are classified as follows: first, glomerulate inflorescence: Cajamarca, Copacabana, Cuzco, Challapata, Cochabamba, Sicuani, Junín, Ancash, Glorieta, and Dulce; second, amaranthiforme inflorescence: Achacachi, Puno, Real, Potosi, Puca, Sucre, and Pichincha.

Quinoa grows from sea level to the Andean highlands. Thus, one of the most useful classifications is that describing five ecotypes: sea-level, valley, subtropical, salar, and altiplanic (Table 1).

Cultivation Practices

The cultivation of quinoa is related to the crop rotation seen in potatoes. This is the usual practice that improves quinoa yield and preserves soil fertility. Moreover, the biological cycle of several pathogenic microorganisms is broken down. Together with residues of fertilizer previously applied to the crop, nitrogen is sometimes applied. Cultivation of the quinoa plant requires loose soil that can retain an adequate amount of moisture.

Quinoa tolerates a wide range of acidic conditions of the soil, from pH 6.0 to 8.5. The plant is not affected from around $-1\,^{\circ}C$. However, it tolerates high temperatures not above $35\,^{\circ}C$. Quinoa is frost-resistant when the frost occurs before flowering; after that significant damage may occur. Quinoa flowers are sensitive to frost. Quinoa is drought-resistant. It is able to develop even in regions where annual rainfall is in the range 200–400 mm.

The planting season varies from August, in the Andean highlands, extending through December, and in some areas from January to March. Seeds may be spread, but weed control and mechanized practices become difficult. Quinoa is planted in rows (row spacing range 40–80 cm) when mechanized agriculture practices are used. In dry areas, seeds can be deposited at the bottom of the furrows; once

Table 1 General categories of quinoa

Ecotypes	*Location*	*Growth altitude (m)*	*Varieties*	*Characteristics*
Sea-level	South of Chile	< 500	Chilean varieties	Unbranched, long day plants, yellow, bitter seeds
Valley	Andean valley	2000–4000	Blanca de Junín, Rosada de Juní, Amarilla de Matangani, Dulce de Quitopamba, Dulce de Lazo	Big plants, branched, short growth period
Subtropical	Subtropical area of Bolivia (Yungas)	2500–3000		Plants with intense green color that turns orange as they mature; small seeds, white or orange
Salar	Bolivian Salares	3700–3800	Real	Plants adapted to salty and alkalinic soils; bitter seeds; high saponin content
Altiplanic	Area around Lake Titicaca	3500–4000	Cheweca, Kancolla, Blanca de Julí	Short plants with straight stems; short growth period; resistant to frost

planted, the seeds are covered with soil. When rain is more abundant, seeds are deposited on the top of the ridge.

Sowing density may vary according to the region. It has been reported from 0.4 to 0.6 g m^{-2} in Bolivian Altiplano, from 0.5 to 2.3 g m^{-2} in Puno, and from 0.8 to 1.4 g/m^{-2} in Ecuador. A density of 1.2 g m^{-2} has been recommended in Puno for mechanical drilling. However, sowing density could be related to the climatic conditions of the region where it is cultivated.

At physiological maturity quinoa is harvested. The grains become dry and hard, making it difficult to break them with a finger nail. Physiological maturity may be reached within 70–90 days after flowering. Depending on the variety, it takes between 5 and 8 months for a plant to mature.

Traditional harvesting is done manually. The plants are either pulled or cut with a sickle, then placed in windrows to dry completely. Threshing is performed by rubbing the panicles by hand against a stone or using threshing on the floor with sticks, animals, or vehicles followed by winnowing. Mechanical threshers have been applied using stationary threshers, some of which are adapted from those used for cereals. The yield of quinoa can be in the range of 45–500 g m^{-2} depending on the variety and growing conditions.

The most important fungus disease is downy mildew (*Peronospora farinosa*), which requires high humidity and temperature as ideal conditions to grow. However, it succeeds in low humidity and low temperature (6–10 °C) found in the north Altiplano. The main symptom is chlorotic lesions on the upper surfaces of the leaves, with a white or purple mycelium on the lower surfaces.

The disease brown stalk rot is produced by *Phoma exigua* var. *fovaeta*. Low temperature, high humidity, and wounds in the plant, such as those produced by hail, favor the growth of pathogen. Dark brown lesions with a vitreous edge (5–15 cm) on the stem and inflorescence are the main symptoms. The stem is often shrunken, the plant may become chlorotic, and progressive defoliation toward the apex may occur.

Kcona kcona (*Scrobipalpula* sp.) is probably the most serious pest of quinoa. When drought periods and high temperatures are present, insects attack intensely. Larvae destroy first leaves and inflorescence. Later on, when the plant is mature, larvae destroy the panicle and grains. Sometimes, a white powder around the base of the plant is seen as a result of grain destruction. Treatment is performed just before harvest to prevent contamination of seeds and consequently postharvest losses.

Morphology of the Plant

Quinoa is not a true cereal grain: it is a pseudocereal, which is dicotyledonous. In contrast, cereals are monocotyledonous. In spite of that, the composition of cereals and quinoa is similar as regards the main components.

Quinoa, as a plant, grows 1–3 m high (Figure 1). The seeds can germinate very fast, in a few hours after being exposed to moisture. Roots can reach depths of up to 30 cm. The stem is cylindrical (3–5 cm diameter); it can be either straight or with branches, and its color is variable. Depending on the variety it changes from white, yellow, or light brown to red. Leaves are shaped like a goose's foot. They are formed by petioles and lamina; petioles are long-channeled on their upper side. Lamina is polymorphous in the same plant; rhomboidal or triangular in the lower lamina of leaves, triangular or lanceolate in upper leaves.

The flowers are incomplete; they do not have petals. Quinoa has both hermaphrodite flowers, located at the distal end of a group, and female flowers located at the proximal end. Quinoa inflorescence is full of bunches (racemose), which emerge on the upper part and do not have branches. The arrangement of flowers in raceme is considered to be the panicle; the length of the panicle varies from 15 to 70 cm high. Flowers can be clustered in different forms – either amaranthiforme or glomerulate.

Figure 1 (see color plate 124) Quinoa plant. Courtesy of Ing. Carlos Nieto C. Pronaleg-Iniap.

Quinoa is a fruit of the Chenopodium family. The fruit of quinoa is an achene. It produces small, circular-shaped seeds, about 2 mm diameter (250–500 seeds per gram: Figure 2). It is covered by perigonium, which is the same color as the plant: white, yellow, gray, light brown, pink, black, or red. It is easily removed when it is dried. Another two layers enclose the seed. Pericarp adheres to the seed; it contains saponins which confer the bitter taste characteristic of quinoa. Episperm encloses the cylindrical seed as a thin layer. The embryo can be up to 60% of the seed weight. It forms a ring around the perisperm. The high protein content in quinoa, unlike cereals, is explained by the high proportion of embryo.

Figure 2 (see color plate 125) Quinoa seeds. Courtesy of Silvia Valencia Ch.

Chemical Composition and Nutritional Value

The diet of ancient inhabitants of the Inca empire has generated interest due to its extremely nutritious quality. Quinoa seeds contain carbohydrates, protein, fat, minerals, and vitamins. The chemical composition of quinoa depends on the variety and the environment of its cultivation.

Quinoa seeds

Protein The protein content of quinoa seeds varies from 8 to 22%, which on average is higher than common cereals such as rice, wheat, and barley (Table 2). However, it presents less than 50% of the protein found in most legumes. In quinoa, most of the protein is located in the embryo.

In pseudocereals, such as quinoa, albumins and globulins are the major protein fraction (44–77% of total protein), which is greater than prolamins (0.5–7.0%). Using a modified Osborne's method, a protein fraction of quinoa was reported – 75.1% of albumins + globulins and 19.4% of glutelins (insoluble); no prolamins were found. Thus, quinoa is considered to be a gluten-free grain because it contains very little or no prolamin. Quinoa provides a nutritional, economical, easy-to-prepare, flavorful food source which is of particular relevance for people with gluten intolerance, such as those with celiac disease.

Quinoa has a good balance of the amino acids that make up the protein. It is exceptionally high in lysine (Table 3), an amino acid which is not overly abundant in the vegetable kingdom. It is also a good complement for legumes, which are often low in methionine and cystine.

The nutritional evaluation of quinoa protein has been reported in several studies. The protein

efficiency ratio (PER) in raw debittered quinoa was 78–93% that of casein. These figures increased when quinoa was cooked, and became 102–105% those of casein. Similar results were found when quinoa from the San Luis Valley of Colorado was used. Thus, the quality of protein in quinoa matched that of the milk protein casein. (*See* **Amino Acids**: Metabolism; **Protein**: Quality.)

Carbohydrates The major component in quinoa is carbohydrates, which varies from 67 to 74% of the dry matter. Starch is about 52–60%. The starch compound is located in the perisperm of the seed; starch can be present as simple units or as spherical aggregates. The amylose content is about 11%, which is lower than in cereals, for example, rice (17%), wheat (22%), and barley (26%).

The diameter of quinoa starch granules is in the range of 0.4–2.0 μm. Starch granules in quinoa are smaller than those reported for maize (range 1–23 μm) and for wheat (2–40 μm). Small-granule starches exhibit a higher gelatinization temperature; for quinoa the gelatinization temperature range is 57–64 °C. Other carbohydrates are found in small amounts, such as monosaccharides (2%) and disaccharides (2.3%), crude fiber 2.5–3.9%, and pentosans 2.9–3.6%. (*See* **Carbohydrates**: Classification and Properties.)

Fat, vitamins, and minerals Quinoa contains from 2 to 10% fat. Quinoa and soya oils exhibit similar fatty acid composition; thus, quinoa is a rich source of essential fatty acids such as linolenic (18:2*n*-6: 52%) and linolenic (18:3*n*-6: 4%). Quinoa is a good source of minerals. It contains more calcium, magnesium, iron, and zinc than common cereals, and the iron content is particularly high (Table 4). Polishing and washing quinoa seeds reduce the mineral content to some extent 12–15% in the concentration of iron, zinc, and potassium, 27% loss of copper and 3% loss of magnesium. Quinoa contains more riboflavin (B_2) and α-tocopherol than rice, barley, or wheat (Table 4). Quinoa seeds can be a source of vitamin E.

Nutritional disadvantages Saponins and phytic acid are the main disadvantageous factors in quinoa. Other inhibitors, trypsin inhibitor, and tannins are present in low levels.

Trypsin inhibitor in eight varieties of quinoa (range 1.36–5.04 TIU mg^{-1}) was lower than for soybean (24.5 TIU mg^{-1}). Trypsin inhibitor is a thermolabile compound which is inactivated by heat treatments.

Polyphenols (tannins) are present in small amounts (0.53 g 100 g^{-1} in whole quinoa seeds), which are reduced after scrubbing and washing with water (0.23 g 100 g^{-1}).

Saponins A bitter taste compound called saponin is located in the outer layers of quinoa seeds. This protects them from birds and insects.

Saponins are glycoside compounds which occur in two groups. According to the nature of the sapogenin moiety they are conjugated with hexoses, pentoses, or uronic acids. The sapogenins are steroids (C27) or triterpenoids (C30). Using a gas chromatography method, the sapogenins oleanolic acid, hederagenin, 30-*o*-methylspergulagenate, and phytolaccagenic acid are identifiable in sweet and bitter genotypes of quinoa.

Quinoa saponins are soluble in methanol or water. They have strong detergent properties which form very stable foam in water solutions, and reduce the superficial tension of aqueous solutions. They also show hemolytic activity and are in general toxic to cold-blooded animals which obtain oxygen directly from water. Saponins are also present in common foodstuffs such as peanuts, asparagus, garlic, onion, and spinach.

The amount of saponins present depends on the variety of quinoa. It is higher in bitter-flavor varieties than in sweet, or low-saponin, varieties. Quinoa comprises saponins from 0.1 to 5%.

The saponins of quinoa seeds are reduced to low levels after dry polishing and washing with water. These levels are apparently nontoxic to humans.

The reduction of plasma cholesterol and bile salt concentration has been attributed to the presence of certain saponins in the diet. However, some saponins can form insoluble complexes with minerals, such as zinc and iron, which make the minerals unavailable for absorption in the gut.

Phytic acid Phytic acid (myoinositol 1,2,3,4,5,6-hexakis dihydrogen phosphate) is found in most cereals and legumes at concentrations of 1–3% dry matter. It is also found in some fruits and vegetables.

In cereals, phytic acid is located in the germ. In quinoa seeds, phytic acid is located in the external layers as well as in the endosperm. It has been reported that mean (value) phytic acid concentration, in five varieties of quinoa, was 1.18 g $100\,g^{-1}$.

Studies *in vivo* and *in vitro* have shown that phytic acid interferes with mineral absorption in the gut of humans, because of its ability to form insoluble complexes with divalent minerals such as iron, zinc, and calcium. Even small amounts (0.5 μmol g^{-1}) of inositol hexaphosphate or pentaphosphate may reduce the solubility of iron.

Inositol hexaphosphate (IP_6) was mainly found in varieties from Ecuador: sweet INIAP-Tunkahuan (11.3 μmol g^{-1}) and bitter INIAP-Ingapirca (8.6 μmol g^{-1}). These figures were almost completely reduced to 0.3 μmol g^{-1} after fermentation of the germinated quinoa flour. At the same time a five- to eightfold increase in the amount of soluble iron was found.

Quinoa Leaves

The leaves of quinoa are compared to spinach as regards flavor. Quinoa leaves are cooked as a green vegetable or used raw in salad. Leaves contain (on a dry basis) carbohydrates 4.8 g 100 g^{-1}; protein 3.3 g $100\,g^{-1}$; fat 1.8 g $100\,g^{-1}$; ash 3.3 g $100\,g^{-1}$, fiber 1.9 g $100\,g^{-1}$. The protein concentration of quinoa leaves is similar to spinach; however, it contains slightly more isoleucine (5.8 g $100\,g^{-1}$ protein) and valine (7.5 g $100\,g^{-1}$ protein). The amount of fatty acids such as palmitic (16:0; 16.7%) and stearic (18:0; 1.3%) is higher than in the grains. Quinoa leaves are a rich source of vitamin A: they contain 2085 μg RE (retinol equivalents) $100\,g^{-1}$ (fresh wt), and vitamin E 2.9 mg α-TE (alpha-tocopherol) $100\,g^{-1}$. Fresh quinoa leaves contain more magnesium (83 mg $100\,g^{-1}$ fresh wt) and sodium (289 mg $100\,g^{-1}$ fresh wt) than spinach leaves. Using a gas chromatography method, sapogenins were detected in the leaves of four sweet and bitter genotypes of quinoa. Sapogenins increased as the plant matured. After 120 days of sowing, the sapogenin content on the leaves of sweet genotypes varied between 0.013 and 0.017 g $100\,g^{-1}$ (dry matter) and in bitter varieties varied between 0.02 and 0.16 g $100\,g^{-1}$ (dry matter). Hederagenin was the major sapogenin present in the leaves. (*See* **Phytic Acid**: Properties and Determination; Nutritional Impact.)

Uses

Quinoa has a natural seed coating containing saponins, which encases the seed and confers the bitter taste which is characteristic of quinoa. Saponins must be removed before consuming. External coatings are removed using either a wet or dry process. The traditional wet process used in rural areas is hand scrubbing in alkaline water. This process is used on a commercial scale; it involves abrasive dehulling to remove the external coverings, followed by a thorough washing. However, this method has economical and ecological restrictions: the water demand is high and waste water is contaminated with saponins, which are toxic to cold-blooded animals. Moreover, wet seeds must be dried immediately, or they may germinate after a few hours in wet conditions.

A dry method is also used. The seeds are scrubbed and polished in order to remove, as fine powder, external coatings. The equipment used to polish other grains has been adapted for use with quinoa seeds, with excellent results. This method presents several advantages; no water is needed, no heat treatment to dry the seeds is required, and no environmental contamination is produced. This method is best suited to sweet varieties (low saponin content) of quinoa.

A combination of dry and wet processes is applied to bitter varieties (high saponin content) of quinoa. Saponin is first removed by polishing, when most of the saponin is removed. Then, saponins that remained in the seeds are washed with water, followed by a dry

process. Any of the processes described above makes the quinoa ready for use by the consumer or further processing such as grinding.

After removing the saponins, quinoa seeds can be boiled in water (15–20 min) and served as a grain. Cooked seeds swell to about two or three times their original size. Seeds become transparent, with tiny white bands circling across the midsection.

In Chile, Ecuador, Peru, and Bolivia, the whole seeds are used in soups, salads, casseroles, chilli and stew, as well as roasted and ground in several kinds of desserts.

Quinoa can be eaten as a rice replacement, as a hot breakfast cereal, or boiled in water to make an infant cereal. The seeds can even be popped like popcorn. Seeds can be ground and used as a flour, or sprouted. The sprouts need to turn green before they can be added to salads.

Quinoa flour can be mixed with maize or wheat flour. Several levels of substitution of quinoa flour have been reported, for instance, in bread (10–13% quinoa flour), noodles, and pasta (30–40% quinoa flour) and sweet biscuits (60% quinoa flour). All yield products of excellent quality. Quinoa flour can also be drum-dried and extruded, providing products with good physical, sensorial, and nutritional qualities. Solid-state fermentation of quinoa with *Rhizopus oligosporus* Saito was performed, giving a good-quality tempeh.

In Bolivia, in 1975, the government adopted a resolution mandating that 5% of quinoa flour must be added to all pastas, crackers, and breads.

Leaves, like the seed, can also be cooked, made into a spinach-like dish, or may be served raw in a salad. Tonics, puddings, and syrups can also be prepared from the leaves. The foaming qualities of saponin are sometimes used to produce a frothier chicha.

In industry, saponins from quinoa have multiple purposes. They are used as soap for washing hair or clothes, in a compound for a fire extinguisher, or in photo processing. Dried stalks of the plant are used as fuel, or may be used in preparing bleach or dyes.

Future Perspectives

The nutritional excellence of quinoa has been known since ancient times in the Inca empire. Nowadays, quinoa has been recognized for its nutritional benefits all over the world, and for its protein, mineral, and vitamin content.

The importance that quinoa could play in nutritional behavior is being emphasized, not only in developing countries but also in the developed world. In the Andean countries, quinoa crops could play an important role in the future of their economies, giving a new export market, as well as in national subsistence. Moreover, quinoa could be a strategic crop used to complement the diet in rural/marginal regions where energy-protein malnutrition affects most of the population of the developing countries. Quinoa, as the 'mother grain,' represents an exotic and healthy rediscovery in the developed world.

Germplasm collection should continue in countries of the Andean region. Agronomic research, including plant density, potential cultivation, phenology, morphology, physiological maturity, yield, and weed control, should be performed. Further research is needed in order to study the adaptability of different cultivars to 'new homes of quinoa' in the USA and Europe. Using mechanized agriculture may facilitate mechanical harvesting of the grain, reducing post-harvest losses.

Improving methods for removing saponins without significant modification of nutritive value are encouraged. The selection of sweet genotypes with a very low saponin content in the seeds, large grain, and high yield are the main breeding goal. Sweet genotypes could be selected early in plant development in order to speed up the selection process. Further research is needed to find markers for indirect selection for sweet genotypes.

The need for intensive cultivation of quinoa should be emphasized; this could meet quality and quantity needs by the food industry. Besides, aggressive promoting campaigns should be carried out to encourage greater consumption of the grain. Finally, quinoa is been promoted as an extremely healthy food – a supergrain – of the future (gluten free). It is a food of the twenty-first century.

RADIOACTIVITY IN FOOD

J F Diehl, Karlsruhe, Germany

Principles

Radioactivity is the process of spontaneous disintegration of unstable atomic nuclei, a process associated with emission of ionizing radiation. Radioactive substances, of natural origin or man-made, are present in all foodstuffs. This article describes the radionuclides of interest and considers the internal radiation exposure of man resulting from incorporated radionuclides. The relative contribution of natural and man-made radionuclides to the resulting effective dose is discussed.

Naturally Occurring Radionuclides

Radioactive species of certain elements are continuously formed in the upper atmosphere by interaction of cosmic radiation with elements present in the atmosphere ('cosmogenic radionuclides'). Thus, carbon-14 (^{14}C) and tritium (^{3}H) are produced by interaction of cosmic-ray neutrons with nitrogen. They disintegrate, ^{14}C with a half-life of 5730 years, ^{3}H with a half-life of 12.3 years, emitting electrons or β-*radiation*. (The *half-life*, also called the physical half-life or radioactive half-life, is the time required for the disintegration of half of the atoms of a given radioactive substance.) The unit of radioactivity is the becquerel (Bq); 1 Bq corresponds to one nuclear disintegration per second. Formerly, the Curie unit (Ci) was used; 1 Ci equals 3.7×10^{10} Bq.

Other radioactive species were formed in the nuclear processes associated with the earth's origin ('primordial radionuclides'). A representative of this group is potassium-40 (^{40}K), which disintegrates with a half-life of over 10^{9} years, emitting electrons and γ *radiation*, an electromagnetic radiation. The adult human body (70 kg) contains about 13 kg of carbon with 3000 Bq of ^{14}C, 50 kg of water with 20 Bq of ^{3}H, and 140 g of potassium with 4300 of Bq ^{40}K. The major cosmogenic and primordial radionuclides and some of their properties are listed in Table 1. The α *radiation* emitted by some of the radionuclides listed in the table consists of particles containing two protons and two neutrons (i.e., helium nuclei).

With regard to the cosmogenic radionuclides and ^{40}K, data concerning activity concentrations in foods and in the human body are rather uniform in the whole world, whereas the radionuclides of the uranium and thorium series may be present at considerably higher levels (compared with Table 1), depending on local geological conditions. The population living along the Kerala coast of India, for instance, has an annual intake of 40 Bq of radium-226 (^{226}Ra) and 2000 Bq of radium-228 (^{228}Ra), and similar intakes are found in the population of the volcanic Minas Gerais area of Brazil. Another case of elevated intake relates to aboriginals of uranium-rich areas of Western Australia, where the annual intake of lead-210 (^{210}Pb) from the carcasses and offal of sheep and kangaroos can be as high as 3000 Bq. Arctic lichen accumulate polonium-210 (^{210}Po), and reindeer graze mostly on lichens in the winter, so that a further accumulation occurs in reindeer meat. Laplanders consuming reindeer meat may have a 10-fold higher intake of ^{210}Po than populations of the temperate latitudes. Refer to individual foods.

Table 1 Radionuclides naturally occurring in foods

Radionuclide	*Radiation emitted*	*Half-life*	*Concentration in foods*	*Annual intake (Bq per person)*	*Human body weighing 70 kg contains (Bq)*
Cosmogenic					
Carbon-14	β	5730 years	230 Bq per kilogram of C	20 000	3 000
Tritium	β	12.3 years	0.4 Bq per kilogram of water	500	20
Beryllium-7	γ	53 days	2 Bq per kilogram of leafy vegetables, 3 Bq per kilogram of cereals	1 000	
Sodium-22	β/γ	2.6 years		50	
Primordial

Source: UNSCEAR, 1982 and 1993 Reports, updated from other sources.

The occurrence of certain natural radionuclides in food plays a role in analytical methods. Fossil fuels do not contain ^{14}C or tritium, because their age is much greater than those radionuclides' half-lives. This is of interest in food control because adulterations of alcoholic beverages with synthetic ethanol, natural vinegar with acetic acid, or plant extract flavoring with synthetic flavors can be recognized by a lower ^{14}C and ^{3}H content of the synthetic product. (*See* **Adulteration of Foods**: Detection.)

In contrast to α and β radiation, which cannot penetrate matter deeply, γ radiation has a high penetrating power. The ^{40}K in a body can thus be determined by measuring γ radiation outside this body. Whole-body counters for humans and animals are available that permit measurement of ^{40}K and other γ-emitting radionuclides. Since adipose tissue is more or less free of potassium, lean body mass can be determined in this way. The principle can also be used for nondestructive estimation of the fat content of meat.

Much of the knowledge of metabolism in animals and plants is based on tracer studies with radioactively labeled substances. In radioimmunoassays (RIA), which permit extremely sensitive analyses of veterinary drugs, anabolics, pesticides, bacterial toxins, and many other substances in food, and in the RAST inhibition (radioallergosorbent test) for detection of food allergens, radioactive labeling is utilized, usually with tritium. (*See* **Analysis of Food; Immunoassays**: Radioimmunoassay and Enzyme Immunoassay; **Protein**: Synthesis and Turnover.)

Man-made Radionuclides

Consequences of Atmospheric Explosions of Nuclear Weapons

Since the first nuclear test explosion in the desert of New Mexico on 16 July 1945, large amounts of radioactive fission products have been released into the stratosphere and have eventually settled on the earth's surface as 'nuclear fallout.' Short-lived radionuclides such as ^{131}I, a β and γ emitter with a half-life of 8 days, disappeared quickly, whereas long-lived species remained in the biosphere for many years, the most important species being ^{90}Sr, a β emitter with a half-life of 29 years, and ^{137}Cs, a β and γ

emitter with a half-life of 30 years. The total release of ^{90}Sr and ^{137}Cs by atmospheric tests was about 600 and 960 PBq, respectively (P, peta $= 10^{15}$). Fallout radioactivity in food reached a peak in 1964, when an agreement between the former Soviet Union and the USA to stop atmospheric nuclear weapons tests became effective. This is demonstrated in Figure 1 for ^{90}Sr in total diet samples collected in New York City. The majority of nuclear weapons tests were carried out in the northern hemisphere. The extent of radioactive contamination was therefore considerably lower in the southern hemisphere, as shown for Argentina.

Yearly averages of specific activity of radiocesium and radiostrontium in total diet samples from Germany are shown in Figures 2 and 3, respectively. Results obtained during the 1960s and 1970s in other countries of the north 30–70° latitudes, which received the highest fallout deposits, were similar. After the peak of 1964, cesium activity (Figure 2) decreased faster than strontium activity (Figure 3). This was a consequence of binding of cesium ions to clay minerals in the soil, which makes this element rather unavailable to the roots of plants, whereas the uptake of cesium ions deposited on the leaves of plants is quite rapid. In most soils, the availability of strontium is much higher than that of cesium. Uptake of ^{90}Sr ions through plant roots continued long after deposition of fallout had decreased to below a measurable level; indeed, it continues even today, so that the present food supply still contains traces of the radiostrontium deposited in the 1950s and 1960s. The distribution of strontium and cesium in the human and animal body resembles that of calcium and potassium, respectively. In vertebrates, radiostrontium accumulates in the bones, whereas radiocesium is rather evenly distributed in muscle tissue.

Consequences of Nuclear Accidents

A severe accident occurred on 10 October 1957 at the Windscale Works, later known as Sellafield, in northwest England, when a graphite fire broke out in a uranium reactor primarily designed for production of plutonium. The accident released 740 TBq of ^{131}I, 22 TBq of ^{137}Cs, 0.07 TBq of ^{90}Sr and other radionuclides (T, tera $= 10^{12}$). Authorities restricted the consumption of milk in an area of 500 km^2 for various periods of time. Environmental monitoring of radioactivity was not well developed at that time, and the extent of contamination remained largely unknown.

The accident at the Three Mile Island reactor in Pennsylvania, USA, on 28 March 1979 released less than 1 TBq of ^{131}I and no ^{90}Sr or ^{137}Cs. Radioiodine at barely detectable levels was found in some foods produced in the area.

According to information provided by the former Soviet Government, the catastrophe of the Chernobyl reactor on 26 April 1986 released 260 PBq of ^{131}I, 38 PBq of ^{137}Cs, 18 PBq of ^{134}Cs, 8 PBq of ^{90}Sr, 5 PBq of ^{241}Pu, and large quantities of many other radionuclides during a period of 10 days. Shifting winds carried the radioactive clouds over various parts of the former Soviet Union, Scandinavia, Central Europe, the Balkan countries, and Turkey. The dominant radionuclide during the first 2 weeks was ^{131}I.

Cows' milk in some parts of Austria, Germany, and Switzerland reached activity concentrations of several hundred becquerels per liter during the first week of May. Owing to its short half-life, radioiodine disappeared quickly from the environment, and the two cesium nuclides became dominant. As shown in Figure 3, the levels of ^{90}Sr were little affected in Central Europe. Released radionuclides of low volatility, such as plutonium, were deposited mostly in the near vicinity of the accident site.

The results presented in Figure 2 allow a comparison of radiocesium in total diet after the Chernobyl accident with that observed at the time of atmospheric testing of nuclear weapons. The data of the preChernobyl years represent ^{137}Cs alone (measurable levels of ^{134}Cs were not present in the fall-out from weapons tests), whereas those of the first postChernobyl years also show ^{134}Cs, which – owing to its short half-life – had fallen to below measurable levels by 1990. It may seem surprising that Figure 2 indicates a higher radiocesium ingestion in 1987 than in 1986. This is mostly due to the fact that in 1986, radioactivity from Chernobyl played a role only from May to December. With the exception of milk and fresh fruit and vegetables, most of the food and feed consumed in 1986 came from the harvest of 1985; only when the preChernobyl supplies of grain, potatoes, and frozen and canned foods had been largely exhausted, was the peak daily intake of 11 Bq of ^{137}Cs and 5 Bq of ^{134}Cs reached in March 1987.

Activity concentrations of ^{137}Cs in various foodstuffs in the years 1986 and 1996 are presented in Table 2, with the natural ^{40}K-levels for comparison. As in Figure 2, the data are based on the situation in

Table 2 Typical activity concentrations of ^{137}Cs in various foodstuffs of the postChernobyl harvest (1986) in Germany, compared with annual (arithmetic) mean concentrations in the year 1996, and with concentrations of ^{40}K

Food	*Bq per kilogram fresh weight*		
	^{137}Cs (1986)	*^{137}Cs (1996)*	*^{40}K*

the Federal Republic of Germany. In all areas, the local deposition of Chernobyl fallout varied considerably, mostly depending on the amount of rainfall during the critical days ('washout effect'); the radioactivity in crops and animal products differed accordingly, samples taken in southern Germany generally showing two- to fivefold higher contamination than those taken further north. In Switzerland, milk produced in the Kanton of Ticino had 10 times higher activity concentrations of ^{131}I and radiocesium than milk from the area around Geneva. Data given in the 1986 column of Table 2 can therefore only serve as a rough approximation. In field crops and products obtained from farm animals, the ^{137}Cs concentration had returned to the preChernobyl level by 1996; venison, wild growing mushrooms and blueberries, and fish from the Baltic Sea still showed elevated levels of radioactivity, although these do not seem to be high when compared with the natural levels of ^{40}K. Accumulation of cesium in mushrooms is species-dependent; in the first years after the Chernobyl accident some species, such as *Xerocomus badius*, reached radiocesium levels of many thousands of becquerels per kilogram in some samples, whereas other species growing in the same habitat accumulated very little radioactivity. The sometimes very high concentrations of radiocesium in venison are at least partly, perhaps primarily, due to consumption of mushrooms by the animals. High radiocesium activities in wild growing blueberries and other species of forest berries are probably due to the generally more acidic pH of forest soils, which makes cesium more available to absorption by plant roots.

Radiation Exposure from Incorporated Radionuclides

Natural Exposure

Radioactivity alone, measured in becquerels, does not provide enough information to evaluate possible risks associated with the intake of radionuclides, because one becquerel of one radionuclide does not usually have the same biological effect as one becquerel of another radionuclide. It is the amount of energy deposited in living tissues that primarily determines the possible biological effects of radiation. The radiation energy imparted per gram of tissue, the type of radiation (α, β, γ), the distribution of the particular radionuclide in the body and its rate of excretion, and the different vulnerability to radiation of different tissues and organs must all be taken into account. Following procedures developed by ICRP (the International Commission for Radiological Protection), the *effective dose* can be calculated, taking all these factors into consideration. It was formerly called the 'effective equivalent dose;' it is an approximate measure of the actual ('effective') risk of genetic and somatic radiation damage to man during the remaining life time. For brevity it is simply referred to as 'dose' in the following discussion – unless the full term is required for clarification. The dose unit is called the sievert (Sv), and 1 Sv is defined as 1 J kg^{-1}.

Following the ICRP procedure, the annual dose caused by ingestion of various naturally occurring radionuclides has been estimated to be 380 μSv for adults (world-wide average), with ^{40}K making the largest single contribution (Figure 4). A comparison of Figure 4 with Table 1 shows that the radionuclides of the uranium and thorium series contribute significantly to the ingestion dose in spite of their low activity concentration in the diet. This is partly due to the higher vulnerability of biological systems to α radiation as compared to β and γ radiation, but the long biological half-life of some of these α emitters also plays a role. (*Biological half-life* is the time required for the human or animal organism to eliminate half of a given substance).

It would be difficult – and not advisable – to try to achieve a total ingestion dose of much less than 380 μSv by resorting to special diets. Potassium (and with it ^{40}K) is an essential mineral under close homeostatic control in the body. Carbon (and with it ^{14}C) is contained in all foods. The elements of the uranium and thorium series are present in most foods of plant

or animal origin, although at very low concentrations. Populations living in areas where the soils are rich in uranium/thorium minerals or individuals regularly consuming reindeer meat, brazil nuts, or shellfish can reach annual exposure levels of 1000 μSv.

Ingested radionuclides are not the only source of radiation to which man is inevitably exposed. Inhalation of the natural radionuclides ^{222}Rn and ^{220}Rn causes an annual dose of 1000 μSv (Figure 4). This must be seen together with an annual external dose of f650 μSv, of which 250 μSv come from cosmic radiation and 400 μSv from terrestrial radiation, for instance the gamma radiation emitted from ^{40}K present in the soil and in building materials. The dose from ingested natural radionuclides thus contributes 19% of the total dose of 2030 μSv from all natural sources.

Actual dose levels can vary widely above and below the average values presented in Figure 4. The contribution from cosmic radiation increases with increasing altitude; that from terrestrial radiation and from inhalation fluctuates considerably with local geological conditions. In Switzerland, for instance, the average dose from cosmic radiation is 350 μSv, from terrestrial radiation 450 μSv and from inhalation 1600 μSv; the internal dose of 380 μSv contributes 14% to the total dose of 2780 μSv from all natural sources. Recent studies from several countries tend to assign higher dose contributions to inhalation of radon, sometimes also to cosmic and terrestrial radiation, with the effect of lowering the contribution from ingestion to 12% and even less.

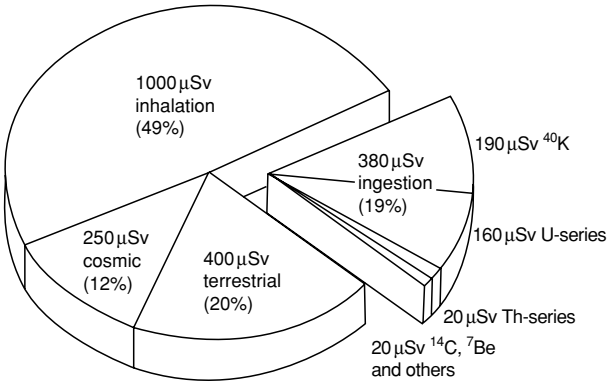

Figure 4 Effective dose from natural sources of radiation. The dose from incorporated radionuclides contributes 19% of the total of 2030 μSv per person.

Man-made Exposure

The average intake of ^{137}Cs from fallout in 1964 reached 9 Bq per day in Central Europe (Figure 2), or 3280 Bq in the whole year. For adult individuals, this meant an effective dose of 46 μSv. The daily intake of 1.1 Bq of ^{90}Sr (Figure 3), or 400 Bq per year, added 14 μSv. In all, the intake of fallout radioactivity up to 1985 in adults living in Central Europe resulted in a lifetime dose of 240 μSv from ^{137}Cs and 160 μSv from ^{90}Sr.

The effect of the Chernobyl disaster on the internal dose received by adults in the Federal Republic of Germany during the years 1986–1993 is demonstrated in Table 3. The data were calculated from the intake (Bq per year) with total diet (Figures 2 and 3), using the ICRP's conversion factors. For comparison, the external dose from radiocesium deposited on the ground is also shown. Inhalation of radionuclides occurred only during the few days when the radioactive cloud was present, and the dose resulting from inhalation was negligible, compared with that from ingestion and from external radiation. An ingestion dose of 3 μSv caused by ^{131}I during 1986 was not included in the table, because radioiodine had disappeared after a few weeks. It should be noted that a small part of the exposure caused by ^{137}Cs and a large

Table 3 Annual effective dose from ingestion and from external exposure to man-made radionuclides (adults, Germany)

Calendar year	*Ingestion dose (μSv per person)*				*External dose resulting from radiocesium (μSv per person)*
	^{137}Cs	*^{134}Cs*	*^{90}Sr*	*Sum of columns 2–4*	
1986	21.5	14.6	4.4	40.5	70
1987	37.8	22.0	3.3	63.1	30
1988	9.2	5.4	2.2	16.8	25

1990	2.5	1.7	2.9	7.1	20
1991	1.8		1.6	3.4	19
1992	1.6		1.5	3.1	18
1993	1.2		1.6	2.8	17
Total	80.1	45.9	20.3	146.3	220

Source: Federal Research Center for Nutrition, Karlsruhe, data bank 'Leitstelle Umweltradioaktivitöt.'

part (around 90%) of that caused by ^{90}Sr originated in the nuclear test fallout of the 1960s rather than the Chernobyl accident. Except for the year 1987, the dose from external radiation was always higher than that from ingestion, and the relative importance of external exposure will grow as time progresses. Disregarding the contribution from ^{90}Sr and adding that from ^{131}I, the ingestion dose attributable to the Chernobyl accident reached about 129 μSv by 1993 and is unlikely to exceed a total of 140 to 150 μSv in the future. In the UK, the average effective dose resulting from ingestion of radionuclides from Chernobyl has been estimated to be less than 20 μSv. These calculated lifetime doses are small compared with an *annual* dose of 0.38 mSv from ingestion of natural radionuclides. They are also small compared with the ICRP *annual* dose limit of 1 mSv for the general public. The large regional variations in deposition and in activity concentrations of groups of foodstuffs observed in Germany, Switzerland, and other countries were not reflected in similarly large variations of the internal radiation dose. Even farm families nowadays buy much of their food in supermarkets, where products from many parts of Europe and from overseas are offered. As a result, ingestion dose levels in different areas of one country rarely differ by a factor of more than two.

A dissimilar situation prevails in the area surrounding the accident site. There, the highest contribution to the effective dose received during the first year came from external gamma radiation (50%), and about 25% each from inhalation and ingestion. The radionuclide contributing the highest fraction of the total dose was ^{131}I. Retrospective calculations indicate that some 270 000 living in an area of 10 000 km^2 have received a total dose of > 50 mSv, most of it during the first year. The former Soviet Government set a 'temporary dose limit' of 100 mSv (combined internal and external) for the population during the first year after the accident. In an effort to minimize the number of persons exceeding this limit, some 135 000 people were evacuated from a 30-km zone around the reactor. For various periods of time, the sale of various locally produced foodstuffs was restricted. Among the inhabitants who stayed or returned in the meantime, those living in towns could purchase uncontaminated food brought in from other regions. However, many of the people in the area live on small farms, and they and their domestic animals eat crops from their farms. Radiocesium in the soil of the family farm is now the main source of human contamination. As a consequence of high ^{131}I-exposure during the first few weeks after the accident, both from inhalation and food intake (especially milk), the incidence of thyroid cancer in children and adolescents has sharply increased in the more severely affected areas of Belarus and the Ukraine in the years since 1990, with a less pronounced increase in the bordering area of the Russian Federation. Other consequences reported in the media, such as an increased incidence of leukemia or other forms of cancer, have not been confirmed by scientific investigations. However, since the peak in the incidence of radiation-induced cancer may occur more than 10 years after the exposure, final conclusions concerning the long-term health effects attributable to radioactive contamination must await the results of ongoing epidemiological studies.

Regulation and Control

Most countries have established systems of governmental control of environmental radioactivity in the 1960s, including surveillance of food. In Europe, the EURATOM Treaty, which came into effect in 1958, obliged member countries to organize the surveillance of radioactivity in air, water, and soil, and to report the results annually to the European Commission. Milk was later included in the system, followed by certain other foodstuffs. After the Chernobyl accident, many national and regional authorities had taken steps to limit the intake of man-made radionuclides by setting maximum permitted levels of activity concentration in foods. These limits varied widely, and such variations did not inspire confidence in a wary public. The Commission of the European Communities announced a European Community Regulation on 31 May 1986, setting the following limits for radiocesium (i.e., ^{137}Cs plus ^{134}Cs): milk and milk products 370 Bq l^{-1}, baby food 370 Bq kg^{-1}, all other foods 600 Bq kg^{-1}. These limits initially applied only to foods imported into the EC, but were subsequently applied also to the internal market. Some countries outside the EC adopted more stringent standards, some going so far as to require the complete absence of ^{134}Cs and ^{137}Cs or even – forgetting the presence of natural radionuclides – 'zero radioactivity.' This caused considerable difficulties in world food trade. In an effort to overcome the confusion, the Codex Alimentarius Commission has proposed the Guideline Levels cited in Table 4. A higher dose per unit intake factor (Sv/Bq ratio), as it applies to the α-emitting nuclides of americium and plutonium, demands a lower Bq kg^{-1} limit than the lower intake factor of the γ emitters, with the bone-seeking β emitter ^{90}Sr taking a position in between. Because of the high sensitivity of the young thyroid to radioiodine, the limit for ^{131}I in infant food and milk is lower than in food destined for general consumption.

Table 4 Codex Alimentarius Guideline Levels for radionuclides in foods

Dose per unit intake factor ($Sv\,Bq^{-1}$)	*Representative radionuclides*	*Guideline level ($Bq\,kg^{-1}$)*
Foods destined for general consumption		
10^{-6}	^{241}Am, ^{239}Pu	10
10^{-7}	^{90}Sr	100
10^{-8}	^{131}I, ^{134}Cs, ^{137}Cs	1000
Milk and infant foods		
10^{-5}	^{241}Am, ^{239}Pu	1
10^{-7}	^{131}I, ^{90}Sr	100
10^{-8}	^{134}Cs, ^{137}Cs	1000

Guideline Levels are intended for use in regulating foods moving in international trade. When the Guideline Levels are exceeded, governments should decide whether, and under what circumstances, the food should be distributed within their territory or jurisdiction. The levels indicated above are designed to be applied only to radionuclides contaminating food moving in international trade following an accident and not to naturally occurring radionuclides that have always been present in the diet. The Guideline Levels remain applicable for one year following a nuclear accident.

Countermeasures

In the 1960s and again after Chernobyl, many proposals for the removal of radionuclides from the food chain or for the reduction of activity concentrations in foods have been published. Radioactive contaminants adhering to the surface of vegetables and fruit can be largely removed by washing, removal of outer leaves, or peeling. In the process of milling, much of the radioactivity in grain remains in the bran, low-extraction flour being more or less free of radioactive contamination. Dairy processing of milk produces butter that is essentially free of nuclides of cesium or strontium. If ^{131}I is present, the butter can be stored until the radioiodine has disintegrated sufficiently. Acid precipitation of curd leaves almost all radiocesium, -strontium, and -iodine in the whey, thus producing decontaminated cheese, whereas in enzymatic (rennet) precipitation, most of the radiostrontium originally present in milk is found in the curd. Many studies, some of them on a semi-industrial scale, have been carried out on the removal of cesium and strontium ions from liquid food (milk, fruit juices, tomato juice) by ion exchange or electrodialysis. Efficient decontamination can be achieved, but the treatments are relatively expensive. Some authors have described undesirable effects on sensory quality or on nutritional value. Many of these studies were probably carried out with a war situation in mind, when food would be at a premium. Should another nuclear disaster occur during peacetime, it will be more economical under most circumstances to bring in uncontaminated products from other areas than to try to decontaminate food by procedures more costly than simple washing or peeling.

Another approach is the reduction of contamination during agricultural production of food. Contamination of farm animals can be reduced by keeping them indoors during the fallout period. Root uptake of radiocesium in relatively acid soils can be minimized by liming. The fecal excretion of radionuclides can be greatly increased and their uptake into meat and milk minimized by adding adsorbents, such as bentonite or complexing compounds, such as ammonium ferric hexacyanoferrate (Prussian Blue), to the feed. The efficiency of such methods is high, and the cost is moderate.

The assessment of the radiological impact of releases of radionuclides to the terrestrial and freshwater aquatic environments requires knowledge of the transfer of various radionuclides from soil to plants, plants to animals, and food to man, and of the many factors that influence the rates of transfer. Numerous studies have been carried out with this aim since the 1960s; tables of transfer coefficients are available. Complex mathematical models, such as ECOSYS, have been developed to permit prediction of the biological consequences of a major radioactive release. Experience after the Chernobyl catastrophe has shown that these systems, when fed with solid data, allow reasonably accurate predictions to be made. In contrast, many of the population dose estimates announced soon after the accident under the pressure of circumstances later turned out to be several-fold too high.

RAPE SEED OIL/CANOLA

N A M Eskin and R Przybylski, University of Manitoba, Winnipeg, Manitoba, Canada

Introduction

Oilseed rape species that produce canola oil and meal are from the *Brassica* genus in the Cruciferae family. It was first cultivated in India almost 4000 years ago. Large-scale plantings of oilseed rape were first reported in Europe in the thirteenth century. The Brassica species probably evolved from the same common ancestor as wild mustard (*Sinapis*), radish (*Raphanus*), and *Eruca*.

Development of Canola

Rapeseed was first introduced into Canada from Poland in 1936. Because of oil shortages during

World War II, *Brassica rapa* seeds were tested for agronomic adaptation. At the same time, rapeseed (*B. napus*) seeds of Argentinean origin were obtained from the USA and grown under contract in the Province of Saskatchewan. During the war years, acreage increased with the first rapeseed crushing plant built in 1945. The first Canadian *B. napus* cultivar, Golden, was registered in 1954, followed by Echo, the first Canadian cultivar of *B. napus* in 1964. Oil shortages during the war suggested that Canada must develop its own domestic oil supply. Because of its agronomic adaptation, rapeseed was selected.

Early rapeseed cultivars, however, had very high levels of eicosanoic and erucic acids in the oil as well as glucosinolates in the meal. These factors were of concern if rapeseed were to be marketed for human consumption and approved by the Food and Drug Directorate of the Department of National Health. High levels of erucic acid were shown to produce fatty deposits in the heart, skeletal muscles, and adrenals of rodents as well as impair the animal's growth. Plant-breeding programs were initiated to reduce the level of erucic acid in rapeseed oil. In 1959, Liho, a rapeseed line containing low levels of erucic acid was identified. A program of backcrossing and selection was conducted to transfer the low-erucic trait into agronomically adapted cultivars. This led to the release of the first low-erucic-acid cultivar of *B. napus*, Oro, in 1968 and the first low-erucic-acid *B. rapa* cultivar, Span, in 1971. Because of health concerns related to high levels of erucic acid, over 95% of the rapeseed grown in Canada in 1974 were low-erucic-acid varieties.

Glucosinolates were also considered detrimental in rapeseed meal fed to poultry and ruminants. Its hydrolyzed products, isothiocyanates and other sulfur-containing compounds, were shown to interfere with the uptake of iodine by the thyroid gland, contribute to liver disease, and reduce growth and weight gain in animals. Consequently, breeders realized that if rapeseed meal were to be used in animal feed, the glucosinolate content had to be reduced. A Polish line with a low-glucosinolate trait, Bronowski, was identified by Dr. Keith Downey in the late 1960s. Breeding efforts to introduce this trait into low-erucic lines by Dr. Baldur Stefannson resulted in the release of the world's first low-erucic, a low-glucosinolate cultivar of *B. napus*. This was followed in 1977, by the release of the first low-erucic, low-glucosinolate cultivar of *B. rapa*, Candle, by Dr. Keith Downey. Approximately 80% of the total Canadian rapeseed acreage in 1980 consisted of the double low cultivars. (*See* **Glucosinolates**.)

The name 'canola' was registered by the Western Canadian Oilseed Crushers in 1978. The name included those cultivars containing less than 5% erucic acid in the oil and 3 mg per gram of aliphatic glucosinolates in the meal. The canola trademark was subsequently transferred to the Canola Council of Canada in 1980. In 1986, the definition of canola was amended to *B. napus* and *B. rapa* lines with less than 2% erucic acid in the oil and less than 30 μmol per gram of glucosinolates in the air-dried oil-free meal and was added to the 'generally recognized as safe' (GRAS) list of food products in the USA.

It was much more difficult to introduce the low-erucic-acid trait into the European rapeseed lines because they were primarily of the winter type. This extended the time required to produce each generation and crosses between spring low-erucic-acid rapeseed (LEAR) cultivars and winter lines resulting in undesirable segregates. Nevertheless, the development of European LEAR varieties was accomplished within 15 years. European acreage of rapeseed declined during the 1970s as a result of health concerns. In 1977, the low-erucic-acid trait was mandatory in Europe in 1977. Initially, the new LEAR cultivars produced lower yields and oil content compared with the traditional cultivars. Subsequent plant breeding overcame this problem with European production of LEAR increasing substantially by 1984.

Distribution and Adaptation

Canola is the only oilseed crop adapted to temperate regions. Its ability to germinate and grow at low temperatures permits production in cooler regions and at higher elevations compared with other oilseed crops. As a result, it can be grown as a winter crop in Europe where the winters are not too severe. The major producers of canola and rapeseed are China, European nations, India, and Canada, with Canada, China, and India accounting for over 65% of the world's total production.

Different species of *Brassica* crops are grown throughout the world, although *B. napus* and *B. rapa* are both grown in Canada. *B. napus* is higher-yielding as well as slightly higher in oil and protein content than *B. rapa*. However, *B. rapa* matures 2–3 weeks earlier and can be seeded in areas with a shorter growing season (less than 95–110 days). In addition, *B. rapa* is shorter, more shatter-resistant and frost-resistant, containing less chlorophyl and fiber than *B. napus*. The main canola species grown in western Canada are spring types, except for a small amount of high-erucic-acid rapeseed (HEAR) grown for industrial purposes. Winter cultivars of both *B. napus* and *B. rapa* are grown throughout Europe, except Sweden. In northern Sweden, spring types predominate. In the Indian

subcontinent, high-erucic-acid, high-glucosinolate spring *B. juncea* and some *B. rapa* types are grown. Winter types of *B. napus* and *B. rapa* are grown in central and southern China, whereas spring types predominate in western China. Spring *B. juncea* is also found in China. Asia still grows mainly the HEAR varieties.

Development of New Cultivars

During the last 20 years, breeding goals in Canada included increasing yields, oil and protein contents, earlier maturity, development of yellow seeded varieties, reduced green seed, and improved disease, insect, and herbicide resistance. The first triazine tolerant cultivar was released in Canada in 1984, followed by agronomically improved Tribute.

Genetic breeding is now used to modify oil quality. Using mutagenesis, a low-linolenic (C18:3)-acid cultivar, Candle, was developed. Similar techniques by researchers at Pioneer Hybrid produced a mutation that blocked the desaturation of C18:1 to C18:2, producing a high-oleic (C18:1) oil. The resulting mutation was then crossed with low-linolenic (C18:3) cultivars producing a high-oleic/low-linolenic line. A successful transformation by Calgene produced canola strains high in stearate (C18:0) and high in laurate (C12:0), with future plans for high-palmitate (C16:0) lines.

Oil Production

Canola/rapeseed oil accounts for 16% of the world supply of edible oils compared with 32 and 18% for soybean and palm and palm kernel oil, respectively. In 1997, canola oil accounted for 70.4% of all deodorized fats and oil, 72.8% of the vegetable oils, and more than 80% of the salad oils produced in Canada. The growing demand for canola products resulted in 424 000 tonnes of oil to the USA in 1996–1997, accounting for over 80% of the total oil exports. (*See* **Vegetable Oils**: Types and Properties.)

Canola Oil Extraction

On an 8% moisture basis, canola seeds contain between 38 and 44% oil. The most efficient method for extraction involves mechanical pressing or expelling in which 60% of the total oil is released. The remaining 40% is solvent-extracted, the common practice for most other oilseeds. The various stages involved are summarized below. (*See* **Vegetable Oils**: Oil Production and Processing.)

Seed Cleaning

The first step is designed to remove weed seeds, grain seeds, other foreign material as well as any canola seed fragments. This involves a combination of aspiration and screening. The foreign material removed accounts for less than 2.5% of the remaining seed and is used for animal feed.

Preconditioning

This involves preheating the seeds prior to flaking to temperature of 30–40 °C. This is achieved directly with a fluid bed type using hot air or steam or indirectly in rotary kilns equipped with steam-heated coils. This renders the seed more pliable, preventing it from shattering.

Flaking

The preheated seed is then flaked on smooth-surface rolling mills. This can be performed using a single-stage operation or as two separate stages; flakes of 0.2–0.3 mm thickness are obtained.

Cooking

Flakes are indirectly heated on steam-heated surfaces in stack cookers or in rotary cookers with steam coils. The cooking temperature is held between 75 and 100 °C. In order to adjust the moisture content of the material to 5–7% for the expeller operation, ambient air may be admitted to the cooking equipment. Besides coelescing minute oil drops into large drops, this step alters the protein and makes the oil more extractable. In addition, it also inactivates a number of enzymes, particularly myrosinase, responsible for the hydrolysis of glucosinolates to sulfur-containing compounds, lipases, and phospholipases responsible for the formation of nonhydratable phosphatides.

Oil Extraction by Prepressing

The heat-conditioned flakes are then subjected to continuous screw-presses or expellers to reduce the oil content from around 42 to 16–20%. The expellers are designed with a rotating screw shaft in a cylindrical barrel to allow oil to flow between the flat steel bars of the barrel while retaining the solid material or presscake.

Solvent Extraction

Before extracting with solvent, the presscake is cooled with ambient air to minimize hexane vaporization when it enters the extractor. The solids, now at around 80 °C, are washed with hexane in several stages. In the first stage, hexane is already high in oil content (miscella), followed by progressively leaner

miscella and ultimately pure hexane. A variety of different extractors are available, all using some type of countercurrent extraction system. The oil content in the meal is reduced to around 1%, depending on the type of equipment and throughput rate, as well as on the type of cooking, flaking, and prepress operations conducted. The resulting meal and miscella are stripped to insure the production of solvent-free meal and crude oil. The prepressed and solvent-extracted canola oils are usually blended before subjecting them to degumming.

Canola Oil Refining and Processing

Crude canola oil is converted to an edible oil using the same processing principles applied to other vegetable oils. The following steps are typical for the overall production of refined edible oils for food application.

Degumming

This process removes phosphatides from the crude oil, present at around 1.0–1.5% and measured as phosphorus, 400–600 mg kg^{-1}.

Two methods are used:

1. Degumming with water in which oil at 80 °C is intensely mixed with 2% water for 5–30 min in an agitation tank or reactor. The majority of the phosphatides are precipitated in suspension and then removed by centrifugation leaving around 0.25–0.5% phosphatides or 100–200 mg per kilogram of phosphorus in the oil. Nonhydratable phospholipids are not removed by this process.
2. Degumming with acid and water, also known as 'superdegumming,' also removes nonhydratable phosphatides. This involves intensively mixing the crude oil with 0.1–0.5% of a 50% solution of citric or malic acids for up to 15 min, depending on the mixing rate. Then, 2% of water is added, before or after cooling the mixture to 25–45 °C and is mixed in a continuous stirred reactor for 1–3 h. The precipitated phosphatide particles are removed by centrifugation. The phosphatides remaining range from 5 to 50 mg per kilogram of phosphorus, depending on the amount of nonhydratable phosphatides in the crude oil.

Refining

Degummed oils are further purified by bleaching followed by either alkali refining or physical refining process, winterization, and deodorization.

1. Bleaching. Adsorptive bleaching is performed with 1–3% of acid-activated clays to remove colored components, metals, and phospholipids. Oil is mixed with clay at 100 °C under vacuum for up to 30 min at 10–15% moisture, and then clay is removed by filtration. Chlorophyls will be reduced to below 0.05 mg kg^{-1}. Other adsorbents are rarely used for canola oil.
2. Alkali refining. This is the most commonly used process to remove phosphatides and free fatty acids (FFA). Firstly, oil is mixed with 0.05–0.1% concentrated phosphoric acid to precipitate phospholipids. Secondly, the oil is treated with 12% aqueous sodium hydroxide to neutralize FFA and phosphoric acid, and precipitate phosphatides. In both cases, intensive mixing and a short contact time at 40–90 °C are applied, followed by centrifugation, and then the oil is washed with water to remove soaps. Alkali refining reduces FFA and phosphorus to below 0.05% and 3 mg kg^{-1}, respectively, chlorophylides are reduced by up to 70%, and iron and copper are removed.
3. Physical refining. The acid-degummed oil first undergoes phosphoric acid pretreatment followed by bleaching with acid-activated clay. The bleached oil is then subjected to physical (steam) refining which removes the free fatty acids by steam distillation in the deodorizer.
4. Winterization. Salad oils are winterized to remove wax esters, which can cause sediment formation in oil. Oil is chilled to 5 °C and filtered to reduce wax content to below 50 mg kg^{-1}.
5. Deodorization. This process is performed for up to an hour at 225–260 °C under vacuum, 2–4 mm of mercury with 1–3% steam blown through the oil to remove flavor components. During this process, some tocopherols and sterols are removed from oil together with FFA. When oil is cooled to 60–90 °C, additives are added, and spurging with nitrogen gas is performed.
6. Hydrogenation. Hydrogenation modifies the melting and crystallization behavior of the fat or oil as well as rendering it more resistant to oxidative and thermal damage. This process is performed at 160–200 °C and 100–300 kPa pressure in the presence of catalyst, usually nickel. During this process, saturated and isomerized fatty acids are formed that change the physical properties of fat. Hydrogenated fats containing *trans* fatty acids have a tendency to crystalize to the β′ form producing products with a smooth and pleasing mouth feel and good spreadability. Health concerns have resulted in the reduction of *trans* isomers by searching for new catalysts or by blending. An alternative method to hydrogenation used in Europe and only to a limited degree in North America is interesterification.
7. Interesterification. This process is used to obtain fats similar to hydrogenation by applying chemical

or enzymatic rearrangement of FA in glycerides within oil and between oils. Chemical process is performed with an alkaline catalyst, sodium methoxide or sodium hydroxide, at 100–150 °C for up to an hour. The enzymatic process conditions are dictated by the enzymes applied. The main advantage of this method is that no *trans* fatty acid isomers are formed.

Properties of Canola Oil

Physical

The physical properties of canola, including density and viscosity, the main engineering parameters, are presented in Table 1.

The density and viscosity of canola oil decrease with temperature increase in a linear and exponential fashion, respectively. Most of the canola oil physical parameters are within the range found for other vegetable oils and are governed by composition of fatty acids.

Chemical

The average composition of canola, rapeseed, and soybean oils is presented in Table 2. (*See* **Fats**: Classification.)

Triacylglycerols or triglycerides are the main components of vegetable oils composed of glycerol and three fatty acids attached to it. The composition of triglycerides defines the physical properties of oils and their oxidative stability. (*See* **Fats**: Classification.)

Tocopherols are the natural and most efficient antioxidants produced by plants. There are four isomers of tocopherols produced, and canola oil contains about twice as much γ isomer than α, both isomers being present in important amounts. The tocopherol content in canola oil is at the higher end among vegetable oils. (*See* **Tocopherols**: Properties and Determination.)

Phytosterols or plant sterols have been neglected for many years, although the nutritional importance of some of these components is receiving considerable attention. Some plant sterols appear to lower plasma cholesterol by inhibiting the absorption of dietary cholesterol and reabsorption of biliary cholesterol. In fact, canola oil contains high amounts of sterols second only to corn oil.

The sensitivity of canola oil to deterioration is often related to the presence of pigments such as chlorophyls. They are capable of transferring light energy into chemical energy and can initiate formation of radicals responsible for oxidative degradation of oils. The content of chlorophyls in canola oil is dependent on the maturity of seeds used for processing, as even fully matured seeds contain a few p.p.m. of these components.

The presence of components containing sulfur in the structure is normal for oils produced from oilseeds from the Cruciferae family because of the presence of glucosinolates. In canola oil, minor fatty acids with sulfur in the structure have been detected.

The composition of fatty acids in canola oil is unique when compared with other oils. Canola oil contains the lowest amount of saturated fatty acids and is second after olive oil in the content of oleic acid. The presence of essential fatty acid, such as linoleic and linolenic, is intermediate, both acids being important nutrients in the control of cardiovascular diseases. The main fatty acid that differentiates canola oil from rapeseed oil is erucic acid, which was reduced to less than 2% in canola.

Table 1 Physical properties of canola oil

Parameter	*Value*
Relative density ($g\,cm^{-3}$; 20 °C/water at 20 °C)	0.914–0.917
Refractive index (n_D 40 °C)	1.465–1.467
Viscosity (kinematic at 20 °C; $mm^2\,s^{-1}$)	78.2
Smoke point (°C)	220–230
Flash point, open cup (°C)	275–290
Specific heat ($J\,g^{-1}$ at 20 °C)	1.910–1.916
Thermal conductivity ($W\,m\,^0K^{-1}$)	0.179–0.188

Table 2 Composition of canola, rapeseed, and soybean oils

Component	*Canola*	*Rapeseed*	*Soybean*
Triglycerides (%)	94–99	92–99	93–99
Phospholipids (%)	Up to 0.1	Up to 0.1	Up to 0.2

Nutritional Properties

Dietary fats serves as an important source of energy and essential fatty acids, and serves as a carrier for fat-soluble vitamins. In addition, it makes an important contribution to the feeling of satiety, palatability of food products, and textural properties of foods.

Recently, interest in dietary fat originated from its involvement in the etiology of cardiovascular diseases, cancer, obesity, and hypertension. It is not disputed importance of lipids but type and the amount of fats to be responsible for the development of these chronic diseases, cancer, obesity, and hypertension. Lipids, particularly the type and amount of fats, are now considered responsible for the development of these chronic diseases. Nutritional recommendations in Europe and North America stipulate a reduction of total fat intake to 30% and saturated fat intake to less than 10% of total energy. Over the past 30 years, there has been a major shift from the consumption of animal origin fats to vegetable oils. In Canada, canola oil has become the major oil consumed and processed. The shift to vegetable oils did not reduce saturated fat consumption because a significant number of these oils were used as hydrogenated fats in margarine and shortening. Where unsaturated fatty acids were hydrogenated, both saturated fatty acids and *trans* isomers were produced to obtain fat with proper technological properties such as a higher melting point and crystallization structure and texture. *Trans* isomers have a similar effect on plasma cholesterol level to saturated fatty acids. The composition of fatty acids in canola oil is compatible with nutrition recommendations directed to reduce the consumption of saturated fat and to have a ratio of omega-6 to omega-3 within 3–5. Canola oil has a ratio of 2 and has been found to be equally effective as soybean, sunflower and corn oils in reducing plasma levels of total and LDL cholesterol in normal and hyperlipidemic subjects. Diets containing canola oil also increased the content of long-chain polyunsaturated fatty acid in plasma and platelet phospholipids indicating the transformation of linoleic and linolenic acids. Consumption of canola oil alters clotting activity and thrombogenesis, and protects against cardiac arrhythmias. All these findings and the positive ratio of linoleic to linolenic acids in canola oil make this oil suitable as a source of fat for infant formulas and as part of any nutritious diet.

RASPBERRIES AND RELATED FRUITS

M P Pritts, Cornell University, Ithaca, NY, USA

Background

Raspberries are a high-value crop owing to their unique flavor, exacting climatic requirements, high costs of production, and perishability. This article describes the relationships among various raspberry species and relatives, discusses the commercial raspberry industry, describes the morphology, anatomy, and chemical composition of fruit, reviews harvesting and handling techniques for fresh fruit, and presents various food uses for the raspberry.

Taxonomy and Commercial Importance

Raspberries are a diverse group of flowering plants that are closely related to blackberries. Both raspberries and blackberries belong to the genus *Rubus*. Taxonomists recognize 12 subgenera within *Rubus*, but only the raspberries (*Idaeobatus*) and blackberries (*Eubatus*) have obtained commercial significance. Species of a third group, the arctic raspberries (*Cylactis*), are harvested from the wild, and are popular in Scandanavia for making liqueurs, but these are not cultivated. The fruit of raspberries detaches from the receptacle when picked, leaving a white torus attached to the plant and a hollow fruit. This characteristic distinguishes them from

blackberries in which fruit abscission occurs behind the receptacle.

The genus *Rubus* is a member of the rose family (Rosaceae), which also includes important fruit crops such as apples, pears, cherries, peaches, plums, and strawberries. Wild raspberries occur on five continents, but are most abundant in the northern hemisphere. The temperature and subtropical region of eastern Asia is recognized as the center of origin where the most diversity exists. More than 200 species have been identified, but only a few are important commercially. These include the European red raspberry (*R. idaeus* ssp. *vulgatus* Arrhen.), the North American red raspberry (*R. idaeus* ssp. *strigosus* Michx.), and the black raspberry (*R. occidentalis L.*) of the eastern USA. Hybrids between the red and black raspberry are commonly called purple raspberries because of the fruit and cane color, and these were once given the specific rank of *R. neglectus* Peck. However, most taxonomists do not recognize hybrids as distinct species. Interspecific hybrids with blackberries have also been made; some of these are commercially important, such as Tayberry, Loganberry, Boysenberry, and Youngberry.

Several other species within the genus *Rubus* have edible fruit, or have been used by plant breeders to improve cold hardiness and resistance to diseases and insects in raspberries. Examples are *R. glaucus* Benth., a South American tetraploid black raspberry that is probably a raspberry × blackberry hybrid, *R. leucodermis* Torr. and Gr. (the western North American black raspberry), and *R. spectabilis* Pursh. (salmonberry); the Asiatic species *R. coreanus* Miq., *R. phoenicolasius* Maxim. (Japanese wineberry), *R. parvifolius* Nutt. (trailing raspberry), *R. ellipticus* Sm. (golden evergreen), *R. illecebrosus* Focke (strawberry raspberry), *R. kuntzeanus* Hemsl. (Chinese raspberry), and *R. nivens* Thumb.; the Hawaiian species *R. macraei* Gray and *R. hawaiiensis* Gray (Akala berries); and the arctic raspberries of Europe (*R. arcticus L.*) and North America (*R. stellatus* Sm.).

Commercial Industry

Raspberries were first introduced into cultivation in Europe nearly 450 years ago. By the early nineteenth century, more than 20 cultivars of red raspberry were grown in both England and the USA. English cultivars were then exported to the USA, where crosses between them and North American seedlings gave improved cultivars. Red raspberries are the most widely grown, whereas black raspberries are popular only in certain regions of the eastern USA. The progeny of black and red raspberries have purple fruits and canes; these types are popular in eastern North America. Yellow-fruited *R. idaeus*, caused by a recessive mutation, is also grown on a limited scale for specialty markets. *R. occidentalis* genotypes with yellow fruit are not grown commercially.

The three major raspberry production regions are (1) Russia, (2) Europe (mostly in Poland, Hungary, Serbia, Germany, and the UK), and (3) the Pacific Coast of North America and Canada (British Columbia, Washington, and Oregon). Much of the fruit produced in these regions is harvested mechanically and processed. In other production regions, such as eastern North America, nearly all the production is for the fresh market. Many other countries, such as Chile, New Zealand, and Australia, have a significant production as they supply the fresh market during winter in the northern hemisphere. World production is estimated at more than 400 000 tonnes.

Patterns of production in North America shifted dramatically in the early 1900s. In 1920, New York State growers (East Coast) harvested more than 4000 ha. The systemic 'mosaic virus disease' infected most of the planting stock, and the processing raspberry industry collapsed in this region. With the development of tissue culture propagation techniques, virus-indexing of nursery stock, and breeding for resistance to the virus vector, the raspberry processing industry redeveloped on the West Coast. In Britain during World War II, little attention was paid to maintaining the health of raspberry stock. It was not until the 1970s that the raspberry industry reorganized with certification programs and heat-treatment therapy for the elimination of viruses. Currently, there is interest in both Europe and North America in greenhouse raspberry production to supply local markets during winter and spring.

Varieties

Two types of bearing habits are found in commercial red raspberries. The first type is called a 'summer-bearing' habit. Canes originate from either crown buds or adventitious root buds in early spring. Canes elongate during the growing season, forming fruit buds in the axils of leaves in the autumn when temperatures decrease and day lengths shorten. The plants become dormant for winter, and then the buds on the cane grow the following spring once the chilling requirement has been fulfilled. The chilling requirement varies considerably among summer-bearing varieties, ranging from a few hundred hours to more than 1800 h. The lateral axillary buds on dormant canes contain both leaf and flower primordia. At the onset of warm weather, buds break, and flowering occurs about 6–10 weeks later. Fruiting occurs in early to late summer, depending on variety,

and then the entire cane senesces. While these second year canes (floricanes) are flowering, first-year canes (primocanes) are growing from the crown or roots. These primocanes will fruit the following year. More than 40 summer-bearing red raspberries are grown commercially, and these change with the release of new, improved varieties. Among the major varieties originating in North America are 'Boyne,' 'Canby,' 'Killarney,' 'Meeker,' 'Reveille,' 'Taylor,' 'Titan,' 'Tulameen,' and 'Willamette.' The Glen and Malling series are important varieties from the UK. The Scottish Crops Research Institute is the leading institution in the world for raspberry variety development.

The second type of growth habit is called 'fallbearing.' In some varieties, fruiting laterals will develop from the top of first year primocanes after they reach a certain height, without any chilling. If the growing season is sufficiently long, fruit can be harvested from the upper portion of these canes through autumn. The lower portion of the cane will fruit the following summer, if it is allowed to remain in the field. The major variety worldwide is 'Heritage;' other important varieties are 'Amity,' 'Autumn Bliss,' 'Polana,' and 'Autumn Britten.'

At least 13 varieties of black raspberries are grown in North America. The most successful are 'Allen,' 'Bristol,' 'Haut,' and 'Jewel.' 'Royalty' is the most popular purple raspberry. Several yellow or golden raspberry varieties are grown on a small scale for specialty markets.

Morphology and Anatomy of Fruit

Each raspberry flower contains 60–160 ovaries. Each ovary contains two ovules, but one usually aborts after differentiation. About 1 month after pollination, the ovaries ripen simultaneously to form the fruit.

Fruits ripen in three phases. Pollination is followed by a period of rapid cell division. In the second phase, cell division slows while the embryo develops, and the seed coat hardens. Finally, very rapid growth occurs as a result of cell enlargement. Each phase lasts 10–12 days. Considerably variation in fruit size exists, with a range of 1–5 g. Under certain conditions, fruit can exceed 10 g.

As with most climacteric fruit, ethylene production in the raspberry begins in the receptacle when the fruit starts to color and peaks when fully ripe. Respiration, however, decreases as ripening proceeds. Growth stresses help to fracture the middle lamella and walls of cortical cells where the fruit attaches to the receptacle. Cell-wall breakdown and disintegration are complete when the fruit is fully ripe. The detachment force is small, usually 25 g, when fruits are ripe. A 12-fold difference in detachment force can exist between underripe and overripe fruit. This differential is exploited by mechanical harvesters.

The raspberry fruit is not a true berry, but rather an aggregate of many individual drupelets. Each drupelet is anatomically analogous to a cherry with a hard endocarpic seed (pyrene) surrounded by a fleshy mesocarp and an outer exocarp. The fleshy mesocarp is composed of thin-walled, turgid parenchymatous cells. Just below the exocarp is a thin layer of oval, collenchymatous cells. Large seeds are undesirable, but there is a relationship between seed size and drupelet size. Small seeds tend to be associated with small drupelets. An average seed has a mass of about 1 mg, and comprises 4–5% of the total mass of a berry. A 100-g sample of raspberries may contain more than 4000 seeds.

The cohesion of individual drupelets results from the entanglement of unicellular, epidermal hairs that are most abundant on the sides and base of the drupelet. In some black raspberry varieties, fusion of the cuticle or wax also contributes to drupelet cohesion. Drupelets cannot normally be separated without tearing the exocarp. Considerable variation in fruit firmness and drupelet cohesion exists among commercial varieties. If the percentage of developed drupelets is low, cohesion will be poor. Firmness is related to cell diameter and tissue compactness.

Chemical and Nutritional Composition

Fruit Composition

The main constituent of the raspberry fruit is water (approximately 87%). Of the remaining solids, 9% are soluble and the rest insoluble. Pectins comprise 0.1–1.0% of the soluble fraction, but this amount decreases with ripening owing to hydrolysis.

The main sugars are glucose, fructose, and a smaller amount of sucrose. These comprise the major soluble component of the juice. A typical ripe raspberry fruit contains 5–6% sugar. Citric acid is the second largest component of the soluble fraction; raspberries contain very little malic acid, but at least 10 other acids in trace amounts. The amount of acid in the fruit increases early in development, then decreases as the fruit begins to ripen. The balance between the sugars and acids is important for consumer acceptance. A fruit with a low sugar:acid ratio will taste tart; one with a high ratio will taste bland. A typical pH of a ripe raspberry fruit is 3.0–3.5; the ratio between sugars and acids (w/w) is approximately 1.0. Fruits grown under warm, dry summers (daytime temperatures near 25 °C) are sweeter, less acid, more aromatic, and more highly colored. Hot weather (temperatures greater than 30 °C) reduce the

aroma of the fruit, and wet weather reduces the sugar content.

A large number of volatile compounds are found in raspberry fruit, but most are present at less than 10 p.p.m. and are below the threshold of detection by the human nose. Compounds include alcohols, acids, esters, carbonyls, ketones, and other hydrocarbons (naphthalene and related compounds). A particular ketone, 1-(*p*-hydroxyphenyl)-3-butanone has an odor very characteristic of raspberry.

Considerable changes occur in phenolic compounds as fruits mature. Raspberry juice from ripe fruit contains 0.10–0.14% polyphenols, mainly as catechin and chlorogenic, ferulic, and neochlorogenic acids.

Raspberry fruits contain small amounts of vitamins; only vitamin C is present at a significant level. Amino acids include alanine, serine, asparagine, glutamic acid, glutamine, (gamma)aminobutyric acid, valine, leucine, and aspartic acid. The high levels of antioxidants and ellagic acid in raspberries have been highlighted in the popular press as public interest in cancer prevention increases. Table 1 presents data on the vitamin and nutrient content of red raspberries.

Table 1 Reported values or ranges of nutrient content in 100 g of fresh raspberries

Nutrient	*Amount*
Water (g)	84–87
Food energy (kcal)	31–49
Protein (g)	0.42–1.40
Fat (g)	0.20–0.55
Carbohydrate (g)	5.8–11.6
Fiber (g)	3.0–7.4
Ash (g)	0.40–0.51
Minerals (mg)	
Calcium	22–50
Iron	0.57–1.20
Magnesium	18–30
Phosphorus	12–50
Potassium	130–221
Sodium	0–2.5
Zinc	0.46
Copper	0.07–0.21
Manganese	1.01
Sulfur	17.3
Chlorine	22.3–22.8
Boron	71–125
Vitamins (mg)	
Carotene	0.05–0.08
Thiamin	0.01–0.03
Riboflavin	0.03–0.10
Pantothenic acid	0.24–0.30
Nicotinamide	0.20–1.00
Vitamin B_6	0.06–0.90
Vitamin C	13–38
Tocopherols	0.3–4.5

Fruit Color

The color of raspberry fruit is imparted by anthocyanins. The anthocyanin molecule in raspberry consists of cyanidin and pelargonidin with glucose attached at the 3 position. Additional glucose, rhamnose, or xylose sugars may be present in various combinations to give diglycosides or triglycosides. Fruits with a preponderance of pelargonidin glycosides have an orange–red color, as opposed to a deep red color with cyanidin glycosides. The type and concentration of anthocyanins in the fruit are controlled by a few major genes. Fruits with a yellow color are produced when one or more of these genes suppress anthocyanin production. Molecules that are complexed with the anthocyanin also affect color development, and the pH of the fruit has a small effect. During storage, raspberry fruits increase in anthocyanin, darken, and become more blue, owing in part to an increase in cytoplasmic pH.

Handling and Storage of Fresh Produce

Harvest Considerations

Raspberries have one of the highest respiration rates of any fruit. This, coupled with their thin skin and sugary interior, makes them among the most perishable of all fruits. With any given variety, fruit on a bush will ripen over a period of several weeks. Harvesting the same planting frequently (once every 2 days) is critical. Fruit harvested before it is fully ripe will have a much longer shelf-life than fully ripe or overripe fruit but will be lower in sugar and anthocyanins. The optimum stage of maturity for the raspberry occurs when the berry first becomes completely red but before any darker hues develop.

Fruit quality for fresh market raspberries usually declines as the season progresses. Marketing channels must be open before the first berries ripen, as these are likely to be of the highest quality and largest size for the season. Berries should not be touched before harvest, and only undamaged berries with a good appearance should be placed in the pack. The magnitude of injury caused by human pickers can be so great as to mask any other causes of deterioration. Overripe or damaged berries should be harvested and discarded, because they are susceptible to molds.

Botrytis is the most common pathogen of raspberry fruit. Once the mold growing on overripe berries sporulates, large amounts of inoculum will be present to infect other ripening fruit. Overripe berries also attract ants, wasps, and other pests.

Containers holding approximately 150 g of raspberries are typically used. Wide, shallow containers are preferable to deep containers; each should have no more than four layers of raspberries to prevent crushing. Many different types of containers are available, but among the most popular today are plastic clamshells.

Postharvest Considerations

The objective of postharvest handling of raspberries is to slow down the respiration and transpiration rate of fruit. Respiration and transpiration result in shrinkage and reduced sweetness. Conditions that slow down the respiration process are low temperatures, high carbon dioxide levels, and low oxygen in the storage chamber. Transpiration is slowed down by high humidity.

Temperature is the easiest environmental variable to modify for extended storage of raspberries. A 5 °C reduction in temperature reduces the respiration rate by approximately 50%: at 0 °C, the respiration rate is 24 mg of carbon dioxide per kilogram of raspberry per hour; at 5 °C, the rate is 55; at 10 °C, the rate is 92; at 15 °C, the rate is 135; and at 20 °C, the rate is 200. Rapid movement of cold, humid air through the berries is essential during the first few hours after harvest to slow down respiration and prevent deterioration. Large growers may have a precooling facility, specifically designed for removing field heat, and an additional storage cooler. For every hour's delay in cooling, the shelf-life can be reduced by 1 day. Growers take advantage of natural night cooling by harvesting fruit as early in the morning as possible. Mechanical harvesting is often done at night.

Once the berries are cool, containers are wrapped in plastic to prevent water loss from the fruit and condensation on the berries when they are removed from the cooler. The plastic is not removed until the temperature of the berries approaches ambient temperature. The storage room can be maintained as low as − 1 °C. Berries will not freeze at or above this temperature, because the sugars in the fruit depress the freezing point.

When the temperature is lowered, the amount of moisture in the air is reduced. For raspberries, it is critical to maintain a humid atmosphere (90–95%) simultaneously with a low temperature to prevent water loss from the fruit. Special cooling units designed to maintain a high humidity are required for raspberries. At 25 °C and 30% relative humidity, fruits lose water 35 times faster than at 0 °C and 90% relative humidity.

A high carbon dioxide (15–20%) and/or low oxygen (5–10%) atmosphere will reduce respiration and mold growth. *Botrytis*, *Rhizopus*, *Alternaria*, *Penicillium*, and *Cladosporium* can cause postharvest fruit rots, depending on the storage temperature and carbon dioxide level. Modified atmospheres are used frequently when raspberries are transported long distances. Special semipermeable wraps are sometimes used by shippers to create a modified atmosphere (low oxygen, high carbon dioxide) within individual containers. Low-oxygen atmospheres will extend the shelf-life of raspberries, but bad-tasting aldehydes and alcohols can accumulate in the raspberry fruit when oxygen is limited for an extended period of time. Off-flavors and browning also develop when raspberries are held under elevated carbon dioxide levels for an extended period. Raspberries are considered to be at moderate risk of physiological injury from high-carbon dioxide or low-oxygen atmospheres.

The loss of raspberries from harvest to the consumer's table has been estimated at more than 40%. A 14% loss occurs from farmer to wholesaler, a 6% loss occurs from wholesaler to retailer, and 22% is lost between the retailer and consumer. Most of these losses result from poor handling of berries after harvest.

Fruit Uses

Raspberries have been eaten fresh for thousands of years. Medicinal uses of raspberries are frequently found in the literature, with references to raspberry leaf tea dating to the sixteenth century. In the early 1900s, black raspberry juice was extracted, concentrated, and used as an edible dye for foodstuffs, such as meat. Raspberries were also dehydrated for long-distance transport. Today, raspberry fruits are either harvested by hand and eaten fresh, or machine-harvested and processed. Approximately 27 000 tonnes are processed each year. The major products of processing are IQF, block frozen, purée frozen (8–15° Brix), juice (about 9° Brix), concentrate, canned, aseptic packs, and preserves. These products are then packaged and sold directly to the consumer, or reprocessed into jam, jelly, dessert topping, pie filling, icecream, yogurt, and other desserts. Raspberry juice is usually blended with apple, pear, or grape juice, because the flavor is too intense for direct consumption. Recently, the demand for fruit wines has increased, and raspberries make one of the better wines. Some wineries add raspberry juice to grape wine to obtain a less expensive raspberry-flavored wine. Raspberry beer is also made at breweries and meaderies. The popularity of raspberries continues to grow as many raspberry-containing products are now on supermarket shelves.

RECOMBINED AND FILLED MILKS

W Kneifel, University of Agricultural Sciences, Vienna, Austria

General Considerations

The manufacture of recombined milk and milk products is a technology that has emerged over the past three decades. During this time, there has been a worldwide development in the establishment of dairy recombination plants, mainly in countries that have a limited indigenous dairy industry, or in regions suffering from seasonal deficiencies in milk supply. Recombined dairy products are therefore ensuring a year-round supply for many households in developing countries, and also enabling the extension of the local dairy industries. However, for the industrialized countries, milk recombination offers the opportunity to transfer raw materials (milk powders, anhydrous milk fat, etc.) from surplus production areas to deficiency areas, in order to compensate for the abovementioned problems and to open up new markets. Hence, it should be taken into consideration that world stock levels and prices of butter and milk powder are strongly affecting the development of recombination industry as well as the trend of prices of recombined dairy products.

Definitions

In principle, most types of dairy products can also be produced in a reconstituted or recombined form. In the *Code of Principles Concerning Milk and Milk Products*, the Codex Alimentarius Commission of the Food and Agriculture Organization and World Health Organization has considered the relation between conventional and recombined milk products: it was determined that all products must be based on the use of fresh milk, reconstituted milk, or recombined milk. Recombined products can be subcategorized into seven main groups: milk, cream, evaporated milk, sweetened condensed milk, cultured milk products, butter, and cheese. According to definition, a *reconstituted milk product* is the product resulting from the addition of water to the dried or condensed form of the product in the amount necessary to reestablish the specified water: solids ratio. A *recombined milk product* is the product resulting from the combining of milk fat and milk solids-nonfat (SNF) in one or more of their various forms, with or without water. This recombination must be made in order to reestablish the product's specified fat: SNF ratio and solids: water ratio. Among these two fundamental categories of special milk products, the following designations are also commonly distinguished: *toned milk* is a product containing locally produced milk enriched with reconstituted skim-milk solids in order to obtain the average milk composition (e.g., high-fat milk, such as buffalo milk, is adapted to cows' milk composition, or local cows' milk showing adverse variations in composition is adjusted to normal composition). *Blended milk* is a product in which recombined milk is used in mixture with local fresh milk in order to restore the fluctuations in local milk production. *Filled milk* is a recombined product in which milk fat is partly or completely replaced by locally available vegetable oils.

Ingredients Used for Recombination

The quality of recombined dairy products is directly influenced by the quality of the ingredients used. Nutritional, technological, and sensory specifications

of raw materials must be considered in order that the recombined products resemble the original products. Typical compositions of some selected products are shown in Table 1.

Dried Milk and Milk Protein Powders

Skim-milk powder is generally the most usual component for providing milk proteins in the manufacture of recombined dairy products. *Whole-milk powder* (prevailingly 'instantized' types) can be used as a source for both SNF and milk fat, but oxidative changes in the fat phase, leading to sensory deterioration, are limiting its application. Certain proportions of *buttermilk powder* can be used more or less advantageously to enhance typical flavor characteristics. In addition, different types of *whey protein powders* and *caseinates*, and, recently, *retentate powders* (for the manufacture of cheese) made from ultrafiltered milk are coprocessed because of attributing certain functional properties to the final products.

Table 1 Typical composition of recombined milk products

Ingredients	*Product formulations (kg t^{-1})*			
	Recombined milk		*Recombined cream*	*Recombined sweetened condensed milk*
Skim-milk powder	80.5	85	30	229
Buttermilk powder	9.7		45	
Anhydrous milk fat	33.3	35	190	88.5
Water	876.4	880	733.2	250
Carrageenan			0.3	
Emulsifiers			1.5	
Sucrose				432
Seed lactose				0.5

(*See* **Casein and Caseinates**: Uses in the Food Industry; **Whey and Whey Powders**: Production and Uses.)

Reconstitutability, heat stability, and viscosity properties are the most important parameters, limiting as well as enabling the utilization of milk powders in recombined products. These properties are determined mainly by the preheat treatment applied during milk powder production as well as by seasonal variations in raw milk composition. Because a number of milk proteins are heat-labile, the extent to which they are denatured reflects the heat treatment applied during milk powder manufacture. This effect is also used as an indicator for its suitability to be applied in a diverse array of recombined products. The amount of undenatured whey protein (as characterized by the 'whey protein index' or the 'heat number' analysis) is usually taken as a measure for milk powder classification, but for certain purposes, dried milk is also classified, based on other analytical indicators (see Table 2). Besides these parameters, moisture and fat content, solubility index, bulk density, flowability, wettability, scorched particles, rennetability, emulsification properties, titratable acidity, sensory aspects, and bacteriological requirements are also included in various milk powder specifications. Most of these properties can be influenced to a certain extent by applying a defined powder technology. However, some particular factors are additionally improved by using certain additives to the product. (*See* **Whey and Whey Powders**: Protein Concentrates and Fractions.)

Milk powder is usually received in 25-kg multiwall bags, with an inner layer consisting of polyethylene. Alternatively, large bulk bins with a capacity of 200–1000 kg are used.

Table 2 Heat classification and applicability (*) of skim-milk powder to recombined dairy products

	Categories of skim-milk powder				
	Extra-low heat	*Low heat*	*Medium heat*	*Medium-high heat*	*High-heat*
Classification parameters					
Whey protein index (ADMI[a], IDF)	nd	≥ 6.0	5.9–4.5	4.4–1.5	≤ 1.4
Heat number (IDF)	nd	≤ 80	80.1–83.0	83.1–88.0	≥ 88.1
Cysteine number	26–33	34–41	42–49	50–60	≥ 60
Recombined products

[b]Specially manufactured, 'heat-stable,' high-heat powder is used.
nd, no data available.

Fats and Oils

Among the traditional dairy-based fat sources – *anhydrous milk fat* (AMF), *unsalted butter*, *anhydrous butter oil*, *butter oil* – AMF has been used most because of its better keeping quality. In order to maintain a good storage stability (6–12 months) of AMF, suitable packaging in steel drums under an inert atmosphere must be applied. Recently, fresh frozen milk fat and soft-fat fraction (produced by fractional crystallization from milk fat) have also been successfully employed in recombined products. Because of their pronounced organoleptic properties, the use of vegetable oils for the manufacture of filled dairy products is restricted to a few oil sources. Only *palm oil*, *coconut oil*, *soya bean oil*, and, to a certain extent, *maize oil* have proved to be suitable. For filled milks, highly refined, bleached vegetable oils are suggested. Some of the oils contain considerable amounts of natural antioxidants. However, all fat components have to be regarded as very sensitive to oxidative and lipolytic rancidity, leading to the formation of objectionable off-flavors. Specifications regarding fats or oils usually contain parameters such as fat and moisture content, fatty acid composition, maximum concentration of free fatty acids, rancidity, peroxide value, trace elements levels, and organoleptic properties. (*See* **Butter**: The Product and its Manufacture.)

Water

Water is the major constituent in many of the recombined dairy products. It is therefore essential that the water used fulfils several standards for *drinking water*, as laid down by the World Health Organization. Besides sensory properties, physical, chemical, (micro)biological, and radiological factors are important. It has been shown that some physicochemical parameters strongly coinfluence deposit formation during thermal processing of recombined products. Today, many countries impose established limits and specifications for drinking water. According to the recommendations of the International Dairy Federation (IDF), water to be used for the recombination of dairy products should not exceed the following maximum salt concentrations: total hardness, 100 μg of calcium carbonate ($CaCo_3$) per gram of water; chloride, 100 $\mu g\,g^{-1}$; sulfate, 100 $\mu g\,g^{-1}$; nitrate, 45 $\mu g\,g^{-1}$.

Additives

Additives can fulfil several targets in recombined products. Owing to certain losses during production and storage, the raw materials used for recombination may contain a lower vitamin content than conventionally produced milk products. In this case, the final vitamin content of the recombined product would be reduced. Fortification with *fat-* and *water-soluble vitamins*, either as single components or in readily prepared mixtures, is therefore applied frequently or is even obligatory. In general, it was noted at the last IDF seminar on milk recombination, in 1988, that recombined dairy products are of a high nutritive value and comparable to conventional dairy products. (*See* **Vitamins**: Overview.)

Antioxidants exhibit a very complex function in preventing the generation of oxidized flavor of the fat components in the product, Since some particular vitamins (tocopherols and ascorbic acid) are capable of inhibiting free radical chain reactions in the lipid phase, they are commonly added as antioxidants. (*See* **Antioxidants**: Natural Antioxidants.)

Stabilizers and *emulsifiers* (carrageenan, alginates, gelatin, lecithin, and glycerolmonostearate) are used to stabilize the fat phase and also to improve the texture and the mouth-feel of the products. (*See* **Emulsifiers**: Uses in Processed Foods; **Stabilizers**: Types and Function.)

Different *salts* (sodium citrates, phosphates, calcium salts, and sodium chloride) are used to assist the reconstitution properties, heat stability, and coagulation, and to act as stabilizing reagents.

Besides *rennet*, the addition of *glucono-δ-lactone* helps to improve the coagulation properties of milk in the manufacture of recombined cheese. Pregastric *lipases* are applied to enhance the development of the desired cheese flavor.

Sugar, as needed for recombined sweetened condensed milk, must fulfil high-quality requirements: sucrose should be of a refined 'A1 granular quality' and of a 'water white' color; the lactose seed material must be finely ground with a maximum particle size of 10 μm.

Depending on the wishes of the consumers, various natural or synthetic *flavors* and *colors* of different origin are also added. (*See* **Colorants (Colourants)**: Properties and Determination of Natural Pigments; Properties and Determinants of Synthetic Pigments; **Flavor (Flavour) Compounds**: Production Methods.)

Recombination Technology

The processes for recombination of dairy products range from rather simple (e.g., recombined pasteurized milk) to more advanced technologies, such as those applied in the manufacture of defined cheese varieties or sweetened condensed milk. Milk recombination plants are normally built with capacities of up to 15 000 l h^{-1}. Parallel lines are installed to achieve higher performances. In general, the

recombination technique has been derived from the conventional processes of dairying, which were further adapted and supplemented by procedures such as weighing, dissolving, mixing, and filtration. 'Tailor-made' recombination systems are frequently built in order to meet the individual requirements. The raw materials are processed using discontinuous weighing, and semicontinuous or continuous recombination systems. Typical equipment for batchtype milk recombination basically consists of the following parts: a jacketed *mixing vat*, which is equipped with a calibrated sight glass or mounted on load cells, so that its contents can be exactly measured, and is thermostatically controlled by circulation through a heat exchanger; a *powder–liquid blender* or a *dumping funnel* with a circulating pump for adding and dispersing powder; equipment for *melting milk fat*; a *clarifier* or *duplex filters*; a two-stage *homogenizer*; equipment for *pasteurization*; a *packaging* line; equipment for *refrigerated storage* of the products.

Modern, continuously working equipment for milk recombination with automatic fat dosage, as designed by Alfa Laval (Lund, Sweden), is shown in Figure 1. It consists of *mixing tanks* (6), in which warm water at 40–50 °C is metered. Skim-milk powder is supplied to the *funnel* (4) and transported automatically into the mixing tank by water flowing through a bypass line. The agitator in the mixing tank is started at the same time as the *circulation pump* (5). After completely dissolving the milk powder, AMF is added via a *measuring tank* (3) from the *fat storage* and *melting tanks* (1). Then, the whole mixture is agitated until complete fat dispersion is obtained. The process is repeated in the next tank when all ingredients have been mixed in and added to one tank. The mixture is continuously drawn from the full mixing tank by a *pump* (7), which propels the mixture through *duplex filters* (8), which remove foreign particles. After preheating in the *heat exchanger* (11), the product is pumped through a *homogenizer* (10), where the fat dispersion is completed. A *vacuum deaerator vessel*

(9) installed in the line before the homogenizer can be used to eliminate the air occluded in the powder particles as well as that picked up during powder mixing. The homogenized product is then cooled in the *plate exchanger* (11) before storage in buffer tanks or packaging.

Besides high-capacity recombination systems such as those shown in Figure 1, other automatic processors can be used advantageously. The Primodan (Holbaek, Denmark) recombiner, for example, is equipped with an adjustable steam-heated butter melter and is capable of milk production capacity of up to 25 000 $l\,h^{-1}$. Another fully automated and energy-saving milk powder dissolver is available from Jongia (Leeuwarden, The Netherlands).

Mixing and Fat Melting

In smaller plants, the powder bags are mostly handled manually; they are emptied directly into the mixer. In larger plants, automatic emptying systems are installed, and the powder is transported pneumatically into storage silos, from which it is mechanically conveyed to the mixing system via a weighing hopper or a screw-feeder.

Milk powder is usually dissolved at high stirring or mixing rates. Simple mixing devices consist of a centrifugal pump attached to a tank filled with the defined amount of warm water, with a powder funnel mounted between. The pump is connected to the jacketed tank with a pipe enabling sufficient circulation. The milk powder is transported into the tank by the vacuum thereby obtained.

In general, the choice of mixer used for dissolving the powder and dispersing the fat depends on the viscosity and/or the dry matter content of the product mix. For recombined products of low viscosity (pasteurized, sterilized and ultra-heat-treated (UHT) fluid milk, stirred yogurts), the following systems are used: turbine or propeller mixers (e.g., Alfa Laval; APV Rosista, Horsens, Denmark; Scanima, Aalborg, Denmark) driven by an electric motor; Venturi jet mixers (e.g., Danish Turnkey Dairies, Aarhus, Denmark); static mixers (Primodan, Jongia); high-speed blenders (TMP mixer, APV Rosista; Tri-Blender, Tri-Clover, Kenosha, WI, USA). The best dispersion is achieved when applying a continuous recirculating motion in the mixing tanks. High-speed blenders are also suited for the preparation of high-viscosity recombined products (e.g., evaporated and sweetened condensed milk, icecream). Another category of mixers are the disc mill mixers, which are also mainly used in the production of recombined sweetened condensed milk. The so-called Disko-Eulgiermix (Figure 2a), capable of simultaneously homogenizing whilst recirculating, and of working under vacuum conditions,

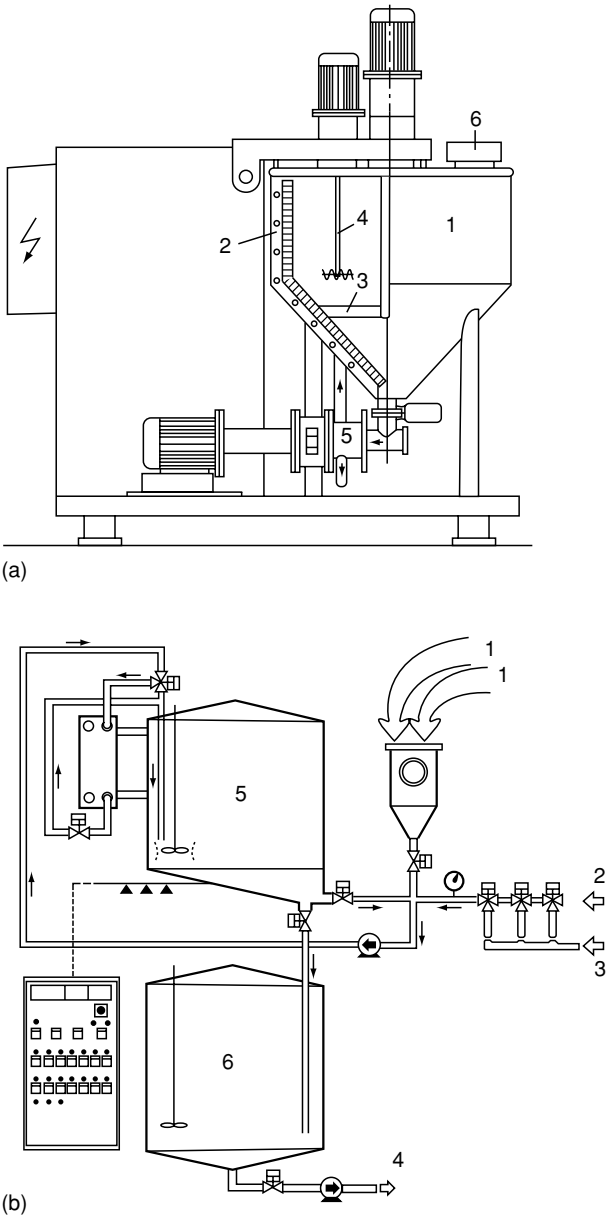

Figure 2 Examples of special mixing units. (a) Disko-Emulgiermix (courtesy of Balik GmbH, Vienna, Austria): 1, vacuum mixing tank; 2, thermostatically controlled jacket; 3, anchor-type stirrer; 4, disk mill dissolver; 5, flow-through homogenizer; 6, milk powder intake. (b) Weighmatic (courtesy of Alfa Laval Food Engineering AB, Lund, Sweden): 1, powder intake; 2, liquid inlet; 3, cleaning-in-place inlet; 4, product outlet; 5, weighing tank; 6, buffer tank. Reproduced from Recombined and Filled Milks, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

was introduced recently (Balik, Vienna). It is suitable for preparing products of different viscosity ranges. By applying a defined vacuum, foaming and picking up of air can be avoided during mixing. Another example for a sophisticated mixing unit is the

Weighmatic (Figure 2b) two-tank system (Alfa Laval), which has been specially designed for the manufacture of recombined icecream and confectionery. The whole mixing process is performed with high accuracy under computer-controlled conditions.

Different systems are used for melting the milk fat. If the fat is packed in cans, the melting process is carried out by placing the cans in water at 80 °C for 2–3 h. Drums containing AMF are either stored in rooms at 45–50 °C for 24 h or rapidly treated in steam tunnels or in a hot-water-heated Primodan butter melter before use. The fat or oil is added into the mixing tank after complete dissolution of the milk powder has been achieved. Depending on the equipment, the melted fat is either pumped or discontinuously added into the mixing vessel.

Filtration, Homogenization, and Pasteurization

From the mixing tank, the product is transferred via a balance tank to a separation unit, consisting of either duplex filters, made from stainless steel with nylon nets, or a clarifier, in order to remove extraneous matter and undissolved particles. Most recombined milk products are homogenized. Depending on the product type, different conditions of homogenization are employed. For most of the products, two-stage homogenization should be preferred. Typical pressures are 14 MPa plus 3.5 MPa for whole milk, 17 MPa plus 3.5 MPa for evaporated milk. (*See* **Filtration of Liquids**.)

Pasteurization is carried out mainly following the conventional dairy technology, using continuous heat exchangers rather than batch heating. The latter system is used only in small-scale production units. Typical conditions are 73 °C for 15 s for whole milk, 75–80 °C for 20–30 s for evaporated milk, 86–92 °C for 30 s for sweetened condensed milk. (*See* **Pasteurization**: Principles.)

Normally, the recombined milk flows from the production line to the filling station, thereby passing buffer tanks. They should be of the aseptic type in the case of sterilized or UHT milk. (*See* **Heat Treatment**: Ultra-high Temperature (UHT) Treatments; **Sterilization of Foods**.)

Future Perspectives

Scientific progress has contributed considerably to the development of improved technologies for recombination of dairy products as well as to the successful use of special dairy-based ingredients. Examples such as the manufacture of recombined feta-type and other cheeses, using retentate or high-protein powders from ultrafiltration technology, confirm this trend. In this context, the functional properties of various components should be well recognized, since they can be utilized specifically. Furthermore, in many of the countries with a recombination industry, long-life milk products would allow a more convenient distribution and storage. Following this aim, modern processes such as UHT technology, cleaning-in-place cleaning facilities and aseptic packaging lines must be considered as factors of growing importance. (*See* **Cheeses**: White Brined Varieties.)

REFUGEES

A M Madden, London Metropolitan University, London, UK

Introduction

A refugee is a person who, 'owing to a well-founded fear of being persecuted for reasons of race, religion, nationality, membership of a particular social group, or political opinion, is outside the country of his nationality, and is unable ... to avail himself of the protection of that country,' as defined by the United Nations High Commission for Refugees (UNHCR). It is estimated that there are approximately 12.1 million people in the world today who have legal status as refugees and that a further 1.2 million people, described as asylum seekers, are in the process of applying for refugee status. It is also estimated that another 25–30 million people have fled their homes for the same reasons as refugees, but as they have not left their country of origin, they are classed instead as displaced people. These groups are distinguished from economic migrants who retain, at least theoretically, the protection of their country of origin. The problems relating to food and nutrition for refugees, asylum seekers, and displaced people are similar and, in many situations, indistinguishable. For simplicity in this article, the term 'refugee' will be used to include all asylum seekers and displaced people except where there is a significant legal difference which pertains to their ability to purchase food or obtain employment.

Since data were first collected in 1951, the total number of individuals categorized as refugees has increased substantially overall and in most regions of the world (Table 1). War and its consequences have led to the movement of the greatest numbers of refugees during this period, as typified in Europe after the Second World War, in South-east Asia following the prolonged and geographically widespread effects of the Vietnam war, and in India where 10 million people fled to India in 1971 following the Bangladeshi war of independence. In many situations, the effects of war have been exacerbated by famine,

either directly or in combination with drought, as in the Horn of Africa during the 1980s.

In addition to large movements of populations whose motivation is primarily survival, some people become refugees as individuals and for personal reasons. These may include political persecution, conscientious objection to war or military service, or fear of attack for refusing to comply with cultural expectations, for example, wearing restrictive clothing or undergoing genital mutilation. Inevitably, the nutritional implications of refugee-hood for such individuals are very different from those affecting refugees displaced in large numbers as a consequence of armed conflict.

The food and nutritional issues affecting refugees vary considerably depending on their geographical homeland and area of relocation, the health and nutritional status of individuals before displacement, the duration of displacement, external factors such as conflict and loss of infrastructure, and the availability of humanitarian relief. In addition, psychosocial and cultural influences may also have a major effect on the nutritional well-being and food needs of these people which in total represent almost 1% of the world's population. Against this background, the food and nutrition of refugees can be considered in two separate contexts: first, the emergency provision of food in refugee camps and, second, the nutritional well-being of refugees after moving to countries of asylum.

The Emergency Provision of Food in Refugee Camps

Article 25 of the Universal Declaration of Human Rights (1948) states that 'Everyone has the right to a standard of living adequate for health ... including food ....' While recognizing the indispensable need for food, it is impossible to consider the nutritional requirements of refugees in isolation without acknowledging the essentiality of a place of physical safety and access to clean water, sanitation, and health care facilities. These factors, along with nutrition and food aid, represent the five pillars which support the Humanitarian Charter, an interagency collaboration aiming to increase the effectiveness of humanitarian assistance to people affected by disasters. Each pillar of the Charter is in turn supported by a set of universal minimum standards. The standards for nutrition focus on general nutrition support to the population and nutrition support to those suffering from malnutrition; the standards for food aid consider the food rations required, targeting of food, resource management, logistical operations including transport and storage, and food distribution to the people in need.

Food Rations for Refugees

Food rations for refugees generally comprise a staple cereal, vegetable oil, and sometimes pulses and salt. Some rations are deficient in overall energy content and provide inadequate micronutrients. As a result, refugees may suffer from diseases of nutrient deficiency, including protein energy malnutrition, beriberi, pellagra, and scurvy. In 1997, the average nutritional requirements for refugee food rations were increased by the World Food Programme and UNHCR to 2100 kcal (8782 kJ) per person per day, in line with World Health Organization recommendations (Table 2). These figures are based on a defined demographic profile which, if different from the population under consideration, will necessitate adjustment to the average requirements.

In order to prevent or correct micronutrient deficiencies, the World Food Programme and UNHCR recommend that at least some of the food rations should be provided in the form of blended foods, particularly for refugees who are totally dependent on food aid. Blended foods are a precooked mixture of cereal and oil seed and sometimes a pulse such as chickpeas to which a vitamin and mineral mixture has been added. Generally, they are expensive as most are produced in the USA, although the World Food Programme has also procured some produced locally to requirements.

Powdered or modified milk should not be included in general food distribution to refugees because of the potential hazards associated with inappropriate dilution, contamination and, in some populations, lactose intolerance. Support for breast-feeding is paramount as facilities for safely preparing formulae are rarely available in refugee camps; in situations where sanitation is inadequate, the death from diarrheal disease

Table 2 Average nutritional requirements used for initial planning purposes in refugee camps, based on a defined demographic pattern

Nutrient	*Mean population requirement*
Energy	2100 kcal (8782 kJ)
Protein	10–12% total energy (52–63 g) but < 15%
Fat	17% total energy (40 g)
Vitamin A	0.5 mg retinol equivalents
Thiamin	0.9 mg (or 0.4 mg per 1000 kcal intake)
Riboflavin	1.4 mg (or 0.6 mg per 1000 kcal intake)
Niacin	12.0 mg (or 6.6 mg per 1000 kcal intake)
Vitamin C	28.0 mg
Vitamin D	3.2–3.8 μg calciferol
Iron	22 mg (low bioavailability, i.e., 5–9%)
Iodine	150 μg

is 14 times higher in artificially fed babies than in those who are breast-fed.

Suitability of Food Aid

Although in extreme starvation people might consider eating any potential food, it is well recognized that the acceptability of foodstuffs provided for refugees in humanitarian relief operations must be considered in order to optimize any nutritional benefit. Unpopular, unpalatable, or difficult-to-prepare foods may be exchanged for preferred items as observed, for example, in camps in Kenya, Guinea, and Zaire, where refugees sold maize at a financial loss in order to buy rice and nonfood requisites. Although the resulting diets had an improved micronutrient content, the total energy content fell, further jeopardizing nutritional well-being. Generally, blended cereal foods are well accepted, particularly by people who are already familiar with porridge-type foods. In Ethiopian refugee camps, where only a limited variety of food items were available for approximately 6 months, sensory-specific satiety or ration fatigue has been observed. It has been suggested that the provision of sugar, chilli, and other spices may alleviate poor appetites induced by repeatedly eating the same foods; although flavorings and condiments contribute little nutritional value of their own, they may help refugees eat sufficient to maintain an adequate intake.

Nutritional Well-Being After Moving to Countries of Asylum

While considerable attention has been given to the nutritional needs of individuals living temporarily in refugee camps, relatively less regard has been paid to the nutritional well-being of refugees once they have settled in a host country which is often geographically and culturally distant from their homeland. Governmental data indicate that approximately 418 000 people applied for refugee status in European countries during a 12-month period to March 2001, with approximately 18% of applications being received in the UK (Table 3).

The provision of housing, legal assistance, and basic health care is usually amongst the first priorities dealt with by organizations assisting newly arrived refugees and asylum seekers, with education and psychological support, primarily for the young, also receiving attention. Few systematic studies have been undertaken to evaluate the nutritional status of refugees living in western countries, although there are a number of factors which suggest that they may be at nutritional risk (Table 4).

Psychological issues

Nutritional Status on Arrival

The nutritional status of some individuals may be suboptimum when they arrive in the host country and this will be influenced by their general health, the nature of their departure from their homeland, the journey undertaken in flight, and any intervening periods spent in camps en route. Refugees from some countries, for example, Ethiopia, Somalia, and Sudan, may have been exposed to communicable and parasitic diseases, including tuberculosis, malaria, and schistosomiasis, which may further impair an already diminished nutritional status. Individuals arriving from European countries are less likely to suffer from obvious nutritional depletion, generally because of their better initial nutritional status, shorter periods of displacement, and prior vaccination to common communicable diseases, although inevitably there are exceptions. Some refugees who have endured long overland journeys, often covertly crossing several international borders, may arrive depleted and at risk of weight loss and subclinical micronutrient deficiency after consuming an inadequate diet for several weeks or longer.

At present, many templates for the health screening of newly arrived refugees in the UK do not make reference to nutritional variables. This is a cause for concern, particularly for infants and children who are most likely to be at nutritional risk and for whom the consequences of nutritional depletion are greatest. Evaluation of their nutritional status on arrival is, therefore, imperative.

Not all newly arrived refugees have nutritional problems, however, and many are generally in good health and physically fit. There is evidence that the health status of some refugees deteriorates and is worse 2–3 years after arrival in the host country. In some cases the cause for this deterioration may relate specifically to their situation as refugees, for example with tuberculosis and mental health problems, while in others, it may be a consequence of adopting an unhealthy urban lifestyle and diet. Obesity has been observed in Chilean and Bosnian refugees in Sweden, even after adjustment for socioeconomic status, and there is a high incidence of dental caries in young Vietnamese refugees which increases with the length of stay in the host country.

Poverty

After arriving in a host country, many refugees live in poor housing, receive limited financial support, and have difficulty obtaining paid work. As a consequence, their ability to purchase food and eat a healthy diet is constrained. Policies of dispersal in the UK have resulted in many refugees being housed in areas away from their initial point of entry, but typically, refugees settle in the poorest areas of large cities. Many of these deprived urban areas, where few supermarkets are located, are considered 'food deserts' and, in the absence of adequate cheap transport, the local residents have little choice but to buy their food from small corner shops. Generally, these sell a limited range of food products and few fresh fruit and vegetables, for which they charge relatively high prices. Asylum seekers are initially housed in temporary accommodation until their refugee status is legally confirmed, which may take several months or longer. Such accommodation is usually found in bed-and-breakfast establishments or small hotels where there are few cooking facilities and limited storage for food. Inevitably, it is difficult for people living in these situations with limited money to eat a healthy diet.

The financial support provided for refugees varies between host countries, the legal status of the applicant and, in some cases, where the application for refugee status is made. In most countries, no benefit is paid to people applying for asylum until they are granted legal refugee status unless they can demonstrate financial hardship and then they may receive reduced levels of benefit (Table 5). For example, asylum seekers in Germany receive their accommodation, a food parcel, some clothing, and a small sum of money for 'personal requirements' each month. Financial benefit is only paid in exceptional circumstances and then, for the first 12 months, at a rate 20% lower than that given to other members of the community. Similarly, in the UK, asylum seekers are supported through a virtually cashless system, receiving vouchers to a value of 30% less than income support paid to other recipients. Vouchers can be exchanged for food and basic necessities only at designated shops but cannot be traded for money. This has caused some difficulty for refugees wishing to purchase halal meat from specific outlets. The introduction of food vouchers is unpopular and has been widely criticized by a number of refugee and nutrition organizations as inflexible and potentially compromising nutritional intake. Applications for asylum may take several months or longer to be processed, during which a single adult aged over 25 years would receive £36.54 per week in vouchers. The quantity and quality of food that can be purchased for this figure is limited, particularly if access to cheaper shops and cooking facilities are not available. If individuals are granted legal refugee status they are entitled to cash benefits at the usual value of income support to other UK claimants and may also be entitled to a back-dated cash sum. On being granted legal status, refugees are entitled to move from temporary

Table 5 Eligibility of asylum seekers for benefits and employment

Country of asylum	*Financial and other benefits*	*Employment eligibility*
Australia	Financial hardship only: 89% of standard benefits	Dependent on visa (if any)
Belgium	Theoretically eligible but local authority-dependent	Provisional work permit if claim deemed admissible
Canada	Welfare assistance available if meet financial criteria	Eligible to seek work after submitting appropriate form
France	Financial help as a cash sum. Eligible for social security	No access to labor market unless authorized
Netherlands	Free board and lodging plus small monthly cash sum	Not eligible
Sweden	Eligible for social benefit, paid daily if necessary	No work permit required if decision expected < 4 months
Switzerland	Eligible for welfare benefits at reduced rates paid 'in kind'	Not eligible for first 3 months
USA	Information not available	Not eligible

Adapted from Bloch A and Levy C (1999) *Refugees, Citizenship and Social Policy in Europe*. Basingstoke: Macmillan Press.

accommodation to a more permanent residence where the cash sum could be used to purchase kitchen and other essential household items which might help facilitate an improved food intake.

The term 'refugee' embraces people from a multitude of backgrounds and includes people with a wide variety of employment skills. Although varying greatly with area of origin and gender, a high proportion of refugees are well-educated and professionally trained. However, obtaining work is forbidden in most host countries until legal refugee status is established, and even then, is often very difficult, even for professionals whose qualifications may not be recognized (Table 5). As a result, there is a high level of unemployment in most refugee communities and, of those who are working, many are employed in low-paid, unskilled, and sporadic jobs. Whilst not influencing food intake directly, the difficulty in obtaining work and consequent relative poverty exacerbates the problems already outlined and makes it difficult for individuals to work their way out of financial hardship.

Cultural Factors

Refugees are not a homogenous group which can be considered together, coming as they do from many different countries from all geographical regions of the world and bringing with them a wealth of culture and tradition which may differ considerably from those of their host country (Table 6).

In addition to providing dietary energy and essential nutrients, food plays important social and cultural roles for most people. The foods eaten, the methods of preparation and serving, and the context in which they are consumed often have significant social meaning and help define group identity. For refugees displaced from their homeland and often separated from their families and friends, the importance of food symbolism may grow and in some cases may represent one aspect of their lives over which they have some control. However, difficulties arise when familiar food items are unavailable or can only be purchased at great expense or from specialist shops in areas where there is a refugee community of significant numbers. Similarly, familiar cooking implements or facilities may not be available and preclude the preparation of specific dishes. Whilst most refugees quickly become skilled at adapting available substitutes and learning new skills, food intake will by necessity change and may lead to a diet which is nutritionally inadequate compared to their traditional fare.

Food habits may also need to be adapted in terms of who prepares the meals and with whom food is shared. Refugees who traditionally live in extended families where women frequently undertake most of the food preparation and do not have outside employment may find themselves living in smaller and more isolated nuclear family groups where a large shared meal is no longer a major focus of the day. Many refugees are young men who may have had little practical experience of preparing their own food. A study of single male Ethiopian refugees living in Ottawa, Canada, found that their total energy intake was related to their domestic skills and that a lack of such skills was the most commonly perceived dietary problem.

Children who may have been expected to contribute to food preparation and cooking in their homeland may be influenced by their host country peers, who generally have less responsibilities, and as a result wish to avoid participation in household tasks which might be viewed by others as exploitation. In Minneapolis, USA, 30–45% of adolescent refugees from South-east Asia report primary responsibility for preparing the evening meal. A Kurdish mother in London described how 'at home, an eight-year-old could cook a meal. Now they can't do anything. They just watch television all day'. Some children may select a more western-type diet in order to try to fit in with their contemporaries or to distance themselves from painful memories of their homeland while others may cling to traditional habits and avoid the stress of trying unfamiliar foods.

Communication

Some, but not all, refugees arrive in the host country speaking the local language. For those who do not, an inability to communicate easily may increase difficulties experienced in many aspects of life, including shopping for food. This becomes an increasing problem when the available foods are unfamiliar and ingredients or cooking instructions cannot be read.

Table 6 Origin of asylum applicants in Europe (2000–2001)

For refugees who may be familiar with growing much of their own food or shopping in a market, food shopping can present some difficulty. Generally, school-aged children and men are more likely than women to speak the host country language and yet women are often charged with shopping for food. Whilst interpreters may sometimes be available, they generally assist with legal issues or essential health matters and are rarely used for what may be considered more mundane food-related communication. However, health authority interpreters in the UK provide a free service for hospitals and general practice surgeries and should be available for nutritional consultations if required.

Psychological Issues

Refugees may have faced many diverse experiences before arriving in their host country. Some have suffered violence, loss, separation, family disruption, and terrifying journeys. Concerns may continue even when a place of perceived safety is reached, including uncertainty over asylum, anxiety for relatives left behind, difficult living conditions, hostility from local people, and the challenges of settling into a new life. As a consequence, many refugees report psychological problems, with two-thirds of adult refugees in the UK experiencing anxiety or depression and 90% of Bosnian children in the USA showing signs of posttraumatic stress disorder. Other symptoms, which may be exacerbated by poverty and isolation, include poor sleep patterns, loss of memory, panic attacks, and agoraphobia. Loss of appetite and lack of interest in food may also be a problem.

Approaches to psychological well-being vary between cultures. Refugees from some backgrounds may be uncomfortable with western-style counseling or 'talking treatments' and prefer instead to attend to practical issues which they consider will make their lives better. Interestingly, food and nutrition are perceived by many as 'safe' subjects and have been used as a focus for discussion groups in both Canada and the UK as a way of providing practical and emotional support for refugee women in a nonthreatening environment. The cooking of traditional recipes and sharing of food has also been used as therapy in a group of London-based refugees recovering from torture.

RELIGIOUS CUSTOMS AND NUTRITION

P Christian, Johns Hopkins University, Baltimore, MD, USA

Religious Dietary Laws and Nutritional Status

Food in all human societies is more than just a source of nutrition required for survival. It is deeply entrenched in the religious, social, and economic aspects of life and carries with it various symbolic meanings, many of which express the relationship between humans and their deities. Among numerous factors that shape dietary practices, religious laws are most prevailing. Religious dietary regulations which determine food-related behaviors of individuals are codified in the written religious texts and holy scriptures, although different interpretations of these may also be found. The extent to which individuals follow food-related prescriptions or proscriptions may depend on their religiosity – the degree to which they adhere to a set of religious beliefs. Some dietary habits may not have their origins in religious doctrines, but are adhered to due to a strongly held cultural or traditional belief common to the members of a religious group and may be tied to a religious or historical event.

The origins of religious dietary laws have been extensively debated by both ancient and modern-day scholars, although no single theory appears to be well-accepted. Among theories that exist, the ones that are related to dietary laws being divine commandment, or having allegorical parallels or esthetic origins are considered subjective and emotional in nature. Other theories, based on reasons of health and sanitation, ethnic identity, and ecology, are generally more well-accepted. For example, reasons of health and sanitation are considered the best scientific explanations for the prohibition of carrion, pork, and blood in Judaism and Islam. Supporters of this theory contend that the cause–effect relationship between ingestion of specific foods and the manifestation of disease are reflected in the dietary laws prescribed in the scriptures. On the other hand, the ecologic theory propounds that because the environment is more favorable towards the availability of certain types of flesh foods but not others, proscriptions regarding eating the latter type of animal foods makes economic sense. The hypothesis pertaining to ethnic identity suggests that dietary laws and codes set aside one religious/ethnic group from another and tend to foster religious and ethnic cohesiveness.

Noteworthy are the shared attributes of the dietary regulations across different religions. All major religions have prohibitions, either permanent or temporary, regarding consumption of animal foods. In Hinduism and Buddhism, killing living creatures is abhorred and meat consumption is forbidden. Judaism and Islam forbid the consumption of pork, and meat intake is restricted on fasting days among orthodox Christians, and on Fridays among Catholics. Most religions also advocate religious fasting, usually associated with religious observances. Fasting is considered to be an act of penitence and is practiced in order to gain spiritual merit. Most religious fasts last over a brief period of time with either total abstinence from food or from specific food items. The Ramadan fast, observed every year by Muslims, worldwide, is the most studied of all religious fasting customs. The Eastern Orthodox Church observes two major fasts: the Lent fast and the Advent fast in the 40 days preceding Easter and Christmas, respectively.

Religious dietary prescriptions or proscriptions as outlined by dietary laws and guidelines can be broadly classified into ceremonial, periodic, or habitual (Figure 1). Ceremonial prescriptions, such as

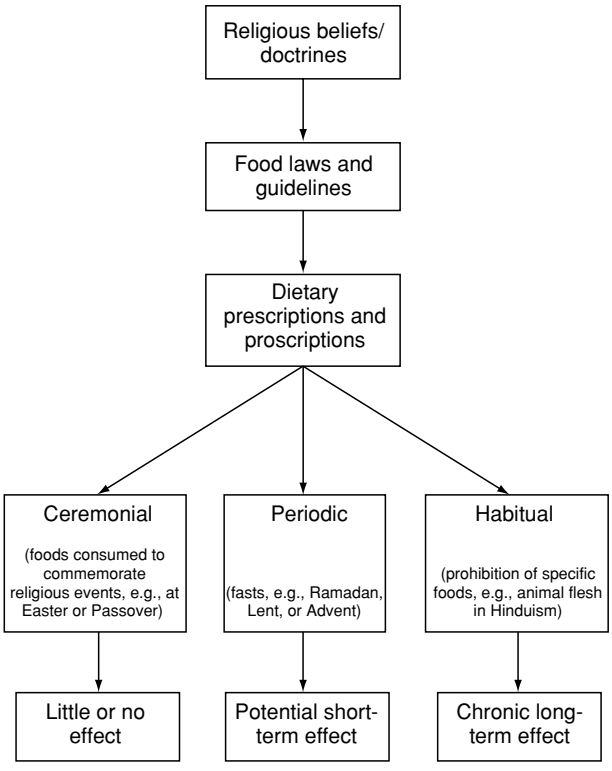

Figure 1 Religious dietary laws and types of nutritional effects.

eating lentil soup on Good Friday, symbolizing the tears of the Virgin Mary, or lamb on Easter, or 'seder' plate with foods symbolic of events in Jewish history at Passover, may have little or no nutritional effects and are not considered here. Periodic customs such as religious fasting may result in a potential short-term alteration in a group's nutritional status. Dietary guidelines that prohibit all animal foods, such as in Hinduism and Buddhism, are habitual and likely to have chronic long-term effects on nutritional status and health. Prohibition of pork in Judaism or Islam falls in this category of dietary proscriptions but its nutritional effects are unknown. Data are scant on the relationship between religious customs and nutritional status. Also, certain food practices may be latent in modern times, with little known about their nutritional effects. None the less, particular groups of individuals, following clearly defined and unique dietary customs of their religion, have been studied, to some extent, in order to understand better the nature of such customs in relation to their nutritional and health outcomes. These cover religious dietary customs of each of the five major religions of the world – Christianity, Islam, Judaism, Hinduism, and Buddhism – and are described below in more detail.

The Fast of Ramadan

One of the most common religious practices uniformly followed by Muslims throughout the world is that of fasting in the month of Ramadan. Fasting in Ramadan is one of the Five Pillars of Islam, the others being the statement of faith, prayers five times a day, giving your dues to the poor, and pilgrimage to Mecca. The holy scriptures of Qur'an reveal the reasons for fasting: the main one is the Revelation of Qur'an, a guidance for mankind and the criterion of right and wrong, which occurred in this month (2.185). Fasting is also considered a training in self-control, of restraining one's needs and desires, and in deepening spiritual life. According to Prophet Mohammed, fasting can also improve health, and Muslims fast for better health.

Fasting during Ramadan is partial or controlled, as Muslims abstain from food and drinks during the hours from sunrise to sundown. Fasting is obligatory for every adult Muslim, although sick individuals or those traveling, and pregnant and lactating women are exempt but have to make up for the missed days. Elderly people and children under the age of puberty are also exempt, although the former group is expected to give food, cash, or kind to a needy person for each day of missed fast. Fasting is forbidden for women during menstruation but they are also required to make up for the missed days.

On the night before fasting commences and each night thereafter, Muslims consume a predawn meal called 'sahoor', after which they abstain from eating or drinking until sundown. Immediately after sunset the fast is broken with a meal called 'iftar'. There are primarily three types of changes that occur in the food-related behaviors of Muslims during this month. One is the change in the frequency and time of meal consumption, with long periods of fasting and short periods of food intake which might result in gorging. Frequency of eating decreases from an average of 4.4 times to 2.8 times per day during Ramadan. The second change that occurs is in the types of foods consumed during Ramadan. It is customary to prepare and consume special foods which are rich in protein and carbohydrates as well as eat fresh or dried fruits and vegetables. The third notable change is in the sleeping pattern, since the number of hours of sleep is reduced due to the predawn partaking of breakfast.

Fasting During Ramadan and Nutritional Status

Ramadan fasting has drawn considerable interest among nutritional scientists as it provides an excellent opportunity to study the effects of restricted energy intake and altered periodicity of meals on changes in body weight, composition, fluid, and electrolyte balance, and metabolic and biochemical changes, especially those of serum lipid concentrations in free-living populations. Most data are derived from studies using small numbers of subjects who are examined before and after the Ramadan fast. Rarely are nonfasting control groups used to account for seasonality or other changes that occur during the month, nor are the long-term effects of these annual fasts described.

Energy intake and weight changes during Ramadan

Fasting during Ramadan results in moderate body weight losses in both men and women, primarily due to declines in energy intake. Body weight decreases range between 0.3 kg and almost 2.5 kg, with energy intake reductions, in some cases, as high as 20–25%. Significant reductions in skinfold thickness and elevation in plasma glycerol concentrations suggest that decreased body fat may be the main component of body weight loss. Decreased water intake by more than half a liter per day can cause dehydration, also contributing to a reduction in body weight. A pattern of slower decline in weight observed in a few settings may be attributed to metabolic adaptation and reduction in physical activity over time.

Although in general there is a reduction in body weight during Ramadan fasting, some individuals or

groups may experience no change, or in some cases, even weight gain. The weight increase may be related to increased consumption of foods high in sugars and protein which is common during Ramadan. It is also customary to eat meals with friends and relatives, which is conducive to higher food intake. Further, a decline in respiratory exchange ratio reflecting increased mobilization of body fat is suggestive of a metabolic adaptation to fasting.

Dehydration due to abstinence from drinking fluids over long periods of time during Ramadan has been a cause for some concern, especially in hot tropical climates. Negative fluid balance among fasting individuals is evident by increased hematocrit, serum sodium, calcium, protein, creatinine, urea, and modified electrolyte balance. Increased concentration of urine and decreased urine volume and salt retention are some of the compensatory mechanisms to achieve fluid balance. The season in which the month of Ramadan falls may have a big effect on the evaporative water loss that can occur. Studies have shown conflicting results: some suggest no negative fluid balance while others show this may be due to environmental factors such as temperature and humidity of the place and season in which the studies were carried out.

The effects of Ramadan fasting on changes in carbohydrate metabolism are not well-known. Although fasting levels of glucose and insulin tend to remain unchanged, or decline initially but then return to normal later, circadian profiles of gastric pH, plasma gastrin, insulin, glucose, and calcium are modified during Ramadan. Increased concentrations of urea and uric acid suggesting increased catabolism have not always been confirmed.

The effect of Ramadan fasting on plasma lipids and lipoproteins has received some interest. Almost consistent reports of no change in total cholesterol and low-density lipoprotein-cholesterol (LDL-C) and beneficial increases in high-density lipoprotein cholesterol (HDL-C), apo A-1, and apo A-1 to apo B ratio are found. While these effects may be sustained for about a month after Ramadan ends, the impact of such transient annual changes on cardiovascular disease remains unknown and open for research.

Pregnancy and Lactation and Ramadan Fasting

The rules of exemption from fasting in certain conditions such as during pregnancy or while breastfeeding an infant appear to have varying degrees of acceptance and interpretation. In some cultures, pregnant women may either be unaware of this exemption or may choose to fast with the rest of the family rather than alone, at a later time, due to the inconveniences of a different meal pattern and cooking. Cases of unsuccessful lactation due to fasting have led to unhygienic alternatives being offered to the young infant in lieu of breast milk, resulting in adverse health effects. The effects of dehydration due to abstention from drinking water during Ramadan on lactational performance suggest that, although lactating women may lose some of their total body water during the daylight hours, plasma indices of dehydration over a 24-h period remain in a normal range. This may occur because women adapt by superhydrating themselves overnight and by restricting urinary output. Despite these mild changes in their state of hydration, there may be marked changes in breast milk osmolality, lactose, sodium, and potassium concentrations, reflecting disturbed milk synthesis. Accounts of drastic effects of fasting on young breast-feeding infants is found in the 1930s when severe forms of xerophthalmia (clinical signs of vitamin A deficiency) occurred in infants whose mothers participated in long-term religious fasts.

Scientific knowledge on the health and other impacts of fasting during pregnancy is scant, although metabolic consequences of fasting during pregnancy, such as declines in concentration of serum glucose, insulin, lactate, creatinine, and a rise in triglycerides and hydroxybutyrate suggests a state of a phenomenon termed as 'accelerated starvation.' Although pregnancy outcome, including birth weight of infants whose mothers observed Ramadan fast during pregnancy, does not appear to be affected in affluent settings, increased rates of low birth weight, stillbirths, and perinatal mortality are observed among populations living in poor, more stressful environments. It is hard to determine, however, whether the adverse outcomes are a direct result of the fasting. Interestingly, increased full-term births have been recorded during the 25-h-long fast of Yom Kippur.

The Hindu Conception of Vegetarianism: The Sacred Cow

In the pre-Aryan Indus valley civilization, it was the bull, not the cow, that was venerated. Cattle were prized assets and considered objects of worship, as recounted in the hymns of Rig-Veda, the holy Hindu scriptures written in 1500–100 BCE. The Atharva-Veda, which came later, is where the first accounts of the prohibition of the slaughter of cows are found. While meat eating was practiced, and cows were occasionally slaughtered for guests and at times of festivity, the sacredness of the cow, manifest as the Vahan (carrier) of god Shiva became complete in the great epic Mahabharata. Here the sanctity of a cow is recognized and attributed to being a source of food (milk), promoting fertility, removing evil influences,

and assisting the soul in crossing the river of death at the end of life's journey. Even the Dravidian agricultural civilization recognized the practical value of cattle to provide manure as a fertilizer or to work pulling ploughs, apart from providing milk and its products which had great nutritional value to families and communities.

The taboo of killing living creatures at large is tied to the concept of ahimsa or nonviolence that prevails widely in Hinduism, Buddhism, and Jainism. Vegetarianism is practiced by devout Hindus (especially Brahmin priests of the highest caste), Buddhists, and Jains. It is difficult to assess the nutritional effects of this habitual religious prescription of vegetarianism in populations which are primarily vegetarians due to a lack of adequate control omnivorous groups from the same population. Nonvegetarian groups living in the same environment may come from differing religious or socioeconomic backgrounds. Further, nutritional deficiencies common in developing countries where vegetarianism is practiced (for example, India) may occur due to multiple environmental and other factors, which makes it hard to study the solitary effects of a vegetarian diet. However, there is a significant amount of literature gathered over the past few decades of the effects of vegetarianism as practiced among Hindus, Buddhists, and other Asian groups who have emigrated to Europe or North America. The diet and nutritional status of these populations has been compared with that of omnivores of indigenous origin living in the same environment and with similar socioeconomic backgrounds.

Hindu Vegetarianism and Nutritional Status

The nutritional adequacy of vegetarian diets (predominantly lactovegetarian) adhered to by certain religious groups has focused on minerals such as iron, zinc, copper, and vitamins B_{12} and D. The observation that infants born to predominantly vegetarian Hindu women have consistently low birth weight, although birth length is comparable to those of the indigenous Caucasian populations, has resulted in studies to examine whether nutritional deficiency, either of total calories or specific micronutrients such as zinc or iron might be a factor, although genetic differences cannot be completely ruled out. Zinc and copper intakes of vegetarian, pregnant Hindu women are lower compared to those of European pregnant women. However, no association is found between measures of zinc or copper status and birth weight. Moreover, plasma zinc and copper concentrations are surprisingly similar in both vegetarian and nonvegetarian Asians, whether living in India or Europe, suggesting that vegetarianism *per se* may not be associated with poor intrauterine growth and that ethnic differences are likely to explain the detrimental birth weight among Asians.

Influence of maternal vegetarianism on essential fatty acid status of newborn and pregnancy outcome has also been examined in Asian vegetarians compared with white omnivores. Although intake of eicosapantaenoic acid and docosahexanoic (DHA) acid are absent in the diets of vegetarians and infants of these women have significantly lower DHA in their plasma or cord blood, these factors are, again, not related to the outcome of pregnancy such as birth weight, length, and head circumference of infants. The prevalence of iron-deficiency anemia is higher among emigrant females and male vegetarian populations than that observed in omnivorous Caucasian populations in North America and western Europe, which may be related to the high fiber and phytate content of the former's diets. The major source of cereal grains in these populations is unleavened bread (chapatti). Although total iron intake is similar in both groups, the nonheme form is the major source of iron among vegetarians.

Diets of vegetarian Gujaratis (from the state of Gujarat in India) living in the UK have also been found to be lower in vitamins D and B_{12}, although intakes of other vitamins, such as A, B_1, B_2, and folic acid, are similar to those of the European nonvegetarian controls. It is interesting that subclinical vitamin D deficiency among vegetarian Asians (mostly Gujarati) in the UK resolves spontaneously during the summer months. No such seasonal variation is found among the Caucasian population, consistent with their adequate vitamin D status. Increased exposure to sunlight during the summer months followed by cold dark winter months in a population with dietary insufficiency of vitamin D may be an explanation for this seasonal phenomenon. Osteomalacia and rickets are more likely to occur in Asians living in the UK, especially the vegetarian Hindus, and young Asian children also have lower serum 25-hydroxycholcalciferol concentrations compared to white children.

Risk of tuberculosis (TB) in immigrant Asians (especially Gujaratis) is also found to be high and consistently higher than that recorded in their country of origin. TB rates are three to five times higher among vegetarian Asians than either nonvegetarian Muslims or Asians consuming a mixed diet. A range of socioeconomic, migration, and lifestyle variables fail to explain the risk of TB, suggesting a contributory role of dietary factors in determining susceptibility to disease. Vitamin D deficiency has previously been linked to impaired host defense against TB by increased mycobacterial reactivation. An early summer peak in notified cases of TB in the UK among Asians

is indicative of low postwinter trough concentration of 25-hydroxycholecalciferol contributing to the reactivation of latent infection.

The other deficiency frequently found among vegetarian Hindus residing in Europe is that of vitamin B_{12}. Milk is a source of vitamin B_{12}, but boiling milk to extract the fat, which is a common practice among Indians, can destroy much of the vitamin. Apparently healthy lactovegetarian Indians tend to have lower concentrations of vitamin B_{12} in serum and urine compared to nonvegetarians. This deficiency is not, in most instances, due to a metabolic defective absorption caused by the lack of intrinsic factor which results in pernicious anemia, but due to nutritional cobalamin deficiency. Although vitamin B_{12} deficiency is common on the Indian subcontinent, the evidence of a large-scale problem of megaloblastic anemia became apparent through studies of vegetarians who emigrated on a large scale from East Africa to UK. In India, however, many cases described as nutritional megaloblastic anemia may be due to both cobalamin and folate deficiencies.

Seventh Day Adventists and Vegetarianism

Not all the effects of vegetarian diets prescribed by certain religions have negative nutritional effects. In fact, when availability and diversity of food are not found to be confounding factors, the beneficial effects of a vegetarian diet have been well demonstrated. A good example is that of the most widely studied of modern religious groups, the Seventh Day Adventist (SDA) Christians who espouse primarily lactoovovegetarian diets and refrain from smoking or drinking. While these proscriptions are not found in the Bible, the SDAs maintain that the dietary practices are based on the general theological consideration that the human body is the temple of the Holy Spirit and should be protected. Numerous studies have documented the improved benefit of the SDA dietary and lifestyle factors on their health and survival. Rates of cancer and cardiovascular disease mortality are much lower among Adventists from the USA, Australia, and the Netherlands compared to non-Adventist groups. Because most SDAs do not smoke or drink alcohol, and have varying degrees of meat consumption, it is hard to distinguish between the beneficial effects of vegetarian diets versus lifestyle factors. However, there is evidence to suggest that among SDAs, vegetarians are healthier than nonvegetarians but this may not be ascribed only to absence of meat intake.

All-cause mortality among SDAs is shown to be negatively associated with green salad consumption and positively associated with consumption of eggs and meat. Low meat and saturated fat intake and high intakes of carbohydrates and dietary fiber may be associated with these marked protective effects. Low levels of cholesterol and blood pressure have been observed among some SDA groups. The protective effect against major sites of cancer may be due to higher intakes of foods providing vitamins A and C or in some SDA groups the lower frequency of digestive tract cancers may be due to consumption of broiled - meat or fish, which produces little or no benzo(α)pyrene and nitrosamines, which are carcinogenic products of heated or burnt meat. Higher consumption of all or dried fruits has been associated with reduced risks of lung, prostate, and pancreatic cancer among the Adventists adjusted for sex, age, and cigarette smoking history.

Although there might be some concern regarding inadequate intakes of certain trace minerals obtained through a vegetarian diet, dietary intakes and status of various nutrients such as iron and zinc have been found to be adequate among SDAs, despite the high content of total dietary fiber and phytate of a vegetarian diet and low intakes of iron and zinc from flesh foods. Body mass index, vitamin A, and hemoglobin concentrations among vegetarian and nonvegetarian SDAs are generally similar, although instances of low vitamin B_{12} have been reported in countries where food fortification with vitamins is not done and supplementary vitamins are not consumed.

Buddhist Vegetarianism

Similar beneficial effects of a vegetarian diet have been observed among young modern Chinese Buddhists. Their diet is high in carbohydrates with a moderate fat content since rice and soybean provide most of their calorie and protein requirements. The blood concentrations of cholesterol, glucose, and uric acid concentration of a vegetarian Buddhist are lower, and that of apo A-1 to apo B ratio higher, compared to Chinese omnivores, suggesting a protective effect of a vegetarian diet for chronic degenerative diseases. Similarly, the blood pressure of Buddhist vegetarians is significantly lower than those of nonvegetarians of similar age, sex, and body mass. This might explain in part the lower all-cause mortality observed among Zen Buddhist priests who consume a traditional Japanese diet comprising vegetables and seafood with low amounts of meat.

Jewish Dietary Laws and Nutrition

Although many accounts of Jewish dietary laws, their origins, and scientific rationalizations are found

in the literature, the effects of Jewish dietary prescriptions and proscriptions on the nutritional status of Jewish people are not well-examined. The Jewish dietary laws, called the Kashruth, are codified in the Torah in the books of Deuteronomy 14 and Leviticus 11. The Kashruth pertains to the type of foods allowed for consumption and the methods of their preparation. All fruits and vegetables and herbivorous, ruminant animals (domesticated and wild) whose hooves are wholly cloven are categorized as 'clean' and permitted. Pork is forbidden and only aquatic creatures that have at least one fin and scale are permissible. Animals are to be slaughtered by bleeding them to death after cutting through the neck below the larynx (the ritual slaughter is called shehitah). Also, animals with certain defects or injuries are not permitted. Only animals treated thus are considered kosher. Consumption of blood is disallowed, as is consumption of certain portions of 'clean' animals such as the sciatic nerve and certain fat portions. Carrion meat is also forbidden and it is prohibited to cook or eat meat and milk together. Thus, the dietary laws are complex but whether their practice poses any adverse or beneficial effects on the nutritional status of the Jewish people who follow them is unclear. There is no evidence to show that lack of pork meat in the diet results in any adverse nutritional outcome. Among the ultraorthodox Hasidic Jews living in Montreal who are strict followers of the Kashruth, all-cause mortality is low, primarily due to a strikingly lower mortality from diseases of the circulatory system, although community cohesiveness and affiliation may, to some degree, mediate these beneficial effects. Dietary intakes of Hasidic Jews are lower in energy, fat, and saturated fat compared to those of other Montrealers, Canadians, and to the NHANES II sample, although intake of cholesterol is higher in the Hasidics. Orthodox Jewish men and women living in Jerusalem also have a significantly lower consumption of total and saturated fats and higher carbohydrates compared to secular Jews. These dietary differences are reflected in the lower concentrations of plasma cholesterol, triglycerides, and LDL-C concentrations observed in the former group. A substantially higher risk of myocardial infarction among secular versus orthodox Jews is also observed.

Conclusion

Religious customs pertaining to diet can have potentially significant effects on the health and nutritional well-being of individuals depending on the degree to which they are prescribed. There remains a paucity of scientific data on the effects of dietary habits of religious origin on the nutritional status of populations, unconfounded by other cultural, social, and economic influences. There appear to be changes in aspects of nutritional status associated with chronic long-term or periodic shorter-term dietary practices, although the long-term implications of the latter changes on health are unclear.

RENAL FUNCTION AND DISORDERS

Contents

Kidney: Structure and Function

T T Rosa, University of Brasilia, Brasilia, Brazil

Background

The human kidneys are located in the lumbar area, as a pair in the retroperitoneal space, and are composed of about a million nephrons, which are the functional units. Each nephron contains a glomerulus which carries out blood filtration and there is tubular system, divided into 14 segments, which are different morphologically and functionally. The combined action of these structures produces urine. The glomerulus is located in the outer part of the kidneys, called the cortex, and the tubules are located in the inner part, called the medulla. These structures are connected by interstitial tissue and contained by a fibrous capsule, named Bowman's capsule, in a similar shape to a bean (Figure 1).

Within the kidney are located the renal hilum, as well as the renal pelvis, formed by the exit of the renal vein, which it drains from the vena cava; the renal artery, a branch of the abdominal aorta artery; the lymphatics; and a nerve plexus. In addition to these components are those of the urinary branches. These are the renal pelvis and ureter, which transports urine to the bladder, from where it exits via the urethra, completing the system of renal excretion (Figure 2).

Glomerular Ultrafiltration

The first stage of the process of urine formation is glomerular ultrafiltration. About 170 l of plasma is ultrafiltered every 24 h, representing more than 30 times volume. The resulting product, in the form of urine, corresponds to less than 1% of that volume. The difference is the result of the balance between the reabsorption process and the secretion process accomplished by the tubular system.

Marcello Malpighi first described the structure which is now called the glomerulus in 1662. As a result, the corpuscle was just known as corpuscles of Malpighi for a long time. Carl Ludwig, in the

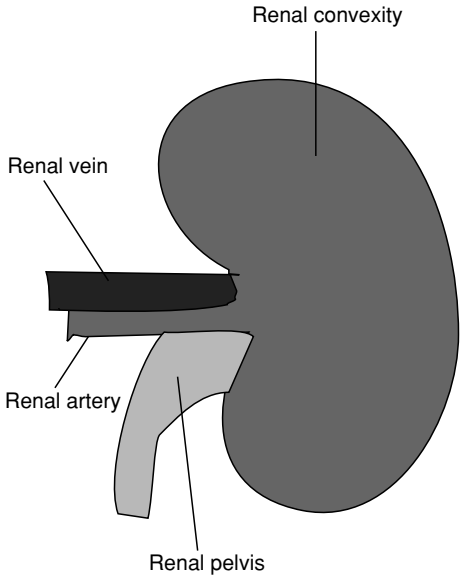

Figure 1 Macroscopic renal structure.

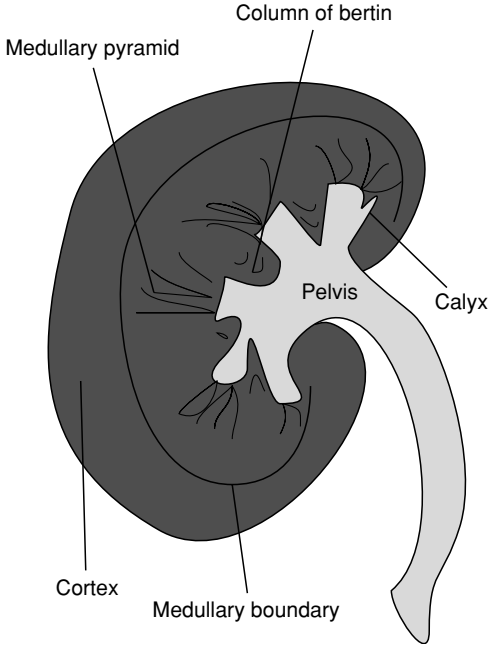

Figure 2 Renal hilum.

nineteenth century, described the ultrafiltration process as the passage of water, electrolytes, and small molecules, from the glomerular capillaries to Bowman's space. In 1924, this theory was proven: glucose, chloride, but no proteins were detected in the Bowman's space. All the energy for that process is created by the heart, acting at the level of the renal microcirculation, and this characterizes ultrafiltration as a physical phenomenon.

Glomerular filtration rate (GFR) in humans is approximately 120 ml min^{-1}. It is the result of ultrafiltration achieved by about 2 million nephrons.

As a physical phenomenon ultrafiltration results from a balance of pressure between the glomerular capillary and the internal space of Bowman's capsule. The glomerular tuft forms a conductive system in parallel, located between the afferent and the efferent arterioles (Figure 3). The pressures involved in this process are as follows:

$$\Delta P_H = P_{IG}.P_{CB} \quad (1)$$

where P_H represents the variation in hydrostatic pressure resulting from the difference between P_{IG}, the hydrostatic intraglomerular pressure, and P_{CB}, pressure inside the Bowman's capsule. It is similar to the physical principle behind a domestic water filter.

The concentration of proteins in the plasma also interferes with the process, as it adds to the filtrate a pressure that is opposed to the hydrostatic pressure, called oncotic pressure (P_O). That pressure represents a vector that addresses the filtered flow in an inverse direction, in other words, from Bowman's capsule to the glomerular capillary once the protein concentration is minimum in the Bowman's capsule, close to zero, because the wall of the glomerular capillary does not allow proteins to pass. In that way, the effective filtration pressure (P_F) is expressed in agreement with eqns (2) and (3):

$$P_F = (P_{IG}.P_{CB}) - P_O \quad (2)$$

or

$$P_F = \Delta P_H - P_O. \quad (3)$$

The renal plasma flow should be adapted to allow a balance of those pressure forces and the permeability of the glomerular wall should be unaffected if the process is to happen in a physiologic way. This last variable is represented by a variable called the coefficient of hydraulic conductance and represented by the symbol K_f. In comparison to the domestic filter, this coefficient measures the porosity of the filter. In the glomerulus it is defined by the product of the intrinsic permeability of the glomerular wall (K) for the total surface available for the filtration process (S), and is represented as follows:

$$K_f = K \times S. \quad (4)$$

The decrease in K_f determines a decrease in GFR, that it is not as pronounced as variations due to alterations in hydraulic and oncotic pressure.

To tune so many variables involved in glomerular ultrafiltration it is necessary for there to be self-regulation, so that variations in systemic blood pressure (SBP) do not interfere markedly in the process of urine formation that begins with ultrafiltration. If such a mechanism did not exist, dynamic variations in SBP would affect GFR.

Self-regulation is effected by an increase or decrease in resistance of the afferent and efferent arterioles defined by vasoconstriction or vasodilatation of these arterioles, if SBP falls or rises, respectively. This vascular movement is caused by three factors: vasomotor reflex, when the vein contracts its smooth muscle and reduces its diameter, when there is an increase in hydrostatic pressure within; metabolite production in response to the increase in blood flow in those arterioles, causing vasoconstriction; and the mechanism of glomerular tubule feedback.

In this last factor, the tubular structure is involved; this is called the macula densa and is located in the distal convoluted tubule. Alterations in the load of filtered sodium give rise to renin secretion; renin is produced in the cytoplasm of differentiated cells, and is present in the macula densa and in cells contiguous to the glomerulus, which comprise the justaglomerular device. Production of increased renin results in an increase in circulation of angiotensin II level, by a cascade of reactions shown in Figure 4. Angiotensin II stimulates local receptors in the afferent

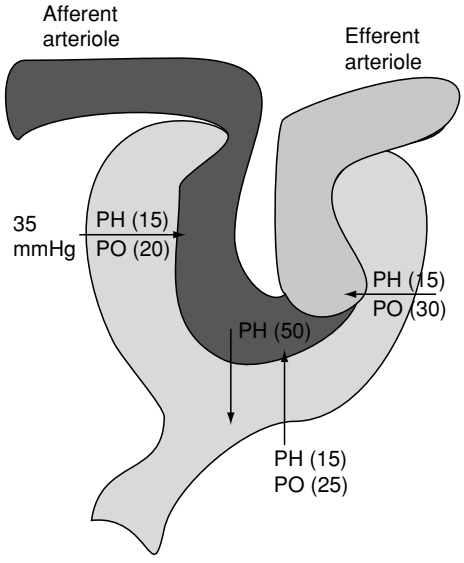

Figure 3 Renal microcirculation.

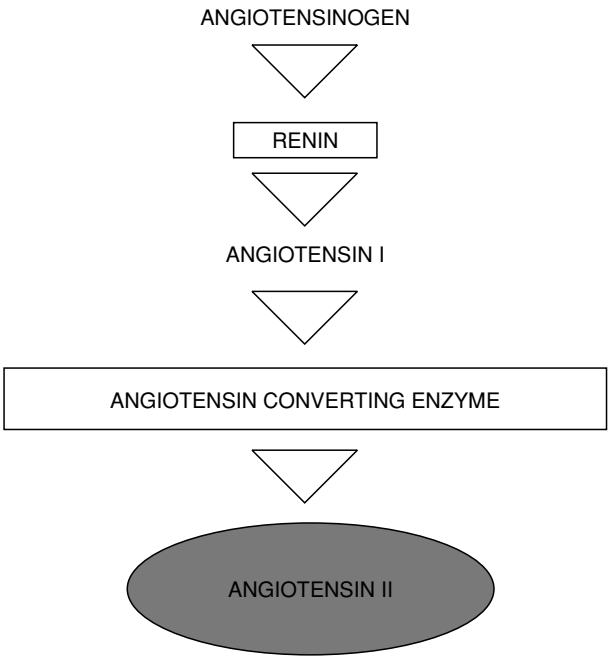

Figure 4 The renin–angiotensin system.

arterioles promoting vasoconstriction and a decrease in flow in the nephrons and a consequent decrease in glomerular filtration rate, balancing out the process of glomerular filtration associated with the secretion and tubular reabsorption, and resulting in the glomerular tubular balance.

To estimate GFR it is necessary to carry out clearance of a substance that is only filtered, and is not reabsorbed or secreted by tubules. Clinically, it is preferred for a substance to be produced endogenously, rather than having to administer an exogenous drug. Calculation of the endogenous creatinine clearance is commonly used. The clearance of any substance is always given by the product of its urinary concentration (U) and urinary flow (V), divided by its plasma concentration (P). Urinary flow is always calculated in ml min^{-1}.

In fact creatinine is not ideal for calculation of GFR, as it is partly secreted by the renal tubules, and appears in the urine as a result of filtration and a small amount of secretion, but results are very close to those obtained with inulin, an exogenous substance, which is totally filtered, and is used in experimental assays for the exact determination of GFR. Besides, the method of creatinine dosage is easy and cheap, which is a distinct advantage in clinical use.

In contrast, the simple creatinine level in plasma gives us an idea of how renal filtration works, because it is always in balance in the organism, as are almost all endogenous products. That means that its excretion should equal its production. Mathematically we have: creatinine production ($Prod_{Cr}$) = urinary excretion of creatinine (U_{Cr}) × urinary flow (V). As with the creatinine, the excreted load is the same as the filtered load, and can be written: $Prod_{Cr}$ = plasma concentration of creatinine (P_{Cr}) × GFR, that is: $P_{Cr} = Prod_{Cr} \times \text{GFR}$. As creatinine production is constant, its plasma concentration is an inverse hyperbolic function of GFR.

Most components in plasma are filtered by the kidney.

Tubular Reabsorption

Unlike glomerular filtration and tubular secretion, tubular reabsorption is not part of the process of renal excretion. In fact it is a renal mechanism that saves essential element, to the homeostasis of the internal environment, such as water, glucose, and amino acids. The transport of fluid from the inside of the tubule to the internal environment through the tubular wall is complex and involves several mechanisms. Some of these spend energy of the organism (adenosine triphosphate or ATP), while others are made passively, by gradients created among the compartments involved. Those gradients may be physical (differences in the electric charge or in the pH), chemical (differences in the concentrations of several substances) or osmotic (difference of concentration of solutes). There is also so-called facilitated transport, such as when glucose transport is facilitated by sodium transport. Those substances that need carriers are located in the membrane of the tubular cells which are linked to the substance to be transported in the border with the inner tubule. The carriers make transport through the cytoplasm to the border with the renal interstice, where the peritubular capillaries are located, liberating them to the internal environment of the organism.

Of the 170 l plasma that is filtered, and one more small rate of secretion, tubular reabsorption is about 1.5–2 l day^{-1} to the external environment, in the form of urine. The difference is returned to the internal environment by tubular reabsorption.

The main site responsible for reabsorption is the convoluted proximal tubule, which is the tubular portion that is located immediately after the glomerulus. These cells have quite a heterogeneous form and the borders contain microvilli that provide a larger contact surface with the fluid to be reabsorbed, optimizing the process. Despite this, reabsorption, as well as secretion, takes place along the whole renal tubular system.

The main substances reabsorbed in the renal tubules are amino acids, glucose, electrolytes, bicarbonate, and urea.

Tubular Secretion

Tubular secretion is the term given to the transport of substances from the medullary peritubular capillary to the inside of the tubule. It happens predominantly in the final part, the straight section, of the proximal convoluted tubule. It is also a method of renal excretion and can be calculated by the clearance of substances that are not filtered, or reabsorbed, but which appear in the urine, such as paraaminohippurate. This is a salt of paraaminohippuric acid and it is used to calculate renal plasma flow, after excretion. The transport mechanisms involved in secretion are very similar to reabsorption, especially as regards energy (ATP) expenditure.

The main substances secreted by the kidneys are urea, hydrogen, organic acids, and exogenous substance such as drugs and antibiotics.

Renal Metabolism of Water

Water makes up the largest part of the human organism, comprising about 80% of the total. The sensation of thirst originates in the hypothalamic center of thirst, which is sensitive to a variation in plasmatic osmolality of at least 1% and it is located in paraventricular and supraoptical nuclei. An increase in plasmatic osmolality stimulates the secretion of antidiuretic hormone (ADH) from the hypophysis as a result of those hypothalamic impulses. ADH acts, among other structures, at the level of the collector ducts, in the distal nephron, promoting the reabsorption of water and the consequent normalization of plasma osmolality.

In this way, the final urine under the action of ADH is more concentrated, it has larger osmolality. When there is an excess of water in the organism, an inverse mechanism results; there is inhibition of ADH and the urine produced has less osmolality. The first situation is more frequent, when maximum capacity of urinary concentration is reached, whose resultant osmolality can be up to 1200 mosm ol l^{-1}.

The mechanism by which nephrons concentrate urine is called countercurrent mechanism (similar to that described by thermodynamics) and it involves the proximal segments, the loop of Henle, and the distal segments of the renal tubules. It acts by an established osmolar gradient in the renal medulla and in inside the tuble, as a result of active transport of NaCl and the diffusion of H_2O through membranes with special permeabilities along the long loop nephrons, which are especially adapted for that function, located in the boundary between cortex and medulla. The result of that complex mechanism is a concentration of urine in such a way that the plasma osmolality is maintained constant and normal.

Endocrine Functions of the Kidneys

One of the most important hormones produced by the kidney is 1α-25-dihydroxycholicalciferol, the active form of vitamin D_3, and it acts directly in the renal metabolism of calcium and of phosphorus. A fall in plasma calcium stimulates the secretion of parathormone (PTH) in the parathyroid glands and so, they act in the renal medulla, promoting the synthesis of activated vitamin D_3. This acts in the small intestine, increasing the reabsorption of calcium in the bone tissue, increasing demineralization, and in the renal tubules, increasing reabsorption, at the same time as it promotes an increased excretion of phosphate, as phosphaturia.

A reduction in phosphate in the plasma stimulates vitamin production, directly activated by vitamin D_3, by the renal medulla and, in the absence of PTH renal tubular reabsorption of phosphate and greater excretion of calcium (calciuria) are promoted.

Thus the product of plasma concentration between calcium and phosphorus is maintained constant.

Action of Kidneys in the Acid–Base Balance

In addition to the important mechanism of acid–base control accomplished by the lungs, promoting the elimination of the carbon gas in its volatile form, the kidneys also participate in controlling the metabolism of bicarbonate (HCO_3) and of the ion H^+, which are respectively reabsorbed and secreted by the renal tubules.

This balance is fundamental to maintain organic biochemical reactions that keep constant blood pH, at around 7.4.

The transport of those two ions takes place in the proximal convoluted tubule and in the convoluted distal tubule. It happens in a connected way: one ion H^+ secreted for each reabsorbed HCO_3 molecule. In the proximal convoluted tubule, bicarbonate is regenerated from the inner tubule by two principal mechanisms: excretion of carbonic acid dissolved in the tubular fluid and secretion of fixed acids, such as sulfuric, hydrochloric, and phosphoric, among others. At the level of the distal convoluted tubule, there is reabsorption of HCO_3 starting from the cellular synthesis of ammonia with the secretion of the ammonium ion.

Renal Control of Blood Pressure

In the distal convoluted tubule is located the macula densa: it has longer cells and cytoplasmic granules. Close to it there are segments of afferent and efferent arterioles that have a greater amount of cytoplasmic

granules. These granules correspond to renin, the proteolytic enzyme that is synthesized there. This group of structures is termed the juxtaglomerular apparatus.

The main incentives for renin production are a reduction in blood pressure with a consequent fall in hydrostatic pressure of the afferent arteriole, and a reduction in renal plasma flow and variations in the concentration of sodium in the distal convoluted tubule.

Renin acts on a substratum called angiotensinogen, a duodecapeptide, of hepatic synthesis, transforming it to the decapeptide called angiotensin I. This undergoes action by another proteolytic enzyme, called angiotensin-converting enzyme (ACE), which is mainly synthesized in the capillary endothelium, creating the octapeptide angiotensin II, which is a substance which has a larger effect on the vasoconstrictor produced by the organism.

Receivers exist for angiotensin II in the afferent and efferent arterioles, altering GFR, when there is an increase in that peptide in the circulation. In the systemic circulation there is an increase in peripheral resistance and therefore also in blood pressure. There are also receivers in the adrenal cortex which when stimulated synthesize aldosterone, a hormone whose main action is to promote reabsorption of sodium in the distal convoluted tubule.

Thus it is easy to understand that arterial blood pressure is controlled by this renal mechanism and dysfunction of is system, called the renin–angiotensin–aldosterone system, will result in arterial hypertension.

In short, the renal structure is adapted to achieve vital functions for the human organism. The most difficult stage in the evolution of animal life on earth was considered to be the adaptation from an aqueous environment, the kidneys are essential to make life on earth viable, saving water and mineral salts and maintaining the necessary metabolic homeostasis for the hemodynamic adaptation and of the pH of blood.

Nutritional Management of Renal Disorders

B E Engel, Royal Infirmary, Stoke-on-Trent, UK

Introduction

The nutritional state of the body is dependent on the intake of adequate amounts of nutrients in food and fluids and the ability of the body to utilize these substances and dispose of the excess and the waste products created from metabolic processes. One of the main functions of the kidney is the disposal of some of these waste products, in particular, the nitrogenous waste from the breakdown of protein as well as excretion of fluid, sodium, potassium, phosphate, hydrogen ions, and organic acids, in order to achieve homeostasis. The kidney also has a synthetic function converting 25-hydrocholecalciferol to 1,25-dihydroxycholecalciferol ($1,25(OH)_2D$ – the active form of vitamin D), and in producing the hormone erythropoietin (EPO), which is important in promoting the formation of red blood cells. In many types of kidney disease, these functions are impaired, resulting in the accumulation of toxic waste products in the blood, and the development of hypertension, bone disease, anemia, and hyperlipidemia.

The main aims of dietary management in kidney disease are therefore to:

1. Reduce the accumulation of waste products and thus prevent or ameliorate uremic toxicity and the adverse effects of alterations in various metabolic pathways.
2. Maintain or improve nutritional status (identifying and treating malnutrition at an early stage).
3. Maintain or improve the kidney patient's quality of life.

Finally, dietary interventions may help contribute to slowing down the progression of the disease.

The various kidney diseases that lead to end-stage renal failure (ESRF) show many similarities in their clinical and pathological features, and thus dietary management is not necessarily modified by the original cause of the disease. In this chapter, the main subjects discussed are: (1) chronic renal failure, (2) nephrotic syndrome, (3) ESRF requiring dialysis and transplantation, (4) acute renal failure, and (5) renal stone disease.

Chronic renal failure (CRF)

Giovanetti described CRF as a chronic reduction of glomerular filtration rate (GFR) below the normal

Table 1 Main causes of chronic renal failure

Glomerulonephritis	Hypertension
Chronic pyelonephritis	Polycystic kidney disease
Obstructive, reflux, analgesic nephropathies	Systemic disease: scleroderma, systemic lupus erythematosus
Diabetic nephropathy	Vasculitis
Renal transplant failure	Myeloma, amyloidosis

Table 2 Stage of renal failure related to creatinine level

Stage	*Plasma creatinine concentration (μmol l^{-1})*	*Glomerular filtration rate (ml min^{-1})*
Early	120–150	40–60
Moderate	150–300	20–40
Advanced	> 400	10–20
End-stage renal failure	> 600 – requires RRT	< 10

range (*c.* 120 ml min^{-1}) irrespective of the underlying cause (Table 1). The increase in plasma constituents such as creatinine and urea is used as a general marker to indicate the severity of the disease (Table 2). Reciprocal plots of creatinine against time are commonly used to chart the progression of CRF. The excretion of creatinine (formed from creatine and phosphocreatine in muscle tissue) occurs predominantly by renal filtration. A decrease in GFR below 50% of normal leads to a rise in plasma creatinine. However, as creatinine production is proportional to lean body mass and is also influenced by animal protein intake, a loss of lean body mass or decreasing appetite during the course of CRF can give the false impression that the rate of decline of renal function is slowing down. In addition, a plasma creatinine of 1000 µmol l^{-1} may indicate a GFR of < 10 ml min^{-1} in a 70-kg man, whereas a creatinine of 600 µmol l^{-1} would indicate the equivalent level of renal function in a person of lower body weight.

Protein Metabolism and Requirements

A well-planned and monitored reduction in protein intake in CRF patients will decrease the amount of nitrogenous waste, phosphorus, potassium, and acids that must be dealt with by the kidney. Urea is the main metabolite of protein, and in CRF, plasma urea increases as GFR decreases. A decrease in the urea:creatinine ratio after starting a reduced protein diet may be used as a measure of compliance with the diet. Other factors, however, may raise plasma urea further, e.g., a high dietary protein intake, drugs such as frusemide and steroids, gastrointestinal bleeding, and a hypercatabolic state leading to muscle catabolism. Urea itself is nontoxic, but its elevation correlates with the rise in plasma levels of more toxic compounds, e.g., guanidines, amines, phenols, and organic acids. Plasma urea levels are therefore used as a surrogate marker for these toxins.

Most of the research in this area has focused on the effect of a low-protein diet on slowing down the progression of renal disease. The diets have aimed to provide 0.6 g of protein per kilogram of ideal body weight (IBW), which is the minimum requirement advised by the World Health Organization. It is still recommended that at least 50% of the protein should be of high biological value (HBV) – essentially from meat, fish, and diary products in order to provide all essential amino acids, although vegan and vegetarian diets can maintain the nitrogen balance as long as proteins are obtained from a combination of low biological value (LBV) sources, such as grains, pulses, etc. The protein intake from food can be reduced further to 0.3 g kg^{-1} IBW if the diet is virtually vegetarian and supplemented with essential amino acids or their keto analogs. In practice, even with considerable support from dietitians, it seems difficult – certainly in Western society – to maintain this level of protein restriction. In the largest trial ever completed on this subject, the Modification of Diet in Renal Disease, patients' actual intake was 0.7–0.8 g protein per kilogram per day. At this level, overall nutritional status was maintained throughout the 2 years of the trial, although the energy intake was less than the recommended 35 calories per kilogram per day. A reduction of protein intake by 0.2 g kg^{-1} resulted in a 30% reduction in the rate of decline of GFR, i.e., a prolongation of the time to ESRF by 41% in patients with advanced renal failure. Some clinicians argue that this level of improvement is not significant enough to justify a diet that is difficult to achieve, requires a lot of support from dietitians as well as family, and may lead to nutrient deficiencies in the long term. There are none the less other benefits from reducing protein intake: the improved biochemical indices that result from this intervention will help reduce some of the classic symptoms of uremia that are related to the accumulation of protein metabolites and imbalances particularly in phosphorus, potassium and lipid metabolism (Table 3).

Energy Requirements

There is no evidence to suggest that requirements are affected by renal disease itself. Calculation of energy requirements should be made depending upon the need for weight loss, maintenance, or gain in the normal way, e.g., Schofield or Harris–Benedict equations or 30–35 kcal kg^{-1} IBW. As hyperlipidemia (increased triglycerides and/or cholesterol) and some degree of glucose intolerance are common, the source of calories should be from complex carbohydrates

and mono-polyunsaturated fats (with overall fat intake providing 30% of the energy) in line with advice for healthy eating.

Vitamins and Minerals

Some of the clinical features of uremia may be linked to subclinical vitamin and mineral deficiencies. Dietary protein, phosphate, and potassium restrictions will limit the intake of various micronutrients, and even when intake is adequate, the metabolic pathways may be affected, reducing the availability or efficacy of the nutrients. Specifically, a low-protein diet was found to contain low levels of B vitamins (B_1, B_2, B_6, B_{12}), iron, calcium, and zinc. A low-potassium diet will limit folic acid and vitamin C intake. However, there may be reduced renal losses of some nutrients, and cases of hypervitaminosis A have been recorded. It is recommended that vitamin and mineral status should be part of a renal patients regular nutritional assessment.

Phosphorus and Calcium

Hyperphosphatemia and hypocalcemia are characteristic of CRF. A decreasing GFR will lead to a reduced renal clearance of phosphate, even at the moderate stage of CRF, and eventually will lead to an increased plasma phosphate. Simultaneously low levels of active vitamin D cause a reduction of calcium absorption from the gut, hence lowering the plasma calcium. These two factors stimulate parathyroid hormone (PTH) release, which in turn causes bone resorption. The release of calcium from the bone is an attempt to normalize plasma calcium levels, unfortunately at the expense of the integrity of the skeletal system (and a further rise in plasma phosphate), resulting in osteodystrophy. A raised plasma calcium × phosphate product ($> 5\ \text{mmol}^2$) also results in calcification of soft tissues and has been linked with an increased risk of cerebrovascular disease (stroke) in these patients.

A low-phosphorus diet (*c.* 0.3–0.5 mmol per kilogram IBW per day) (Table 4), in combination with phosphate binders such as calcium carbonate, has been prescribed to maintain plasma phosphate within the normal range. A phosphorus intake at the lower recommended level can only be achieved with some degree of protein restriction, particularly the HBV proteins. This diet will also limit calcium intake, hence there is a dual role for calcium tablets: as a binder of phosphorus and to provide a calcium supplement. Prescription of 1,25-dihydroxy or 1-hydroxy cholecalciferol can help to suppress PTH production. Calcium levels must be monitored regularly, as, due to the medication, there is a risk of hypercalcemia from increased intestinal absorption. Plasma levels for phosphate and calcium should be maintained within the normal ranges. As yet, there is no consensus regarding the optimum level of renal failure at which to advise a reduction in phosphorus intake, i.e., it may be of benefit to reduce intake before plasma levels exceed the normal range, as PTH may already be increasing in order to maintain homeostasis.

Table 3 Uremic manifestations

System affected	*Uremic symptoms*
Cardiovascular	High blood pressure, fluid overload, pericarditis, cardiomyopathy
Gastrointestinal	Nausea, vomiting, gastritis
Peripheral nervous system	Neuropathy, myopathy
Central nervous system	Confusion, drowsiness, impaired higher mental functions, insomnia, coma
Blood	Anemia
Skeletal	Renal osteodystrophy, bone pain, fractures
Skin	Pruritis, pigmentation, calcification

Potassium

Hyperkalemia does not tend to develop until the GFR $< 10\ \text{ml min}^{-1}$ (i.e., ESRF). It can occur in moderate CRF under certain circumstances such as increased catabolism: infection, trauma, acidosis, or medication: angiotensin-converting enzyme (ACE) inhibitors, cyclosporin A, and EPO. A raised plasma potassium $> 6.5\ \text{mmol l}^{-1}$ can increase the risk of asystolic cardiac arrest. Hence, it is advised that levels should be maintained within the normal range using a combination of dietary restrictions of high-potassium foods and appropriate cooking methods such as

Table 4 Phosphate (mg):protein (g) ratio of some common foods

Phosphate:protein ratio < 10	*Beef, lamb, turkey, chicken, pork, cod, haddock, tuna, corned beef*
Phosphate:protein ratio 10–15	*Bacon, ham, meat paste, plaice, plaice, herring, mackerel, salmon, cottage cheese, white bread, white pasta*
Phosphate:protein ratio 15–20	*Liver, pilchards, mussels, prawns, soya milk, peanuts, pulses, white rice*
Phosphate:protein ratio > 20	*Milk, icecream, cheese, yogurt, pate, roe, sardines, whitebait, nuts, chocolate, wholemeal bread, brown rice, brown pasta, bran flakes, sponge, scones*

NB: Although wholemeal products are higher in phosphate, patients are still encouraged to have them as part of a healthy diet and to help bowel function.

boiling vegetables and discarding the water. It is not possible to state an absolute amount for the advised intake; 0.6–1 mmol kg^{-1} IBW will help to keep the plasma levels below 5.5 mmol l^{-1}. The use of potassium-losing diuretics and calcium resonium – a potassium binder – may be appropriate.

Sodium and Water

Kidney diseases such as diabetic nephropathy and some forms of glomerular nephritis are characterized by retention of sodium and water with resulting hypertension and edema. However, interstitial nephritis, e.g., chronic pyelonephritis, may initially present with a failure to concentrate urine, leading to sodium and water loss and potential dehydration. The nonpharmacological approaches that have been used to treat hypertension in the nonrenal population may be of some benefit in the renal population: dietary sodium restriction, weight control, and control of other risk factors for coronary heart disease. Sodium restriction also potentiates the action of ACE inhibitors, diuretics, and β blockers. As the kidney loses its ability to respond rapidly to changes in sodium intake, any restrictions should be implemented gradually. The dietary changes would include not adding salt to cooking or at the table and reduction of processed, tinned, or convenience foods. Compromises have to be made for the elderly patient who relies on these foods as dietary staples. To improve the palatability of the diet, a wide range of herbs and spices can be used. The recommended level of restriction is usually 80–100 mmol (1.8–2.3 g) of sodium per day.

Table 5 gives a summary of dietary advice for conservative management (prior to starting RRT).

Other Nutritional Concerns

Malnutrition A spontaneous decline in nutritional intake has been recorded in patients approaching ESRF. Unfortunately, loss of body weight is often masked by increasing levels of fluid, giving the impression that the weight is stable. A poor nutritional state when the patient enters the dialysis program will have a negative affect on morbidity and mortality, so it is important to monitor these patients as they approach ESRF irrespective of whether any dietary restrictions have been advised.

Anemia The anemia of CRF has many causes, including (1) decreased production of EPO, (2) poor iron, folate or B_{12} intake due to a low protein diet or a poor appetite, (3) poor iron absorption due to drug interactions, and (4) chronic blood loss due to disturbed clotting mechanisms. Anemia contributes to extreme fatigue, loss of appetite, and taste changes. Plasma levels of ferritin, hemoglobin, vitamin B_{12}, and red blood cell folate help determine the need for iron, folate and B_{12} supplements, and EPO injections.

Hyperlipidemia Hyperlipidemia (raised cholesterol and triglycerides) is a common complication of renal failure. There is evidence in animal models that it may increase the rate of progression of the disease, but this has not been shown in humans except in the progression of diabetic nephropathy. There is, however, a greatly increased risk of cerebro- and cardiovascular disease, which accounts for 60% of deaths in renal patients. HMG CoA (3 hydroxy, 3 methyl giutaryl coenzyme A) reductase inhibitors are being used to reduce cholesterol levels, and trials of fish oil supplements are promising. Although diet and drug interventions have been shown to reduce risk factors, including improving the lipid profile, as yet, there have been no studies to show that this actually results in decreased mortality in renal patients. Extrapolating from the nonrenal population, it seems wise to encourage the principles of healthy eating, weight loss if the body mass index is higher than 30, and regular exercise.

Table 5 CRF diet (conservative management prior to ESRF)

Nutrient (recommended daily intake)	*Rationale*
Protein 0.6–1.0 g kg^{-1} IBW	As described in the text. With the lower-protein diet, the patient is given a meal plan comprising HBV (60%) and LBV (40%) protein foods: to insure all the amino acid requirements are met
Energy 35 kcal kg^{-1} IBW or use Schofield equations, for example	Normal adult requirements. Calorie sources should not exacerbate hyperlipidemia, i.e., total fat 30% of energy, low saturated fat. Encourage good glycemic control in diabetics. NB: Monitor for signs of malnutrition
Phosphate 0.3–0.5 mmol kg^{-1} IBW	Plasma levels should be maintained between 0.8 and 1.5 mmol l^{-1}.
Sodium 80–100 mmol per day. Fluid – no restriction usually required	Salt restriction will help potentiate action of antihypertensives
Potassium 0.6–1 mmol kg^{-1}	Levels should be maintained between 3.5 and 5.5 mmol l^{-1}. Restriction may not be necessary until patient has reached ESRF
Vitamins and minerals	May be required with lower protein diets and if potassium restriction is advised

Nephrotic Syndrome (NS)

NS is characterized by proteinuria >3 g per day, hypoalbuminemia, edema, and hyperlipidemia. It is usually also associated with hypertension. NS appears as an additional complication in a number of types of kidney disease (Table 6). Treatment involves antihypertensive agents, immunosuppressants, diuretics, salt-poor albumin, and dietary modifications.

Protein

Historically, a high protein diet was advised on the grounds that protein losses in the urine needed to be replaced. However, studies comparing low (0.8 g kg^{-1}) and high protein (1.5 g kg^{-1}) diets showed that proteinuria was reduced with the lower protein diets, although not all studies showed a corresponding increase in plasma albumin levels. It has been shown that a high protein intake causes increased permeability and hyperfiltration in the basement membrance of the kidney glomeruli, and this may be the mechanism that explains the poor results of high protein diets in NS. In addition, phosphate, lipid and renin levels tended to improve on the lower protein diets. An intake of 0.8–1 g of protein per kilogram per day has been recommended.

Salt

The kidneys tend to retain sodium and water in NS, and patients benefit from a moderate dietary sodium restriction: 80–100 mmol per day, and if edema is present, a fluid restriction is also necessary. Sodium restriction can potentiate the antihypertensive and antiproteinuric effects of ACE inhibitors.

Fat

Both triglycerides and cholesterol are raised in NS. The incidence of myocardial infarction has been reported as 5.5 times greater in NS compared with normal. Lipid lowering agents are used in conjunction with standard lipid-lowering advice.

Micronutrients

Iron, copper, zinc, and vitamin D are also lost as a result of proteinuria. Vitamin D losses can result in derangements of calcium metabolism, and supplementation may be necessary.

Renal Replacement Therapy

Hemodialysis (HD) and continuous ambulatory peritoneal dialysis (CAPD)

The nutritional problems of renal patients do not stop once renal replacement therapy is started. Even with dialysis, it is not possible to maintain body fluid, potassium, and phosphate levels within the normal ranges without some degree of dietary restriction. On the positive side, some of the symptoms of uraemia such as nausea, taste changes and gastrointestinal disturbances improve. Usually, there is an increase in appetite within 1 month of starting dialysis.

Dialysis itself has a number of negative effects on the nutritional state (Tables 7 and 8). In addition, some global factors affect the patient's well-being:

- The procedure itself is time-consuming, and traveling to and from hospital for unit HD severely disrupts the patient's day, including meal times.
- It is important that the risk of infections from the procedures be minimized as the catabolic effects of line infections and peritonitis can have long-term consequences for the patient's nutritional status.
- Underdialysis – as measured by urea and creatinine clearance – leads to impaired nutritional intake. There are now set standards that describe the amount of dialysis required in order to minimize morbidity and mortality.
- Depression can affect the patient for a number of reasons: inability to keep full-time employment, financial problems, body-image problems – as the treatment can be disfiguring, restrictions on traveling, dietary restrictions, and physical weakness due to the long-term metabolic effects on bone and muscle metabolism.
- It is important to maintain normal hemoglobin levels as anemia causes decreased appetite and poor physical functioning. Injections of EPO and iron are normally required to achieve this.

A team of professionals is necessary to treat the renal patient and help them achieve the best quality of life. In addition to medical and nursing staff, this should include a dietitian, social worker, physiotherapist, and counselor.

It is estimated that 30 – 70% of dialysis patients fall into the moderate- to high-risk categories for malnutrition. Protocols for routinely assessing the nutritional status of each patient must be in place in order to identify problems early. Subjective global assessment has been validated for use in dialysis

Table 7 HD diet

Nutrient (recommended daily intake)	*Rationale*
Protein 1.1–1.3 g kg^{-1} IBW	From nitrogen balance studies (although numbers were small and may not be applicable to all ethnic groups). 8–12 g of amino acids lost per dialysis. Possible poor intake on dialysis days
Energy 35 kcal kg^{-1} IBW or use Schofield equations.	Normal adult requirements. 25 g of glucose lost if glucose free dialysate is used
Phosphate 0.5 mmol kg^{-1} IBW	Plasma levels should be maintained between 1.2 and 1.7 mmol l^{-1}. Phosphate is not well dialyzed, so restriction is necessary, aided by phosphate binders
Sodium 80–100 mmol per day. Fluid 500 ml + previous day's urine output	Urine output decreases once dialysis starts. Salt restriction will help prevent thirst. Maximum of 2 kg interdialytic weight gain recommended. Fluid overload leads to left ventricular heart disease and hypertension
Potassium 1 mmol kg^{-1}	Plasma levels should be maintained between 3.5 and 6.5 mmol l^{-1}

Table 8 CAPD diet

Nutrient (recommended daily intake)	*Rationale*
Protein 1.2–1.5[a] g kg^{-1} IBW	From nitrogen balance studies (although numbers were small, and nitrogen balance was achieved at lower levels in some individuals). 9 g of protein/amino acids lost per day.
Energy 25–30 kcal kg^{-1} IBW + energy from dialysate or use, e.g., Schofield equations	Normal adult requirements. 70% of glucose is absorbed from the 'bag' of dialysate fluid. This can provide 300–1000 calories per day, depending on the glucose concentration in the bag. This leads to hypertriglyceridemia, obesity, and poor glycemic control in diabetics
Phosphate 0.5 mmol kg^{-1} IBW	Plasma levels should be maintained between 1.1 and 1.6 mmol l^{-1}. Phosphate is not well dialyzed, so restriction is necessary, aided by phosphate binders
Sodium 80–100 mmol per day. Fluid 500 ml + previous day's urine output. Additional fluid may be taken if the patient ultrafiltrates (removes fluid during dialysis) well	Urine output decreases once dialysis starts. Salt restriction will help prevent thirst. Overdrinking leads to overuse of the higher sugar containing bags of dialysis fluid and the problems described above
Potassium ~1 mmol kg^{-1} IBW	Levels should be maintained between 3.5 and 5.5 mmol l^{-1}. As dialysis is continuous, hyperkalemia is less of a risk than on HD. The diet can be more varied with respect to high-potassium foods
Vitamins (HD and CAPD)	There is no consensus on the routine use of vitamins. Folate, pyridoxine, and vitamin C levels are reported to be low without supplementation. Folic acid supplements may also reduce homocysteine (risk factor for CVD). Fat-soluble vitamins are not supplemented, except vitamin D, as discussed earlier.

[a]Larger protein requirements applicable during peritonitis.

patients; this combines medical history, including dietary assessment, with a physical examination of fat and muscle stores. There is a wide range of nutritional supplements available for the first-line treatment of malnutrition, and for the more severely malnourished patient, gastrostomy feeding (HD and CAPD) and intradialytic parenteral nutrition (IDPN) in HD patients have been used successfully. An amino acid containing CAPD solution is available and may be of use in certain cases of hypoalbuminemia caused by a persistent low protein intake.

The dialysis diet should be tailored to the individual patient taking into consideration their medical treatment and psychosocial factors. It is also guided by regular monitoring of biochemical profiles that usually occur monthly for HD and every 2 months for CAPD patients. For the well-nourished patient, healthy eating principles should continue to be encouraged within the constraints of the potassium restriction.

Transplantation

The positive effects of transplantation are to relieve the patient from dietary and other lifestyle restrictions imposed by dialysis, and the patient experiences a general improvement in well-being. This in itself can lead to large gains in body weight as the patient eats more in general. In addition, the immunosuppressive therapy can exacerbate the long-term metabolic effects of CRF such as bone disease, muscle

wasting, and cardiovascular disease. The main aims of dietary therapy are to reduce the risk factors for cardiovascular disease, which is the cause of 60% of deaths in transplant patients. All the aspects of 'Healthy Eating' should be encouraged. Patients may be reluctant at first to increase their intake of fruits and vegetables and even oily fish, as these would have been restricted on the dialysis diet. Intensive dietary counseling prior to discharge with regular follow up in outpatient clinics has been shown to reduce the average weight gain from 12 to 6 kg in the first year. Lipid levels can also be improved with advice on appropriate fat and sugar intake. An increasing amount of literature is showing that encouraging exercise at all stages of renal disease helps to improve physical mobility, and extrapolating from the nonrenal population may further reduce risk factors for CVD.

Acute Renal Failure (ARF)

ARF can be defined as an abrupt decline in renal function. Initially, there is oliguria (< 400 ml per day) or anuria, retention of the end products of protein metabolism, acidosis, and electrolyte imbalance. Biochemical profiles show a rapid increase in urea and creatinine, and also potassium and phosphate levels can increase. ARF is usually reversible, and as renal function returns, there may be polyuria to an extent where potassium and phosphate levels can drop below normal, and salt and water depletion can occur. As the causes of ARF are so varied, the effect on nutritional requirements may be negligible or, in the case of severe trauma or sepsis, cause a hypercatabolic state. Protein and energy requirements are calculated using standard formulae and stress factors and are related to the underlying causes. ARF in itself has specific effects on protein, fat, and carbohydrate metabolism, but the literature is less clear about how this impacts on the final nutrient prescription. ARF can be divided into three categories:

1. Noncatabolic: nontraumatic causes such as obstruction and interstitial nephritis from drugs.
2. Catabolic: postsurgery, rhabdomyolysis, and hemolytic uremic syndrome.
3. Hypercatabolic: major trauma (road traffic accident), burns, and sepsis.

Noncatabolic ARF

As in CRF, the aims of treatment are to slow down the build-up of uremic toxins and fluid overload in order to prevent or alleviate symptoms, to maintain good nutritional status, and to prevent weight loss. Dialysis may or may not be necessary. Nausea and lack of appetite are common features, and the main concern is insuring the patient is meeting their nutritional requirements sometimes with the help of dietary supplements. Restriction of dietary protein < 0.8 g protein per kilogram is not recommended. It is usually acceptable to aim for a 'normal' protein intake of 1 g per kilogram IBW per day. Advice on salt intake – aiming for 80–100 mmol per day, fluid restriction – 500 ml plus PDUO (previous days urine output) and potassium restriction < 1 mmol kg^{-1} may be necessary. In practice, all that is usually required is a simple diet sheet advising the patient and their relatives on suitable snacks and drinks. The usual 'treats' that people receive in hospital, i.e., fruit juice, fruit, and chocolate, may not be acceptable. High plasma phosphate levels can be controlled by phosphate binders.

Catabolic and Hypercatabolic ARF

The patient will almost certainly require dialysis treatment as the rate of production of waste products will otherwise cause severe and potentially fatal uremia. The type of dialysis will also affect nutrient requirements and the ability to provide them through nutritional support. Intermittent HD may be sufficient in noncatabolic or moderately catabolic patients, but as the severity of catabolism increases, continuous dialysis may be required, e.g., continuous arteriovenous HD (CAVHD). Losses of 9–13 g of protein per day can occur with this therapy. With 1.5% glucose in the dialysate solution, there is a net gain of glucose of 6 g h^{-1}, which represents an energy intake from dialysis of 550 kcal per day. The effects of dialysis on nutrient losses and gains should be taken into consideration when prescribing the feeding regimen.

Protein requirements Catabolic patients require in the region of 9–14 g of nitrogen (56–87 g of protein) per day. Hypercatabolic patients may break down up to 40 g of nitrogen (235 g of protein) per day, but the liver cannot deaminate more than 20 g of nitrogen (117 g of protein) per day, so this is the maximum that can be replaced by nutritional support.

Carbohydrate Glucose utilization is limited by ARF, and excessive amounts can cause lipogenesis, fatty liver, and increased carbon dioxide production. Provision of carbohydrate should not exceed the maximum oxidation rate of 4 mg per kilogram IBW per minute.

Fat As the metabolism of fat is impaired in ARF, an upper limit of 1 g of fat per kilogram per day is recommended.

Fluid and electrolytes With intermittent HD, a feeding regimen containing reduced fluid, sodium, and potassium may be necessary and may limit the macronutrient provision from an enteral or parenteral feed. Continuous dialysis and ultrafiltration obviate the need for a fluid (and usually also electrolyte) restriction.

Phosphate Hyperphosphatemia is a common feature of ARF, and initially, TPN (total parenteral nutrition) regimens can be phosphate-free. Anabolism and dialysis will lower serum phosphate, and the requirements would be reassessed at this stage.

Vitamins and minerals Requirements for micronutrients are not well documented. Water-soluble vitamins tend to be given daily in the standard amounts and trace elements given only once or twice a week. Fat-soluble vitamins are not required in the short term.

Renal Stone Disease (Nephrolithiasis)

Renal stone formation occurs as a result of increased urinary concentration of promotor substances and decreased concentration of inhibitor substances (Table 9). This is partly influenced by dietary factors but can also be linked to congenital abnormalities, as seen in polycystic kidneys, horseshoe kidneys, and medullary sponge kidney or to short bowel syndromes such as Crohn's disease. The stones vary in composition, but the main types include combinations of calcium, oxalate, and phosphate. The size of the stones can vary from microscopic to the large 'staghorn' calculi, and can lead to kidney failure if the kidney or urinary tract becomes obstructed.

A number of dietary factors can contribute to the management of stone disease.

Fluid

An adequate fluid intake of 2–3 l a day is encouraged to ensure a minimum urine output of 2 l per day. Specifically, patients are told to drink 250 ml every four waking hours, with 250 ml at meals. Compliance with this single measure has been shown to reduce new stone formation by diluting the concentration of stone-forming salts, and may prevent new stone formation in up to 60% of patients with ideopathic calcium urolithiasis.

Table 9 Risk factors for renal stones

Low urine volume particularly < 1000 ml per day
High urinary concentrations of:
Calcium
Oxalate
Low urinary concentrations of:
Citrate
Urine acidity

Calcium

Forty to 50% of people who develop stones have a higher level of calcium in the urine (daily excretion $>4\,mg\,kg^{-1}$, although absolute amounts are also relevant).

There are a number of dietary factors that can cause hypercalcuria:

- excessive intake of calcium or vitamin D particularly as supplements;
- high salt intake; and
- high protein intake, particularly from animal protein.

The ideal level of calcium intake has not been ascertained – what is known is that a low dietary intake of calcium will exacerbate intestinal absorption of oxalate and promote stone formation. In a number of patients, a low calcium diet will also escalate an underlying tendency to osteoporosis. Intake of calcium supplements, however, is associated with an increased risk of stone formation, and therefore, on balance it is advisable to aim for the normal reference nutrient intake for calcium (700–800 mg per day) from diet, not supplements. There is also evidence showing that calcium excretion increases with sodium intake and protein intake. A moderate intake of no more than 100 mmol of sodium per day is recommended, and 1 g of protein per kilogram of body weight is thought to be appropriate.

Oxalate

Calcium oxalate stones account for up to 75% of stones formed. Oxalate is mostly formed endogenously; only 10% comes from the diet, although the proportional change in excretion is quite significant if calcium intake is decreased or oxalate intake increases. Therefore, it still helps to avoid or reduce intake of high oxalate foods such as tea, rhubarb, beetroot, chocolate, cocoa, nuts, spinach, and strawberries. American sources also name gooseberries, sweet potato, leek, parsley, okra, and wheat bran. Unfortunately, there are no comprehensive lists of oxalate-containing foods and their bioavailability. High vitamin C intake increases oxalate production, although the doses stated are in excess of 1 g per day.

Other dietary factors that may have a role are dietary fiber and phytates, which reduce the amount of calcium absorbed by the gut, but this may then increase the amount of oxalate absorbed.

Uric Acid

Uric acid excretion is involved in calcium and also uric acid stone formation. Uric acid is an end product of purine metabolism, and dietary restriction of purines and animal protein will reduce its urinary excretion. Purine-rich foods include liver, kidney, brain, anchovies, sardines, herring, mackerel, mussels, scallops, goose, partridge, and yeast.

In summary, stone formation is multifactorial, so in order to give appropriate dietary advice, it is necessary to have an analysis of the stone composition and urinary concentrations of the risk factors (Table 9). It is then necessary to take a detailed diet history in order to identify excesses or deficiencies or general trends in dietary intake.

Physical Properties

Retinol (9,13-dimethyl-7-[1,1,5-trimethyl-6-cyclohexene-5-yl]-7,9,11,13-nonatetraene-15-ol) is a pale yellow crystalline powder or oily mass, depending on purity. It is insoluble in water but readily miscible with most organic solvents. Its formula, formula weight, and certain other characteristic physical properties are summarized in Table 1, along with those of the two commercially significant ester derivatives.

Chemical Properties

All-*trans* retinol, considered the parent compound of the vitamin A group, is a complex unsaturated alcohol. Its trivial name originated with the historical recognition of its role in vision. This generic structure, illustrated in Figure 1, shares a common β-ionone ring, with attached conjugated isoprenoid side chain.

Chemical and structural modifications to the ring, side chain, or polar functional group generate many retinoids possessing a wide spectrum of properties. In nature only relatively few of these compounds exhibit significant vitamin A activity. These include the predominant all-*trans* forms of retinol (originally designated vitamin A_1) and its esters, retinal, retinoic acid, and their associated 9-, 11-, and 13-*cis* isomers. The *cis*-isomers are selectively interconvertible with the *trans*-forms in the body and thereby express fractional biological activities of approximately 0.25, 0.50, and 0.75, respectively, relative to the all-*trans* vitamer. Some marine and fresh-water fish contain significant quantities of the cyclic diene 3-dehydroretinol (originally designated vitamin A_2), which possesses approximately 40% of the bioactivity of all-*trans* retinol.

Vitamin A activity is commonly expressed in international units (1 IU is equivalent to 0.300 μg all-*trans* retinol, 0.344 μg retinyl acetate, or 0.549 μg retinyl palmitate), or, more recently, retinol equivalents (1 RE is equivalent to 1.0 μg all-*trans* retinol). Such units have been useful in nutritional studies where contributions from numerous vitamin A active congeners may be combined to yield a single value. For the food scientist, it is probably more appropriate to express vitamin A content as the summation of each retinoid, in absolute mass units (usually μg).

The dominant structural feature of retinol is the extensive conjugated double-bond system, to which many of the physicochemical and biological properties may be attributed. It is also the principal factor in the lability of vitamin A. Thus, retinol and its derivatives are particularly sensitive to oxidizing conditions and are rapidly destroyed by heat, light,

COOH all-trans retinoic acid

and acids when in solution. Isomerization, oxidation and, ultimately, molecular cleavage may all occur concurrently, depending on the extent of environmental stress. Cleavage may result in the formation of volatile β-ionone fragmentation products which have importance in the development of off-flavor in some foods. Retinol is, however, relatively resistant towards alkali, and most degradation processes are minimized if it is maintained under inert gas at low temperature and in the absence of short-wavelength light.

In solution, several fat-soluble antioxidants offer protection, while in foods and food extracts, accompanying lipids and endogenous antioxidants such as phospholipids, tocopherols, and carotenes act to stabilize retinol until they are sacrificially depleted. Both thermal processing and storage expose vitamin A in foods to the risks of considerable loss (5–40%), although published data are often highly variable. (*See* **Antioxidants**: Natural Antioxidants.)

Retinyl esters are considerably more stable than the parent alcohol, a feature which is exploited in the principal commercial formulations available to the food industry. Although minor differences in absorption efficiency have been reported, dietary retinyl esters are considered to exhibit identical biological activities as a result of their conversion to retinol in the intestinal wall.

Occurrence and Forms in Foods

All forms of vitamin A found in foods ultimately derive from the provitamin A carotenoids, which are ubiquitous in the higher plants and lower animal organisms. Humans obtain preformed vitamin exclusively from animal sources, while carotenoids are gained from foods of both plant and animal origin.

Retinol and its derivatives are not widely distributed in foods. Fish liver oils are by far the most concentrated natural source, while animal liver, milk (and dairy products), and eggs contain significant quantities. The average western diet is generally assessed as satisfying the recommended daily intake level of 1000 RE total vitamin A, with about 25% supplied by β-carotene. (*See* **Carotenoids**: Occurrence, Properties, and Determination; Physiology.)

Retinoids in foods occur mainly as mixtures of retinyl esters, with lesser contributions from retinol itself. The predominant forms are long-chain esters, notably palmitate, with contributions from stearate and oleate. However, eggs are an exception, where unesterified retinol is the major form. Certain foods also contain contributions from retinal (eggs and fish roe) and *cis*-isomers (mainly 13-*cis*), the latter particularly in foods subjected to processing.

Table 2 Preformed vitamin A content of selected foods, expressed as retinol

Food	*Retinol content (range) of edible portion ($\mu g\,100\,g^{-1}$)*[a]
Milk	32–45
Butter	800–1000
Eggs	140–250
Beef	2–5
Liver (lamb)	7000–10 000
Mackerel	25–50
Cod liver oil	15 000–30 000

[a]To convert to IU per 100 g, multiply by 3.33.

Vitamin A deficiency is one of the prevalent diet-related issues and has received global attention. Consequently, nutritional tables are replete with information regarding retinol distribution in foods. Table 2 lists the vitamin A content of a few representative foods. Carotenoid-rich vegetable sources are not included. Refer to individual foods.

Use in Food Fortification

Increasing the vitamin A intake amongst populations at risk of retinol deficiency is a simple expediency and has been employed for several decades, both prophylactically and therapeutically. Many of the specific symptoms of severe deficiency (e.g., xerophthalmia, keratomalacia) are usually reversible, provided other nutritional criteria are similarly satisfied. In the developed nations, potential risks of subclinical deficiency are also avoided through food enrichment, thereby insuring satisfactory intake. (*See* **Food Fortification**.)

Fat-based foods such as margarine, milk, and infant formula provide an ideal carrier in which to supply supplemental vitamin A. Dried milk, by reason of cost and convenience, is globally the preferred foodstuff and additionally offers a high-quality protein and mineral enrichment medium appropriate to nutritional rehabilitation programs. An increasing range of alternative food items are being used as carriers, ranging from specialized dietary beverages to breakfast cereals.

In most cases, supplementation is performed with synthetic all-*trans* retinyl acetate or palmitate. The esters in the case of margarine are usually added directly in an oil carrier, often in the presence of appropriate antioxidants. Where additional stability is required, or when dried food products are involved, it is common practice to use a powder preparation in which vitamin A (and stabilizer) is deposited in a suitable carrier, such as gelatin carbohydrate, although alternatives (e.g., acacia gum) have recently been developed. However, uneven vitamin

distribution is a common problem when dry-blending food products.

Water-miscible vitamin A powders have been developed containing emulsifiers that facilitate reconstitution into aqueous solution. These solutions can then be processed directly into fluids such as milk prior to drying. Using the wet-blending technique, the protective environment of the additive is hopefully substituted by intimate interaction with the lipid phase of the finished food. The principal advantage of this supplementation route is an enhanced vitamin homogeneity in the finished product. However, the added ingredients are generally found to be less stable than their endogenous counterparts. (*See* **Emulsifiers: Uses in Processed Foods.**)

During food storage there are significant advantages in using packaging which provides effective oxygen and light protection. The use of cans allows nitrogen purging of the head space, thereby greatly enhancing the oxidative stability of the food and extending its shelf-life, particularly in developing countries with extreme climates.

Extraction and Clean-up

During analytical procedures, precautions are mandatory to exclude exposure of vitamin A to ultraviolet radiation, thermal, and oxidative stresses. Protective antioxidants and exclusion of air are essential to the success of the analysis. Purity of vulnerable retinoid standards is important during quantitative investigations, and spectrophotometric procedures are generally necessary to ascertain accurately their purity concentration.

Alkaline digestion (saponification) is most commonly employed as the first stage during analysis of retinol in foods. A representative sample is homogenized and digested in ethanolic potassium hydroxide or similar media. Saponification has the threefold effect of eliminating the bulk of lipid materials, releasing the vitamin from within the sample, and converting the various esters into free retinol. The procedure can be performed under reflux temperatures, or at ambient temperature (for longer periods), the details of which are determined by the sample matrix. In some food samples where the vitamin A concentration may be low, a preliminary fat extraction step will assist in achieving the required assay sensitivity.

Retinol is partitioned from the digest into a binary organic solvent, commonly consisting of hexane and a polar modifier such as an ether. The solution is washed with water, dried, and usually concentrated by evaporation, to provide a crude extract. Direct spectrophotometric or fluorometric assay of retinol may be impractical in poorly characterized foods, owing to interfering coextractives, and further clean-up is often necessary. Traditionally this has been achieved by open-column or thin-layer chromatography, using silica or alumina stationary phases, while gel-permeation chromatography has also been advocated. The laborious nature of these clean-up techniques has largely been overcome through the online automated use of prepacked, solid-phase extraction columns.

As the majority of native and supplementary retinol in foods exists in esterified form, there are analytical advantages to be gained through avoiding preliminary saponification, providing the nature of the food allows such simplified methodology. The total lipid fraction of such foods may therefore be directly extracted into organic solvent, which is then ready for analysis of the intact esters. Advantages include a reduction in the number of manipulative steps and the decreased risk of analyte loss through retinol degradation.

Chromatographic and Other Methods of Determination

The detection of retinol is based on its extensive conjugated double-bond functionality, which provides an intense and relatively specific chromophore in the long-wavelength ultraviolet region. The sensitivity and selectivity of spectral analysis are consequently enhanced, irrespective of the separation techniques used. In addition, retinol exhibits a strong fluorescence which offers selectivity advantages and often reduces the need for preliminary clean-up. In situations involving well-characterized foods, and where discrimination between retinol and related compounds is unnecessary, spectrophotometric or fluorometric measurement of the crude extracts can often supply a reliable estimate, providing the limitations of such strategies are recognized. (*See* **Spectroscopy: Fluorescence.**)

The traditional Carr–Price method for determination of retinol in foods has exploited the reaction with antimony trichloride to produce a blue complex in direct proportion to vitamin A concentration. Although the color is transient and difficult to control, the reaction is still employed in laboratories with limited access to modern chromatographic instrumentation. Other Lewis acids, notably trifluoroacetic acid, will react in a similar way and offer some manipulative advantages over the Carr–Price approach.

It is now accepted that a reliable estimate of vitamin A content in foods is best achieved through exploiting chromatography to separate coextracted substances and, in particular, to differentiate the active retinoid species. Most variants of chromatography have been

used during attempts to separate and quantify the retinoids. Thin-layer chromatography (TLC) and low-pressure liquid chromatography, while reasonably successful, have traditionally lacked the resolving power for reliable quantitative measurements, although high-performance TLC shows potential. Gas-liquid chromatography has not been widely utilized, as retinol (and its esters) degrades at elevated temperatures. The use of high-performance liquid chromatography (HPLC) has dominated vitamin A measurement over the last 20 years and has been largely responsible for the rapid proliferation of knowledge regarding this vitamin. This nondestructive technique facilitates a rapid analysis with minimum sample preparation. Recently, variants of micellar capillary electrophoresis (CE) have been applied to fat-soluble vitamin separations. Although representing an alternative to HPLC techniques, the application of CE to the hydrophobic vitamins is currently in its infancy. (*See* **Chromatography**: High-performance Liquid Chromatography; Thin-layer Chromatography; Gas Chromatography.)

Since isomerization can be a common phenomenon during food production, *cis* and *trans* differentiation may be required, with the application of appropriate factors to account for their selective bioactivities. In addition, inactive oxidation products such as oxyretinoids, epoxyretinoids, and their fragmentation products, as well as various retroretinoids, can exist in many food samples. Published literature is available for the determination of retinol isomers and esters, 3-dehydroretinol, retinal, and retinoic acid in a wide variety of foods. These analyses are accomplished using normal- or reversed-phase HPLC, often with simple isocratic solvent systems. Normal-phase is generally the more efficient mechanism for isomer separations, while esters are best resolved under reversed-phase conditions. Figure 2 illustrates the isomeric distribution in a saponified sample of cod liver oil utilizing normal-phase conditions.

The estimation of retinal and retinoic acid in foods is not frequently required. They exist in some foods as metabolites of the live animal but their contribution to the vitamin A pool is negligible compared to that of retinol. Despite the occurrence of 3-dehydroretinol in fish and particularly fish liver oils, retinol remains the primary source of vitamin A owing to its higher biopotency. Thus retinol, and its esters, are generally the retinoids of major interest during routine food analysis.

The specific details of HPLC procedures used for retinol analysis are too numerous to cover comprehensively. However, there are several features common to most schemes, notably the almost universal use of ultraviolet (either dual-wavelength

Figure 2 A 1-g sample of commercially refined cod liver oil was saponified with alcoholic potassium hydroxide and extracted into hydrocarbon. A portion was analyzed by normal-phase high-performance liquid chromatography using a Waters Radial-PAK silica column with a mobile phase of hexane:2-propanol (96:4 v/v) at 1.5 ml min^{-1}. Measurement was by fluorescence detection at 325 nm (excitation) and 470 nm (emission). Peak identification: 1, 11,13-di-*cis*-retinol; 2, 11-*cis*-retinol; 3, 13-*cis*-retinol; 4, 9,13-di-*cis*-retinol; 5, 9-*cis*-retinol; 6, all-*trans*-retinol.

or photodiode array) or fluorescence detection. Both electrochemical and mass spectrometric detection techniques have been reported but are not currently in widespread use. Normal-phase separations are generally performed on 5–10-μm particulate silica columns, replacing the earlier use of alternative adsorbents (alumina, keiselguhr, etc.). Amino-, cyano- and diol-bonded silica is sometimes advocated to circumvent the problems associated with moisture on underivatized silica. The primary mobile-phase component is usually a hydrocarbon in binary combination with a polar organic modifier, although ternary systems are sometimes recommended. Reversed-phase separations are usually confined to C_{18} bonded-phase columns, although other hydrophobic derivatives are sometimes used (C_2, C_8, C_{30}, and phenyl). Mobile phases are often a simple binary

combination of methanol (or acetonitrile) and water, and in some cases may be entirely nonaqueous.

Many foods, including poorly characterized or unknown samples, will usually be assayed subsequent to saponification, which offers the option of employing either chromatographic mode, and permits analytical simplification through conversion of multiple esters to a single retinol form. Milks, dairy products, and fortified cereals, may, alternatively, be tested by direct injection of a total lipid extract. Figure 3 illustrates a typical chromatogram obtained for a milk-based infant formula by this procedure. While retinyl acetate is the additive, the long-chain endogenous esters are visible as a composite peak, which are resolvable by independent nonaqueous, reversed-phase chromatography, as illustrated in the insert.

In fats and oil products, retinyl esters can be assayed by direct dissolution in hydrocarbon, followed by clarification and injection into the chromatographic system. Analytical success with these strategies relies on the selective nature of spectral detection modes, the narrow elution window of the various esters, and their extinction equivalence.

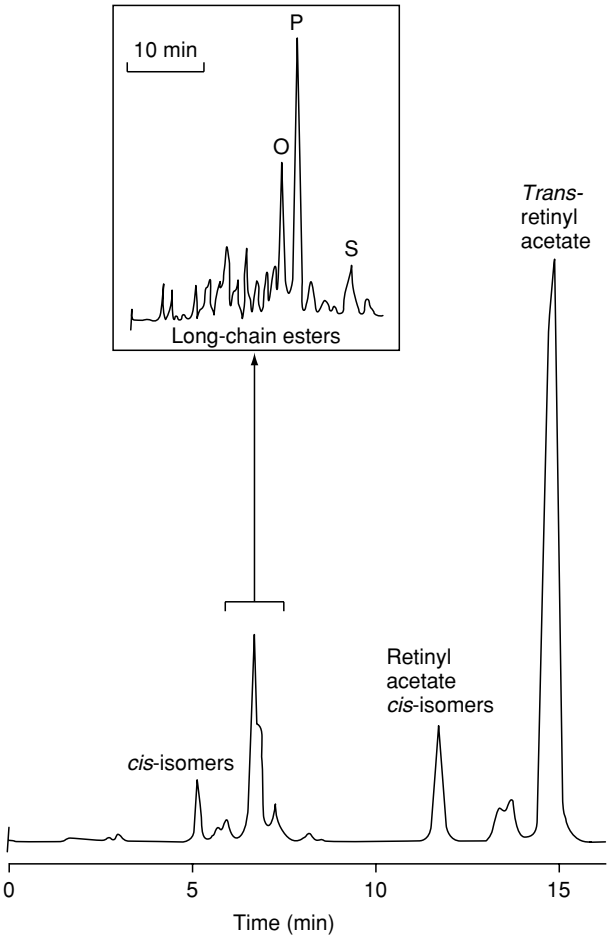

Figure 3 The lipids from 2 g of milk-based infant formula (22% fat) were extracted without saponification into 5 ml of organic solvent: 100 μl was injected directly into high-performance liquid chromatography (HPLC) equipped with a silica column and a fluorescence detector (325 nm excitation, 470 nm emission). Mobile-phase composition was hexane:2-propanol (99.92:0.08 v/v). Insert: The endogenous esters were collected and separated by nonaqueous reversed-phase HPLC on a C_{18} column with an isocratic mobile phase of acetonitrile:dichloromethane (80:20). The major identified long-chain esters are retinyl oleate (O), retinyl palmitate (P), and retinyl stearate (S).

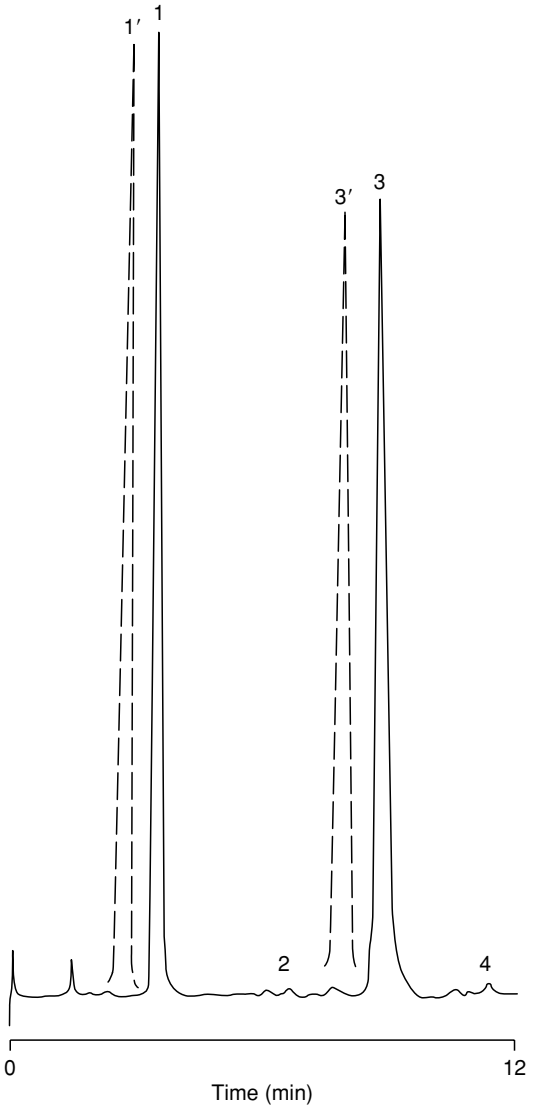

Figure 4 Retinyl acetate was extracted from a multivitamin formulation without saponification, using dimethyl sulfoxide (DMSO). High-performance liquid chromatographic (HPLC) analysis was achieved on a Waters C_{18} Radial-PAK column with a methanol (100%) mobile phase flowing at 2 ml min^{-1}. Detection was achieved by ultraviolet at 280 nm, 0.3 aufs. Vitamins D, E, and K can be assayed concurrently. Peak identification: 1, retinyl acetate (vitamin A); 2, cholecalciferol (vitamin D_3); 3, tocopheryl acetate (vitamin E); 4, phylloquinone (vitamin K_1). The elution positions of retinol (1′) and tocopherols (3′) are also indicated.

Limitations of these approaches include the requirement for normal-phase conditions in order to avoid triglyceride column fouling, and anhydrous or isohydric eluents to obtain reproducible retention. In addition, any nonesterified retinol present in the sample will not be concurrently viewed owing to its tenacious retention on silica relative to the esters.

High-potency pharmaceutical preparations and vitamin premix formulations can also be successfully assayed without the need for saponification. Thus, providing the carrier materials are free from significant fat, the retinyl esters can be extracted into a suitable solvent (e.g., dimethylsulfoxide), insuring release from encapsulation, diluted into ethanol, clarified, and injected on to a reversed-phase column. Such products usually contain vitamins D, E, and K, all of which can be concurrently assayed using both wavelength and sensitivity attenuation. However, under these conditions, it is difficult to analyze for retinyl acetate and palmitate concurrently, as the latter is highly retained by nonpolar columns. This problem can be circumvented by performing the analyses subsequent to saponification and thereby recovering total vitamin A as retinol. Figure 4 illustrates a typical chromatogram of retinyl acetate in a pharmaceutical product. The elution position of retinol is also indicated.

Absorption, Bioavailability, Transport, and Distribution

'Vitamin A' is the collective term for compounds that show the biological properties of retinol, including maintenance of epithelial tissue and visual function. This classification includes retinol, retinyl esters, and retinal. Retinoic acid is included, even though it does not sustain visual function, because it has been found to be the active metabolite that carries out many of the functions of vitamin A. These are isoprenoid compounds, having in common an 11-carbon polyene chain attached to a trimethyl substituted cyclohexenyl ring (**Figure 1**). The term 'retinoids' refers to all compounds, natural or synthetic, that show some biological activity typical of vitamin A, such as promoting differentation of cells in culture; not all retinoids can support all the functions of vitamin A, such

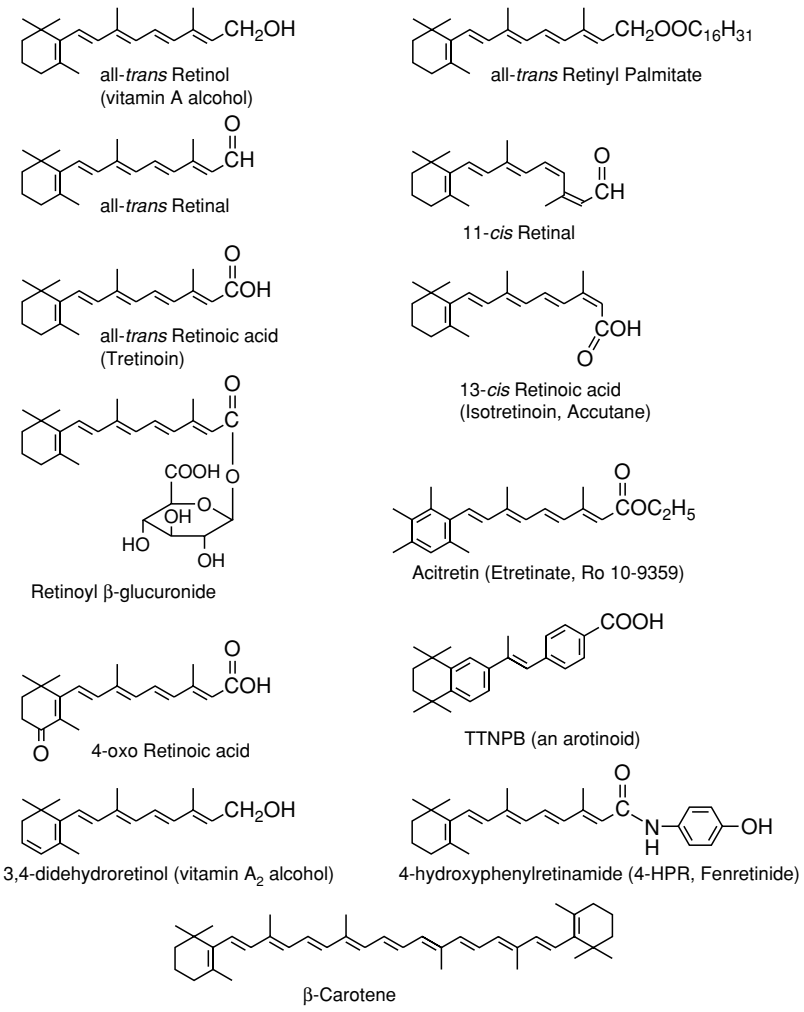

Figure 1 Chemical structures of some representative retinoids.

as vision. Vitamin A compounds are not found as such in plant tissues, but rather are characteristic of the animal kingdom; the notable exception is 13-*cis* retinal, which serves as a chromophore in the purple membrane of certain halobacteria.

Dietary vitamin A is provided by two sources: preformed vitamin A and provitamin A carotenoids. Preformed vitamin A (mostly as esters of retinol with long-chain fatty acids) comes from animal products or from dietary supplements; retinyl esters, e.g., retinyl acetate and retinyl palmitate, are more stable chemically than is free retinol. Provitamin A carotenoids arise mostly from plant products: β-carotene is the most active and is widely distributed in plants, but other carotenoids (such as α-carotene and β-cryptoxanthin and β-apo-carotenals) can be important sources of vitamin A from particular foods (*See* **Carotenoids**: Physiology). The relative importance of these sources of vitamin A is very dependent on diet. Other carotenoids, such as lycopene and xanthophyls (including lutein and zeaxanthin), are major carotenoids in some foods and may have other important physiological functions, but they have no provitamin A activity in higher animals.

Typical estimates of dietary vitamin A absorption efficiency are 70–85%. Estimates of carotenoid absorption are usually much lower, but are confounded by slow intestinal absorption and rapid metabolism; there is considerable species variability in absorption efficiency and in metabolism of carotenoids. Animal-feeding studies show that the biological matrix of food carotenoids has profound effects on their bioavailability.

Since both vitamin A and carotenoids are lipids, intestinal micelle formation with bile acids is essential for their absorption. Human subjects with impaired bile acid formation or flow (e.g., with biliary atresia) may require intramuscular supplementation with vitamin A and the other fat-soluble vitamins. Within the intestinal lumen, vitamin A esters (retinyl esters)

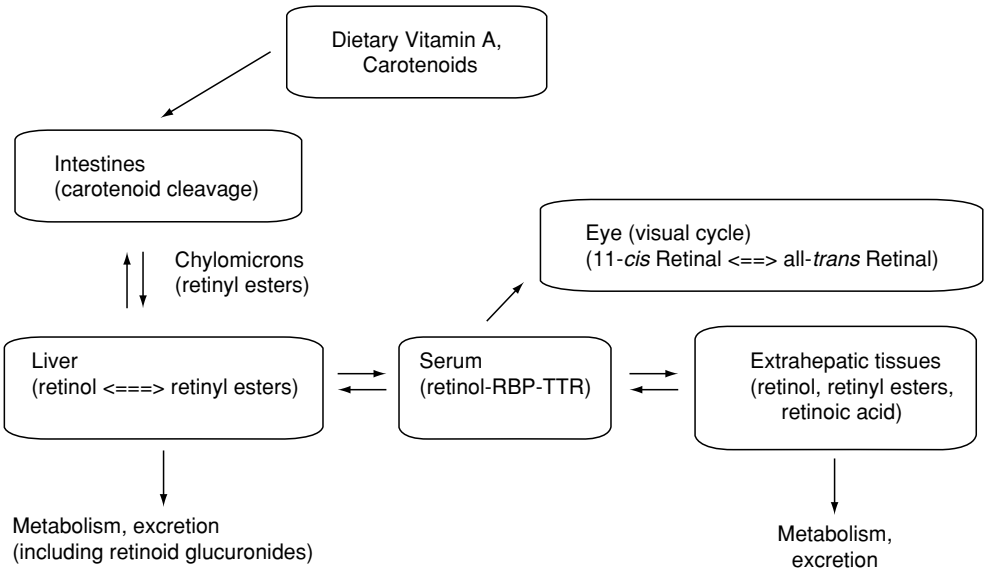

Figure 2 Overview of vitamin A metabolism.

are hydrolyzed to free retinol and are absorbed as such; this free retinol is promptly reesterified within the intestinal cells. (Figure 2). Provitamin A carotenoids, such as β-carotene, are often cleaved within intestinal cells; this metabolism is predominantly by central cleavage (mediated by the enzyme carotene 15,15′-dioxygenase), although asymmetric cleavage followed by chain shortening may play a role. Retinal (also called retinaldehyde or vitamin A aldehyde), the final product of carotenoid cleavage, is enzymatically reduced to retinol and is then esterified. The physiological ligand for this esterification process seems to be retinol bound to an intracellular retinol-binding protein (CRBP II, molecular weight (MW) approximately 14 600 Da, one of several small intracellular retinoid-binding proteins); the primary retinyl ester synthesizing activity transfers fatty acid from phosphatidyl choline (lecithin:retinol acyltransferase, LRAT), although an acyl-coenzyme A-dependent esterifying activity (acylCoA:retinol acyltransferase, ARAT) is also present.

Regardless of their dietary source, the retinyl esters are incorporated in the core of chylomicra and transported in the lymph. After removal of triacylglycerols by lipoprotein lipase as the lipoprotein particle circulates through peripheral tissues, the chylomicron remnants are rapidly taken up by the liver, and the vitamin A esters are hydrolyzed by retinyl ester hydrolase there. The resulting retinol is then either reesterified (primarily by LRAT, although ARAT activity may be important at high retinol concentrations) and stored in the liver, or released into the plasma as a complex with plasma retinol-binding protein (RBP). The two cell types involved in liver vitamin A metabolism are the hepatocytes (parenchymal cells) and the lipocytes (also called stellate cells, Ito cells, or fat-storing cells). The hepatocytes are the major site of RBP synthesis and retinol-RBP release; some retinyl esters are also found here. The lipocytes store retinyl esters in cytoplasmic lipid droplets, which also contain triacylglycerols and some cholesteryl esters within a phospholipid coat. It has been suggested that RBP transfers vitamin A, as retinol, between lipocytes and hepatocytes.

Because most forms of vitamin A are hydrophobic, the transport, metabolism, and function of vitamin A are dependent on a series of binding proteins, each specific for its ligand and tissue. Plasma RBP typically has molecular weight of approximately 21 000 Da in mammalian species; the complete amino acid composition has been determined for several species, and the gene from some species has been cloned. RBP binds retinol with 1:1 stoichiometry. The hydrophobic retinol molecule fits into a 'barrel' within the protein, shielded from interactions with the aqueous environment. Holo-RBP, in turn, binds transthyretin in plasma (TTR; formerly called prealbumin); a TTR tetramer can bind up to four molecules of RBP. Usual concentrations of human plasma RBP are 1.9–2.4 μM (40–50 $\mu g\,ml^{-1}$); typically, total circulating RBP is 80–90% saturated with retinol ligand. Although retinol, retinal, and retinoic acid bind to RBP with similar affinity, retinol is present in highest concentrations and is the predominant ligand. Retinyl esters have much less affinity for RBP and are transported by serum lipoproteins instead.

The release of holo-RBP from liver hepatocytes is carefully controlled to maintain levels of circulating

retinol within narrow limits, but the mechanism of this control is not yet clear. In the absence of adequate vitamin A, apo-RBP accumulates in the liver, ready to be released as soon as vitamin A is available (this is the basis of the Relative Dose Response assay for vitamin A deficiency, as discussed below). Clearly, this mechanism has developed because of the dichotomy of vitamin A action: vitamin A is essential, in small amounts, for proper differentiation and maintenance of epithelial cells, but excesses of vitamin A are toxic and must be avoided by the organism.

Metabolism, Storage, and Excretion

Vitamin A in excess of immediate requirements is stored in the liver as esters of long-chain fatty acids (Figure 2); the ratio of liver retinol to retinyl esters decreases as total liver vitamin A increases, but typically, 95% of total liver vitamin A is present as the esters. Retinyl palmitate is the primary ester in the liver of the human, rat, cow, sheep, rabbit, cat, frog, trout and polar bear, although significant amounts of other esters are found (especially oleate and stearate), and the liver retinyl ester composition can be affected by dietary fatty acid composition. (Remarkably, the predominant vitamin A ester in rat adrenal cortex is retinyl stearate.) Liver frequently contains as much as 90% of total body vitamin A, although other organs, such as kidney, testes, and adrenal glands, also contain detectable retinyl esters. The efficiency of liver storage of vitamin A is particularly noteworthy in the polar bear, where concentrations as much as 36 μmol (10 380 μg) per gram of liver have been reported. Typical values for human liver vitamin A (autopsy specimens) are 0.44–0.74 $\mu mol\ g^{-1}$ (126–211 $\mu g\ g^{-1}$) in the USA.

Kinetic studies carried out in rats have shown that there is extensive cycling of liver vitamin A stores, and extensive recycling of vitamin A between liver and other tissues; this assures an ample supply of retinoid to tissues in response to immediate needs. It is certain that retinol-RBP is the major form of transport from liver to peripheral tissues; although the transport of vitamin A from other tissues back to the liver may be via retinyl esters transported by lipoproteins (normally present at about 5–10% the serum concentration of retinol-RBP), transport via retinol on RBP synthesized in the outlying tissues may be an important pathway (mRNA for plasma RBP has been detected in a number of other tissues in addition to liver). In vitamin A-deficient rats, the recycling is even more extensive, and catabolism of vitamin A is markedly diminished.

The rat has served as a valuable model for vitamin A metabolism in the human, particularly for aspects that can not be studied readily in humans. In the rat, catabolism of vitamin A occurs by oxidation of the cyclohexenyl ring (particularly at the 4-position), epoxide formation at the 5,6-positions, hydroxylation of the ring methyl groups, and chain shortening. The resulting metabolites are generally inactive, although some may have a little biological activity. These more polar retinoids are excreted in the urine and in the bile.

Retinol can be reversibly oxidized to retinal (vitamin A aldehyde); retinal can be oxidized to retinoic acid, but retinoic acid cannot be converted back to the other forms. Thus, retinol, retinyl esters, and retinal have equal biological activity because they are freely interconverted; retinoic acid fills some (but not all) of the functions of retinol, but it and its derivatives are not stored. Typical human serum concentrations of retinoic acid are 5–10 nM (1.5–3 $ng\ ml^{-1}$), compared with typical retinol concentrations of 1–2 μM. Retinoyl β-glucuronide and retinyl β-glucuronide (formed in the liver from retinoic acid and retinol, respectively) are secreted into the bile but can be hydrolyzed and reabsorbed in the intestine (enterohepatic circulation); both these compounds have vitamin A activity in a variety of tests, are found in human blood, and may have regulatory roles in vitamin A function.

Roles in the Body

Vision

The major roles of vitamin A are in vision and in control of gene expression (including differentiation of epithelial tissues, and in the immune system, as well as a host of other systems). Metabolism of vitamin A in the retina of the eye is unique, in keeping with the unusual role of vitamin A in that tissue. Vitamin A is stored in the retinal pigment epithelium as retinyl esters. All-*trans* retinyl esters are simultaneously hydrolyzed and isomerized to 11-*cis* retinol by an isomerohydrolase enzyme that uses the free energy of hydrolysis of the retinyl esters to drive the isomerization reaction. 11-*cis* Retinol, a compound unique to the eye, is then oxidized to 11-*cis* retinal by an alcohol dehydrogenase. 11-*cis* Retinal is transferred from the pigment epithelium cells to the rod cells by interstitial retinoid binding protein (IRBP), a distinct binding protein (MW 140 000). In the rod cells, 11-*cis* retinal binds (as a Schiff base with the ε-amino group of a specific lysine residue) to the protein opsin to form the visual pigment, rhodopsin. When a photon of light is absorbed by a rhodopsin complex, the 11-*cis* retinal is isomerized to all-*trans* retinal and released from the protein complex; the resulting conformation change of the protein initiates a cascade of reactions, resulting in a neural signal to the brain. The protein opsin is then available to bind another molecule of 11-*cis*

retinal for another round of the visual cycle. The all-*trans* retinal that was released from the protein complex is transferred back to the pigment epithelium via IRBP, enzymatically reduced to all-*trans* retinol, and esterified again. In contrast to the high turnover rates of vitamin A in other tissues, vitamin A in the eye is highly conserved, with little leakage back to the liver. Prolonged vitamin A deficiency, however, leads to reduced sensitivity to light, usually first noted as impaired vision at night (night blindness). These effects of vitamin A deficiency are generally reversible by subsequent vitamin A supplementation.

In a very different role of vitamin A in the eye, the cornea depends on vitamin A for proper cell differentiation and for secretion of protective glycoproteins. In vitamin A deficiency, these tissues are susceptible to attack by opportunistic bacteria; such attack may result in permanent scarring and permanent vision loss. These effects of vitamin A deficiency, unlike those in the retina, may not be reversible by subsequent vitamin A supplementation. Such vitamin A-dependent corneal degeneration (given the general name 'xerophthalmia') accounts for an estimated 500 000 new cases of blindness in preschool children in the world each year.

Control of Gene Expression

Overview of control of gene expression Vitamin A and its metabolites are required for embryonic development, cellular differentiation, growth, reproduction, adult tissue homeostasis, vision, and maintenance of the immune system. Over the past several years, it has become clear that retinoids mediate many of their pleiotropic effects by regulating the activation or inhibition of gene transcription. It is well documented that retinoids regulate the expression of many genes involved in their own transport and metabolism. The genes for different retinoid receptor subtypes, the cellular retinol binding proteins (CRBP) I and II, and the cellular retinoic acid binding protein II (CRABP II) are regulated by either all-*trans* retinoic acid (RA) or 9-*cis* RA (Figure 3). These vitamin A metabolites exhibit hormonal action by binding to their nuclear receptors that interact with DNA response elements within target genes to affect gene transcription. The retinoid receptors are members of the steroid/thyroid/retinoid superfamily of nuclear receptors. There are two distinct families of nuclear retinoid receptors: the retinoic acid receptors (RARs) and the retinoid X receptors (RXRs). It has been suggested that the two classes of receptors have a distinct functional activity, the RARs being important in cell development and differentiation, and the RXRs being important in metabolic regulation. Nuclear receptors of the steroid/thyroid/retinoid superfamily can act as either inhibitors or activators of transcription. The mechanism whereby these regulatory properties are propagated is via the recruitment of accessory proteins to the nuclear receptor. In the absence of ligand, such as all-*trans* RA, corepressor proteins are bound to retinoid receptors and cause inhibition of transcription of the target gene. Conversely, binding of ligand causes a conformational change in the receptor such that corepressor proteins are released, and coactivator proteins are recruited to the retinoid receptor. The association of coactivators with the nuclear retinoid receptor causes induction of transcription of the target gene, initiated by retinoic acid binding to its specific nuclear receptor.

Nuclear retinoid receptors As indicated previously, there are two distinct classes of nuclear retinoid receptors, the RARs and RXRs. Both RARs and RXRs bind the naturally occurring metabolites of vitamin A with a similar order of affinity (all-*trans* RA > retinal > retinyl acetate > retinol), but RXRs require from 10- to 40-fold more ligand for comparable transcriptional activation. A downstream metabolite of

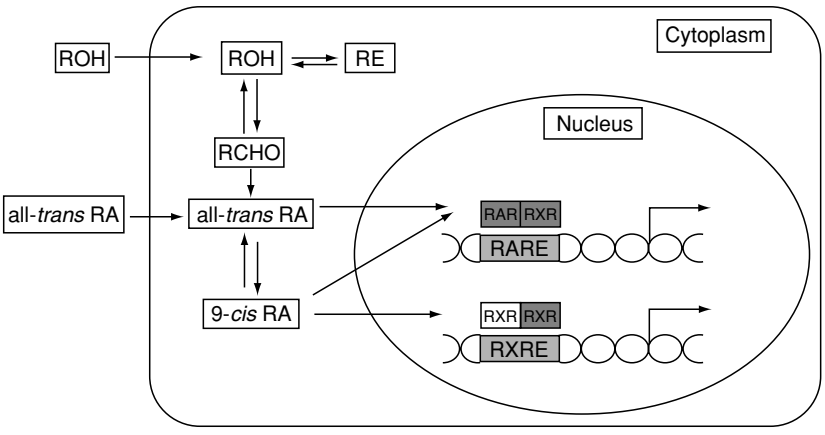

Figure 3 Retinoid action in the nucleus.

all-*trans* RA, 9-*cis* RA, has been shown to be the naturally occurring, high-affinity, ligand for the RXR. The binding of ligand to nuclear retinoid receptors induces dimer formation and initiates transcriptional activation of a target gene via the DNA response element(s) in the promoter/regulatory region of the gene. Retinoid receptors act in a dimeric conformation and bind to specific RA response elements (RARE) within the 5′promoter/regulatory regions of target genes. The DNA response elements are usually a direct repeat (DR) of six nucleotides in a specific sequence separated by a defined number of nucleotides that vary depending on the type of DNA response element. RAR/RXR heterodimers can activate or repress gene transcription, depending on the type of RARE to which they bind in the promoter region of a target gene. If the RAR/RXR heterodimer binds to a DR-5 RARE, the RAR/RXR complex activates transcription in response to the RAR ligand all-*trans* RA. In contrast, RAR/RXR heterodimers bound to a DR-1 RARE exhibit no response to RAR-specific ligands and repress the response to RXR-specific ligands such as 9-*cis* RA. Therefore, the RAR/RXR heterodimer can be stimulatory, neutral, or inhibitory, depending on ligand, all-*trans* RA or 9-*cis* RA, and the DNA RARE to which it is bound. This is partially explained by the fact that there is a specific polarity to the binding of RAR and RXR heterodimeric partners, determined by the DNA itself. RAR/RXR heterodimers bind with the RXR occupying the upstream half-site of a DR-5 element, but this orientation is reversed on a DR-1 element. Further investigation of this polarity of RAR/RXR heterodimer binding has shown that transactivation by RAR bound to a DR-5 RARE involves the ligand-dependent dissociation of a bound corepressor (discussed below), but RAR bound to a DR-1 RARE does not respond to ligand by dissociation of a bound corepressor. Therefore, transcription is not stimulated in the later response. In this regard, the DNA itself is considered an allosteric regulator of receptor–accessory protein interaction.

All of the RAR and RXR subtypes, α, β, and γ, are encoded by separate genes at distinct chromosomal loci. However, the protein products encoded by these genes have certain common modular structures, particularly in the DNA-binding and ligand-binding domains, which define, in part, their membership within the steroid/thyroid/retinoid superfamily. The amino acid sequence of the RARs can be divided into six regions (A–F). The amino acid sequence of the RXR genes has a similar domain structure to the RARs. Among the retinoid receptors, the DNA-binding domain (C) is a highly conserved region of approximately 70 amino acids that contains two zinc fingers; the zinc-finger configuration is responsible for specific DNA response element recognition. According to Evans and colleagues, a sequence of three amino acids within the first zinc finger (the P box) determines recognition of the half-site sequence of a DNA response element, and five amino acids in the second zinc finger (the D box) are critical for recognition of the spacing between half-sites. Nuclear magnetic resonance spectroscopy of the DNA-binding domain indicates a secondary structure comprising three α-helices; the first helix is postulated to fit across the major groove of the DNA response element. In this orientation, the third helix interacts with the minor groove of the DNA, such that Lys and Arg residues make contact with the phosphate backbone and stabilize protein–DNA interactions. This third helix in the DNA-binding domain is also thought to mediate protein–protein interaction required for dimer formation. The ligand-binding domain (E) is also highly conserved among the RAR and RXR genes and mediates the ligand-dependent transcriptional activation function. The amino-terminal region (A) is less well conserved and is subtype-specific. Both regions A and B are responsible for ligand-independent transcriptional activation. The amino-terminal part of domain D may function as a nuclear localization site.

In addition to subtype differences in RARs and RXRs, there are also different mRNA isoforms for each gene. These isoforms are generated by different transcription start sites and alternative splicing, which affects the 5′ untranslated region (UTR) and the A domain such that either a deleted or altered A region is combined with a common B–F region.

The biological activity of vitamin A metabolites is further extended by the interaction of the retinoid receptors with other members of the receptor superfamily. The RXRs serve as heterodimeric partners with RARs, thyroid hormone receptors (TR), and the vitamin D receptors (VDR) and have been shown to increase the affinity of RAR, VDR, and TR, for their respective response elements (favored DR motifs DR-2/DR-5, DR-3, and DR-4, respectively), and to activate transcription in the presence of the appropriate ligand. This indicates a central role for the RXR as a heterodimeric partner with the other nuclear receptors of this superfamily. Interestingly, only one ligand is required to stimulate the heterodimeric complex and affect transcriptional activation. However, the RXR is unique in that it can function as a homodimer. In this capacity, it can stimulate gene transcription favoring the DR-1 hormone response element and is dependent upon the 9-*cis* RA ligand. The RXR also forms a heterodimeric complex with the peroxisome proliferator-activated

receptor (PPAR) and, for example, mediated by a DR-1 motif in the promoter of the acyl-CoA oxidase gene, stimulates transcription in response to both 9-*cis* RA or clofibric acid (a peroxisomal proliferator). Recently, it has been shown that dietary polyunsaturated fatty acids (PUFA) activate PPAR, and via PPAR–RXR heterodimer formation, dietary PUFA regulate both lipid and glucose metabolism. Clarke refers to dietary PUFA as 'fuel partitioners' that act, via PPAR activation, to increase glycogen storage and fatty acid oxidation while decreasing triglyceride synthesis.

The multiplicity of nuclear retinoid receptors reflects developmental and tissue-specific differences in their expression. In the mouse embryo, RARα is ubiquitously expressed, whereas RARβ and RARγ are more restricted, and nonoverlapping, in their expression. RXRβ genes are widely expressed in the mouse embryo, whereas RXRα is found in liver, kidney, intestine, and skin, and RXRγ is more restricted still. In the adult, both RARα and RXRβ are found in most tissues, whereas RARβ, RARγ, RXRα, and RXRγ are more limited. RXRα is highly expressed in liver, kidney, spleen, and visceral tissues, indicating a possible role for this RXR in retinoid, lipid, and carbohydrate metabolism. The demonstrated RXR responsiveness of numerous genes including the CRBP II, apolipoprotein (apoAI), acyl-CoA oxidase and the phosphoenolpyruvate carboxykinase (PEPCK) genes further supports this hypothesis.

Nuclear coactivators and corepressors associated with nuclear retinoid receptors Recently, several coactivators and corepressors that associate with nuclear retinoid receptors and affect their ability to regulate target genes have been cloned and characterized. It has been established that retinoid binding induces conformational changes in nuclear retinoid receptors and promotes their association with a diverse group of nuclear proteins that function as coactivators of transcription. Alternatively, unbound receptors recruit nuclear proteins that repress transcription of target genes. It has been demonstrated that all-*trans* RA binding to RAR, with subsequent activation of transcription of a target gene, requires dissociation of corepressor proteins and recruitment of coactivator proteins. It is thought that corepressors contribute to the formation of condensed chromatin structure, prohibiting activation of target genes. Conversely, most coactivators cause a loosening of chromatin conformation, allowing nuclear receptors to activate transcription of target genes.

Regulation of the PEPCK gene by retinoids The multifaceted action of vitamin A is indicated by its role in regulation of the gene encoding PEPCK, the rate-determining enzyme of gluconeogenesis in liver (Figure 4). All-*trans* RA and 9-*cis* RA, in equal concentrations, induce the PEPCK promoter by approximately sevenfold in hepatoma cells in culture. Studies in mice *in vivo* have shown that vitamin A deficiency causes a decrease in PEPCK gene expression. Specifically, with food deprivation, hepatic PEPCK mRNA levels are not induced in vitamin A-deficient mice. Induction of the PEPCK gene can be reestablished with retinoid treatment of vitamin A deficiency. Retinoid regulation of the PEPCK gene has been tested *in vivo* in two lines of transgenic mice. Results from these experiments indicate that expression driven by both the −460/+73 and −355/+73 PEPCK DNA sequences is decreased with vitamin A deprivation. Subsequent treatment of vitamin A deficiency with all-*trans* RA increases expression driven by the −460/+73 promoter or the minimal −355/+73 promoter. The second retinoid isomer, 9-*cis* RA, however,

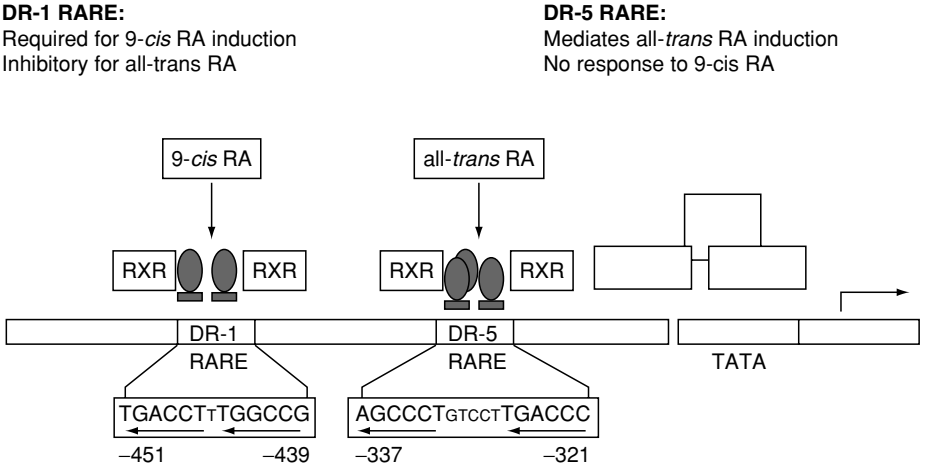

Figure 4 Retinoic acid response elements involved in regulation of the PEPCK gene.

increases expression driven by the −460/+73 promoter, but not the −355/+73 promoter. Therefore, the two active retinoid isomers in liver have different molecular signaling mechanisms and activate the PEPCK gene at different DNA response elements.

Additionally, it has been shown that appropriate developmental regulation of the PEPCK gene during fetal development and the perinatal period is dependent on adequate vitamin A nutriture. Vitamin A deficiency causes a decrease in hepatic PEPCK mRNA during late gestation, a stage in development when the PEPCK gene is first expressed in liver. At birth, with adequate vitamin A nutriture, the PEPCK gene is rapidly induced. This is consistent with the need of the newborn to conduct gluconeogenesis because of removal from the maternal glucose supply. The rapid induction of PEPCK gene expression at birth is significantly decreased with vitamin A depletion in the newborn. Overall, adequate vitamin A is required for the appropriate developmental expression of the PEPCK gene in late gestation and at birth. The fact that vitamin A is an active regulator of expression of the PEPCK gene indicates a significant role for this nutrient in the regulation of carbohydrate metabolism overall. This is a new area of investigation of vitamin A regulation of gene expression as it expands the known role of vitamin A beyond the regulation of genes involved in vitamin A metabolism itself.

Human Health

Infection and Disease

Early in the study of vitamin A requirements, it was appreciated that vitamin A-deficient animals are more susceptible to disease. Attempts to extend these observations to human health long gave inconsistent results, however. Recently, it has been shown that supplementation of children with vitamin A reduces the severity of measles and diarrhea (although vitamin A supplementation may not reduce the incidence and duration of diarrhea). Although vitamin A prophylaxis may not reduce measles severity, supplementation of measles patients with vitamin A (200 000 international units (IU), i.e., 60 000 μg of RE, 209 μmol) during infection does reduce hospital stay and mortality rate and is now recommended by WHO in communities where vitamin A deficiency is prevalent. Currently, it is not believed that vitamin A supplementation can provide any benefit for other respiratory diseases (nonmeasles pneumonia). The possible role of vitamin A status in tuberculosis, malarial infection, and HIV infection is not clear. However, vitamin A public health programs can have a tremendous impact on child morbidity and mortality in developing countries.

The mechanism(s) by which retinoids affect the immune system have not yet been delineated, but it seems safe to assume that control of gene expression is involved. In at least some experiments, the function of vitamin A can be filled by all-*trans* or 13-*cis* retinoic acid, consistent with current knowledge of retinoids and gene expression. Both antibody-mediated and cell-mediated immune responses are reduced in vitamin A deficiency. Interpretation of human studies of the relationship between vitamin A status and immune response is complicated by the fact that plasma retinol concentrations (often used as a convenient measure of vitamin A status) fall during infection even in vitamin A-replete subjects, and chronic infection reduces vitamin A absorption and mobilization.

Dermatology One of the first pharmaceutical applications of retinoids was the use of 13-*cis* retinoic acid (isotretinoin) to combat cystic acne, ichthyosis, and follicular keratosis; 13-*cis* RA inhibits sebaceous gland size and activity by promoting CRABP II mRNA expression. The process of keratinization (differentiation and maturation) of skin cells is affected both by deficiency and by excess of retinoids. Dehydroretinol and its esters (vitamin A_2) are found in human skin (more so in epidermis than in dermis) and may have specific roles there. Retinoids are now used clinically to treat psoriasis, ichthyosis, Darier's disease, and other disorders of keratinization, acne, and photoaged skin. Synthetic retinoids, such as etretinate and the ethyl ester of the arotinoid TTNPB (Figure 1), as well as the naturally occurring retinoyl β-glucuronide, have been developed in attempts to reduce the toxicity of the naturally occurring retinoic acids without losing efficacy.

Cancer prevention and treatment Retinoids can inhibit cell transformation and tumor development in a variety of cell and animal models, but the effects are not uniform with all malignancies. In general, it seems that retinoids may not prevent initiation of tumors, but more likely interfere with the promotion process. They exert these effects by modulating growth, differentiation, and apoptosis of cells; most, if not all, of these effects may be explained by the role of retinoids in control of gene expression.

Retinoids have been tested against a variety of cancers in human and animal studies. *N*-(4-Hydroxyphenyl)-retinamide (4-HPR, Fenretinide) has been tested clinically for prevention of recurrence of human breast cancer; although results are promising, some toxicity (owing to interference with normal retinol metabolism) has been observed. Incidence of skin tumors associated with xeroderma pigmentosum is reduced by treatment with 13-*cis* retinoic acid.

Perhaps the most dramatic application is the use of retinoic acid (tretinoin) against promyelocytic leukemia; this disease results from a chromosomal translocation producing the fusion of the RARα gene with the PML gene to produce an oncogene and responds well to high doses of all-*trans* retinoic acid.

Requirements and Recommended Intakes

Because of confusion among the various units for presenting vitamin A values, the concept retinol equivalent (RE) has been proposed. One retinol equivalent equals 1 μg of all-*trans* retinol, either free or as the retinyl component of a retinyl ester; 1 RE = 3.33 IU of vitamin A, or 3.5 nmol of retinol or retinyl ester. Although the exact vitamin A value of carotenoids depends on several factors (*See* **Carotenoids**: Occurrence, Properties, and Determination), the retinol equivalent was defined as 6 μg of all-*trans* β-carotene or 12 μg of other provitamin A carotenoids (10 IU of provitamin A carotenoid). To account for updated findings on provitamin A value of carotenoids, the retinol activity equivalent (RAE) has been defined more recently as 1 μg of all-*trans* retinol, 12 μg of all-*trans* β-carotene, or 24 μg of other provitamin A carotenoids.

Liver concentrations provide the best appraisal of vitamin A status. Human liver specimens can be difficult to obtain, but analysis of autopsy specimens can be useful in evaluating the vitamin A status of a population. As indicated above, serum retinol levels are maintained nearly constant and are not generally useful in assessing vitamin A status, except when liver vitamin A reserves fall well below $0.07\,\mu mol\,g^{-1}$ (20 μg per gram of liver). Serum (or plasma) retinol levels are normally 1–2 μM (290–570 $ng\,ml^{-1}$) across a wide range of mammalian species.

Because liver concentrations of vitamin A are not readily measured, and serum retinol values are not an adequate indicator of an individual's vitamin A status, several indirect methods have been developed. Conjunctival impression cytology (CIC) evaluates the development of squamous metaplasia (enlarged epithelial cells) and loss of goblet cells from the conjunctiva of the eye by histological examination of cells transferred from the cornea to filter paper. The relative dose response (RDR) depends on the release of retinol-RBP from liver into serum after a large oral dose of vitamin A (typically, 450 μg of retinyl acetate in human studies); as described above, apo-RBP accumulates in the liver in vitamin A depletion. The RDR is calculated as:

$$\mathrm{RDR} = \frac{A_5 - A_0}{A_5} \times 100\%,$$

where A_5 represents the serum retinol concentration at 5 h after the oral dose, and A_0 represents the fasting serum retinol concentration at the time of the dose. Studies in both humans and rats indicate that an RDR value greater than 20% indicates liver vitamin A reserves less than $0.07\,\mu mol\,g^{-1}$ (< 20 μg per gram of liver), i.e., inadequate vitamin A status. The RDR assay requires, of course, that the oral dose be normally absorbed (an intramuscular injection has been used in human subjects with biliary atresia), and that protein metabolism is normal: protein deficiency or zinc deficiency or liver cirrhosis impairs the dose response. An alternate approach, the modified relative dose response (MRDR), uses the vitamin A analog 3,4-didehydroretinol (vitamin A_2, a form found in some freshwater fish and found in very low levels in human skin). The ratio of vitamin A_2 to vitamin A_1 in serum retinol at 5 h after an oral dose is used as a measure of vitamin A status, with high values (ratio > 0.03 after an oral dose of 100 μg per kilogram of body weight) indicating poor vitamin A status. Chlorinated vitamin A analogs have been used in a similar fashion. The RDR and MRDR, as well as CIC, have been used successfully in human population studies. Isotope dilution of tracer-labeled vitamin A (radioactive or stable-isotope labeling) has been used to estimate human vitamin A status, but technical difficulties have so far prevented general use of the technique.

Nutritional requirements for vitamin A have not been well defined because of the diversity of vitamin A functions. In animal studies, intakes of 3–8 RE per day per kilogram of body weight (10–28 nmol per day per kilogram of body weight) cure deficiency symptoms and intakes of 30–60 RE per day per kilogram of body weight (100–210 nmol per day per kilogram of body weight) produce optimal growth. Kinetic studies of vitamin A metabolism in rats show that irreversible loss of vitamin A is decreased on low vitamin A intakes. Studies on vitamin A requirements have not yet addressed functional criteria such as immune function and possible anticancer effects.

To provide an *adequate and safe human intake*, current WHO/FAO dietary recommendations (1988) and suggested recommended dietary intakes (RDIs) for adults are based on intakes of 9.3 RE per day per kilogram of body weight (33 nmol of vitamin per day per kilogram of body weight). The European Union Scientific Committee for Food has recommended population reference intakes of 700 RE per day (men) and 600 RE per day (women), with estimated average requirements of 500 and 400 RE, respectively, and lowest threshold intakes of 300 and 250 RE, respectively. In contrast, the recommended dietary allowances (RDAs) of the US National

Research Council (1989) attempted to set an *optimal intake level*, and so recommended a higher RDA of 1000 RE per day for men and 800 RE per day for women (the difference being due to a lower body weight, on average). However, the most recent recommendations from the US Institute of Medicine are calculated to *maintain an adequate body pool size* and set an RDA of 900 μg of RAE for adult males, 700 μg of RAE for adult females.

Toxicity

Over 600 individual cases of human vitamin A toxicity have been reported, owing to either acute (single or a few large doses ingested over a brief period of time) or chronic intake (moderately high doses taken frequently for periods of months or years). Acute toxicity in human adults is reported from doses of 300 000–10 000 000 RE (1000–35 000 μmol); chronic doses of 15 000–300 000 RE (50–1000 μmol) have produced hypervitaminosis A. Symptoms include headache, vomiting, diplopia, alopecia, dryness of mucous membranes, desquamation, bone abnormalities, and liver damage. However, single oral doses of 60 000 RE in oil have been successfully used in vitamin A intervention programs for preschool children, with transient toxic symptoms observed in no more than 3% of subjects. Massive doses of β-carotene are not toxic, but may be less efficiently absorbed and used than vitamin A itself. Rodent animal models have been extremely valuable in elucidating vitamin A requirements and metabolism, but the rat seems to be much less susceptible to hypervitaminosis A than is the human.

The toxic effects of high vitamin A intakes are mediated by serum retinyl esters; retinol-RBP concentrations are maintained at normal levels in hypervitaminosis A, but serum retinyl esters are markedly elevated, bypassing the normal homeostatic controls on vitamin A transport. Some carnivores, including the dog, are unusual in having high fasting levels of serum retinyl esters, presumably reflecting differences in lipoprotein metabolism in these species; the implications of this for vitamin A metabolism and for resistance to hypervitaminosis A are not clear.

The most tragic consequences of excessive vitamin A intake are teratogenicity (specifically, malformations of the cranium, face, heart, thymus, and central nervous system) and embryotoxicity. Acidic retinoids such as those that have been used in dermatology are particularly potent, as they can attain high serum levels and can readily pass the placental barrier. Although large intakes of vitamin A itself (> 7500 RE per day, 26 μmol per day) early in human pregnancy can cause birth defects (perhaps owing to metabolism of retinol to retinoic acid?), serum concentrations of retinol and retinyl esters are normally maintained at moderate levels during pregnancy. It is assumed that these teratogenic effects are related to the important role of retinoids in differentiation of cells and that these effects are mediated via the nuclear receptor proteins. (Interestingly, the retinoid β-glucuronides are much less teratogenic than retinoic acid.) In view of these teratogenic effects occurring at less than 10 times the recommended daily intakes, a consensus of several professional organizations is that women should avoid vitamin A supplements during the first trimester of pregnancy, and that subsequent supplements, if taken at all, should be prudently limited to 8000 IU (2400 μg RE, 8.5 μmol) per day, although 10 000 IU (3000 μg RE, 10 μmol) appears to be safe.

The previous two decades have been exciting in retinoids research, with the disclosure of the roles of retinoids in control of gene expression. Continuing challenges in vitamin A research include: (1) the development and confirmation of indirect indices of vitamin A status; (2) elucidation of the mechanism of control of serum retinol-RBP concentrations; (3) more exact determination of vitamin A requirements for specific functions (not only growth and prevention of blindness, but also immune function and cell differentiation in individual tissues); and (4) definition of the role of vitamin A in differentiation in specific tissues, perhaps leading to chemical design of distinctive retinoids to combat specific cancers and dermatologic diseases.

RHEOLOGICAL PROPERTIES OF FOOD MATERIALS

J Lefebvre, Institut National de la Recherche Agronomique, Nantes, France

Introduction

Rheological properties of ingredients and products are involved in all stages of food, from formulation to consumption. Their knowledge is therefore important to many aspects of food science and technology, such as modeling of processing operations (pumping, mixing, heat exchange, etc.), design of the processing and packaging machines, process control, characterization of ingredients, intermediary and end products, and instrumental evaluation of texture. They even concern nutrition, since foodstuffs have to be chewed and swallowed before being digested. The interest of food scientists in rheology is as old as rheology itself, and some of the pioneering work in this comparatively young discipline has been carried out on food materials.

During the last decade, the most active research areas in food rheology dealt with the characterization of the viscoelastic behavior of liquid, semiliquid, or gel food systems. Whereas flow properties are of prime importance in all aspects of processing of liquid materials, viscoelasticity measurements often constitute in practice the only feasible approach (along with microscopy) to obtain information on the structure of complex concentrated systems (solids and liquids) and on how it is affected by composition, or by physical, chemical, or biochemical treatments. They provide a unique tool to adapt formulations or to develop new engineered foods to meet the demands of changing technologies and evolving consumers' requirements.

However, rheometry on food systems has long been limited to the study of flow behavior (viscometry). Because of theoretical and practical difficulties, and especially because of the lack of affordable rheometers with high enough sensitivity, the viscoelastic properties of food systems have only been evaluated empirically, using an impressive variety of instruments and methods of testing, adapted to different specific types of materials or problems, but which did not allow the expression of measurements in terms of relevant physical variables because of the complexity of the deformations and of the mechanical sollicitation patterns they implemented. This situation has completely changed since the mid-1980s with the development of comparatively low-priced performing commercial rheometers. Viscoelasticity studies in shear are now within the reach of the average food science laboratory, opening up new, exciting perspectives. But this does not mean they are easy to carry out and to interpret, and a working knowledge of the essential concepts has not spread as fast and wide as the equipment. The first purpose of this article, focused on viscoelasticity, is to give an outline of these concepts.

Food materials display an amazing variety of rheological behavior. They can nevertheless be reduced to a relatively small number of basic types. The main one along the views outlined above corresponds to transient networks. It will be illustrated here with a few examples which will also be used to point out some

fundamental or practical problems which are especially important or critical in the case of food systems.

Only behaviors in shear (more precisely, in rotational geometries) will be considered, as shear is the most important type of deformation in rheological studies with regard to the orientations of this short article.

Solids and Liquids: Betwixt and Between

Rheology emerged as a science to describe, analyse, and rationalize the complex mechanical behavior displayed by most real materials, for which the classical Hookean elastic solid and the Newtonian viscous fluid represent only limiting behavior, which is seldom encountered in practice. Two types of deviation from the ideal behavior can occur, either separately or together: time-dependence and nonlinearity.

Let us revisit briefly these classical notions with the help of a rheological experiment which is the retardation test (creep and recovery): a stress σ is applied suddenly at time $t = 0$ and maintained till $t = \sigma$. Then, the sample is suddenly unloaded; the strain γ is recorded during the loading period (creep) and after the removal of stress (recovery); the results are expressed in terms of the compliance function $J(t) = \gamma(t)/\sigma$ in both parts of the test.

Viscoelasticity

In time-dependent behavior, the response depends on the duration of excitation. The general case is that of viscoelastic behavior, illustrated schematically in Figure 1c and d. The responses of the ideal elastic solid and of the ideal viscous liquid are shown for comparison (Figure 1a and b); they are instantaneous and defined by a constant value of the compliance $J_e = \gamma_e/\sigma$ (for the solid) or the compliance rate $dJ(t)/dt = 1/\eta$ (for liquid of viscosity η). To reach steady state (i.e. the equilibrium compliance J_e in the case of a viscoelastic solid, or a constant rate of

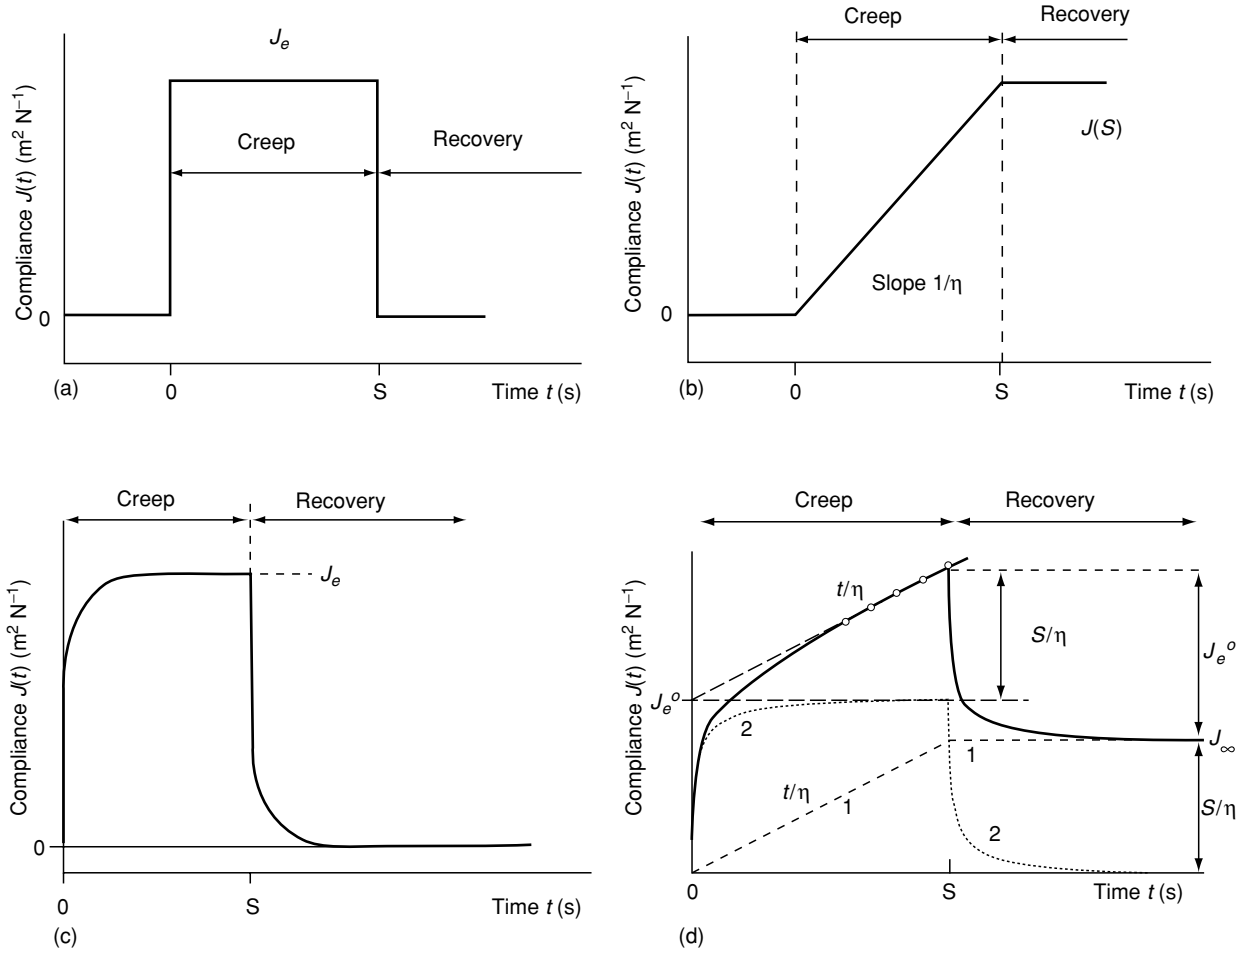

Figure 1 Schematic responses to a retardation test: (a) elastic solid; (b) viscous liquid; (c) viscoelastic solid; (d) viscoelastic liquid within the linearity range. Solid curve: measured total compliance. Curve 1 (dashed line): contribution of flow. Curve 2 (dotted line): recoverable compliance $J_r(t)$.

compliance $dJ(t)/dt$ in that of a viscoelastic liquid) requires a certain length of time after loading. And it is the same after unloading for compliance to reach a constant value. This value is zero in the case of a viscoelastic solid: deformation is entirely reversible, although not instantaneous. In contrast, for a viscoelastic liquid, the strain gathered during creep is progressively recovered after unloading, but only incompletely; the residual compliance J_∞ corresponds to the irreversible part of the deformation, i.e., to the contribution of flow to the total strain at the end of the creep period: $J_\infty = S/\eta$. Flow contribution to strain becomes dominant ($J(t)$ becomes a linear function of time) only after a creep time $t > t_m$; for $t < t_m$, elasticity dominates the response, although flow begins as soon as stress is applied to the material. By subtracting flow contribution t/η from the compliance in creep, the reversible contribution to the compliance is obtained. This contribution similar to the response of the viscoelastic solid is called the recoverable compliance $J_r(t)$; it is identical, in the case of linear behavior (see below), to the part of the final compliance $J(S)$ which is recovered during the recovery part of the test. The plateau value J_e° of $J_r(t)$ can be taken as a gauge of the elastic character of the liquid. The product $t_m = \eta J_e^\circ$ is the longest retardation time of the material and corresponds to t_m.

Such behavior simultaneously displays elastic and viscous characteristics. Elasticity dominates at short times of observation; the behavior appears to be increasingly viscous as the time scale of the experiment broadens. Thus, a given material can display either solid- or liquid-like behavior, depending on the time scale of the deformation process. This scaling is represented by the Deborah number $D = \tau/\Theta$, where τ is a characteristic time of material response (infinite for an elastic solid, zero for a viscous liquid) and Θ is a characteristic time of the experiment. A material will display a solid-like behavior (high D values) if it responds slowly (large τ) or if its response is observed at short time scales (small Θ). Although the distinction between solid and liquid subsists in theory for viscoelastic materials, it can be difficult to draw it in practice. Many materials which are felt as solids in common experience are indeed viscoelastic liquids.

Linearity and Nonlinearity

The notion of linearity, which simply amounts to the proportionality of the response to the solicitation for the ideal solid or liquid (J_e° or η independent of σ, respectively), has to be generalized to the time dependence for viscoelastic materials. The viscoelastic behavior is linear if the response to a sequence of arbitrary solicitations is identical to the sum of the responses to these stimuli if they were acting independently. This is the Boltzmann superposition principle which can be expressed as:

$$\gamma(t) = \int_{-\infty}^{t} J(t-t')\frac{d\sigma(t')}{dt'}dt' \qquad (1)$$

in terms of the stress history. As to the retardation test, linearity means that:

- $J(t)$ is independent of σ;
- The values of the steady-state limiting compliance J_e° and viscosity η are the same when obtained from the creep or from the recovery parts of the test;
- The curve of the recoverable compliance against the recovery time ($t-S$), obtained from recovery, superimposes on that of the recoverable compliance against creep time, obtained by subtracting the contribution of flow from the creep compliance.

Most real materials behave linearly only up to some limit of strain or strain rate limit, which is a material property. Whilst handling and processing the material generally involves solicitations which exceed this limit (which may be fairly low), characterization of its viscoelastic behavior within the linearity range is a prerequisite for studies in the nonlinear regime. In the linear regime, the results of any of the classical rheological tests are independent of the amplitude of the solicitation and they can also be used to predict the behavior of the material in the other tests. Beyond the linearity range, this is no longer the case.

Classical Rheological Tests

The characterization of the rheological behavior of a material requires the study of its viscoelasticity and, in the case of a liquid, that of its steady flow behavior. The rheologist uses very simple 'system of loads' patterns and deformations. Transient regime and dynamic tests are used to study viscoelasticity. Flow behavior is investigated using viscometry.

Very often, the study of viscoelasticity is restricted to the linear range, for the reasons hinted at above. Although within the linearity domain all viscoelasticity tests are equivalent in theory and their results can be interconverted using theoretical relations or semi-empirical approximation methods, their respective applications differ in practice according to the materials and the instruments and the experimentalist should view them as complementary.

Transient Regime Tests

We have already given the principle of the retardation test (creep and creep recovery). This test corresponds to the 'natural' operating mode of stress-controlled rheometers. The transient test with strain-controlled

instruments is the (stress) relaxation test: at time zero, the sample is suddenly deformed to a given value of strain which is then kept constant while the decay of stress with time is recorded. The experiment is analyzed using the relaxation modulus function $G(t) = \sigma(t)/\gamma$, which does not depend on the strain in the linear domain of behavior. The modulus and the compliance functions are linked in the linear regime by the integral equation:

$$t = \int_0^t J(t-u)G(u)du = \int_0^t J(u)G(t-u)du \quad (2)$$

so, $G(t) \neq 1/J(t)$, except in the plateau regions of these functions. Ideal elastic solids store integrally and indefinitely the mechanical energy imput: stress does not relax. For viscoelastic liquids, stress relaxes gradually and vanishes after a long enough time; at intermediate times, a region, called the viscoelastic plateau G_N°, where the decrease of the modulus slackens momentarily, is frequently observed on bilogarithmic scales (Figure 2a). Viscoelastic solids do not relax completely: at long time values, the modulus approaches a constant value G_e, the equilibrium modulus (Figure 2b).

Stress relaxation tests are not easy to perform on liquids with low elasticity or short characteristic times. In such cases, it is preferable to submit the material to a sudden constant shear rate $\dot{\gamma} = d\gamma/dt$ until an equilibrium value σ_e of stress is reached, after which the shear rate is suddenly stopped while stress continues to be recorded (Figure 3). Both parts of this test can be analyzed in term of relaxation modulus:

$$G(t) = (1/\dot{\gamma})|d\sigma(t)/dt| \quad (3)$$

The retardation test is particularly interesting for viscoelastic liquids since the viscoelastic response can be very simply separated from the steady flow contribution (Figure 1d), in contrast to the relaxation test; the latter is better suited for solid materials.

Transient tests allow materials with very long response times to be studied; the upper time limit for the experiments only depends on the stability of the material and the patience of the operator. But since in practice the establishment or the release of a constant value of the stress, strain, or strain rate takes some time, transient tests do not measure correctly the response at short times. Besides, the response often shows at starts and stops transient damped oscillations due to mechanical coupling between the sample and the measuring device. These methods are applicable to materials with characteristic times longer than, say, 1 min.

Transient tests usually require relatively large 'system of loads' to give an accurately analyzable response; this may be a problem for materials with a low linearity limit.

Dynamic Measurements

Dynamic measurement consists of submitting the sample to a sinusoidal 'system of loads' at an angular frequency ω rad s^{-1}. When stress is imposed, strain is measured, and conversely: this type of test can be performed either with stress- or with strain-controlled

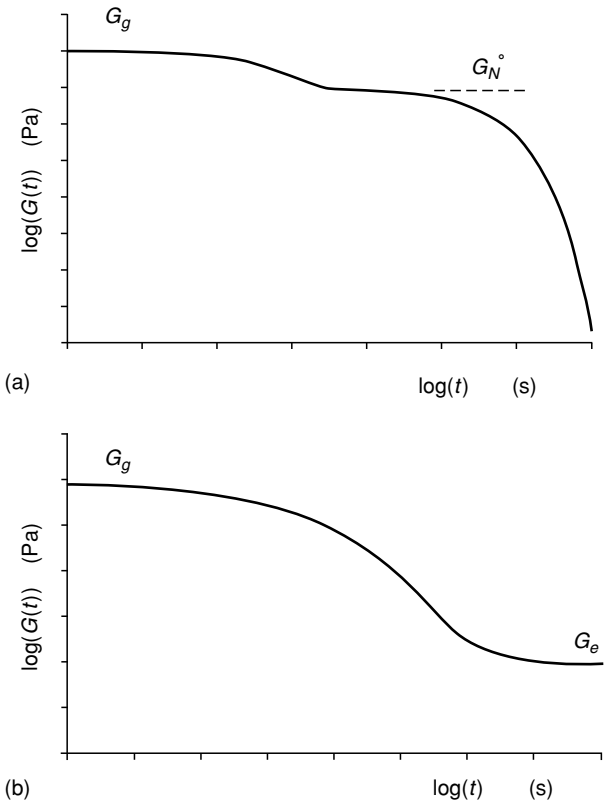

Figure 2 Schematic responses to a stress relaxation test: (a) viscoelastic liquid; (b) viscoelastic solid.

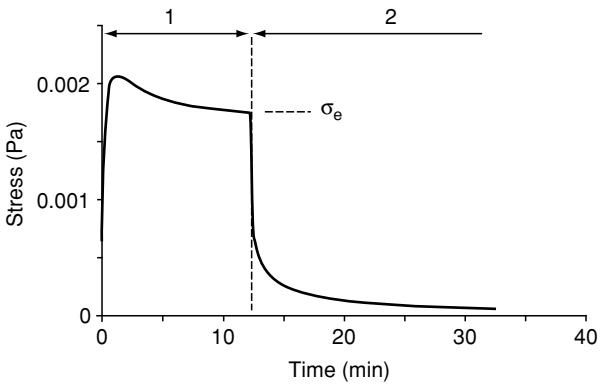

Figure 3 Response of a 3% bovine serum albumin solution (isoionic conditions) to the sudden application of a shear rate of 0.05 s^{-1} over 12 min (step 1) followed by its sudden stop (stress relaxation: step 2).

instruments. Within the range of *linear* viscoelastic behavior, the response of the material is also sinusoidal with the same frequency as the excitation, but out of phase. If a strain $\gamma = \gamma_o \cos(\omega t)$ is imposed, the stress will be $\sigma = \sigma_o \cos(\omega t + \delta)$; the phase angle δ is zero for an ideal solid and $\pi/2$ for an ideal liquid. The results are often expressed in terms of the storage and loss moduli $G' = (\sigma_o/\gamma_o)\cos(\delta)$ and $G'' = (\sigma_o/\gamma_o)\sin(\delta)$, which are the real and 'imaginary' parts of the complex modulus $G^*(\omega) = G'(\omega) + iG''(\omega) = \sigma(t)/\gamma(t)$, respectively. The viscoelastic behavior will be described by the variations of G' and G'' with ω (the mechanical spectrum of the material); however, the two moduli are not independent over the frequency domain. Alternatively, the results can be expressed in terms of the real and 'imaginary' components of the complex compliance, or (for liquids only) of the complex viscosity: $J' = G'/(G'^2 + G''^2)$, $J'' = G''/(G'^2 + G''^2)$, and $\eta' = G''/\omega$, $\eta'' = G'/\omega$. Although these representations contain strictly the same information as G', G'', they can prove more interesting for viscoelastic liquids because they weigh dissipative processes differently on the frequency scale. Qualitatively, a measure at frequency ω in a dynamic test is equivalent to a measure at time $t = 1/\omega$ in a transient test.

Figure 4a and b show the schematic theoretical mechanical spectra of a viscoelastic liquid and a viscoelastic solid, respectively. Whereas $G'(\omega)$ is necessarily a monotonously increasing function, $G''(\omega)$ shows maxima which correspond to concentrations of dissipative processes in the material over certain frequency regions. Two loss peaks are visible on the liquid-type spectrum. They encompass an intermediate frequency range where $G' > G''$ and keeps a nearly constant value G_N° – the viscoelastic plateau; at this time scale, when energy dissipation is showing a relative minimum, the material is transiently quasielastic. On both sides of the plateau, $G'' > G'$ and both moduli are strongly frequency-dependent. At high frequencies, G' and G'' first both increase approximately as ω^a with $a \sim 0.5$ (the transition zone); then G' tends towards its very high 'glassy' limit G_g, whereas G'' drops: the 'glassy behavior' corresponds to solicitations which are too fast for the structural elements in the material to respond. Below the viscoelastic plateau, $G' \propto \omega^2$ and $G'' \propto \omega$; this is the terminal region of the mechanical spectrum, corresponding to flow. For viscoelastic solids, the terminal region is not observed; at low enough frequencies, G' reaches a constant value – the equilibrium modulus G_e. Frequently, the loss peaks overlap strongly; then the viscoelastic plateau reduces to an inflection in G'.

Dynamic measurements are very popular. They are easy to perform, accurate even with fairly fluid materials, and cause minimal perturbation to the sample since the amplitude of strain is controlled and can be kept to quite low values (minimum value $\sim 0.1\%$ on strain-controlled instruments, but $\sim 1\%$ on stress-controlled ones). They permit the study of materials with a low linearity limit.

However, some limitations of dynamic tests should not be overlooked:

- Beyond the linearity limit, the response signal is no longer sinusoidal. The calculation of the real and 'imaginary' components of the rheological functions, as outlined above, performed automatically by the rheometer softwares, is then invalid.
- The frequency range is restricted for practical reasons. Because of mechanical problems, rotational rheometers cannot operate above 200–500 rad s^{-1}, but the upper limit may be as low as ~ 10 rad s^{-1} when rather fluid materials are tested. Instrument softwares generally permit operation down to 10^{-4} rad s^{-1}, but below 10^{-3} rad s^{-1} measurements take an exceedingly long time. The practical range of operation is thus 10^{-3}–100 rad s^{-1}, corresponding to the 10^{-2}–10^{-3} s^{-1} time scale, extending well below the lower limit of transient

tests but stopping short for many materials, as will be shown later.

Viscometry

Flow behavior is usually investigated through viscometric experiments: a shear rate (or stress) is imposed on the liquid and the resulting response (shear stress or rate) is measured; viscosity is defined as $\eta = \sigma/\dot{\gamma}$. Viscometry is primarily concerned with the steady-state response.

Simple liquids and solutions of low-molecular-weight molecules are Newtonian (constant viscosity) over the wide shear rate range of practical interest, which extends roughly from $\sim 10^{-4}$ s^{-1} (sedimentation) to 10^{4} s^{-1} (spraying); chewing and swallowing or pumping and mixing involve intermediate typical shear rate values (10^{1}–10^{3} s^{-1}). But for most materials, viscosity depends on the shear rate (or stress), although generally it tends to be Newtonian at low enough shear rates, and in many applications non-Newtonian flow properties are important.

The usual behavior is shear-thinning: as $\dot{\gamma}$ increases, η decreases from an initial Newtonian plateau η_o to a final one η_{oo}; but one or both of them may often be out of the experimental window (Figure 5). Shear-thickening behavior is exceptional in food systems.

Non-Newtonian flow curves are usually recorded by applying shear rate (or stress) ramps. However, artifacts can result from the inertia of the measuring device or from the viscoelasticity of the sample. It is better to apply a series of shear rate (or stress) steps, waiting at each step for the steady-state response. Performing retardation tests under different stress values is almost the only method applicable to highly viscoelastic liquids (Figure 6) or to very viscous inelastic ones; it allows viscosity measurements at very low shear rates.

Many relatively inelastic shear-thinning liquids display viscosities which also depend on the duration of shear. When viscosity decreases during shear, the behaviour is said to be thixotropic; the reverse case is called antithixotropy; the changes may be completely or partially reversible. Thixotropy is a time-dependent behavior which in principle is to be distinguished from viscoelasticity. But in practice, these two properties may be difficult to differentiate; besides, thixotropic materials often show appreciable

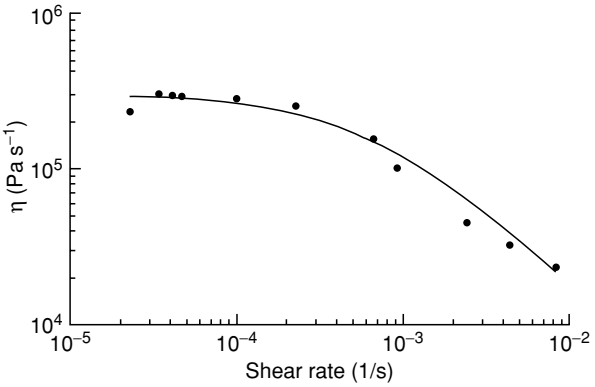

Figure 6 Flow curve of a toothpaste determined from the analysis of creep tests carried out at different values of the applied stress.

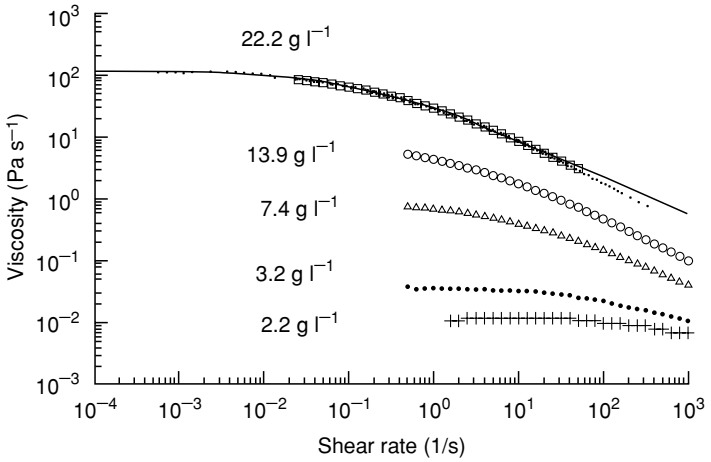

Figure 5 Shear-thinning behavior. Flow curves of solutions of a high-viscosity hydroxyethylcellulose sample at different concentrations. Above a concentration of ~ 2 g l^{-1}, the solutions exhibit typical shear-thinning behavior. The master curve (dots) is built by collapsing the different curves on the 22.2 g l^{-1} one by shifting them along the two axes. The continuous line shows the fit of Cross equation: $(\eta - \eta_\infty) = (\eta_o - \eta_\infty)/[1 + (\dot{\gamma}/\dot{\gamma}_c)^m]$ to the master curve data, where η_o = initial Newtonian plateau viscosity; η_∞ = high shear rate Newtonian viscosity (taken as zero here since it is negligible compared to η); $\dot{\gamma}_c$ = critical shear rate; and m = dimensionless exponent. The fit gives $\eta_o = 118$ Pa s^{-1}, $\dot{\gamma}_c = 0.15$ s^{-1} and $m = 0.60$.

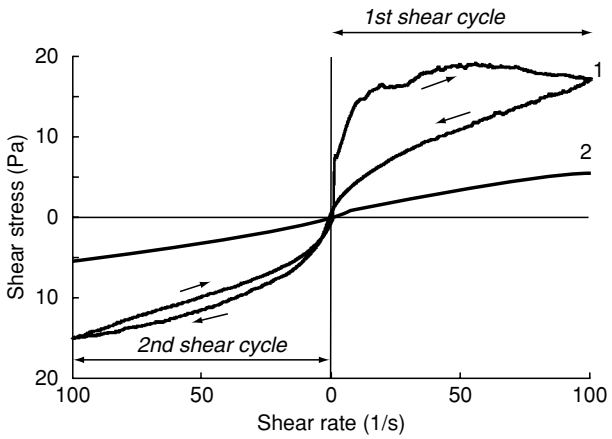

Figure 7 Thixotropic loops. Application of two successive shear cycles (0–100–0 s^{-1}) to a guar gum galactomannan/xanthan mixture (ratio 90/10 w/w) in water at a total polysaccharide concentration of 0.5% w/w (curve 1). The first cycle causes drastic irreversible damage to the structure of the mixed system. A residual slight thixotropic behavior is observed during the second cycle and remains unchanged upon subsequent cycles.

No thixotropy is displayed by guar gum solutions or xanthan solutions; the results for a 0.5% guar gum galactomannan solution are given for comparison (curve 2).

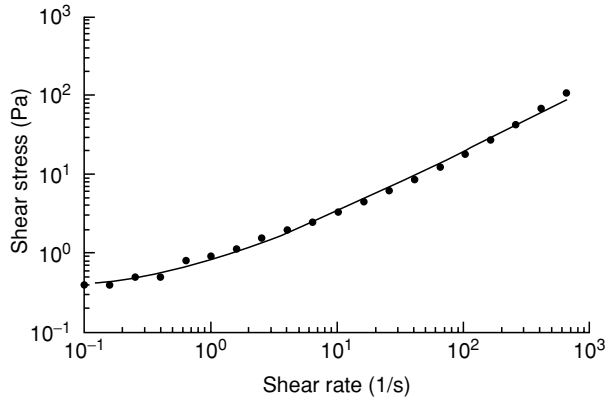

Figure 8 Apparent yield stress behavior. Flow curve recorded at 60 °C of a wheat starch paste prepared in the presence of sodium caseinate (concentrations 6% starch, 7.5% caseinate). The continuous line is the fit of the Herschel–Bulkley equation: $\sigma = \sigma_o + k\dot{\gamma}^n$; it gives an apparent yield stress value $\sigma_o = 0.34$ Pa.

viscoelasticity at the same time. When the material is submitted to a shear rate cycle from zero to a maximum and back to zero, a thixotropic loop is observed (Figure 7). This is a popular way to spot the existence or the apparition of thixotropy, but it only allows comparative work; moreover, there are risks of confusion with inertia effects or with the manifestation of viscoelasticity, which also shows as loops. The responses to sequences of step changes of shear rate are used for thorough studies, but thixotropy is a difficult topic.

Yield stress behavior or plasticity, another type of complex flow properties, has been the subject of much discussion. Plastic material would not flow until the stress has exceeded a yield value σ_o, below which viscosity is infinite (solid behavior). Many materials show apparent yield stress behavior over limited ranges of stress or shear rate (Figure 8). However, whenever it has been possible to go down to low enough stresses or shear rates (using creep test, for instance), such materials were found to flow, but with the peculiarity that viscosity drops from very high values to relatively low ones over quite a narrow range of stress in the region of low shear rates (Figure 9).

Problems in Rheological Characterization of Food Systems

Structural Basis of Viscoelasticity in Food Systems

Viscoelasticity is the manifestation of the internal structure of the material, i.e., the distribution in space of the structural elements and their interactions. Thixotropy and plasticity derive from flow-induced large-scale structural changes.

Structural elements can be molecules, macromolecules, or particles (solid particles, liquid droplets, gas bubbles), or associations of such elements (aggregates, micelles, etc.) and their combinations. The two simplest cases to consider are the solutions of polymer-like chain macromolecules (polysaccharides, gelatin) and the dispersions of (quasi-)spherical particles (including globular protein solutions). When dilute, such systems show no appreciable viscoelasticity in practical conditions – the longest relaxation time of a macromolecular chain or of an emulsion droplet is shorter than $\sim 10^{-2}$ s. Beyond a certain polymer concentration or disperse phase volume fraction in the system, an elasticity of entropic nature develops due to topological constraints between macromolecular chains (entanglements), or from crowding effects between the particles which result in a local order. Semidilute polysaccharide solutions should normally display this type of viscoelasticity. This is indeed the case for guar gum galactomannan solutions; their mechanical spectrum (Figure 10) shows in the upper region of the experimental frequency range the beginning of the viscoelastic plateau due to entanglements. But locust bean gum galactomannan (LBG) solutions progressively depart from this behavior upon aging, with the development of a viscoelastic plateau at low frequencies (Figure 11): the system slowly changes into a gel. This reflects the establishment of relatively long-lived linkages between the chains, probably due to hydrophobic interactions between the 'smooth' regions (devoid of

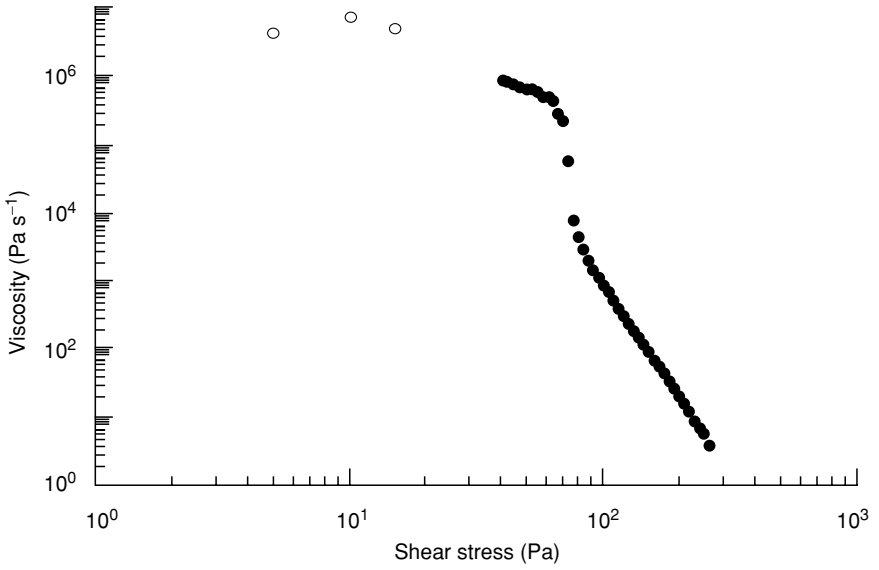

Figure 9 Apparent yield stress behavior. Flow curve of a commercial mayonnaise. The filled circles correspond to the results recorded during the imposition of a shear rate ramp, the empty circles to data obtained by application of retardation tests. The latter data demonstrate unequivocally that the behavior is in fact shear-thinning.

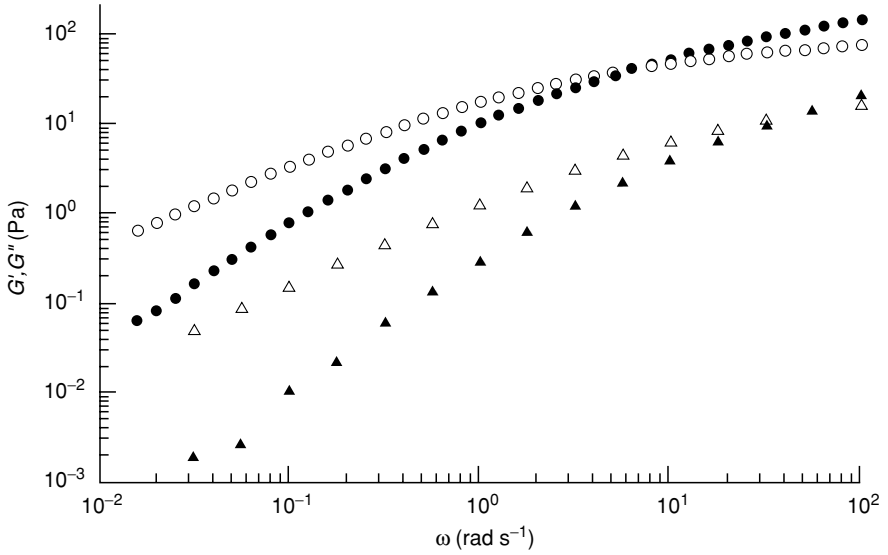

Figure 10 Typical mechanical spectra of biopolymer solutions: guar gum galactomannan solutions in water (20 °C) at two concentrations: 1.87% w/w (circles) and 1% w/w (triangles). Filled symbols, storage modulus G'; open symbols, loss modulus G''.

galactose groups) of the mannose backbone, which do not exist in the case of guar. Similarly, a 3% bovine serum albumin (BSA) isoionic solution departs from the purely viscous and Newtonian behavior expected for dilute hard sphere dispersion (Figure 3), indicating that protein molecules are strongly interacting.

Because of their chemical structure and of the specific properties of water, food macromolecules generally interact through hydrogen and hydrophobic interactions. As a result, viscoelasticity of the transient network type (noncovalent gels) can be observed at relatively low concentrations. Transient networks also result from partial destabilization (flocculation) of suspensions or emulsions due to colloidal interactions.

Monitoring Structural Transitions

The example of LBG solution (Figure 11) showed that viscoelastic measurements can be used to follow structural changes in a system. In this case, the change

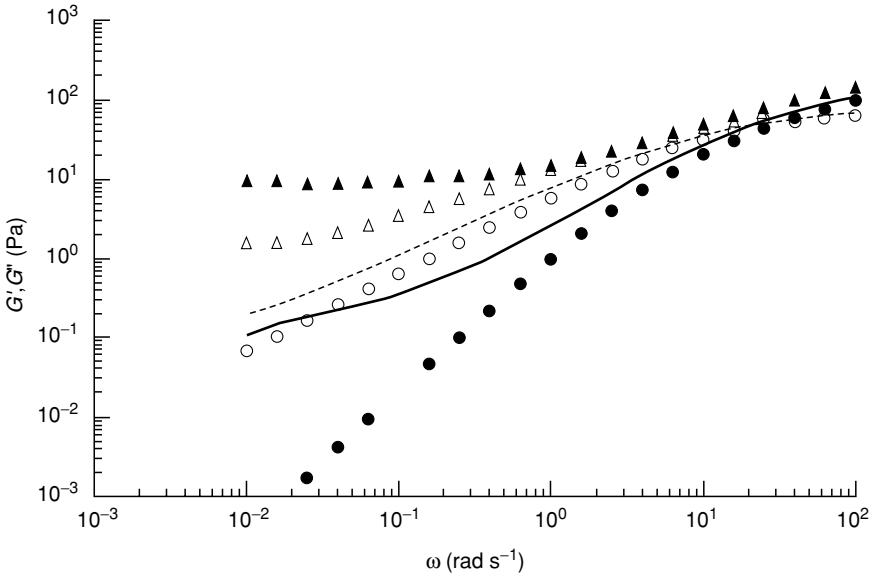

Figure 11 Progressive departure from the solution state during aging of a locust bean gum galactomannan solution (concentration 10 g l^{-1}; 20 °C). Mechanical spectra of the freshly prepared solution (circles), of the system after 6 days' aging (lines), and of the system after 15 days' aging (triangles). Filled symbols and solid line, G'; open symbols and interrupted line, G''.

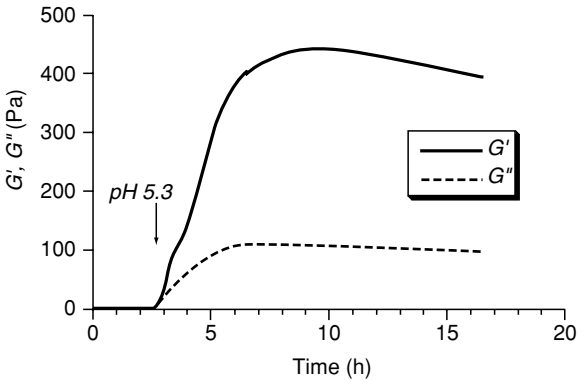

Figure 12 Monitoring lactic acid bacteria milk clotting using dynamic measurements at fixed frequency (40 °C, $\omega = 6$ rad s^{-1}, strain amplitude $\gamma_o = 0.02$). The gelation starts after about 150 min fermentation, when the pH has decreased to 5.3. The decline in the G' curve after ~11 h is an artifact due to syneresis. The experiment was performed using coaxial cylinders to minimize the incidence of syneresis; with cone–plate or plate–plate geometries, syneresis causes slippage and its effect is seen much earlier, even when measuring devices with striated or sanded surfaces are used.

was slow enough to allow viscoelasticity to be characterized over a certain frequency range at different steps of its evolution. However, structural changes are generally rather fast, and once started, can rarely be stopped at will. Single-frequency dynamic measurements, since the time required for each individual measure is short provided that $\omega > 0.01$ rad s^{-1}, are very precious indeed to monitor the kinetics of structure changes, as exemplified in Figure 12 for milk clotting, an instance of colloidal gel formation. But they do not characterize rheologically the evolution of the system. Mechanical spectra can be obtained in the classical way only when the system remains practically unchanged during the time necessary to record them. However, advanced techniques which are outside our scope require much shorter times than with the classical frequency sweep, and allow study of systems undergoing relatively fast structural changes.

In classical follow-up experiments at fixed frequency, the choice of frequency may be critical. No change would be detected in LBG solutions if $\omega = 10$ rad s^{-1} were selected to monitor aging (Figure 11)!

The Need to Enlarge the Experimental Window

Figure 13 shows the mechanical spectra of food systems we know to differ largely in nature and in texture or consistency. Nevertheless, these spectra are qualitatively similar; those of the commercial mayonnaise and the 61 mg ml^{-1} BSA heat-set gel even superimpose. They show the viscoelastic plateau region of transient networks of the colloidal gel type, with gently ascending moduli curves and with G' higher than G'' over the frequency window but relatively large G''/G' ratios (0.1–0.5); in the case of the gluten sample, however, the upper end of the plateau is visibly approached. Beyond this assignation to a general type of structure, such flat spectra allow only a rough estimation of the plateau modulus. But quantitative comparison can be misleading, since the viscoelastic plateau often extends beyond both limits

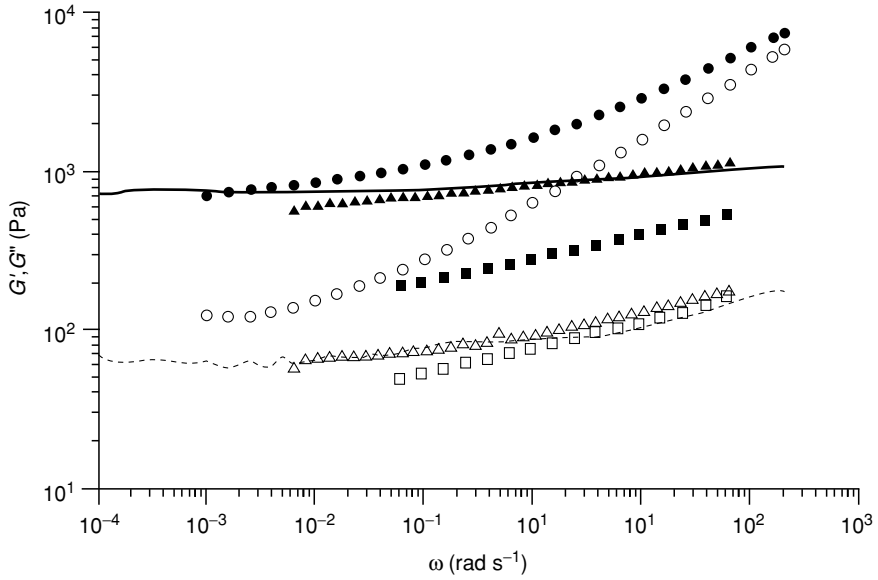

Figure 13 Mechanical spectra obtained at 20 °C by dynamic measurements on various systems of the colloidal gel type. Circles: fully hydrated gluten from a commercial wheat cultivar. Triangles: heat-set gel of bovine serum albumin (61 mg ml^{-1}, pH 7, 0.05 mol l^{-1} NaCl). Squares: experimental yogurt. Lines: commercial mayonnaise. Filled symbols and solid line: G'; empty symbols and interrupted line: G''.

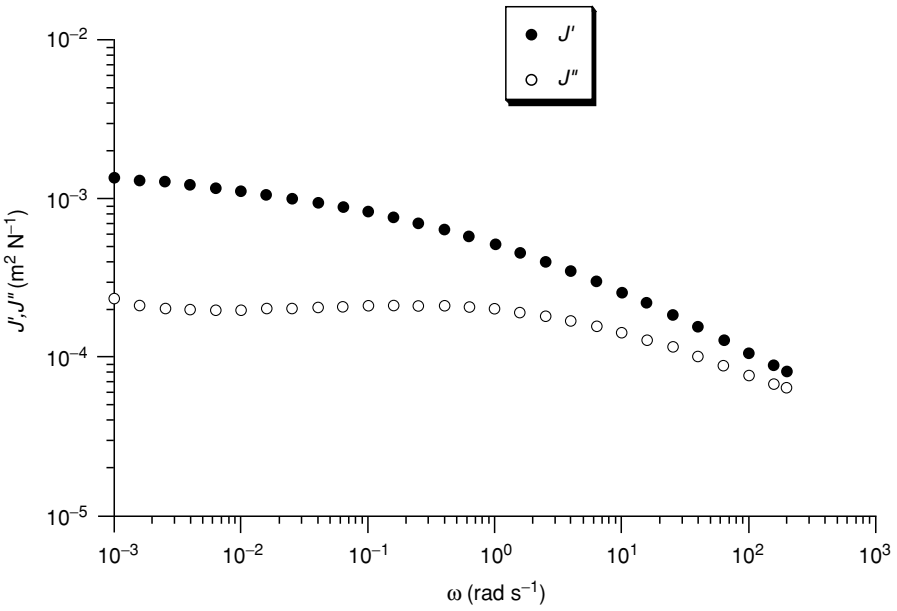

Figure 14 Mechanical spectrum of the same gluten as shown in Figure 13, but plotted as J' and J'' versus angular frequency. The curve of J'' shows a peak with a maximum close to $\omega = 0.16$ rad s^{-1}; it bounds the viscoelastic plateau on the high-frequency side.

of the frequency window of dynamic measurements. Plotting the data as $J'(w)$, $J''(w)$ is sometimes more telling, as shown in Figure 14 for the same gluten as in Figure 13; $J''(w)$ displays a maximum at the right of the frequency range, which at least allows location of the upper end of the viscoelastic plateau on the time scale and possibly opens the way to modeling this region of the behavior.

Enlarging the time scale of observation is required anyway for a full-scale rheological characterization. In the case of classical polymer systems, the time–temperature superposition principle, which means that a change in the temperature of the system is equivalent to a shift of the time scale of the behavior, allows one to describe the viscoelastic behavior over a very large frequency range from data obtained over

a restricted one at different temperatures. This principle does not in general apply to food systems since their elasticity is rarely entropy-driven; anyway, the range of temperature which could be covered is quite narrow because of the presence of liquid water. One has then to combine dynamic measurements with transient tests which permit one to extend the observation window to longer times. Let us give a few illustrations.

A gluten and a reconstituted dough are compared in Figure 15. The mechanical spectra of a gluten and of a 'synthetic' dough prepared by mixing it with starch do not differ much on the 10^{-1}–10^{2} rad s^{-1} range (Figure 15a). The moduli are somewhat larger for dough, because starch granules act as a filler; in fact, their presence also makes dough behavior extremely nonlinear and the dynamic data are only approximate. But when the materials are submitted

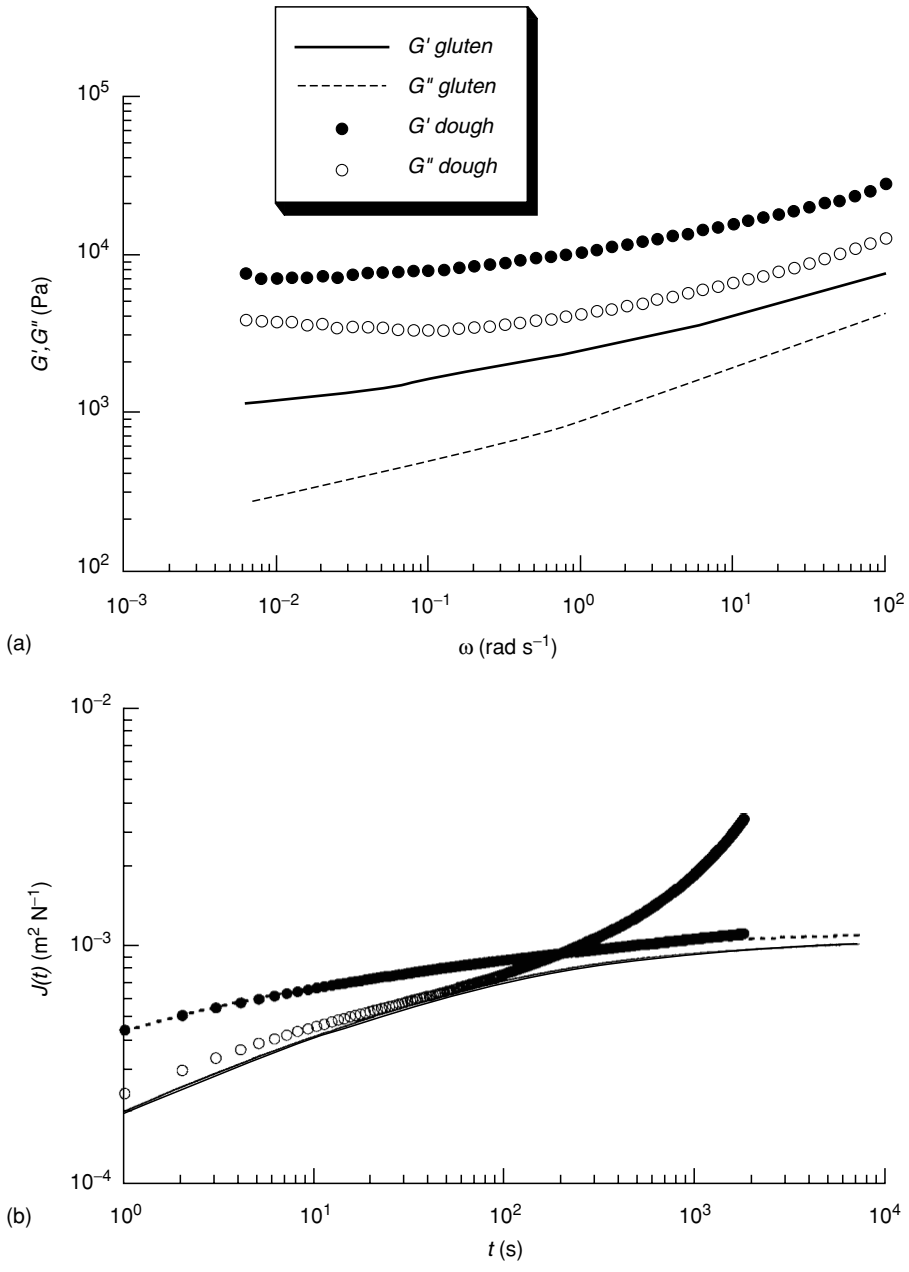

Figure 15 Viscoelastic behavior at 20 °C of a reconstituted dough compared to that of the gluten used to prepare it. (a) Mechanical spectra obtained by dynamic measurements under 0.05 strain amplitude over the 10^{-2}–10^{2} rad s^{-1} frequency range. (b) Creep curves under 350 Pa stress. Symbols: creep compliance $J(t)$; lines: recoverable compliance $J_r(t)$. Filled symbols and dotted line, gluten; empty symbols and solid line, dough.

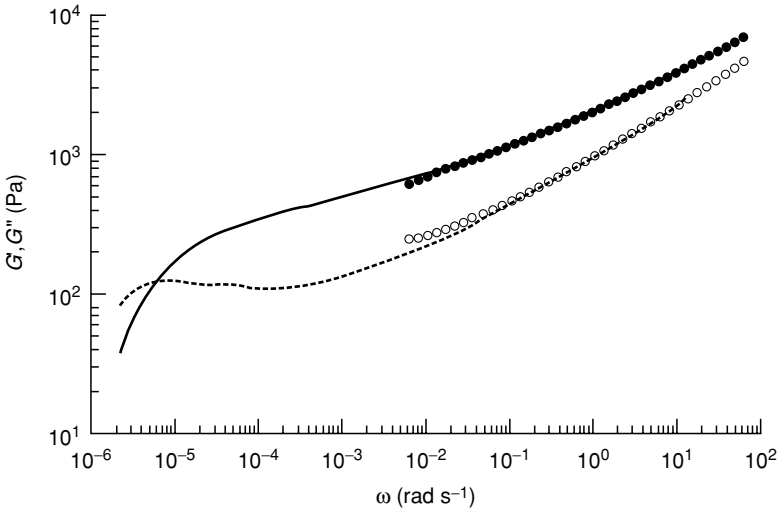

Figure 16 An example of a combination of the retardation test with dynamic measurements in order to describe the viscoelastic behavior of a material over a large time scale. The material is a fully hydrated gluten from an experimental wheat line. Mesurements were performed within the linearity range at 20 °C. The data from the recovery part of the retardation test were converted from the time to the frequency domain using an approximation method. Symbols: dynamic measurements: filled symbols, G'; empty symbols, G''. Lines: recovery data: solid line, G', dotted line, G''.

to a retardation test in the same conditions, the difference becomes striking after 100-s creep (Figure 15b); analysis of the results shows that whereas J_e° is about the same ($\sim 10^{-3}$ m^2 N^{-1}), viscosity is much smaller for dough ($\sim 5\ 10^5$ Pa s^{-1}) than for gluten (10^7 Pa s^{-1}) at comparable shear rates (7×10^{-4} versus 2×10^{-4} s^{-1}).

When the tests are performed within the linearity range, it is possible to convert the data of relaxation or retardation tests from the time to the frequency domain. Combining the data of the retardation test with those of dynamic measurements allowed us to obtain the mechanical spectrum of a weak gluten sample over about eight logarithmic frequency decades (Figure 16). The viscoelastic plateau extends over more than seven frequency logarithmic decades, the terminal region of the spectrum being entered only below $\sim 10^{-5}$ rad s^{-1}. Extended viscoelastic plateaus result from strong interactions and multilevel structures within the material. Such cases are not exceptional in food systems and highlight the fact that rheology is a matter of time.

RHEOLOGY OF LIQUIDS

A E Bell, University of Reading, Whiteknights, Reading, UK

Background

Food materials are multiphase, multicomponent systems whose rheological characteristics frequently present process engineers with difficult handling and pumping problems.

The food industry has, almost since its inception, been concerned with the physical properties of its products, in terms of both their processing and their eating characteristics. Consequently, considerable care must be taken in designing plant and process if the texture, consistency, and quality of the final product are not to be compromised. The selection of appropriate pumps and conveying and mixing systems is especially germane to food materials that may be shear-dependent and/or abrasive in nature. (*See* **Rheological Properties of Food Materials**.)

Although it is a relatively easy matter to describe mathematically the flow behavior of 'simple' liquids, food solid/liquid mixtures present unique problems in describing their flow behavior.

Liquid Behavior

When assessing the behavior of a liquid system, it is usual to investigate the stresses generated when the sample is sheared, that is to say, the force per unit area produced when the 'layers' of liquid move over each other in the direction of flow. This gives rise to the classical definition of a shear viscosity (Figure 1):

Shear rate, $\gamma = V/h$ (s^{-1})
Shear stress, $\sigma = F/A$ (Pa)
Shear viscosity, $\eta = \sigma/\gamma$ (Pa s),

where V is the velocity, F is the force, and A is the area over which it acts.

The range of shear rates observed in the food industries is vast, from values as low as $10^{-2}\,s^{-1}$, for the self-leveling of a liquid due to surface tension, to $10^{6}\,s^{-1}$ seen in the spray drying of slurries. (The chewing and swallowing of foods generate shear values of about 10^{1}–$10^{2}\,s^{-1}$.) This presents us with considerable difficulties with regard to most food systems, as very few behave in an ideal or Newtonian manner, with the shear stress proportional to the shear rate over all of the possible shear rate values.

Since viscosity is essentially related to shear rate and stress, it is possible to operate a viscometer in one or two modes: (1) by applying a rotation and measuring the torque generated (controlled stain), or (2) by applying a fixed torque and measuring the speed generated (controlled stress). These two methods have their advantages and disadvantages; for example, the controlled-strain instruments are relatively cheap, robust, and well understood but usually have a limited shear range (1–1000 s^{-1}). Controlled-stress instruments, however, have large shear rate ranges and can carry out other forms of testing (creep, oscillatory, etc.) but do tend to be somewhat expensive.

Working Liquids

When we work a liquid system, we apply energy to it. This 'force' has a number of characteristics that we can define: (1) the area over which it is applied, (2) the distance over which it acts, and (3) the rate at which it is applied. We may then define the stresses involved (force/area) and the strains produced (relative deformation). If a more complex analysis is required, these forces may be resolved further into three components, the tensile or normal forces, perpendicular to the plane of the applied force, and two shear or tangential forces parallel to it.

The strain (distance moved) when processing or measuring a sample has a considerable effect on its mechanical behavior/flow properties. If a sample is moved such that its molecular domains or structural elements no longer interact/overlap, the network may become 'overloaded' and ultimately break down (Figure 2). For example, a sample of an emulsion

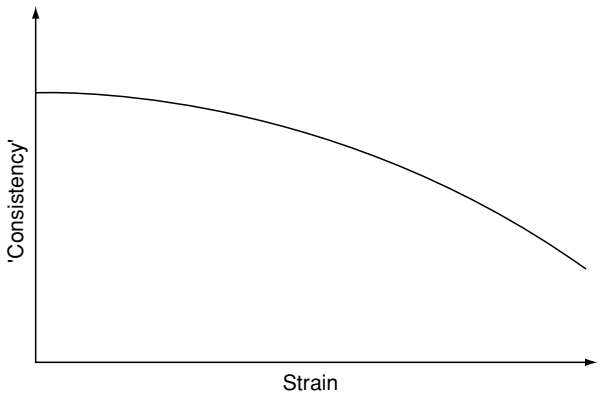

Figure 2 Effect of increasing strain. Reproduced from Rheology of Liquids, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

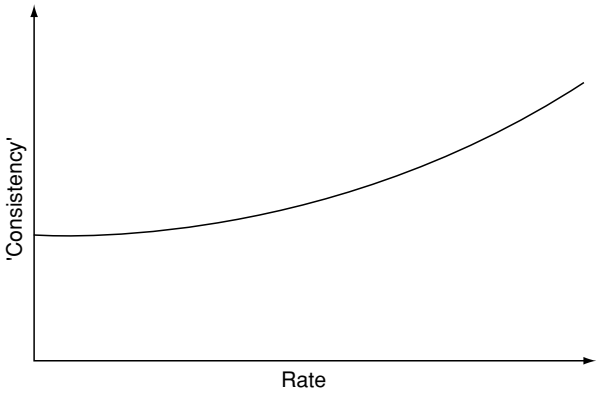

Figure 3 Increasing interaction with shear rate. Reproduced from Rheology of Liquids, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

such as mayonnaise, which is stabilized by electrostatic or steric means, may have a very low value of 'critical strain,' after which structural damage to the emulsion will occur, and it is very important that testing and processing be carried out in such a way so as not to exceed this point. (*See* **Colloids and Emulsions.**)

While, in general, increasing the strain tends to reduce interactions, increasing the shear rate may give rise to either increases or decreases in the apparent degrees of interaction. If we consider the effect of increasing the shear rate on entangled long-chain polymer systems (e.g., a long-chain polysaccharide), at zero shear rate, these chains will be entangled by Brownian motion and will have a degree of interaction based on physical constraints. On moving one of the chains slowly with respect to the others, very little resistance would be encountered, as the molecules would have sufficient time to allow any rearrangements needed to take place. However, if the same process were carried out at a higher rate, the entanglement would have insufficient time for rearrangement and would resist such movement. This would produce a material that appeared to increase its degree of interaction at higher shear rates. Such a system may become unworkable if, for example, one attempted to pump it too quickly (Figure 3). (*See* **Carbohydrates:** Classification and Properties.)

However, if a system were stabilized by, for example, some form of hydrogen bonding, an increase in shear rate might reduce the effectiveness of the interactions. This would lead to a fall in the apparent consistency (Figure 4).

The two parameters, strain and rate, when combined give an overall picture of the behavior of the

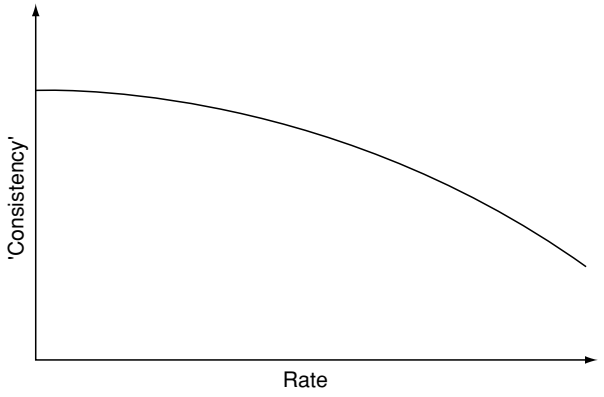

Figure 4 Decreasing interaction with shear rate. Reproduced from Rheology of Liquids, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

liquid. This rheological 'plane' may be very flat (basic Newtonian behavior) or, more commonly, steeply curving (nonideal behavior). The consequences of not having assessed the physical characteristics over a suitable testing regime may prove disastrous in terms of predicting processing behavior.

Behavior as a Function of Time

In the description of the different types of non-Newtonian behavior, it was implied that, although the viscosity of a fluid might vary with shear rate, it was independent of the length of time that the shear rate was applied, and also that replicate determinations at the same shear rate would always produce the same viscosity. This must be considered as the ideal situation, since most non-Newtonian food materials are colloidal in nature, and as such, the flowing

elements, whether particles or macromolecules, may not adapt immediately to the new conditions. Therefore, when such a material is subjected to a particular shear rate, the shear stress and, consequently, the viscosity will decrease with time. Furthermore, once the shear stress has been removed, even if the structure that has been broken down is reversible, it may not return to its original structure (rheological ground state) instantly. The common feature of all these materials is that, if they are subjected to a gradually increasing shear rate followed immediately by a shear rate decreasing to zero, the downcurve will be displaced with regard to the upcurve, and the rheogram will exhibit a hysteresis loop.

In the case of plastic and pseudoplastic materials, the downcurve will be displaced to below the upcurve (Figure 5), whereas for dilatant substances, the reverse will be true (Figure 6).

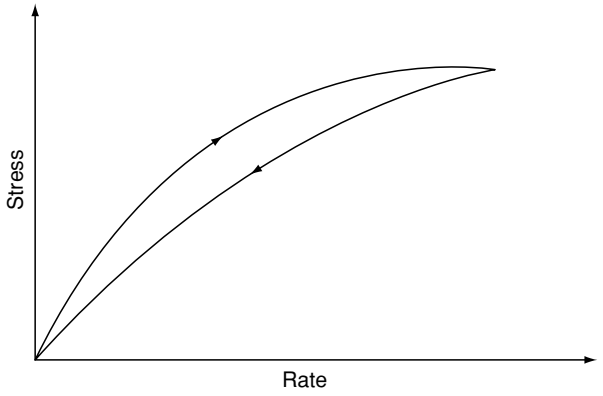

Figure 5 Plastic/pseudoplastic behavior. Reproduced from Rheology of Liquids, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Figure 6 Dilatant behavior. Reproduced from Rheology of Liquids, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

The presence of the hysteresis loop indicates that a 'breakdown' in structure has occurred, and the area with the loop may be used as an index of the degree of 'breakdown.'

The term that is used to describe one such type of behavior is *thixotropy*, which means 'to change by touch.' Strictly, this term should be applied only to an isothermal sol–gel transformation. It has, however, become common to describe as thixotropic any material that exhibits a reversible time-dependent decrease in apparent viscosity. Thixotropic systems are usually composed of asymmetric particles or macromolecules that are capable of interacting by numerous secondary bonds to produce a loose three-dimensional structure, so that the material is gel-like when unsheared. The energy that is imparted during shearing disrupts these bonds so that the flowing elements become aligned, and the viscosity falls, since a gel–sol transformation has occurred. When the shear stress is eventually removed, the structure will tend to reform, although the process is not immediate and will increase with time as the molecules return to the original state under the influence of Brownian motion. Furthermore, the time taken for recovery, which can vary from minutes to days depending upon the system, will be directly related to the length of time that the material was subjected to the shear stress, since this will affect the degree of breakdown.

In some cases, the structure that has been destroyed is never recovered, no matter how long the system is left. Repeat determinations of the flow curve will then only produce the downcurve that was obtained in the experiment that resulted in the material's destruction. Such behavior should be referred to as 'shear destruction' rather than thixotropy, which, as will be appreciated from above, is a misnomer.

An example of such behavior are the gels produced by high-molecular-weight polysaccharides, which are stabilized by large numbers of secondary bonds. Such systems undergo extensive reorganization during shearing such that the three-dimensional structure is reduced: the gel-like nature of the original is then never recovered.

The occurrence of such complex behavior creates problems in quantitative classification because not only will the apparent viscosity change with shear rate, but there will be two 'viscosities' that can be calculated for any given shear rate (i.e., from the upcurve and the downcurve). It is usual to attempt to calculate one viscosity for the upcurve and another for the downcurve. This must assume, of course, that each of the curves achieves linearity over some of its length; otherwise, a defined shear rate must be used: only the former situation is truly satisfactory. Each of

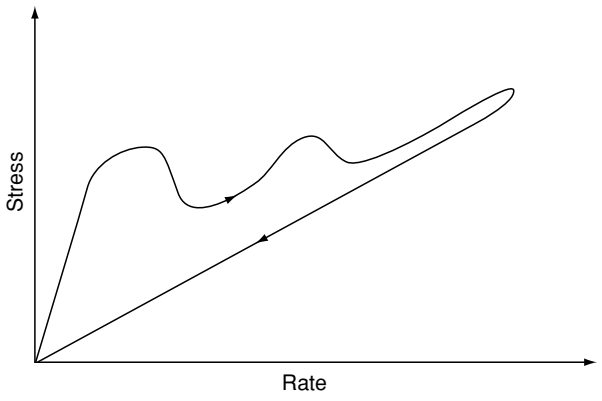

Figure 7 Complex flow behavior. Reproduced from Rheology of Liquids, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

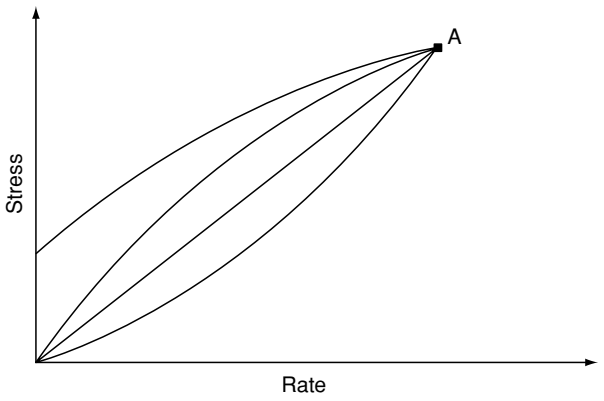

Figure 8 Convergence of flow behavior at a single rate. Reproduced from Rheology of Liquids, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

the lines used to derive the viscosity may be extrapolated to the shear stress axis to give an associated yield value. However, only that derived from the upcurve has any significance, since that derived from the downcurve will relate to the broken-down system. Consequently, the most useful index of thixotropy can be obtained by integration of the area contained within the loop. Of course, this does not take into account the shape of the up- and downcurves, and consequently, two materials may produce loops of similar area but have completely different shapes representing totally different flow behaviors. In order to prevent confusion, it is best to adopt a method whereby an estimate of area is accompanied by yield value(s). This is of particular importance with flow curves that exhibit complex upcurves.

This situation is typical of the type of loop obtained with, for example, some samples of white soft paraffin, where the upcurve exhibits a number of bulges (Figure 7). Those at a lower shear rate are thought to be associated with the initial loss of the three-dimensional structure, while the smoother deviations occurring at the higher shear rates are associated with molecular reorientation. Such behavior is common in food and pharmaceutical systems and is one of the major causes of difficulties in their evaluation.

With such a wide range of rheological behavior, it is extremely important to carry out measurements that will produce meaningful results. It is crucial, therefore, not to use a determination of viscosity at one shear rate (such as would be acceptable for a Newtonian fluid), since it could lead to completely erroneous comparative results.

Figure 8 shows rheograms that are an example of four different types of flow behavior, all of which intersect at point A, which is equivalent to a shear rate of $100\,s^{-1}$. Therefore, if a measurement were made at this one shear rate, all four materials would be shown to have the same viscosity, although they all possess different properties and behavior. Single-point determinations are probably an extreme example but are used to emphasize the importance of properly designed experiments.

It should be noted that while more complex rheological measurements may give rise to parameters other than viscosity (for example, the storage and loss moduli), the arguments given here still apply, and time and shear dependence remain major problems when measuring changing food systems.

Properties and Determination

R Bitsch, Friedrich-Schiller-University, Jena, Germany

Physicochemical Characteristics

Riboflavin, the name prescribed for vitamin B_2 by the International Union of Pure and Applied Chemistry – International Union of Biochemistry, is the biologically active component of the prosthetic group of flavoproteins. Older designations are lactoflavin, ovo-, or uroflavin, which originated from the first isolation. It comprises a tricyclic, nitrogen-containing ring-system, chemically defined as a substituted isoalloxazine with a ribitol side-chain at N_{10}. With the systematical nomenclature, the molecule is named 7,8-dimethyl-10-(1-D-ribityl)-benzo[g]pteridin-2,4-dion. The empiric formula is given as $C_{17}H_{20}N_4O_6$ with a molecular weight of 376.36 (Figure 1). The substance is a yellow to orange–yellow powder and crystallizes in sharp, optically active needles, melting under decomposition at 275–282 °C. The optical rotation is $[\alpha]_D^{25} = -112$ to -122°C at a concentration of 50 mg in 10 ml of 0.02 N alcoholic NaOH). Riboflavin is sparingly soluble in water with a yellow–green fluorescence, very sparingly soluble in ethanol, and insoluble in other organic solvents. It is readily soluble in dilute alkali, but rapidly deteriorated, being accelerated by light. In neutral or acid solutions, it is more stable, even against heat and atmospheric oxygen. Nevertheless, all operations with riboflavin solutions should be handled in the dark or in red light. The light sensitivity of the flavins also has consequences for the stability of vitamin B_2 containing foods. In milk stored in day light, the riboflavin content decreases by more than 80% within hours. Processing losses in foods are given with approximately 20%.

Table 1 Physicochemical data of flavines[a]

Property	*Riboflavin*	*Riboflavin-5-phosphate-Na (FMN-Na)*	*Flavin adenine dinuclectide-Na$_2$ (FAD-Na$_2$)*
Molecular weight	376.36	478.34	829.6
Melting point	278–282 °C (decomp.)	280–290 °C (decomp.)	
Solubility	Readily soluble in dilute alkalis (decomp.)	Soluble in water at pH 7 (30 g l^{-1}, 25 °C)	Soluble in water
	Sparingly soluble in water (70–100 mg l^{-1}, 27 °C)		
	Very sparingly soluble in ethanol (45 mg l^{-1}, 27 °C)	Very sparingly soluble in ethanol	
	Insoluble in acetone, chloroform, ether, benzene		
Absorbance (UV/vis)	223, 267, 374, 444 nm (0.1 N–HCl)		
Fluorescence	Yellow–green fluorescence of aqueous solutions at pH 6–7 (ex. 444 nm, em. 530–565 nm)		ex. 400–500 nm, em. 530 nm
Stability	In neutral and acidic medium relatively stable against heat and oxygen. Rapid photolysis by UV- and visible light to blue fluorescent lumichrome (acidic and neutral solutions) or yellow–green fluorescent lumiflavin (alkaline solutions). After reduction by dithionite, Zn–HCl, sodium hydrosulfite, etc. reversible conversion to leucoflavin (dihydroflavin)		

[a]According to *The Merck Index*, 11th edn. Rahway NJ: Merck & Co. and modified from Eitenmiller RR and Landen WO, Jr. (1999) *Vitamin Analysis for the Health and Food Sciences*, pp. 229–337. Boca Raton, FL: CRC Press.

Light exposure of alkaline solutions decomposes riboflavin to lumiflavin (7.8.10-trimethylisoalloxazine), and in neutral or acidic solutions, the blue fluorescent lumichrome (7.8-dimelthylalloxazine) is formed (Figure 2 and Table 1). Riboflavin is found in free form only in the retina of the eye, whey, and urine. In other biological systems and tissues, the predominant forms are flavin mononucleotide (FMN) or riboflavinphosphate and flavin adenine dinucleotide (FAD). Free riboflavin and FMN-monosodium salt are the most important commercial products. FMN and FAD are effective as coenzymes or prosthetic groups in more than 100 enzymes in the plant and animal kingdoms. The accepted designation for both compounds is incorrect, because FMN is not truly a nucleotide and FAD is not a dinucleotide. The designations arose from the discovery of riboflavin, and have been adopted ever since. Pure riboflavin was first isolated from yeast, egg white, and whey in 1933 (by Kuhn and Wagner-Jauregg). Simultaneously, the so-called 'yellow coenzymes' were discovered (by Warburg and Christian) in yeast and could be identified as FMN. FMN is considerably more soluble in water than riboflavin. Its solubility in organic solvents and its stability against heat and light exposure are comparable with that of riboflavin. The flavoproteins FMN and FAD belong to the enzymatic class of oxidoreductases. The conjugated structure of the pteridine moiety of the basic molecule determines its coloring and light absorbance in the UV and visible spectrum. Absorbance maxima for the flavins are listed in Table 1. Likewise, catalytic hydrogen transfer in the flavin enzymes takes place at both conjugated of bound N_1 and N_5 atoms of the isoalloxazin molecule. The oxidized form of the flavoproteins, the flavoquinone, is thereby reversibly reduced to the colorless flavohydroquinone or leucobase (see Figure 1). The absorbance is lost, because double bonds are dissolved. As an intermediate product during this reaction, a radical semiquinone is formed. During the redox process, the flavin molecule changes its conformation, which is planar in the oxidized state

and folded in a butterfly configuration in the reduced state.

The characteristic yellow–green fluorescence of riboflavin and FMN in aqueous solutions exhibits maximal intensity at pH 6–7. The fluorescence of FAD is about 10–20% of that of riboflavin with the same spectral distribution but exhibiting a maximal intensity at pH 3. The fluorescence of flavins is quenched when bound to proteins. The irradiation products of the flavins also fluoresce, and their spectrum is shifted to the blue (lumichrome) or green (lumiflavin) spectral range. Riboflavin can be quantified by conversion to lumiflavin and by measuring its fluorescence intensity in chloroformic solutions with exitation (ex.) at 270 nm, and emission (em.) at 418 nm.

Methods of Determination

Initially, direct fluorimetry of the intact flavins or after hydrolysis to FMN or free riboflavin have been most frequently used for quantitation of vitamin B_2 active components. Alternatively, the lumiflavin method based upon the conversion of the chloroform-insoluble riboflavin into chloroform-soluble lumiflavin after photodegradation in alkaline solution can be used, despite a transformation rate of only 60–70%. Currently, microbiological assays and HPLC procedures with an enhanced sensitivity are widely used (see also Table 2).

In principle, riboflavin is extracted from dry materials by autoclaving in 0.1 N HCl for 30 min or in a water bath for 1–2 h. By using acid extraction, flavins are released from their protein binding, and FAD and FMN are converted to free riboflavin. In protein-rich materials, acidic extraction may be followed by enzymatic hydrolysis for complete liberation of flavins. It is important to carry out all operations relating to the extraction and quantitation of flavins and riboflavin under dim light and in brown or dark vessels.

Direct Fluorimetry

Direct measurement of the native fluorescence of riboflavin may be applicable for pharmaceutical preparations or food samples with a relatively high vitamin content. After acid extraction, any remaining proteins are removed by precipitation at pH 4.5. Interfering substances are subsequently oxidized with potassium permanganate and excess oxidant destroyed with hydrogen peroxide or sodium bisulfite. The fluorescence of the clear sample solution, commonly spiked with riboflavin as an internal standard, is registered by difference measurement before and after reduction of riboflavin with sodium bisulfite to the leuco form for correction by unspecific fluorescence (ex. = 440 nm; em. = 565 nm).

The detection limit of this method is about 0.1 μg of riboflavin per gram of sample. The direct fluorimetry of flavins had been adopted by the US Pharmacopoeia for the riboflavin analysis in tablets and injections, and by the AOAC for the riboflavin determination in foods, as in milk-based formulas, for example.

Lumiflavin Method

In this method, riboflavin is photodegraded in alkaline solution at pH 10–12 to the stronger fluorescent lumiflavin (ex. = 270 nm; em. = 418 nm). This reaction is specific for riboflavin, since other flavins interfering with riboflavin fluorescence are not converted into lumiflavin. Lumiflavin is separated from riboflavin and other fluorescent substances by extraction with chloroform. The transformation into lumiflavin is not quantitative and ranges between 60 and 70%. Reliable results can be obtained only by comparison

Table 2 Methods of riboflavin determination

Method	*Principles*	*Specials*	*Detection limits*
Direct fluorimetry	Fluorescence measurement of riboflavin at 440 (ex.)/565 (em.) nm	Conversion of FAD and FMN to riboflavin by acidic hydrolysis	0.1 μg B_2 per gram of sample
Lumiflavin method	Fluorescence measurement after irradiation at pH 10–12 (ex. 270, em. 418 nm)	Lumiflavin is separated by chloroform extraction	0.02 ng of B_2
Microbiological assay	Turbidimetric measurement of bacterial growth response dependent on the B_2 content	Interference of growth response with nutrients/food components	0.1–0.5 ng of B_2
HPLC analysis	Separation of flavins on RP-C_{18} materials with aqueous/organic solvents and fluorimetric/UV detection	Differentiated analysis of flavins, combined analysis with other B-vitamins	0.21 ng of riboflavin 0.89 ng of FMN 11.15 ng of FAD 0.02 ng of B_2 (precolumn irradiation to lumiflavin)

with a riboflavin standard under identical irradiation conditions for the sample and standard solution.

Although the original lumiflavin method is rarely used, the principal methodology has been applied to high-performance liquid chromatography (HPLC) analyses of riboflavin content in foods with detection limits of 0.02 ng of riboflavin per injection.

Microbiological Assay

Besides bioassays, as in chicken and curative rat growth tests, for example, microbial assays are the first widely used test methods, measuring the biological activity of preparations containing total vitamin B_2. The most frequently used test organism is *Lactobacillus casei* ssp. *rhamnosus* (ATCC No. 7469). The detection limit is indicated to 0.5 ng of riboflavin absolutely. Occasionally, other test organismus are proposed such as *Enterococcus faecalis* (ATCC No. 10100) or *Leuconostoc mesenteroides* (ATCC No. 9135) with an enhanced sensitivity of 0.1 ng per milliliter of riboflavin. Microbiological assays with *L. casei* have been approved by the Association of Official Analytical Chemists International Methods for riboflavin determination in vitamin preparations. The growth response of bacteria is proportional to the riboflavin content of the medium and can be measured turbidimetrically. Earlier techniques determined metabolically formed lactic acid by titration. However, comparisons of turbidimetrically after 16 h of incubation yielded results that agreed with those obtained by titration of lactic acid after 72 h. Thus, turbidimetric measurement is currently preferred in view of its shorter incubation time and easier handling.

The growth response of *Lactobacillus* species differs significantly between free riboflavin and FMN and FAD. Acidic or enzymatic treatment is therefore needed for releasing and converting the flavins into riboflavin, as described in Methods of Determination, followed by adjustment of the extract to pH 4.5 before incubation. In case of enzymatic release using takadiastase or clarase, it should be noted that some enzyme preparations contain variable traces of riboflavin.

Starch, glycogen, free fatty acids and other lipids, and protein degradation products can interfere with the test by either stimulating or inhibiting bacterial growth. Lipids can be removed either by filtration or by ether or petroleum ether extraction before hydrolysis. Proteins are precipitated at pH 4.5 and starch split by the acidic or enzymatic hydrolysis step. As with the other analytical procedures, the microbiological test should be carried out in dim light. Furthermore, it is important that the glass vessels used do not release any traces of alkali and should thus be cleaned with acid before used, because the flavins are alkali-sensitive. Hence, it is advisable to dissolve riboflavin standards in 0.02 M acetic acid. An optimal extraction procedure applicable for microbiological or HPLC determination of thiamin and riboflavin has been worked out by the European Measurement and Testing Program. The steps of the extraction are detailed in autoclaving food samples in 0.1 N HCI at 121 °C for 30 min and adjusting thereafter to pH 4.0 with 4 M sodium acetate buffer (pH 6.1), followed by the addition of takadiastase (0.1 g per gram of sample), incubation at 37–45 °C (18 h), and then filtration or centrifugation after cooling.

HPLC Procedures

HPLC methods enable separate quantitation of individual flavins or simultaneous analysis of riboflavin, including FMN and FAD. A broad variety of HPLC techniques are described, with variations in the column material, mobile phase, separation mode, and detection system as well. Of the numerous analytical and technical variations communicated during the last 20 years, the separation techniques can be categorized as follows.

In most cases, reversed-phase (RP) C_{18}-materials as stationary phases, and aqueous/organic mobile phases on the basis of water, methanol, acetonitril with or without phosphate or acetate buffer have been used in an isocratic mode. Ion-pair chromatography with sodium salts of hexane or heptane sulfonic acid in the mobile phase (ion-interaction chromatography) was rarely used. In some cases, the separation of riboflavin and flavins was accomplished using the gradient elution technique. Ion-pair HPLC seems more favorable only when riboflavin is to be determined simultaneously with other B-vitamins (e.g., B_1, B_6, niacin, folic acid, B_{12}), because this technique results in better peak shapes.

The retention times of vitamin B_2 active compounds are between 5 (FAD) and 20 (riboflavin) min. Fluorescence monitoring is preferred for detection, and UV or visible absorbance detection at 270 or 446 nm is restricted to early HPLC analyses or measurements of pharmaceuticals and enriched foods. The limits of fluorescence detection at 450/520 nm (ex./em.) for the native flavins were found to be 0.55 pmol (0.21 ng) of riboflavin, 1.96 pmol (0.89 ng) of FMN, and 14.19 pmol (11.15 ng) of FAD. In an earlier HPLC method, the detection limit could be increased to 0.02 ng of riboflavin/injection by irradiation of the sample extract and conversion of the extracted riboflavin to lumiflavin prior to HPLC separation.

In principle, the extraction techniques and sample clean-up suitable for HPLC analysis resemble those

used for quantification by the other methods discussed. Most often, vitamin B_2 active substances are released from the food matrix by autoclaving with 0.1 N mineral acid (HCI or H_2SO_4) followed by enzymatic digestion with papain, takadiastase, or claradiastase. Solid-phase clean-up prodecures on C_{18}-materials or Florisil are often used for support prior to injection. The extraction procedure depends on the type of analysis, whether the total riboflavin content, i.e. the sum of FAD, FMN, and free riboflavin is to be determined, or whether the separated quantitation of FAD and FMN in addition to free riboflavin is required. Treatment with potassium permanganate can be omitted, because possibly remaining extraneous fluorescent substances are chromatographically separated.

Combined acid and enzymatic hydrolysis is advantageous, particularly for foods with a high starch or protein content, to liberate the bound flavins. Occasionally, autoclaving with dilute mineral acid is incomplete, particularly for the conversion of FMN to riboflavin, as indicated by the appearance of an FMN peak in the following chromatogram. In addition, FMN may be partially converted during acid hydrolysis to biologically active isomeric riboflavin phosphates, which can be separated from FMN by HPLC analysis, and are ignored when calculating total riboflavin. The combination of acidic and enzymatic digestion is thus advisable prior to HPLC analysis for the determination of total riboflavin. When using this extraction procedure and following HPLC analysis, the riboflavin content of various foods such as breakfast cereals, porridges, milk, and milk products correlates well with the microbiological assay if *Lactobacillus casei* is used. The simultaneous determination of FAD and FMN besides free riboflavin requires non-degradative techniques, such as extraction of flavins by methanol/dichloromethane followed by partitioning with citrate buffer (pH 5.5) or extraction with 6% formic acid containing 2 M urea. The HPLC separation and quantitation of the flavins were carried out using internal standards (7-ethyl-8-methyl-riboflavin, sorboflavins, isoriboflavin, nicotinamide, and others). This analytical device can be used in the flavin analysis (FAD, FMN, and riboflavin) of milk and dairy products, fruits and vegetables, meats, and cereal products. In many cases, HPLC methods have been developed for the simultaneous or sequential determination of riboflavin and thiamin in foods. Both vitamins are

extracted by a common procedure using acidic and enzymatic digestion.

For biological samples, such as blood or plasma/serum, the preferred extraction medium is 5–10% trichloroacetic acid, which is suitable for denaturating the relatively weak protein binding, while keeping the phosphorylated forms intact. In this way, flavins in whole blood can be analyzed by isocratic RP-HPLC against an external standard. A list of usual HPLC procedures is given in Table 3, and an overview of the methods of riboflavin determination is given in Table 2.

Food Content

Vitamin B_2 is widely distributed in animal and vegetable foods. Protein-rich foods of animal origin are, as a rule, considerable sources of this vitamin with good bioavailability. Particularly rich in riboflavin are offal, such as heart, liver, and kidney. Because of the relative heat stability, only minor vitamin losses occur during preparation. Likewise, pasteurization of milk causes losses of less than 10%. However, exposure to day light may result in a remarkable decrease in the riboflavin content in foods, depending on the surface area exposed. Vitamin losses occur during the milling of cereals. White flour with a low extraction rate contains about one-third of the vitamin content of whole grain flour. Of special importance for the dietary habits in Western countries are milk and dairy products despite only a medium riboflavin content. If these are omitted from the diet, it may be difficult to achieve an adequate vitamin intake (Table 4).

Introduction

Following the earlier identification of riboflavin and the two most common flavocoenzymes, the more recent recognition of the greater diversity of natural flavins has led to a broader appreciation of the multiple functions and metabolic processing of these important compounds. Much of the progress in this area and detail of function of the flavins and flavoproteins have been given in the periodic symposia held on this subject. This article reviews the principal features of the physiological handling of riboflavin and its natural derivatives in the mammalian body and, where known, in the human.

Digestion and Bioavailability

Riboflavin and lesser amounts of natural derivatives are released by digestion of complexes, mostly flavoproteins, contained within foods. Coenzyme forms of the vitamin, mainly flavin adenine dinucleotide (FAD) and flavin mononucleotide (FMN), are released from noncovalent attachment to proteins as a consequence of gastric acidification. Nonspecific hydrolyses of the coenzyme forms by pyrophosphatase and phosphatase occur in the upper small intestine. By such actions, FAD is converted to FMN, which is further converted to riboflavin. Several per cent of 8α-(amino acid)riboflavins originally in covalent attachment as 8α-FAD linked to certain enzymes, notably of mitochondrial origin, are also released by such hydrolases that function together with proteolysis of the attached protein chains, which begins in the stomach with pepsin and continues in the small intestine with trypsin, chymotrypsin and exopeptidases. Traces of other ring and side-chain substituted flavins are similarly released by combinations of the above actions on non-covalently and covalently bound flavins. Riboflavin 5′-glycosides, for example, are cleaved by glycosidases present in the succus entericus. The digestive processes and locale for release of

flavins from ingested material is shown in Figure 1. (*See* **Coenzymes**.)

While the efficiency of release of riboflavin from noncovalently bound forms is essentially complete in the normal gastrointestinal tract, the vitamin is not recovered intact from flavin covalently linked to protein. Since the latter is less than 10% of total flavin within the diverse foods ingested by people and most mammals, the average bioavailability of riboflavin is fairly high. (*See* **Bioavailability of Nutrients**.)

Absorption and Transport

Riboflavin and a fraction of flavin metabolites,including ring-altered forms, e.g., 8α-(amino acid)riboflavins, and side-chain derivatives, e.g., 7,8-dimethyl-10-formyl-methylisoalloxazine, are absorbed primarily in the proximal small intestine by a saturable transport system that is rapid and approximately proportional to dose before levelling off. This saturation level is achieved with about 25 mg of the vitamin given in a single bolus to adult humans. Bile salts appear to facilitate the uptake, and a modest amount of flavin circulates via the enterohepatic system. The initial uptake of riboflavin by enterocytes is Na^+-dependent and reflects an adenosine 5′-triphosphatase (ATPase)-involved active cotransport system. Metabolic trapping by conversion to FMN and FAD occurs before release of the vitamin to circulation by nonspecific pyrophosphatase and phosphatase. (*See* **Bile**.)

Circulatory transport of flavin involves loose association with albumin and tight associations with some globulins. A subfraction of immunoglobulin G (IgG) has been found to bind avidly a small portion of the total free flavin in blood, and several immunoglobulins contribute significantly to plasma transport of the vitamin. Some riboflavin-binding proteins in plasma are pregnancy-specific, including the classic case of the estrogen-induced egg-white protein. These proteins have at least some portion of the binding domain in common and are essential for fetal development. Placental transfer of riboflavin in the human and other mammals involves binding proteins that help vector the vitamin and enhance supply to the fetus.

Uptake processes for flavins by mammalian cells have some characteristics in common, but there are both qualitative and quantitative differences among different cell types. Entry of riboflavin appears to be carrier-mediated (facilitated) at physiological concentrations of the vitamin, since there is relative specificity to a saturable component that is responsible for initial rapid uptake. A riboflavin-binding protein has even been isolated from the plasma membrane of rat liver cells. The nonepithelial hepatocyte does not depend on Na^+ for riboflavin import, as do bipolar epithelial types such as the enterocyte or renal proximal tubular cell. Slower passive diffusion becomes more evident when the facilitating transporter is exceeded by pharmacological levels of the vitamin. In all cases, metabolic trapping of riboflavin by

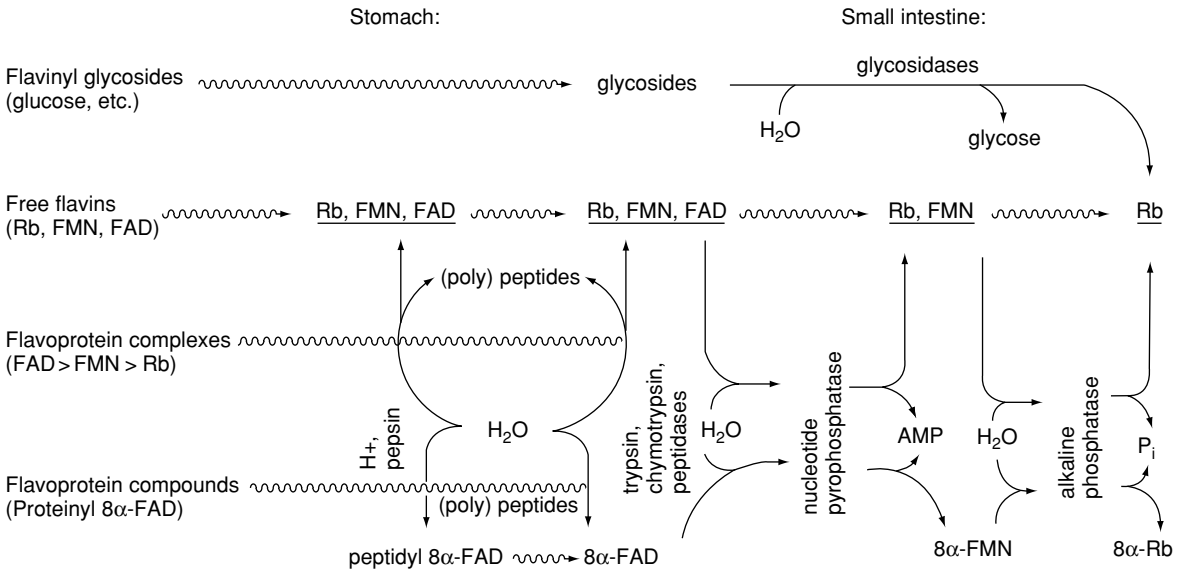

Figure 1 Digestion of flavins in monogastric mammals. Rb, riboflavin; P_i, inorganic phosphate. Reproduced with modifications from Riboflavin: Physiology, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

phosphorylation dependent upon cytosolic flavokinase follows passage of the vitamin through the plasma membrane. Release of riboflavin from cells requires hydrolysis of FMN by nonspecific phosphatases.

Cellular Interconversions

The metabolic interconversions of riboflavin and flavocoenzymes are summarized in Figure 2.

Conversion of riboflavin to coenzymes occurs within the cellular cytoplasm of most tissues, but particularly in the small intestine, liver, heart, kidney, and brain. The obligatory first step is the adenosine 5′-triphosphate (ATP)-dependent phosphorylation of the vitamin catalyzed by flavokinase, which utilizes Zn^{2+}. The FMN product can be complexed with specific apoenzymes to form several functional flavoproteins, but the major portion is further converted to FAD in a second ATP-dependent reaction catalyzed by FAD synthetase, which utilizes Mg^{2+}. It is clear that the biosynthesis of flavocoenzymes is regulated by supply of riboflavin (flavin status), competition for ATP (energy status), and hormonal balances. Thyroxine and triiodothyronine stimulate FMN and FAD synthesis in mammalian systems. This seems to involve a hormone-mediated increase in an active form of flavokinase. As a product of the synthetase, FAD is also an effective inhibitor at this second step and may help regulate its own formation. FAD is the predominant flavocoenzyme present in tissues where it is mainly complexed with numerous flavoprotein dehydrogenases and oxidases. Several percent of the FAD also becomes covalently attached to specific amino acid residues of a few important apoenzymes. Examples for the human include the 8α-N^3-histidyl FAD within the mitochondrial dehydrogenases for succinate, dimethylglycine and sarcosine, and the 8α-*S*-cysteinyl FAD within monoamine oxidase, also of mitochondrial localization. (*See* **Hormones**: Thyroid Hormones.)

Turnover of covalently attached flavocoenzymes requires intracellular proteolysis, and further degradation of the coenzymes involves nonspecific pyrophosphatase and specific 5′-nucleotidase cleavage of FAD to AMP (adenosine monophosphate) and FMN and action by nonspecific phosphatases on the latter.

Storage and Catabolism

There is little storage of riboflavin as such, since most exists within flavocoenzymes that are in relatively tight associations in holoenzymatic systems. During such severe deficiency of the vitamin as leads to death of experimental animals, there is a reduction in the level of extractable flavin that can approach about half of that found in an optimally supplemented control. Hence, there is moderately effective retention of riboflavin by its metabolic commitment to bound forms; however, even a modest deficit of the vitamin is reflected in the decrease in function of certain flavoproteins well before full-blown symptoms of deficiency.

Though certain bacteria, especially of the *Pseudomonas* genus, can extensively degrade both the ring system and side-chains of flavins, mammals are more limited in their abilities to catabolize the vitamin. The considerable diversity of flavin metabolites in and from mammals reflects the composite of reactions of photochemical processes on the skin, microfloral activities in the gastrointestinal tract, as well as somatic actions both directly on flavin and on derivatives presented to cells by circulatory recovery from dermal tissue and by enterohepatic retrieval from the gut. The diverse flavin-related products identified from humans and other mammals are summarized in Figure 3.

Cleavage of the D-ribityl side-chain at position 10 is mainly, if not entirely, attributable to light and intestinal microflora. Both can lead to partial fragmentation to form the 10-formylmethylflavin. This can be oxidized by alimentary bacteria of the ruminant and human to form the 10-carboxymethylflavin, and a further fraction of the formylmethyl compound is interconverted with the 10-hydroxymethylflavin as a result of pyridine-nucleotide-dependent dehydrogenase in tissue. Lumichrome-level compounds not only can result from complete removal of the side-chain by microflora, which can be decreased by antibiotic administration, but can accompany lumiflavin as a photoproduct from action of light on flavin within the dermal tissue. Catabolites of riboflavin that primarily derive from oxidations within tissues

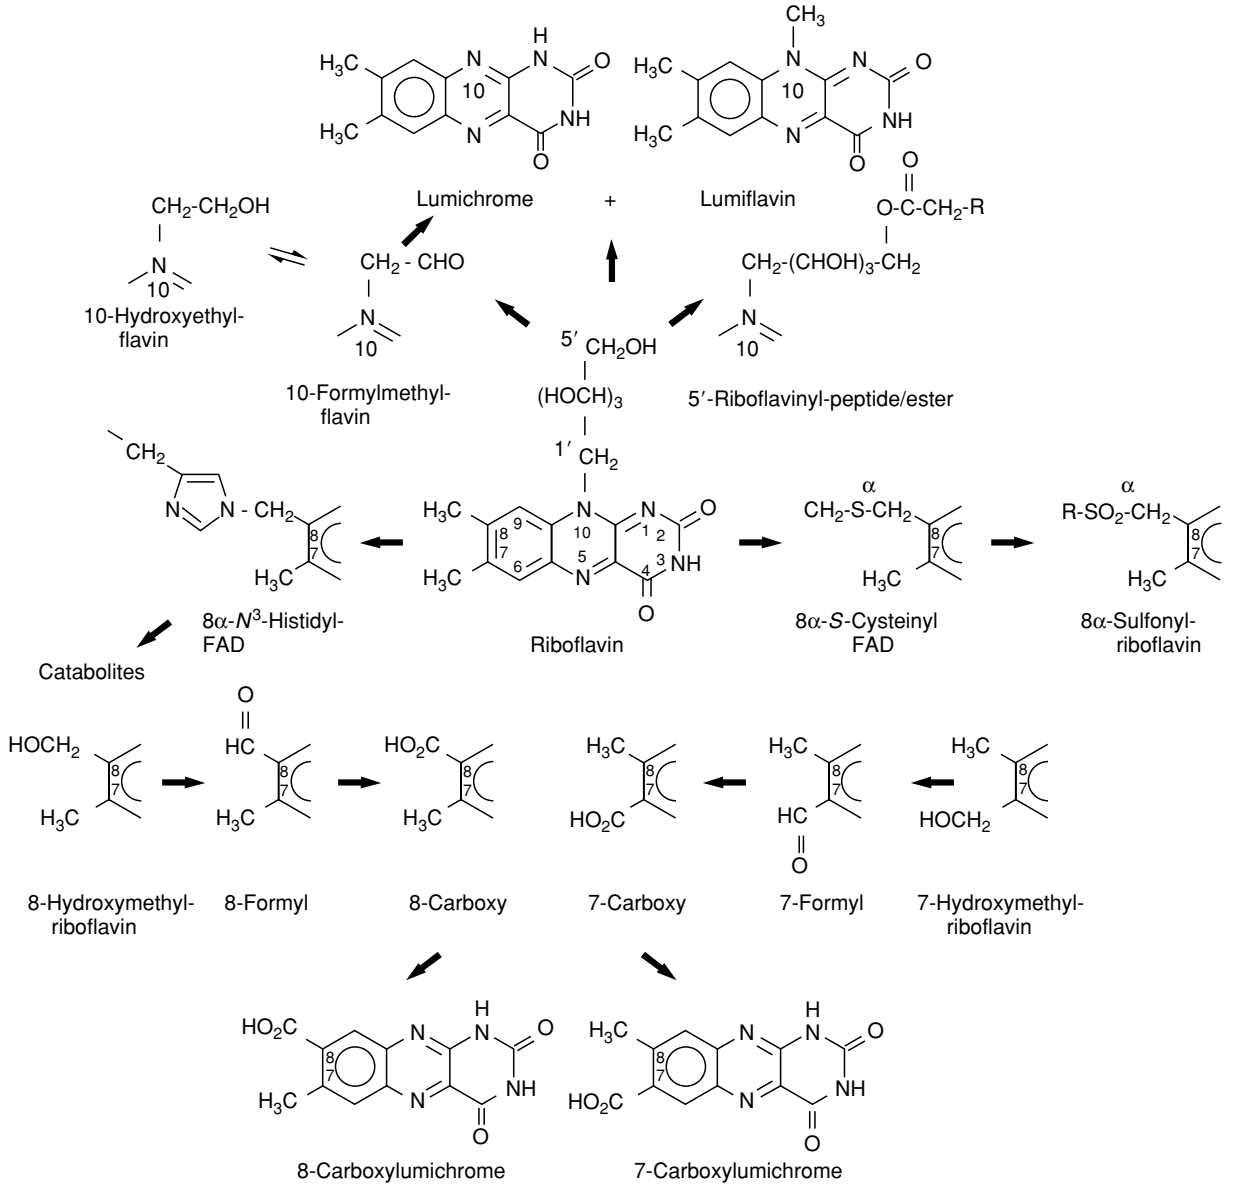

Figure 3 Photochemical, microfloral, and cellular catabolism of riboflavin within mammals. Reproduced from Riboflavin: Physiology, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

are the 7- and 8-hydroxymethylriboflavins (7α- and 8α-hydroxyriboflavins). These, and products from further oxidation of the hydroxymethyl functions to formyl and carboxyl groups, reflect microsomal mixed-function oxidase activity. Other flavin catabolites include those from 8α-(amino acid)riboflavins released from covalently bonded FAD. An 8α-sulfonylriboflavin may derive from the 8α-cysteinyl-FAD of monoamine oxidase. A peptide ester and a glucoside, both linked to the 5′-hydroxymethyl terminus of the vitamin, have also been found.

Excretion and Secretion

Since no isoalloxazine (flavin) can be biosynthesized within the cells of mammals that lack riboflavin synthetase, excretion and secretion reflect dietary intake and catabolic and photodegradative events. Essentially all known catabolites of riboflavin have been detected in urine; many of the lumichrome-level compounds are also in feces. For normal adults eating varied diets, riboflavin comprises 60–90% of urinary flavin, 7-hydroxymethylriboflavin 3–7%,

8α-sulfonylriboflavin 2–15%, 8-hydroxymethylriboflavin 1–8%, 10-hydroxyethylflavin 1–7%, riboflavinyl peptide ester up to 5%, with traces of lumiflavin and, sometimes, the 10-formylmethyl- and carboxymethylflavins.

The presence in milk of 'lactoflavin,' an early name for riboflavin, led to the recognition of this food as a good source of the vitamin. For milk from both cows and humans, the flavin in highest concentration other than the free vitamin is FAD, which can comprise over a third of total flavin. Much of this is hydrolyzed to FMN by pasteurization. Fairly significant quantities of the 10-(2′-hydroxyethyl)flavin are notable, since this catabolite has antivitamin activities, as reflected in competitive inhibition of both cellular uptake and subsequent flavokinase-catalyzed phosphorylation of riboflavin. Hence, this catabolite, which may reach 10–12% of flavin in cow's milk, modestly subtracts from the biological activity of this food. Several percent of both 7- and 8-hydroxymethylriboflavins are also present, with more of the former. Smaller amounts of other catabolites, including the 10-formylmethylflavin and lumichrome, comprise most of the rest. (*See* **Milk**: Dietary Importance.)

Biochemical Functions

In bound coenzymic forms, riboflavin participates in oxidation–reduction reactions in numerous metabolic pathways and in energy production via the respiratory chain. A variety of chemical reactions are catalyzed by flavoproteins. The redox functions of a flavocoenzyme (Figure 4) include one-electron transfers, during which the neutral, oxidized quinone level of flavin is half reduced to the radical semiquinone, which can exist within natural pH ranges as neutral or anionic species. A further electron transfer can lead to a fully reduced hydroquinone. In addition, a single-step, two-electron transfer from substrate to flavin can occur with hydride ion transfer, e.g., from reduced pyridine nucleotide, or by base abstraction of a substrate proton together with carbanion addition.

There are flavoprotein-catalyzed dehydrogenations that are both pyridine-nucleotide dependent and independent, reactions with sulfur-containing compounds, hydroxylations, oxidative decarboxylations, dioxygenations, and reduction of oxygen to hydrogen peroxide. The intrinsic abilities of flavins – to be varyingly potentiated as redox carriers upon differential binding to proteins, to participate in both one- and two-electron transfers, and to react in reduced (1,5-dihydro) form with oxygen – permit wide scope in their operation.

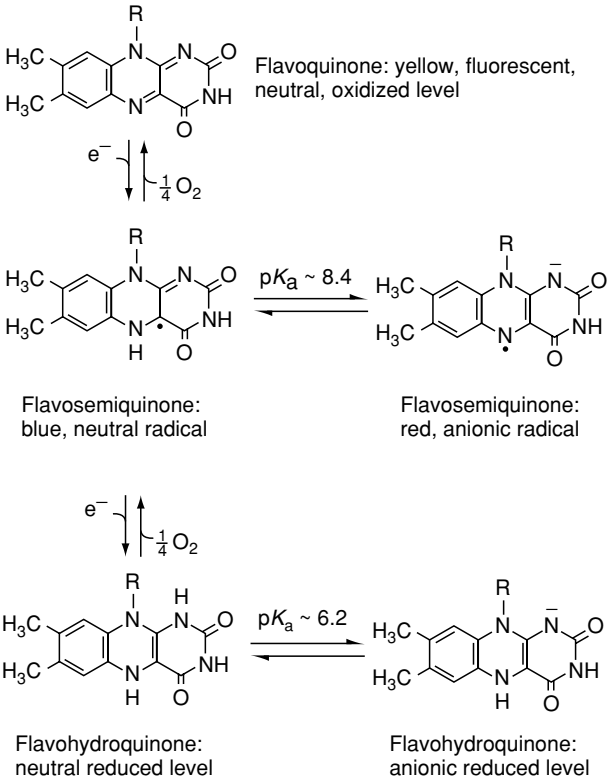

Figure 4 Oxidation–reduction states of flavocoenzymes functioning physiologically. Reproduced from Riboflavin: Physiology, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Requirements and Intakes

The requirement levels for riboflavin, in contrast to those for thiamin, are not raised when energy utilization is increased. Because of the interdependence of protein, energy intake, and metabolic body size, however, allowances calculated on these three bases do not differ significantly. Clinical signs of deficiency in adults can be prevented with intakes of riboflavin above 0.4 mg per 1000 kcal, but over 0.5 mg per 1000 kcal may be required to maintain tissue reserves in adults and children as reflected in urinary excretion, erythrocyte riboflavin, and erythrocyte glutathione reductase. From these considerations, the riboflavin allowances are now computed as 0.6 mg per 1000 kcal for people of all ages. This leads to US Recommended Dietary Allowances (RDAs) ranging from 0.4 mg per day for early infants to 1.7 mg per day for young adult males. However, for elderly people and others whose daily calorie intake may be less than 2000 kcal, a minimum of 1.2 mg per day is recommended in the USA. Since pregnancy imposes extra demands, reflected by decreased excretion

and an elevated FAD stimulation of erythrocyte glutathione activity, an additional 0.3 mg per day is recommended. The lactating woman secretes approximately 35 μg per 100 ml of milk for an output of about 0.26 mg per day (750 ml) during the first 6 months and 0.21 mg per day (600 ml) during the second 6 months. Since the utilization of the additional riboflavin for milk production is assumed to be 70%, an additional intake of 0.5 mg is recommended for the first 6 months and 0.4 mg for the second. (*See* **Lactation**: Physiology.)

Small amounts of riboflavin, largely as digestible coenzymes, are present in most plant and animal tissue. Good sources are eggs, lean meats, milk, broccoli, and enriched breads and cereals. Such losses as occur during cooking are largely attributable to leaching of the heat-stable but light-sensitive flavins into water.

When supplementation or therapy with riboflavin is warranted, oral administration of five to 10 times the RDA is usually satisfactory.

Deficiency Causes and Symptoms

Pure, uncomplicated riboflavin deficiency is probably never encountered in patients, but is accompanied by multiple nutrient deficiencies. Ariboflavinosis can result from such primary and secondary factors as commonly affect supply or utilization of other nutrients as well. Inadequate dietary intake most commonly related to limited availability of food, but sometimes exacerbated by poor storage or processing, remains the major cause. In addition, anorexic persons rarely ingest adequate amounts of riboflavin and other nutrients.

Decreased assimilation results from abnormal digestion, absorption, or both. Lactose intolerance as a result of lactase insufficiency, mostly encountered among Blacks and Asians, argues against such people consuming nonlactase-treated milk, which is a good source of the vitamin. Malabsorption can occur as a result of tropical spure, celiac disease, malignancy and resection of the small bowel, and gastrointestinal and biliary obstruction. Poor absorption also results from disorders that increase motility and decrease gastrointestinal passage time, such as diarrhea, infectious enteritis, and irritable bowel syndrome. (*See* **Food Intolerance**: Lactose Intolerance.)

Rather rarely encountered, but usually significantly improved by therapeutic treatment with riboflavin, are certain inborn errors where the genetic defect is in formation of a normal flavoprotein. Cases in this category include fatty acid desaturases in which specific defects have been found for the mitochondrial FAD-dependent dehydrogenases for short-chain, long-chain, and multi-chain acyl-CoAs (acyl coenzyme As). The young patients have a lipid storage myopathy, often accompanied by carnitine insufficiency, and exhibit glutaric aciduria. A low, FMN-dependent pyridoxine 5′-phosphate oxidase activity due to an erythrocyte deficiency of FMN, confirmed by response to oral riboflavin, was reported in the majority of subjects with D-glucose 6-phosphate dehydrogenase deficiency. Such cases seem to have an accelerated conversion of FMN to FAD so that glutathione reductase is saturated. This contrasts with heterozygous β-thalassemia, in which there is an inherited slow erythrocyte conversion of riboflavin to FMN, a decrease in subsequent FAD, and a high stimulation of the erythrocyte glutathione reductase by extraneous FAD.

Defective utilization can result from disturbances in hormonal production, certainly relating to thyroid hormone, but less likely as a result of taking oral contraceptives. Phenothiazine derivatives appear to impair use of riboflavin.

Increased destruction of riboflavin occurs during treatment of neonatal jaundice with phototherapy. In this case, the side-chain of the vitamin is photochemically destroyed, as it is involved in the photosensitized oxidation of bilirubin to more polar, excretable compounds.

The finding that phenobarbital induces microsomal oxidation of the 7-methyl function of the vitamin lends credence to the belief that long-time use of barbiturates may jeopardize flavin status.

Enhanced excretion of riboflavin occurs in catabolic patients undergoing nitrogen loss. The relationship of the vitamin to protein status has long been recognized. Also, certain antibiotics and phenothiazine drugs increase excretion of riboflavin. (*See* **Drug–Nutrient Interactions**.)

Increased requirements can, of course, be the consequence of one or more of the above-mentioned factors. For example, protein–calorie malnutrition commonly accompanies a diminution in both absorption and utilization of riboflavin. Systemic infections, even without gastrointestinal involvement, sometimes lead to increased requirements that can result from decreased intake, defective absorption, poor utilization, and increased excretion. (*See* **Protein**: Deficiency.)

Clinical deficiency of riboflavin has been reduced by feeding a riboflavin-deficient diet and/or by the administration of an antagonist such as galactoflavin. The deficiency syndrome is characterized by sore throat, hyperemia and edema of the pharyngeal and oral mucous membranes, cheilosis, angular stomatitis, glossitis (magenta tongue), seborrheic dermatitis, and normochromic, normocytic anemia associated

with pure red cell cytoplasia of the bone marrow. As noted above, some of these symptoms, e.g., glossitis and dermatitis, when encountered in the field, may have resulted from other complicating deficiencies. Severe riboflavin deficiency can also affect the conversion of vitamin B_6 to its coenzyme and even curtail conversion of tryptophan to niacin. (*See* **Niacin**: Physiology; **Vitamin B_6**: Properties and Determination.)

Toxicity

Toxicity from ingestion of excess riboflavin by experimental animals or humans is doubtful. The capacity of the human gastrointestinal tract to absorb orally administered riboflavin may be less than 30 mg in a single dose. The limited solubility and absorptivity of this vitamin as encountered in multivitamin preparations and natural foodstuffs, and its ready excretion as typical of water-soluble vitamins, normally precludes a health risk. There is one report of EEG (electroencephalogram) abnormalities in two patients during long-term treatment with riboflavin and niacin.

RICE

B O Juliano, Philippine Rice Research Institute Los Baños, Laguna, Philippines

Global Distribution, Varieties, and Commercial Importance

Rice is the most important crop in the world in terms of total developing world production (480×10^6 tonnes of rough rice) and the number of consumers (2.5 billion) dependent on it as their staple food. It is widely grown in over 100 countries in every continent (except Antartica), from 53 °N to 40 °S, and from sea level to an altitude of 3 km. The total production in 1998 was 568×10^6 tonnes of rough rice. Asia accounts for 134 of the 149×10^6 ha world area that is used for rice cultivation. The mean rough rice yield was 3.74 tonnes ha^{-1} in 1998. About 90% of the world's rice is grown and consumed in Asia. The major rice producers in 1998 were China, India, Indonesia, Bangladesh, Vietnam, and Thailand. In terms of water regime, 54% of the total rice area was irrigated in 1991, 25% rainfed lowland, 13% upland, and 9% as flood-prone wetland, corresponding to total rough rice production of 76% from irrigated, 16% from rainfed lowland, 4% from upland, and 4% from flood-prone wetland. Since the rice-growing area is shrinking, rice production must keep up with the 1.7% per year increase in population in tropical Asia through increased yield.

There are estimated to be about 100 000 rice varieties; only a small proportion is actually widely cultivated. They vary in grain weight, size and shape, degree of dormancy, longevity and seedling vigor, and some have red to purple–black pigments. About 75% of Asia's rice area is planted with varieties of improved semidwarf plant type with erect leaves. The newer, improved varieties have a similar yield

potential to the first variety (IR 8) but have a better resistance or tolerance to biotic and abiotic stresses. 'Super' rice being bred has fewer tillers but with all of them productive (bearing panicle).

Only about 4–5% of the world's rice production enters the international trade. The major exporters in 1997 were Thailand, Vietnam, India, the USA, and Pakistan. The major importers in 1997 were Iran, Brazil, Nigeria, the Philippines, Iraq, Saudi Arabia, Malaysia, South Africa, and Côte d' Ivoire.

Morphology and Anatomy of the Spikelet or Grain

The rice grain (rough rice or paddy) consists of an outer protective covering, the hull (husk), and the edible rice caryopsis or fruit (brown, cargo, dehulled, or dehusked rice) (Figure 1). Brown rice consists of the outer layers of pericarp, seed coat, nucellus, and germ or embryo, which are the maternal tissues, and the endosperm. The endosperm consists of the aleurone layer and the starchy or inner endosperm. Pigment is confined to the pericarp, but there is a varietal difference in the extent of retention of pigment with the degree of milling. The aleurone layer encloses the embryo.

The inedible hull constitutes 16–28% (mean 20%) of rough rice weight. Brown rice consists of 1–2% pericarp, 4–6% aleurone plus nucellus and seed coat, 1% embryo, 2% scutellum and 90–91% endosperm. The aleurone and embryo cells are rich in lipid bodies (spherosomes, 0.2–1.5 μm) and in protein bodies (aleurone grains) containing inclusions of phytic acd bodies or globoids (1–3 μm).

The endosperm cells are thin-walled and packed with amyloplasts containing polyhedral compound starch granules about 3–9 μm in size. Protein occurs mainly in the form of large (1–2 μm) and small (0.5–0.8 μm) spherical protein bodies and crystalline protein bodies (2–4 μm). Spherical protein bodies (PB I) are rich in prolamin (alcohol-soluble protein), and crystalline protein bodies (PB II) are rich in glutelin (alkali-soluble protein). Spherosomes are present in the subaleurone or the two outermost cell layers of the endosperm.

Chemical and Nutritional Composition

Rice has one of the lowest protein contents (7%) among the cereals. The bran layers and embryo are richer in nonstarch constituents than the milled rice (Table 1). The major nutritional advantage of brown rice over milled rice is its higher content of B vitamins. Although higher in minerals, bran phytic acid and probably dietary fiber in the aleurone form complexes with minerals and proteins, reducing their bioavailability. The energy content of brown rice and bran is higher than that in milled rice, owing to the higher fat content. Rice has no vitamin A, C, or D.

From Juliano BO (ed.) (1985) *Rice: Chemistry and Technology*. St. Paul, MN: American Association of Cereal Chemists; United States Department of Agriculture (USDA) (1998) *Nutrient Database for Standard Reference, Release 12*. Riverdale, MD: Nutrient Data Laboratory, USDA Beltsville Human Nutrition Research Center (available at http://www.nal.usda.gov/fnic/food comp/).

Although cereal proteins are deficient in lysine, rice protein has one of the highest lysine contents among them, corresponding to an amino acid score of 59% in milled rice based on the Food and Agriculture Organization/World Health Organization/United Nations University (FAO/WHO/UNU) amino acid pattern of 5.8% lysine as 100% (Table 2). The solubility fractions of protein are about 15% of albumin–globulin (water- and salt-soluble), 20% prolamin (PB I) and 65% glutelin (PB II) in milled rice. Bran proteins are 66–98% albumins. Prolamin is poor in lysine but rich in sulfur amino acids. The high lysine content of rice protein is due to the low prolamin content.

The energy digestibility is higher in milled rice than in brown rice owing to the lower dietary fiber and phytic acid levels, as verified by the poor energy digestibility of rice bran (Table 2). The true digestibility (TD) of milled rice protein is also higher than that of brown rice, but the biological value (BV) is lower, resulting in a similar net protein utilization (NPU). Bran protein has a lower TD but a higher BV than brown and milled rice proteins. The amino acid score corrected for TD in rats proposed by the FAO as a protein quality index shows similar values to NPU for the rice proteins. Black or purple rice has a lower brown rice NPU (72%) and higher tannin level (0.6%) than red (NPU 83% and 0.2% tannin) and nonpigmented rices (NPU 97% and $\leq$ 0.02% tannin), but their milled rices have identical NPUs. Rice

[a]Based on 5.8 g of lysine per 16 g of N as 100%.

[b]In each line, mean values followed by the same letter are not significantly different at the 5% level (by Duncan's multiple range test).

From Eggum BO, Juliano BO, and Maniñgat CC (1982) Protein and energy utilization of rice milling fractions by rats. *Qualitas Plantarum Plant Foods for Human Nutrition* 31: 371–376.

United States Department of Agriculture (USDA) (1998) *Nutrient Database for Standard Reference, Release 12*. Riverdale, MD: Nutrient Data Laboratory, USDA. Beltsville Human Nutrition Research Center (available at http://www.nal.usda.gov/fnic/good comp/).

complements legumes in amino acid composition for human diets.

Cooking and parboiling reduces the TD in growing rats by 5–15%, with a corresponding increase in BV but little change in NPU. However, lysine digestibility remains close to 100%, and cystine digestibility drops to about 82%. The fraction that remains in the feces as fecal protein particles represents the lipid-rich core of large PB I, with less than 1% lysine in its protein but is rich in cystine. PB II is readily digested.

Starch varies in apparent amylose content (as determined by iodine colorimetry): waxy, 1–2%; very low amylose, 2–10%; low, 10–20%; intermediate, 20–25%; and high, 25–33%, all on a milled rice dry-weight basis. The glycemic index of cooked brown rice tends to be lower than that of cooked milled rice owing to the higher amounts of phytic acid and fiber in brown rice. Among cooked milled rices, the glycemic index decreases with increasing amylose content regardless of the cooking method (Table 3). Processing, including parboiling, tends to reduce the glycemic index. Resistant starch is $\leq 5\%$ and may not be as discriminating as the glycemic index in humans.

Breeding efforts to improve the nutritional value of rice grain include: a higher micronutrient density, (higher iron, zinc, and vitamin A), low phytic acid (high phosphate) content, low prolamin content absence of lipoxygenase-3 activity and allergenic globulin, and transgenic rice endosperm with vitamin A, with the soybean glycinin gene, and with the soybean ferritin gene.

Grading, Handling, and Storage

There is no international standard for milled rice size and shape. The International Rice Research Institute (IRRI) uses the following scale for size: extra long, > 7.50 mm; long, 6.61–7.50 mm; medium, 5.51–6.60 mm; and short, < 5.50 mm. For grain shape based on the length:width ratio, the following scale is used: slender, > 3.0; medium, 2.1–3.0; bold, 1.1–2.0; and round, ≤ 1.0. Grades are based on grain size and shape, degree of milling, percentage head or

whole-grain milled rice, immature grains, damaged (discolored) and heat-damaged grains (chalky grains, red grains and red-streaked grains), aroma, and organic and inorganic extraneous matter.

An important property of harvested grain is its moisture content: 14% on a wet-weight basis is considered a safe storage value; grains become susceptible to fissuring from moisture adsorption stress below critical moisture contents of 12–16%, depending on the variety. Aging of sun-/oven-dried rough rice for up to 2 months after harvest at ambient temperature $< 15\,^{\circ}C$ improves milling yields and makes milled rice expand more during cooking and become more flaky. Heating during grain drying accelerates aging.

Processing and Food Uses

The per-capita consumption of milled rice is 86 kg per year in 1999 in Asia as compared with 4–31 kg in other continents. It is consumed mainly as milled rice. About 20% of rice is consumed as parboiled rice. Parboiling consists of boiling or steaming steeped rough rice until the hull starts to open, and then cooling and drying the gelatinized grain. Diffusion of bran B vitamins into the endosperm occurs during parboiling. Mycotoxins are a potential problem in parboiled rice. Milling involves dehulling, followed by removal of the outer 7–10% of the brown rice, either by friction or by abrasion, removing most of the pericarp, seed coat, nucellus, aleurone layer, and the germ. In the Engelberg mills, hull and bran are removed together in one step with high grain breakage. Milling is done in several steps in modern cone mills with tempering in between to minimize breakage. Many modern mills have shifted to milling at >14% moisture to minimize grain breakage and to moisture mist treatment (through hollow shaft) during milling to soften the bran and improve surface gloss.

There are various ways of cooking milled rices. In tropical Asia, they are prewashed to remove dirt, but this results in losses of B vitamins and fat. Presoaking for 30 min reduces cooking time (particularly of parboiled rice). Grain cracking during soaking is minimized by adjusting milled rice moisture content to 15% by high-pressure hydration to minimize cracking. Rice may be cooked in the amount of water that it will absorb, or boiled in excess water and the cooking liquor discarded. A steaming step is used in Indonesia and also for waxy rices. Oil or ghee may be added in the Middle East, and this reduces surface stickiness. Enriched rice premixes containing iron and B vitamins resistant to washing have been developed for rice, but have not been popular because of additional expense; the enriched rice can be readily distinguished from ordinary grain.

Apparent amylose content (AC) correlates positively with water absorption and volume expansion during cooking, and with the hardness of boiled rice. South Asian consumers prefer high-AC intermediate-gelatinization temperature (GT $> 70\,^{\circ}C$) rice, Southeast Asians prefer intermediate-AC, intermediate-GT rice. *Japonica* rices preferred in Japan, Korea, Taiwan, and northern China are mainly low-AC, low-GT ($\leq 70\,^{\circ}C$), with some having an intermediate AC in Europe. Only in Laos and north and north-east Thailand is steamed waxy rice consumed as a staple. The amylopectin of low-GT, high-AC rice has a longer mean chain length than the amylopectin of intermediate-GT, high-AC rice. Among waxy and low-AC rices, low-GT rice is a softer cooked rice than high-GT rice, but among intermediate- and high-AC rices, intermediate GT rice is a softer cooked rice than low-GT rice. Longer-chain amylopectin contributes to the flaky cooked rice of low-GT, high-AC rices. Amylopectin staling is lower in low-GT cooked rice than in higher-GT rice within each amylose type and is reversed by heating.

Specialty rices include Italian Arborio rice for making risotto, waxy rice (sweet rice with an opaque grain), Thai Jasmine rice (aromatic low-AC long grain) and Punjab Basmati (aromatic intermediate AC long grain that elongates when presoaked rice is cooked). 2-Acetyl-1-pyrroline was the first major aroma principle identified in raw and cooked aromatic rices, and others are being characterized.

Various rice products are prepared for which specific AC types are preferred (Table 4). Freshly and well-milled rice is preferred for rice products to prolong shelf-life by minimizing fat rancidity in the stored products. Parboiled rices are preferably high and intermediate AC, whereas extruded and flat noodles use mainly aged, high-AC, low-GT rices. Rice with a low-starch GT is preferred in rice puddings, breads and cakes, and beer adjuncts. Waxy and low-AC rices are preferred for rice wines (for a higher ethanol yield) and in frozen sauces, desserts, snacks, and sweets, because of their slow staling rate. Rice crackers are prepared from waxy and nonwaxy rices. Parboiled rice is preferred over raw rice for *idli* (pudding) and *dosai* (cake) with rice:black gram usually fermented at a 3:1 weight ratio. The thermophysical properties of starch such as the glass transition temperature, gelatinization temperature, enthalpy of raw starch, staled amylopectin melting (45–60 °C), amylose–lipid complex I (< 100 °C) and II (>100 °C) melting, and staled amylose melting (> 130 °C) of gelatinized starch affect the properties of rice

Table 4 Apparent amylose content (AC) type and other properties reported as preferred for various processed rice products[a]

products in addition to the amylose–amylopectin ratio and protein content.

The use of rice bran in cereal products has increased in recent years owing to the hypocholesterolemic effect, in humans, of the factor(s) in the high (up to 4.4%) unsaponifiable fraction of its oil, such as τ-oryzanol (cycloartenol, 24-methylene-cycloartanol and campestrol esters of ferulic acid), tocopherols and tocotrienols, an analog of tocopherol (vitamin E). Defatted bran has no hypocholesterolemic activity, unlike in oats, where the active principle is soluble β-glucan. Inactivation of antinutrition factors – trypsin inhibitor, oryzacystatin, and hemaglutinin-lectin – and lipase and lipoxygenase that are concentrated in the rice bran by heat treatment and extrusion cooking improves the shelf-life of the bran and its nutritional value to poultry. By contrast, the antinutrition factor phytic acid is heat-stable. Phytic acid in rice bran and brown rice has been recently reported to have some medicinal activity in preventing some types of cancer. Phytic acid content of rice bran is highest among cereal brans (3–8% phytic acid, Table 1).

The total rice bran oil production in 1986–1988 was 600 000 tonnes per year, mainly in India, China, Japan, and Vietnam, according to FAO. This represented only 13% of potential bran oil production, requiring immediate oil extraction or stabilization because of bran lipase. The high hull contamination (70%) of rice bran produced by Engleberg mills makes oil extraction from their 'bran' uneconomical. Essential fatty acid content of rice oil is 34.2% 18:2 and 1.5% 18:3. Levels of oryzanol, tocopherols, and tocotrienols and unsaponifiable matter differ among crude oils, and oryzanol, tocopherols, and tocotienols may be reduced by up to 90% by conventional refining and deodorizing.

RICKETS AND OSTEOMALACIA

J J B Anderson and S U Toverud, University of North Carolina, Chapel Hill, NC, USA
S C Garner, Duke University Medical Center, Durham, NC, USA

Introduction

The terms 'rickets' and 'osteomalacia' refer to conditions in which mineralization is impaired, usually as a result of nutritional deficiencies of vitamin D and/or calcium. Although both conditions share common physical and microscopic abnormalities, rickets, which is only seen in infancy and childhood, has more severe manifestations in deformities of bone because of the greater plasticity of the young skeleton. Even though deficiency of vitamin D is a frequent cause of rickets and osteomalacia, vitamin D nutriture of individuals and populations has not been well investigated, in part because of the significant contribution of sunlight exposure to the nutritional status of vitamin D and in part because of the difficulty of accurately assessing vitamin D intakes from foods and beverages. Although rickets still remains a problem in much of the developing world, preventive strategies have led to its virtual disappearance in the developed world – with a few notable exceptions – because of food fortification and supplementation of this essential fat-soluble vitamin. Osteomalacia and the less severe hypovitaminosis D, on the other hand, appear to be increasingly more serious public health problems in the developed nations. As longevity continues to increase, the older segments of populations in affluent nations are at risk of insufficient vitamin D.

Dietary Vitamin D Intakes in the USA

No national survey findings exist on vitamin D intakes by populations. A few studies involving small numbers of subjects have shown that intakes by elderly women and shut-in females and males have been consistently below recommended intakes; low intakes have also been verified indirectly from measurements of serum 25-hydroxyvitamin D concentrations of subjects living at northern latitudes during winter and spring months.

Vitamin D Recommendations

Recommended intakes, also known by the specific term dietary reference intakes (DRIs) in the USA, of vitamin D have been designated in 1997 as adequate intakes (AIs), rather than recommended dietary allowances (RDAs). In its recent reevaluation the Food and Nutrition Board of the Institute of Medicine did not think that sufficient data were available to establish with scientific certainty new RDAs for vitamin D. **Table 1** lists the recently established AIs for vitamin D. Intakes that meet these AIs should

prevent rickets or osteomalacia. Lower intakes of vitamin D by individuals who get adequate sunlight on a daily basis should also be able to prevent these diseases.

Primary Causes and Abnormalities

Human vitamin D deficiency, which may result from inadequate dietary intake and/or skin biosynthesis of vitamin D (Figure 1), is a primary cause of rickets. The active hormonal form of vitamin D, 1,25-dihydroxy-vitamin D ($1,25(OH)_2D$, also called calcitriol, has an important role in intestinal absorption of calcium and phosphate, bone metabolism and mineralization, and calcium homeostasis. Other roles are not yet well understood and include conservation of calcium and phosphate by the kidney, interaction of the hormone with the immune system, skin and skeletal muscle, and enhanced differentiation of cells. Rickets may also be caused by inadequate calcium intake alone, as in the case of children living in Nigeria. It is characterized by several clinical features and laboratory measurements of blood (Table 2).

Rickets describes the disordered growth and mineralization of the growth plate of the long bones. The resulting abnormalities, widening of the growth plate, delayed conversion of the growth plate cartilage to bone, and irregularly arranged bone trabeculae,

Age	*Clinical features*	*Blood serum measurements*
Children	Skeletal deformations (rickets) Impaired growth Undermineralized bone	Hypocalcemia Hypophosphatemia Secondary hyperparathyroidism Low 25-hydroxyvitamin D Elevated alkaline phosphatase
Adults	Undermineralized bone (osteomalacia) Fractures	Hypocalcemia Hypophosphatemia Low 25-hydroxyvitamin D Elevated alkaline phosphatase Elevated osteocalcin[a]

[a]This finding has not been consistently reported: see Vieth R (1990) The mechanisms of Vitamin D toxicity. Bone and Mineral 11: 267–272. Reproduced from Cholecalciferol and Ergocalciferol/Rickets and Osteomalacia, *Encyclopaedia of Human Nutrition*, Sadler MJ, Strain JJ and Caballero B (eds), 1999, Academic Press.

are only seen when the vitamin D deficiency occurs during childhood or adolescence, i.e., before the growth plates close.

Osteomalacia describes abnormalities resulting from delayed and reduced mineralization of mature bone, whether trabecular or cortical. This mineralization defect leads to a widened area of unmineralized bone matrix on the bone surface, called osteoid. Osteomalacia is observed at all ages.

Infants and young children suffer from growth retardation primarily because of the stunted growth of the long bones, and may become bow-legged because of the reduced mechanical strength of these bones. Skeletal muscle weakness and increased urinary excretion of amino acids may also occur.

Radiographic evidence of rickets includes widening of the growth plate of the long bones of both arms and legs, and reduced bone density. In osteomalacia of the adult, undermineralization of the bones may manifest as pseudofractures, which are radiolucent lines on the radiographs that mimic stress fractures. However, the pseudofractures are usually bilateral and often involve nonweight-bearing bones such as the scapula.

Biochemical Changes

Biochemical changes in most cases of rickets and osteomalacia include decreased serum calcium and phosphate levels because of the insufficient intestinal absorption of these ions, increased serum parathyroid hormone levels as a result of the reduced serum calcium concentration, and elevated serum alkaline phosphatase concentration. (Increased alkaline phosphatase results from increased osteoblastic activity related to bone formation.) In cases of inadequate supply of vitamin D or in liver disease, levels of serum 25-hydroxyvitamin D (25(OH)D, a metabolite) are invariably low, but the levels of $1,25(OH)_2D$ (the active hormone) may still be normal, depending on the severity of the condition. Kidney disease will lead to low serum $1,25(OH)_2D$ levels, while serum 25(OH)D may be normal.

Vitamin D Insufficiency and Seasonal Variation in Biosynthesis

A role for vitamin D insufficiency, rather than a frank deficiency, in the elderly is now being recognized as a contributing factor in low bone mass and associated fractures in the aging population. The age-related reduction in synthesis of vitamin D in elderly women and men living in institutions or confined to the home is often made worse by limited exposure to direct sunlight and a decreased intake of vitamin D. The dietary intake of vitamin D may be particularly low in Europe, in comparison with the USA where most dairy products are fortified with vitamin D. Supplements of vitamin D and calcium have proved effective at increasing bone mineral density while decreasing the rate of hip and other nonvertebral fractures in nursing-home residents in Europe.

Large numbers of elderly residents in the northern parts of North America and of Europe have been shown to have depressed circulating levels of 25-(OH)D and, in some reports, also low serum concentrations of $1,25(OH)_2D$, particularly during winter. Such seasonal differences have become well established in these geographic regions, but $1,25(OH)_2D$ insufficiency without symptoms of a full-scale deficiency have only recently been documented. Because of the increasing life spans of so many elderly people, and because so many of them reside in nursing homes or similar facilities which permit little exposure of residents to sunlight, frank deficiency of vitamin D is likely to become more common and may even reach epidemic proportions. The public health consequences of osteomalacic bone tissue and increased fracture incidence could be enormous. Accordingly, some investigators have raised

questions about the adequacy of the current allowances of vitamin D for the elderly.

Secondary Causes

Causes of rickets and osteomalacia include not only insufficient dietary intake of vitamin D or inadequate exposure to sunlight, but also diseases that may interfere with absorption and biotransformation of vitamin D_3 or D_2, as well as conditions leading to decreased tissue responsiveness to the hormone and to renal loss of phosphate (Figure 1). In fact, relatively few cases of rickets in the western world today are due simply to inadequacy of supply of vitamin D, and most of these are due to strict dietary or religious practices that involve vegetarian diets devoid of sources of vitamin D or dress codes that prevent exposure of the skin to sunlight.

Patients suffering from malabsorption of fats may have inadequate absorption of vitamin D from the small intestine. Liver disease may interfere with the conversion of vitamin D to 25(OH)D. Patients whose kidneys have been removed or are severely diseased will have decreased vitamin D hormone production and may develop osteomalacia.

Finally, inborn errors of metabolism may also lead to rickets. Vitamin D-dependent rickets type I is caused by a defect in the kidney enzyme 25(OH)D-1-hydroxylase, which is responsible for the synthesis of $1,25(OH)_2D$. In vitamin D-dependent rickets type II the receptor for $1,25(OH)_2D$ is defective and cannot mediate the genomic action of the hormone. In a third condition, called X-linked hypophosphatemia, defects occur in the renal reabsorption of phosphate, leading to low circulating phosphate levels. Rickets and osteomalacia are present in this condition despite the presence of normal adult plasma $1,25\text{-}(OH)_2D$ concentrations.

Public Health Consequences of Vitamin D Deficiency

Vitamin D, derived either from the diet or skin production, has become an increasingly important molecule in human function because of the extended longevity of human populations in many nations.

Much greater efforts by health organizations are needed to reduce the incidence and prevalence of rickets and osteomalacia in both the developing and the developed nations of the world. Assurance of adequate calcium intakes must be the first priority, and then emphasis needs to be placed on daily sunlight exposure for infants and children.

In recent years, supplements of vitamin D (400 IU or greater) have been increasingly recommended for elderly people, especially those who have become institutionalized or shut-in because of limited mobility or confining conditions and diseases. Since the elderly have declining capabilities of skin biosynthesis and vitamin D conversion, larger doses of vitamin D supplements are being recommended for this section of the population. This recommendation is supported by findings of low circulating blood concentrations of 25(OH)D or $1,25(OH)_2D$. Such low blood levels of vitamin D metabolites are now being defined as characteristic of vitamin D insufficiency rather than frank deficiency.

Oral therapy with 1α-hydroxycholecalciferol has become fairly widespread in the USA among elderly subjects with low bone mass or fractures. The 1α form must be converted in the liver to $1,25(OH)_2D$ by 25-hydroxylation. Dosages are generally low because of concerns about toxic effects. The efficacy of this therapy has not yet been fully evaluated.

Life-Cycle Changes in Vitamin D Production and Metabolism

The skin production of vitamin D does not remain constant throughout the life cycle, and it depends on the changes in the skin tissue itself as well as the environmental conditions in which people live. The skin of older individuals has considerably less capacity, for example, to produce vitamin D from its precursor. In the elderly, the concentration of 7-dehydrocholesterol is diminished, and the rate of conversion to vitamin D_3 is also reduced. When one considers that the elderly usually have reduced sun exposure as well, it becomes clear that they are at great risk of developing vitamin D insufficiency unless they have an adequate dietary supply of vitamin D.

Alterations in the vitamin D endocrine system in old age, such as a decrease in circulating $1,25(OH)_2D$ levels, have been implicated in the pathogenesis of postmenopausal osteoporosis, because reduced serum $1,25(OH)_2D$ levels have been found in some women afflicted with this condition. However, there is no evidence indicating a general age-related decrease in serum $1,25(OH)_2D$ concentration. A recent study of a large group of healthy white adults ranging in age from 20 to 94 years revealed no decline in serum 25(OH)D or $1,25(OH)_2D$ concentrations in either sex. In another study, involving women aged 26–88 years, serum $1,25(OH)_2D$ levels were actually higher after age 65 years than in the youngest subjects, but the rate of intestinal calcium absorption was unaltered, suggesting decreased responsiveness to the hormone with increased age followed by a compensatory increase in hormone synthesis.

Special Problems of Low Vitamin D Intakes

Four categories of individuals who may have significant deficiencies of vitamin D, whether from inadequate diet or insufficient skin exposure, are the elderly, strict vegetarians (vegans), infants and young children who have been maintained on breast milk for periods of a year or longer, and migrant populations. Each of these groups is characterized below.

Elderly

Elderly individuals typically stay indoors most of the time, and some may even be shut-ins who need routine assistance with activities of daily living. It is this latter group of elderly who are most likely to be vitamin D-deficient and who need daily supplementation of vitamin D, independent of season and latitude of their homes, as well as calcium supplementation. Low circulating serum 25(OH)D concentrations provide a strong indication of secondary hyperparathyroidism and bone loss. Long-term vitamin D treatment may improve bone health both by enhancing intestinal calcium absorption and reducing secondary hyperparathyroidism. An elderly group of women living in nursing homes in Lyons, France, had significant hypovitaminosis D that was readily corrected by administration of a combination of vitamin D (800 IU day^{-1}) and calcium (1200 mg day^{-1}) for 18 months, at which time nonvertebral fractures were significantly reduced.

Vegetarians

Vegans are at risk of vitamin D deficiency if they have little or no exposure to sunlight, because they typically consume unfortified plant foods. In addition to the risk of osteomalacia, vegans have other nutritional risk factors that put them at greater risk for osteoporosis.

Long-Term Breast-Fed Infants and Young Children

Rickets is occasionally reported in the USA in infants who are breast-fed for long periods of time. Breast milk is low in vitamin D and these nursing infants are given no other source of vitamin D in their diets. The risk of vitamin D deficiency is even greater in infants with dark skin, as increased skin pigmentation has also been established as reducing the skin's biosynthesis of vitamin D.

Migrant Populations at Risk

Other groups at risk for vitamin D deficiency are dark-skinned populations, especially Muslims, from the Middle East or other Asian nations who have migrated to the UK and other northern European countries. These immigrants are vulnerable to vitamin D deficiency because of inadequate exposure of their skin to sunlight and little or no consumption of vitamin D-fortified dairy products. Cultural practices result in adults, as well as children, wearing clothing that allows very little skin exposure to sunlight. Supplementation with vitamin D and calcium is effective in improving bone health in these populations.

Summary

While no accurate estimates of the prevalence of either rickets or osteomalacia exist, hypovitaminosis D is probably underdiagnosed in otherwise reasonably healthy adults, certainly in hospitalized adult patients. The strong assumption is that vitamin D consumption, and/or skin exposure for vitamin D biosynthesis, are insufficient to permit adequate formation of 25(OH)D, the circulating store of this fat-soluble nutrient. The result of a low 25(OH)D level is a fall in serum calcium and a continuous elevation of serum parathyroid hormone concentration. (Parathyroid hormone is the culprit responsible for increased bone turnover and decreases in bone mass and bone density.) Correction of this problem can be simply made by treatment with vitamin D supplements, typically accompanied by calcium supplements, and the consumption of vitamin D-rich foods, fortified or not. Prevention of this condition among older populations, however, appears currently to be woefully inadequate.

RIPENING OF FRUIT

A R N Teixeira and R M B Ferreira, Universidade Técnica de Lisboa, Tapada da Ajuda, Lisboa Codex, Portugal

Introduction

Most fleshy fruits attain physiological maturity at an unripe state unsuitable for immediate consumption. The ripening process that follows, either on the tree or after picking, is the result of a number of physiological and biochemical processes which are revealed in a sequence of changes in color, texture, aroma, and taste, leading eventually to a physiological state at which the fruit is commercially considered as edible. However, in the context of sensorial changes the meaning of ripening is rather ambiguous as it is based on a subjective appreciation of a very intricate process that involves a number of metabolic changes. **Table 1** illustrates some of the most important organoleptic and physiological changes that occur during ripening and the biochemical processes most likely to be responsible for them.

The ripening process is mainly concerned with changes in components formed during fruit growth and development. So, many fruits are able to ripen after being detached from the mother plant, provided physiological maturity has been attained before picking.

Respiratory Patterns – Climacteric and Nonclimacteric Fruits

Even after detachment from the plant, fruits continue to display for some time the metabolic activities characteristic of living organisms. As changes in respiratory rates are good indicators of alterations in general metabolism, fruit respiration is useful as a reference to physiological state, which determines the potential storage life of a fruit. The first systematic studies of fruit respiration were carried out by Kidd and West in the 1920s with Bramley Seedling apples. Fruits, picked at different stages of development and stored at various temperatures, exhibited a typical respiratory pattern characterized by a decline in the respiration rate after picking which, sooner or later, depending on the storage temperature, was followed by a temporary rise in respiration (Figure 1). The visible changes normally associated with ripening (color, texture, and flavor) began at or shortly after the maximum rate of respiration. The sudden change in the respiration rate was recognized by Kidd and West as a critical phase in the life of the fruit, denoting the transition from maturity to senescence, and was named 'climacteric.' The same authors showed later that a similar increase in respiration also occurred in apples attached to the tree. In this situation the rise in respiration takes place at a slower rate but, eventually, reaches higher peaks than those attained by the detached fruits. Subsequent work indicated that many other ripening fruits exhibit a similar pattern of respiration, most of them, mainly tropical and subtropical fruits, displaying higher climacteric peaks than apples (Figure 2a). On the other hand, some fruits show a continuous decline in respiration throughout maturation and ripening (Figure 2b) and have been termed 'nonclimacteric.' A list of commercially important climacteric and nonclimacteric fruits is given in Table 2.

Table 1 Organoleptic and metabolic changes that occur during ripening

Organoleptic and physiological changes	*Biochemical changes*
Texture	Rise in water-soluble pectins and decreasing degree of esterification through pectolytic activity. Partial cellulose breakdown
Color	Degradation of chlorophyll and unmasking of underlying pigments. Synthesis of new pigments (carotenoids or anthocyanins)
Aroma and taste	Qualitative and quantitative changes in carbohydrates and organic acids. Synthesis of alcohols, esters, and other volatile compounds
Rise in respiration	Autocatalytic synthesis of ethylene. Increased protein synthesis and altered metabolic control of respiratory pathways

Table 2 Fruits with climacteric and nonclimacteric patterns of respiration

Climacteric	*Nonclimacteric*
Apple	Blueberry
Apricot	Cacao
Avocado	Cherry
Banana	Cucumber
Mango	Grape
Papaya	Grapefruit
Peach	Lemon
Pear	Lychee
Plum	Olive
Tomato	Orange
Watermelon	Pineapple
	Strawberry

Climacteric Behavior and Ethylene Production

It was recognized early in this century that ethylene can cause physiological responses in various plant tissues. The suggestion that fruit tissues themselves release gaseous substances that may affect the ripening behavior of nearby fruits was made by Coussins, who reported, in 1910, that gases emanating from oranges caused premature ripening of bananas. It was later showed that the active substance released by ripening fruit was ethylene and that in most climacteric fruits the rise in ethylene production occurred at or prior to the beginning of the respiratory upsurge. So the gas was considered responsible for the initiation of the climacteric and the related ripening processes and was named the 'ripening hormone.'

The climacteric or nonclimacteric behavior of fruits has been associated with the capacity of their tissues to synthesize ethylene. In climacteric fruits the respiratory increment is always accompanied, and often preceded, by an increase in ethylene levels within their tissues. This increase in endogenous ethylene induces an autocatalytic process of ethylene synthesis that, apparently, triggers off the respiratory upsurge of climacteric fruits. On the other hand, in nonclimacteric fruits the ethylene levels are always low and usually tend to decrease slowly during ripening at a rate approaching the rate of diminishing respiration. Climacteric and nonclimacteric fruits also differ in their responses to ethylene applied exogenously. The autocatalytic response of climacteric fruits to applied ethylene leads to the onset of climacteric respiration which, once initiated, cannot be stopped. Even if the exogenous gas is removed, the endogenous levels of ethylene will continue to increase once its catalytic synthesis starts. Thus, the respiratory rate at the climacteric peak does not depend upon the concentration of ethylene initially present. The respiratory rate of nonclimacteric fruits also responds to the application of exogenous ethylene, but does not exhibit an autocatalytic effect. Thus, in nonclimacteric fruits, the magnitude of the response varies proportionally to the concentration of the gas applied and the process can be reversed; that is, the respiration rate decreases to basal levels upon

removal of ethylene, and can be reproduced by renewed applications of the gas. Nevertheless, the application of exogenous ethylene accelerates the ripening in nonclimacteric fruits as it does in climacteric fruits when furnished in the preclimacteric phase.

The belief that ethylene is the only substance directly responsible for the climacteric rise in respiration and the ensuing ripening has recently been under close reexamination. The existence of a strong link between ethylene and respiration is well documented in the literature, being observed in many other plant tissues besides fruits. However, other volatile substances that are produced during ripening when applied exogenously may mimic the respiratory changes caused by ethylene. On the other hand, the onset of increased ethylene synthesis does not always precede the respiratory upsurge in climacteric fruits. The literature reports a variety of fruits in which the increase in ethylene production either coincides with (e.g., Cox's Orange Pippin apples and Anjou pears) or follows (e.g., avocado var. Fuerte and plum var. Wickson) the rise in respiration. It has been suggested that, in these fruits, ethylene is not the only factor that determines the initiation of the climacteric and of ripening. The minimum ethylene production rate that triggers off the rise in respiration, although varying between species and cultivars, is always very low (frequently less than 1 μl kg^{-1} h^{-1}, which is approximately equivalent to an internal concentration of 2 p.p.m.). So, the accurate determination of the relative timing of initiation of the rises in the rates of ethylene synthesis and respiration is rather difficult, particularly if, at this stage, other substances are being formed whose effects add up to those of ethylene. Notwithstanding the evidence suggesting that the stimulation of respiratory activity in fruits and other plant tissues may be induced by a number of factors, in the majority of climacteric fruits the autocatalytic ethylene synthesis begins before the respiratory upsurge and in most nonclimacteric plant tissues respiratory activity is tightly coupled to ethylene concentrations. Apparently, ethylene stimulates metabolism in general and may alter the control mechanism of existing metabolic pathways and induce changes in gene expression.

Climacteric Behavior and Ripening

If the link between ethylene and climacteric respiration is partially resolved, the role of the climacteric respiratory rise in ripening remains obscure. It is now evident that many of the physiological changes associated with ripening (e.g., softening, color changes, and ethylene synthesis) can be, with some manipulation, separated from the respiratory climacteric. Thus, some fruits can initiate softening and pigment synthesis without an increase in respiration and the application of certain plant hormones and of protein synthesis inhibitors may prevent ripening changes without obviating the climacteric rise in respiration. Such observations do not support the opinion that the increased rate of respiration supplies the extra adenosine triphosphate (ATP) required as the energy source for physiological transformations that occur during ripening, such as synthesis of proteins, nucleic acids, and pigments. In fact, the estimated energy demands of ripening are much lower than those provided by climacteric respiration; apparently, the energy generated by the basal respiratory rate is sufficient to drive the ripening events.

The evidence does not uphold the existence of an integrated relationship between the respiratory climacteric and ripening, but rather suggests that the rise in respiration during ripening may simply be a facet of ethylene action. The suggestion that ethylene may act by lowering the organizational resistance of the cell, mainly by increasing membrane permeability, has some experimental support. On the assumption that fruit tissues, like other living tissues, react to any injurious situation by changing their metabolism in order to maintain a homeostatic condition and that such changes are driven by respiration, it has been suggested that the respiratory climacteric is largely a homeostatic response, in an attempt to counterbalance the injury imposed on mitochondria by the initiation of senescence. That is, the degradative effects of incipient cellular senescence, probably accelerated by ethylene, impose a stress on mitochondria which leads to an increased respiratory rate. Such a suggestion is supported by the fact that mitochondrial structure and function, including coupling, are kept intact throughout the ripening process.

Effects on Texture

The texture of a fruit depends on the turgor of the cells as well as on the presence of supporting structures like cell walls and the cohesiveness of the cells. The latter property is conferred by the middle lamella, the intercellular structure that cements together the primary walls of contiguous cells and that is composed mainly of pectic material. Structurally, fruit cell walls are similar to primary cell walls of other plant tissues whose main components are polysaccharides, namely cellulose, hemicelluloses, and pectins. Essential for the structural integrity of cell walls is the presence of calcium. Calcium ions are particularly important in cell-to-cell adhesion, the cementing effect being primarily attributed to the formation of a calcium–pectate complex in the

middle lamella. The role of calcium in the maintenance of cell wall structure is particularly important in fruits in which the middle lamella gives a larger contribution as a cell wall component than in other plant tissues. The extensive softening that takes place during the ripening of many fruits is mainly attributed to changes occurring in cell walls, including the middle lamellae. (*See* **Cellulose; Hemicelluloses**.)

In ripe fruit, cell walls and middle lamellae are partly dissolved as a result of the action of a number of enzymes that break down pectins and cellulose, of which polygalacturonase, pectinesterase, and cellulase are the most extensively studied and whose activities are often correlated with the rate at which softening occurs during ripening. It is apparent from such studies that the major changes occurring in cell walls during ripening are associated with depolymerization and solubilization of the pectic substances due to the action of polygalacturonase and pectinesterase, respectively. The solubilization of pectin during the ripening of apples has been attributed to diminished levels of calcium ions in the cell walls and there is evidence that the softening of the apple fruit is associated with the transfer of divalent cations, particularly calcium, from the cell wall into storage compartments inside the cell. Postharvest calcium treatments that are carried out to prevent some physiological disorders, such as bitter-pit in apples, confer greater firmness to the fruits during storage.

The role of cellulase in tissue softening is not clear. Though it seems likely that hydrolysis of cellulose would weaken the cell wall structure, the experimental evidence is rather inconclusive as to its importance as a primary cause of fruit softening.

Effects on Sweetness

In fresh fruits the main compounds responsible for sweetness are soluble carbohydrates, i.e., sugars. It is apparent from the degree of sweetness of different ripe fruits that their sugar contents vary widely. Even within a particular species the sugar concentration in fruits may depend on the variety and on the environmental conditions and agricultural practices to which the mother plant has been subjected, prior to harvesting. As most climacteric fruits are harvested before ripening, considerable changes in sugar content may occur during storage. The average total sugar contents of most ripe fruits lie in the range 5–10% of fresh weight. Outside this range are, typically, lime and lemon with lower sugar contents (0.5–3.0%), and grape, cider apple and other fruits used for alcoholic fermentation purposes with higher contents (13–20%). (*See* **Carbohydrates**: Classification and Properties.)

The main individual sugars responsible for sweetness in fruits are the monosaccharides glucose and fructose and the disaccharide sucrose. Further monosaccharides may also be present in fruits, but their contribution to sweetness is negligible. The relative proportions of glucose and fructose vary with species but in many fruits glucose levels exceed those of fructose. This does not necessarily mean a higher contribution of glucose for sweetness since the sweetening power of glucose is 2–3 times lower than that of fructose. Two important exceptions are apples and pears in which fructose may be present in concentrations up to three times those of glucose. In grapes, berries, and oranges, both sugars are often present in similar amounts. (*See* **Fructose**; **Sucrose**: Properties and Determination.)

Sucrose is an important product of photosynthesis and the main form in which carbon is translocated from the leaves to other parts of the plant, including fruits. So, it is not surprising that in most fruits sucrose is the main respiratory substrate utilized for the provision of energy and intermediary metabolites for biosynthesis. The first step in the metabolism of sucrose, catalyzed by β-fructofuranosidase (invertase), is the hydrolysis of the disaccharide to glucose and fructose. These facts explain the predominance of glucose, fructose, and sucrose in most fruit tissues. The sucrose concentration varies from fruit to fruit but in most fruits the total hexose content exceeds that of sucrose, and in some fruits (e.g., cherry, grape, and tomato) sucrose is almost absent.

A significant fraction of the sugar translocated to the growing fruit is metabolized and used in various biosynthetic processes, another fraction being stored after conversion into starch, the most common reserve carbohydrate in plants. Starch breakdown is one of the most important biochemical changes that occur during the ripening of many fruits. Some fruits may contain, when mature but unripe, large amounts of starch, the levels of which decrease dramatically during ripening. For instance, bananas may contain up to 20% starch at the mature green stage and less than 1% when fully ripened. Large reductions in starch content also occur during the ripening of other fruits, notably mango, apple, and pear. The increased levels of sucrose, glucose, and fructose present in such fruits when ripened result primarily from the enzymatic hydrolysis of starch. However, some fruits do not accumulate starch during their development, attaining their mature unripe state with little or no starch at all (e.g., melon, pineapple, plum, and grape). In these fruits, carbohydrates are stored in the form of soluble sugars, their sweetness depending, largely, on the transport of sucrose from other parts of the plant, leaves being usually the main source.

Consequently, the optimum sugar content of these fruits cannot be reached if they are harvested before ripening. (*See* **Starch**: Structure, Properties, and Determination.)

Effects on Aroma and Taste

Aroma and taste are considered to be the two major components of flavor, a rather subjective attribute to which all the other senses contribute in an integrated manner. Most of the changes in aroma and taste, together with changes in color and texture, that are responsible for the commercial acceptability of fruits take place during the ripening process. (*See* **Flavor (Flavour) Compounds**: Structures and Characteristics.)

In spite of the important advances in flavor chemistry made in the last decades, our understanding concerning the metabolism of the compounds involved and the way they interact in the perception of aroma and taste is very incomplete. Aroma, being the sensation associated with smelling, requires the presence of volatile, relatively hydrophobic compounds. On the other hand, substances responsible for taste and other nonspecific saporous sensations are water-soluble and most nonvolatile, usually being present at higher concentrations than those responsible for aromas.

Despite the relatively low lipid contents of most fruits, lipid metabolism plays an important role in a number of ontogenic events, including ripening and senescence. Many of the most important aliphatic fruit volatiles are formed through an oxidative degradation of unsaturated fatty acids such as linoleic and linolenic acids. For instance, the action of lipoxygenase and a lyase on linolenic acid leads to the formation of 2-*trans*-hexenal or 2-*trans*-6-*cis*-nonadienal (depending on the site-specificity of the enzymatic attack), these being important aroma constituents of tomatoes and cucumbers, respectively. The aldehydes and ketones generated by lipoxygenase action can be converted further, by the action of dehydrogenases, to the corresponding alcohols, which usually have stronger aromas than the parent carbonyl compounds. For example, the dehydrogenation of 2-*trans*-6-*cis*-nonadienol gives 2-*trans*-6-*cis*-nonadienal, which is important in the aroma of cucumbers and melons.

The class of compounds that most frequently makes the major contribution to the pleasant fruity aromas developed during ripening is the esters of carboxylic acids. These are generated by esterification of the alcohols formed by reduction of the aldehydes derived either from oxidation of long-chain fatty acids or from amino acids. The mechanism of ester formation has not been satisfactorily explained but it is thought that esterification of the alcohols occurs with acyl-coenzyme A derivatives of fatty acids acting as acyl donors. While all the esters present may contribute to the characteristic aroma, certain individual esters have been associated with the aroma of specific fruits (Table 3). Some exceptions are known. For example, the aroma of peaches is attributed to the presence of lactones and that of raspberries to the ketone 1-(*p*-hydroxyphenyl)-3-butanone.

Volatile terpenoids are largely responsible for the characteristic aroma of citrus fruits. The monoterpenes citral and limonene exhibit distinct aromas of lemons and limes, respectively. Sesquiterpenes are also characteristic aroma compounds, such as β-sinensal in oranges and nootkatone in grapefruits.

Of the four basic taste sensations (sweet, sour, bitter, and salt), the dominant changes that occur during fruit ripening involve an increase in sweetness and a decrease in sourness (mainly due to acidity). However, changes in bitterness (due to terpenoids) are important in citrus fruits, as are changes in astringency (a taste sensation due to the association of phenolic substances, including tannins, with proteins in the saliva) that occur during the ripening of bananas, grapes, and other fruits. The changes in the concentration of acids during fruit development and ripening differ with the type of fruit. The optimal acidity is rather high for citrus fruits, somewhat less for pome fruits, and even less for tomatoes. Most fruit tissues accumulate excess acid in the preripening stage of development but, when ripe, each fruit has a range of acid-to-sugar ratio corresponding to optimum taste. In most fruits, citric and malic acids are the major contributors to the desired degree of acidity. (*See* **Acids**: Properties and Determination; **Phenolic Compounds**.)

In postharvest fruits, as in other plant living tissues, organic acids are in a constant state of flux. They may arise or be used up through the operation of

Table 3 Volatile esters associated with the aroma of individual fruits

Ester	*Fruit*
Benzyl benzoate	Cranberry
Ethyl butanoate	Orange
Ethyl 2-methylbutanoate	Melon
Ethyl 3-methylbutanoate	Blueberry
Isopentyl acetate	Banana
Methyl anthranilate	Concord grapes
Ethyl 2-methylbutanoate	Apple
Methyl (3-methylthio)propanoate	Pineapple
Methyl and ethyl derivatives of *trans*-2-*cis*-4-decadienoate	Bartlett pear

glycolysis, the citric acid cycle and, possibly, the glyoxylate cycle. Much of the loss of organic acids observed during ripening is attributed to their oxidation in respiratory metabolism as suggested by the increased respiratory quotient (RQ, the ratio of carbon dioxide evolution to oxygen absorption) during the climacteric. The RQ is approximately 1.0 when sugars are the respiratory substrates, increasing to about 1.3 when malate or citrate is the substrate, and further increasing to 1.6 when tartrate is respired. The rise in RQ during the climacteric is often accompanied by an increased activity of certain decarboxylation enzymes, such as malic enzyme and pyruvate decarboxylase. There is evidence that malic enzyme is synthesized *de novo* during the climacteric of pome fruits.

Changes in Color

During the ripening of almost all fruits there occurs a disruption in the organization of chloroplasts and their reorganization into chromoplasts. As the photosynthetic apparatus is dismantled and the chlorophyll degraded, the color of existing carotenoids is unmasked. This phenomenon may be responsible for the yellow-to-red colors of the ripe fruits, as in bananas where yellowing is due to the unmasking of carotenoids as a consequence of chlorophyll degradation. Although carotenoids are normally synthesized in green tissues, in most fruits that contain carotenoids ripening is accompanied by increased biosynthesis. During postharvest storage such synthesis may be affected by the surrounding atmosphere (decreased oxygen and increased carbon dioxide or nitrogen concentrations inhibit pigment development in the endocarp of some cultivars of oranges and in tomatoes), by light (it appears that light may stimulate its synthesis but it is not required for its induction; in detached green tomatoes it has been shown that light increases carotenoid synthesis, and red light is more effective than white or green light; far red light has an inhibitory effect which suggests a phytochrome-mediated response) and temperature (its effects vary from fruit to fruit but in most cases the optimal temperature for carotenoid synthesis is relatively low; it is around 24 °C for lycopene formation in tomatoes, the pigment not being formed above 30 °C but in other fruits in which lycopene is the main carotenoid, such as watermelons and red grapefruits, its synthesis is not affected by temperature). (*See* **Colorants (Colourants)**, Properties and Determination of Natural Pigments.)

The color of many ripe fruits, including pomes, several types of berries, grapes, oranges, cherries, peaches, plums, bananas, and figs, is due to the production of anthocyanins. These are conspicuous water-soluble plant pigments of phenolic character that accumulate in the vacuoles and are responsible for the pink, red, violet, and blue colors of fruits, flowers, and vegetables. The colours of anthocyanins are strongly affected by pH and can be intensified and stabilized by intermolecular associations with a number of metal ions such as those of aluminum, iron, manganese, and copper. The anthocyanins are typically located in the epidermal layers of the fruits but, like carotenoids, may also be present in the flesh. Anthocyanin synthesis during ripening is strongly stimulated by light. Apparently, this stimulatory effect has at least two mechanisms. By increasing the photosynthetic rate, light increases the availability of the carbohydrate needed to supply the energy and building blocks for anthocyanin biosyntheis. The second photoreaction involves the activation of phytochrome, a photoreceptor pigment that mediates several physiological processes in plant cells, including the synthesis of anthocyanins. Preharvest applications of some growth regulators, such as alar (*N*-dimethylaminosuccinamic acid), can induce earlier formation of anthocyanins in fruits.

Postharvest Storage of Fruits

After picking, the ripening of fruits can be controlled by temperature adjustment or by changing the concentration of gases (usually carbon dioxide and oxygen) in the surrounding atmosphere. These two major methods of fruit storage are usually referred to as 'air refrigeration' and 'controlled-atmosphere storage,' respectively, the latter being normally combined with some degree of refrigeration. Although effective in retarding ripening, both methods of environmental control impose stresses on fruits that may lead to different types of physiological disorders.

Low-temperature Storage

Lowering the storage temperature is one of the commonest methods for extending the shelf-life of fruits. With the exception of tropical and subtropical fruits, the lowest temperature that, in theory, still permits normal metabolism is near the freezing point of a fruit, which in most cases lies between 0 and −2 °C. The reduction of storage temperature decreases the rate of respiration and of metabolism in general by its direct effect on the rate of the enzyme-catalyzed reactions. In climacteric fruits, low-temperature storage also delays the onset of ripening by retarding the autocatalytic production of ethylene and so extending the preclimacteric phase of ripening. Lowering the temperature also reduces the degree of response to exogenous ethylene.

Controlled-atmosphere Storage

A decreased rate of respiration and of other metabolic reactions, including ethylene synthesis, can also be achieved by altering the composition of the atmosphere in which the fruits are stored, usually by increasing the carbon dioxide and decreasing the oxygen concentrations. In controlled-atmosphere storage the proportion of the gases is carefully controlled, usually within $\pm$ 1% of the desired value. When the control of the gas concentrations is less accurate, the practice is named modified-atmosphere storage. For example, in a confined atmosphere the carbon dioxide-to-oxygen concentration ratio may be increased simply as a consequence of the normal respiratory process or by sublimation of solid carbon dioxide (dry ice). Another type of controlled-atmosphere storage is hypobaric storage in which the fruits are kept in partial vacuum (0.1–0.3 atm). The decreased partial pressure of oxygen and the reduction of internal ethylene levels due to the increased diffusibility of the gases formed within the tissues retard the ripening of the fruits. (*See* **Controlled-atmosphere Storage**: Applications for Bulk Storage of Foodstuffs.)

The efficacy of controlled-atmosphere techniques in extending the storage life has been well demonstrated for a number of fruits. Nevertheless, their commercial use has been somewhat limited. Controlled-atmosphere techniques are expensive and some of the more profitable fruits either do not respond favorably to atmosphere regulation or have such a rapid market turnover that the need for an improved storage procedure is curtailed. Nevertheless, conventional controlled-atmosphere storage is currently used for apples and pears and the practice of modified-atmosphere consumer-sealed packs is becoming more popular due to the discovery of new packaging materials having a selective gas permeability that allows the retention of adequate gas concentrations when equilibrium is reached. Hypobaric storage is successfully employed in the storage of cut flowers but, to our knowledge, it has not been utilized for the commercial storage of fruits. (*See* **Chilled Storage**: Use of Modified-atmosphere Packaging.)

Physiological Disorders

Different fruit species or even different cultivars of the same species may exhibit different tolerances to low temperatures and to modified atmospheres. Exposure of a particular fruit either to a temperature or to an atmosphere with a carbon dioxide-to-oxygen concentration ratio outside the recommended range usually causes injuries that lead to a decrease in both quality and storage life. The extent of such injuries depends strongly on the duration of exposure.

The mechanism by which physiological disorders are induced is not well understood. Chilling injuries are generally attributed to a deregulation in metabolism leading to the underproduction of some essential metabolites and the overproduction of substances whose accumulation has toxic effects. For example, accumulation of ethanol, acetaldehyde, and oxaloacetic acid has been associated with low-temperature breakdown of certain fruits, such as apples. Visible effects of cold injury include tissue necrosis, surface pitting, internal browning, and failure to ripen. Some fruits (e.g., pears) normally exhibit a low susceptibility to cold injury, but for most fruits there is a critical temperature below which the fruits may be damaged, particularly if submitted to prolonged exposure. As recovery may often take place after short exposures to potentially damaging temperatures, it is believed that a minimum time of continuous exposure is required for injury to occur. In fact, interrupted exposures are often effective in diminishing damage. The lower temperature limit tolerated by fruits varies with their origin. Many fruits from temperate regions (e.g., apples) may tolerate temperatures in the range 0–4 °C, whilst the banana becomes susceptible at temperatures below 12 °C. Subtropical fruits, such as pineapples, avocados, and citrus fruits, show intermediary limits, often below 8 °C.

Identical metabolic imbalances are induced by extremes in atmospheric composition. Toxic levels of ethanol, acetaldehyde, and succinic acid have been shown to accumulate in certain fruits prior to injury symptoms. Some fruits, such as citrus and pome fruits, are rather susceptible to high carbon dioxide levels and the use of low carbon dioxide concentrations (1–5%) is recommended. For more tolerant fruits, such as cherries, grapes, plums, and strawberries, higher concentrations (15–30%) are usually advised. During storage, a minimum concentration of oxygen is required to support respiration. Below this level, anaerobic metabolism takes over and ethanol is produced. Although many fruits appear to tolerate oxygen concentrations below 5%, the exact limit for normal ripening is variable, depending on carbon dioxide concentrations, temperature, and duration of exposure.

Ionizing Radiation

Although this remains an isolated rather than an extensive method of food preservation, the application of ionizing radiation is effective in delaying the ripening of fruits. Depending on the fruit, doses of 0.3–3.0 kGy can prevent, temporarily or permanently, the onset of fruit ripening. However, the minimum dose required to achieve this effect often

exceeds the maximum tolerable dose. Even when successful in prolonging storage life, fruit irradiation is frequently hampered by a rapid softening of the tissues, possibly due to a direct or indirect activation of pectic enzymes. Actually, the mechanisms responsible for the observed effects of ionizing radiations on fruits are far from clear, but this is not surprising if one considers how numerous are the doubts over the biochemical and physiological control of fruit ripening even under normal conditions. RISK ASSESSMENT

C L K Chan, Safe Food Production NSW, Sydney, Australia

Risk Assessment Applied to Food Safety

As its name implies, risk assessment involves the evaluation of risks. The techniques for achieving this have been developed, improved, and utilized over many decades in a variety of fields, including the insurance industry, financial market analysis, project management, and environmental impact on public health. In recent years, there has been rapidly growing interest in applying risk-assessment techniques to food safety. In this context, the risk referred to is the risk of food-safety hazards causing human diseases.

Food may contain a myriad of hazards that can cause a variety of adverse health effects, ranging from mild symptoms through to serious illnesses and injuries and, in extreme cases, death. These hazards are usually classified as physical, chemical, or biological. Physical hazards may include fragments of glass, metal, plastic, or bone that could sustain injury or choking when the food is ingested. Chemical hazards include contaminants such as environmental pollutants, chemical residues derived from packaging material or product contact surfaces, as well as residues of agricultural or veterinary chemicals used in association with food production. Natural toxins are also chemical hazards in some food. Biological hazards are due predominantly to bacterial or viral pathogens but may also include other microorganisms such as nematodes and algae. The number of

food safety hazards that can potentially be present in food is large, and the complete elimination of them to achieve zero risk is not practically possible.

Risk is defined as a function of both the probability of a hazard causing an adverse health effect in consumers and the magnitude of that effect. Hence, it may be possible for a food to contain a certain pathogenic bacterium, by virtue of its exposure along the production and supply chain to different environments that may be sources of this pathogen. However, the risk of the microbiological hazard may be considered low because of a low probability and/or usually low level of contamination, low consumption of the food, and/or the minor nature of the ill effect that would be caused. Food producers, manufacturers, and the public generally have a notion of the magnitude and likelihood (hence risk) of various food-safety problems. This may be derived partly from experience and partly from impression. However, this is frequently unreliable. It has been demonstrated in surveys that the general public regard the issues of food irradiation and genetically modified food to be high-risk compared to problems of microbiological contamination, when reality is evidently quite the reverse.

Risk assessment provides a scientific framework for the estimation of food-safety risks, thus providing a reliable foundation for policy-making, strategy development, and practical management of food safety.

Risk Assessment: Principles and Practices

Risk assessment is defined as a process to evaluate scientifically the probability of occurrence and severity of known or potential adverse health effects resulting from human exposure to foodborne hazards.

Although the framework according to different organizations may vary somewhat, risk assessment generally consists of the following steps or components. These are:

1. Hazard identification: the identification of biological, chemical, and physical agents capable of causing adverse health effects and which may be present in a particular food or group of foods.
2. Exposure assessment: the quantitative and/or qualitative evaluation of the likely intake of biological, chemical, and physical agents via food as well as exposures from other sources, if relevant.
3. Hazard characterization: the qualitative and/or quantitative evaluation of the nature of the adverse health effects associated with the biological, chemical or physical hazard. Where possible, a dose–response assessment is performed. This is a determination of the relationship between the magnitude of exposure (dose) to a chemical, biological, or physical agent and the severity and/or frequency of associated adverse health effects (response).
4. Risk characterization: the process of determining the qualitative and/or quantitative estimation, including attendant uncertainties, of the probability of occurrence and severity of known or potential adverse health effects in a given population based on hazard identification, hazard characterization, and exposure assessment. The output of risk characterization is known as the risk estimate.

This framework represents a logical flow of thoughts in arriving at an estimate of food safety risks, as illustrated in Figure 1.

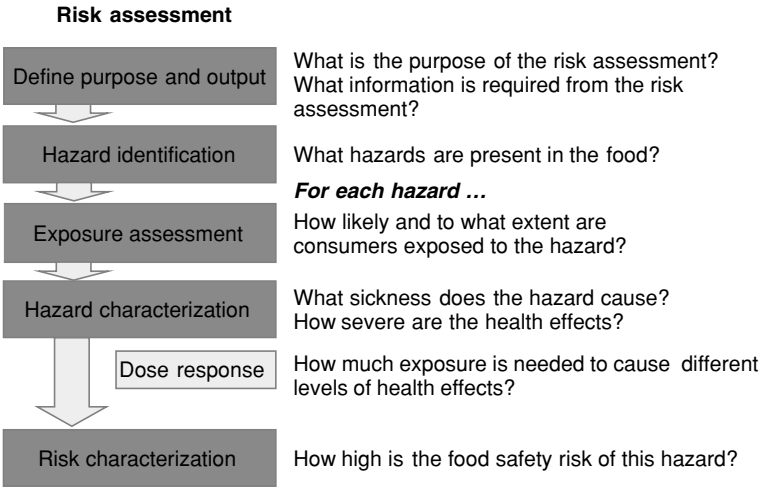

Figure 1 Components of risk assessment and the conceptual questions addressed.

A risk assessment analyzes the state of affairs at one point in time, utilizing the best available information at that time. As situations change, and significant new information becomes available, a reassessment or update should be carried out. A risk assessment can be thought of as a live and continuing process.

Risk Assessment of Chemical Hazards

In hazard identification, information as to what constitutes a hazard is frequently limited. The 'weight-of-evidence' approach is usually adopted, relying on a combination of relevant sources of information, including epidemiological studies, animal toxicological studies, *in-vitro* assays, and quantitative structure–activity relationships. In the majority of cases, clinical, and epidemiological data are unavailable or inadequate, and much reliance is placed on animal studies. These would include long-term chronic studies as well as short-term acute toxicity studies. They are designed to identify the range of toxicological effects, such as cancer, reproductive/developmental effects, neurotoxic effects, and immunotoxic effects. They can also provide information on the relevance of these effects for human risks through characterizing the mechanism of action. *In-vitro* studies may provide information on genotoxicity, pharmacokinetics, and pharmacodynamics.

One particular issue with animal toxicological studies is the need to use a relatively high dosage in order to identify the toxicological effects. However, realistic contamination levels in food are typically orders of magnitudes lower, and the significance of the identified health effects is uncertain. This can pose major issues for hazard characterization.

Animal experiments provide information on dosage at which no ill effects occur in the test animals; this is referred to as the 'no observed effect level.' A dose–response assessment would then need to extrapolate this animal data. There is much uncertainty in this, because the nature of the hazard and mode of human metabolism may change with dose, and the response in humans may be different to that of the experimental animals used. These uncertainties are compensated for with the use of safety factors. Frequently, a multiplication factor of 10 is used to accommodate the differences between how humans and animals might react to the hazard. Another factor of 10 is typically used to take account of the fact that some humans are more sensitive than others to the hazard in question. This yields an 'acceptable daily intake' (ADI) figure. If dietary exposure is below the ADI, it is assumed that there will be no ill effect. This is known as the 'threshold approach.' For genotoxic carcinogens, this approach is not considered appropriate, as it is assumed that there is a finite risk, even with the lowest possible dose. In such cases, a level of negligible/acceptable risk is set, frequently at one in a million.

Exposure assessment is carried out using diet studies. Direct monitoring of residues of the chemical hazard (e.g., organochlorine pesticides) in human tissues and body fluids is also gaining importance as a means of exposure assessment.

Risk characterization then draws on the outputs of hazard identification, hazard characterization, dose–response assessment, and exposure assessment to derive an estimate of the likelihood of adverse health effects in human populations as a consequence of the exposure. For threshold-acting hazards, risk is characterized by comparing exposure to ADI. Risk is notionally zero if exposure is lower than ADI. For nonthreshold acting hazards, risk is calculated as a function of exposure and potency.

As an example of how such a risk assessment can be used, a study may be carried out on the existing or proposed use of an agricultural or veterinary chemical in association with food-production animals. If the estimated risks are deemed unacceptable, consideration can be given to various possible risk-mitigation measures, such as means of reducing exposure. If the risks can be reduced to an acceptable level through such means, the chemical may be considered for registration. The setting of 'safe/tolerance levels' for various chemical residues in food is another application of risk assessment of chemical hazards.

Risk Assessment of Biological Hazards

Biological hazards include pathogenic strains of bacteria, viruses, helminthes, protozoa, and algae. Sometimes, toxins that some of these organisms may produce, e.g., enterotoxins produced by *Staphylococcus aureus* when growing to high numbers in food, are also grouped with biological hazards. Of these, foodborne pathogenic bacteria and viruses present, are by far, the greatest concerns in regard to food safety.

Microbiological risk assessment follows basically the same framework as chemical risk assessment. However, it has its unique set of difficulties and challenges. The list of foodborne pathogens is extensive, and pathogens can be found in abundance in the natural environment, including that for the production, harvesting, processing, storage, transportation, display, retail, and preparation of food. Some of the microbiological hazards, e.g., bacteria, can multiply rapidly in the food as it goes through the production and supply chain, whereas others can also produce toxins or form heat-resistant spores under certain conditions. The survival and proliferation of these

organisms are affected by the complexity of the food matrix, parameters of the manufacturing processes, as well as the temperature profile to which the food is exposed along the production supply chain. So, it is not unusual to find that a specific pathogen in a certain food matrix has caused many cases of foodborne illness, whereas the same pathogen in another food may rarely have been implicated. Moreover, the virulence and infectivity of microorganisms can change, depending on their interaction with the host and the environment. Genetic material can be transferred between microorganisms, leading to the transfer of characteristics such as antibiotic resistance and virulence factors. There is also evidence of very large differences in virulence between different strains of a pathogen, e.g., *Listeria monocytogenes*, that are almost impossible to distinguish by traditional taxonomic methods, and there are usually no easily identifiable virulence markers.

Human susceptibility to specific pathogens can also vary widely. For example, young, old, pregnant, and immunocompromised consumers are highly susceptible to the foodborne pathogen *Listeria monocytogenes*, but the healthy adult population is rarely affected. All these factors can make hazard identification even less clear-cut in comparison with identification of chemical hazards. Like the latter, epidemiological studies remain the most desired information base with which to advise biological hazard identification. Structure–activity relationship studies are used in the absence of, or in addition to, reliable epidemiological data. They compare the disease agent in question with a similar agent whose health effect is better understood.

Exposure assessment aims to define the pathway by which people will become exposed to the pathogen in the food, how much of the pathogen they are likely to ingest, and how frequently. This requires information on the occurrence rate and level of the pathogen in the food in question. These data are usually obtained by conducting microbiological surveys of the food. If surveys are not carried out at the point of consumption, predictive microbiology can be used to 'extrapolate' from the survey point (e.g., the end of production) to the point of consumption, based on typical temperature–time conditions to which the food is exposed, in order to estimate the dose exposure.

A dose–response assessment for microbiological hazards presents an even greater difficulty compared to chemical hazards. Human studies are very limited, and animal studies are generally not used. The relevance of the former is also restricted because of the variability in susceptibility between persons. There have been attempts to derive a dose–response relationship from available epidemiological data, but this approach has yet to be fully developed.

Risk characterization in microbiological risk assessment would include one or more of the following:

1. Risk estimate: depending on the purpose of the risk assessment, this may be expressed as a risk ranking of the hazards considered. This may be done in terms of high-, medium-, and low-risk categories, or in accordance with some arbitrary scale that would also show more quantitatively the relative risk levels. The risk estimate may also be expressed as the probability of human illness for defined exposure scenarios, e.g., in terms of x in a million chance of illness or x cases of illness per year in a specific population.
2. Characterization of uncertainty, variability, and confidence in the risk estimate: the uncertainties associated with each step or component of the risk assessment are identified and, if possible, quantified. Similarly, variability that reflects the heterogeneity of the population under consideration and the diversity in exposure is also identified and quantified. Confidence in the risk estimate is then discussed with reference to the adequacy of data and the weight of evidence.
3. Sensitivity analysis. This is used to show the influence of different variables on the outcome of the risk assessment and the range of response that may be encountered. It can also be used to highlight the impact on the risk estimate if various assumptions are changed.
4. Identification and evaluation of risk mitigation options: various options for mitigating or controlling the major risks are identified and evaluated in terms of their effectiveness.

The risk estimate may be expressed qualitatively, semiquantitatively, or quantitatively, depending on the purpose of the risk assessment, and the availability of relevant data and resources to allow quantification of the risk estimate. Accordingly, the risk assessment is referred to as a qualitative, semiquantitative, or quantitative risk assessment. A qualitative study is much less resource-intensive and may be adequate for some applications, such as prioritization of hazards for further investigation. A quantitative risk assessment may be necessary for purposes such as the setting of food standards and critical limits.

Risk Assessment of Physical Hazards

The possible health effects of physical hazards, such as glass, metal, and bone fragments, are generally obvious. There has been little demand to quantify

physical hazards in a systematic way in the context of food safety. However, attempts have been made to quantify risks according to the size and nature of extraneous objects.

Risk Assessment and Risk Analysis

Risk assessment is not an end in itself and is usually conducted for a specific purpose or objective. For example, it may be conducted to identify the higher-level risks of a food or manufacturing process, with the view of controlling those risks at acceptable levels though better policy setting, strategy formulation, and/or implementation/improvement of process controls. To achieve such an objective, risk assessment has to feed into a process of *risk management*, and both processes have to be carried out in conjunction with *risk communication*. The three elements, risk assessment, risk management, and risk communication, together are referred to as *risk analysis*.

Risk management is the process of weighing policy alternatives in the light of the results of risk assessment and, if required, selecting and implementing appropriate control options, including regulatory measures. It is responding to the findings of risk assessment and determining the most practical and effective way of achieving the purpose or objectives identified. Risk communication is the interactive exchange of information and opinions concerning risk and risk management among risk assessors, risk managers, consumers, and other interested parties. This ensures that the purpose, objectives, considerations, processes, findings, uncertainties, and implications of the risk assessment and risk management are clearly understood by all stakeholders throughout the conduct of the risk analysis. This tends to increase the quality of the process owing to a broadening of the input base for relevant information and expertise. It increases the transparency of the risk analysis and fosters ownership of the process and output. The interrelationship between the elements of risk analysis is illustrated in Figure 2.

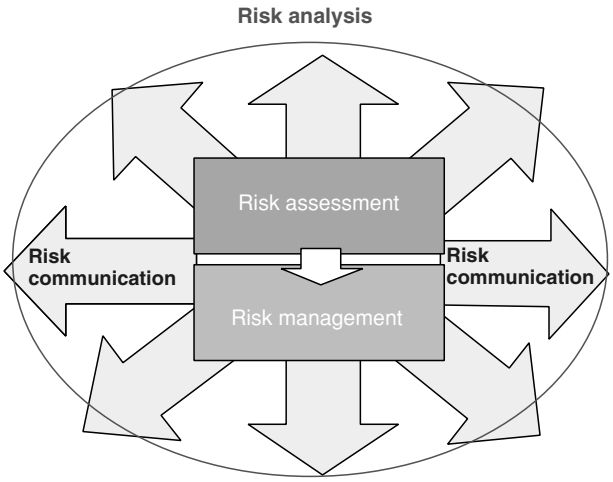

Figure 2 Components of risk analysis.

Application of Risk Analysis

Government Policy Setting

Developed countries have come to recognize food safety as a major social, economical, and political issue. The monetary and social costs of foodborne illnesses to society are very significant. There is also an increasing public awareness of food-safety issues, particularly after a spate of high-profile food-safety incidents, such as the BSE crisis in the UK, the dioxin contamination episode in Belgium, and the Snow Brand milk-poisoning case in Japan. As a result, there is an increasing expectation that the government fulfills a role of protecting the public from undue exposure to food-safety hazards, and in significantly reducing foodborne disease.

In 1997, President Clinton of the USA announced his Food Safety Initiative that recognized the importance of risk assessment as a scientific tool in achieving the goal of improving food safety. Major agencies such as the US FDA, FAO/WHO, and the European Commission have indicated that risk analysis underpins the formulation of their food-safety policy.

Whether at company, industry sector, or national level, food-safety hazards are numerous, whereas the resources for improving food safety are finite. In practice, resources must become more focused on reducing those risks that have the greatest consequences for human health. Risk assessment assists in such decision-making by providing a scientific estimation of the risks of various food hazards, and providing risk-management options that are scientifically sound. This allows the risk managers to prioritize and weigh up the options available. This may lead to government agencies formulating legislative requirements on food production, setting food standards, encouraging industry-based codes of practice, and/or undertaking educational programs.

Standard Setting

Food standards, such as those that specify the maximum allowable level of contaminants in food, or the amount of food additives permitted, are an important instrument for the assurance of food safety. This is particularly the case in international trade, where the food commodity being traded is manufactured in another country, and the history and conditions of

manufacture may not be fully known. International trade on food is based on agreements achieved at the World Trade Organization (WTO), including the Agreement on Sanitary and Phytosanitary Measures and the Agreement on Technical Barriers to Trade. Under these agreements, the Codex Alimentarius Commission (CAC) has the role of implementing the Joint FAO/WHO Food Standards Program, establishing international food quality and safety standards. These standards are adopted or used as models by many countries in their domestic food legislation and regulations.

The CAC takes a risk-based approach to setting of standards and has enunciated the principle of using sound scientific analysis and evidence as the basis of all its food standards. In practice, this means the use of risk assessment and risk analysis for the justification and derivation of food standards. This has set the scene for many countries also to adopt risk analysis as a tool for developing domestic standards.

Determination of Equivalence

It is the sovereign right of a county to determine a desired level of public health protection to be achieved in food production. The exporting country need not apply the same regulations for processing and production of food as the importing country, provided that the controls used will achieve the same level of safety. Risk assessment is a scientific tool that can be used to assess whether the imported food is of an equivalent level of safety as food produced locally or deemed acceptable from other sources. This provides a means of preventing artificial barriers to trade. In recognizing the importance of this science-based approach to fair trade, the WTO has required each member country's food safety measure to be based on risk assessment.

Equivalent systems, once established between trading partners, can result in acceptable export certification of shipments with minimum additional control. This simplifies trade procedures and reduces or eliminates the need for stringent and prescriptive trading conditions.

Underpinning HACCP

Hazard Analysis Critical Control Point (HACCP) has been recognized worldwide as the desired approach to achieve safe food production. There is a close relationship between hazard analysis within the context of HACCP and risk assessment/risk analysis. Much of the information required for hazard analysis is also required for the hazard identification and hazard characterization steps of risk assessment, such as identifying the nature, source, prevalence, and anticipated level of hazards. However, HACCP and risk assessment are different in terms of their scope, application, and focus.

HACCP is generally carried out at company level for a specific food product manufactured by a specific process and may be specific to a single factory, or even one particular production line. The objective is to manage and control the identified significant hazards at acceptable levels, thus ensuring production of safe food from the production line in question. Hazard analysis in HACCP generally does not systematically quantify risks, although a prioritization of hazards is involved, which can be considered an intuitive estimation of relative risk levels.

Risk assessment and risk analysis are normally carried out by government agencies, industry peak bodies, and the like. They have a broader focus than one specific manufacturing process and find application at a policy or strategic level. Usually, the study is carried out for a specific hazard in the context of a food commodity group, e.g., *Salmonella enteritidis* in egg and egg products. Sometimes, it is also carried out for a specific industry sector or food commodity grouping, e.g., significant hazards in seafood produced in a specific region. Systematic quantification (to the extent possible) of the risks of significant hazards is a fundamental element of such a study. The risk estimates provided by a risk assessment will give guidance in prioritization and strategic planning for the management of the risks. The proposed risk mitigation options then feed into the risk-management process to formulate practical work plans and risk control measures.

Owing to the commonality between HACCP and risk assessment/risk analysis, there is also an important interrelationship between them. Hazard identification conducted as an element of risk assessment is generally done more systematically and thoroughly, by virtue of the greater resources and expertise usually made available for such studies. In risk assessment, the hazards are also scientifically evaluated in terms of risks. This distinguishes those hazards that pose a significant threat from others that are no more than perceptions or are of a low impact. Therefore, risk assessment, where available, should provide the foundation for HACCP. The latter should address all the hazards of higher risks identified in the risk assessment and adopt one or more of the risk-management options provided, customized appropriately for the specific circumstances wherein the HACCP plan operates.

Benefits and Limitations

Risk assessment, with its clearly defined framework, provides the necessary discipline to ensure rigorous

problem definition, through examination of relevant data, assimilation of existing knowledge, and identification of variability and uncertainties. This provides for a structured, scientific, and objective inquiry into issues of food safety. Apart from providing a quantification of food-safety risk, a risk-assessment study also produces a report that serves as a database of relevant information, a documentation of considerations justifying the risk estimate and risk-management options, as well as a listing of critical information gaps. The transparency, objectivity, and scientific basis of the study and its findings engender critical thinking and understanding, and provide a firm foundation for sound decision-making, strategic planning, and effective action.

The major problem in conducting a risk assessment, in particular quantitative risk assessment, is the frequent lack of relevant data, whether epidemiological, prevalence, and/or dose–response data. It is also frequently necessary to make broad assumptions on which the robustness of the study rests heavily. As a consequence, this means that the conclusions of a risk assessment are sometimes accompanied by large uncertainties. In most cases, the generation of necessary additional data is not feasible or is very labor- and time-intensive.

The lack of relevant data may also mean that the study can only be qualitative, or at best semiquantitative. As such, the full benefits of a quantitative risk assessment cannot be realized, and the findings may be little more than what is already known based on an intuitive estimation of risk or impressions. In such cases, the main value of the risk assessment is restricted to having documented all relevant considerations in a systematic and transparent manner and identifying the knowledge gaps that need to be filled for future analyses.

Quantitative risk assessment requires the use of simulation modeling and/or animal studies. These models or studies cannot always be validated, and the reliability of the assessment findings would depend heavily on the validity of the modeling or the relevance of the animal studies. Related to this is the large variation in the susceptibility of people to foodborne hazards. Relevant data are generally much more available for the general population than for minority groups that may be more susceptible. Consequently, the risk levels determined may be an underestimation for certain consumer sectors.

A substantial quantitative study is very costly. For example, some quantitative microbiological risk assessments have taken up to 30 person-years to complete. This means that only resource-rich agencies, organizations, or collaborative teams are able to undertake such studies. However, in recognition of this, many major risk-assessment reports have been made freely available through the scientific literature and the Internet. This has allowed others to make use of the collated information and findings.

While the risk assessment process is both objective and systematic, subjectivity cannot be avoided in using the findings in risk management. This is because an acceptable level of food-safety risk is neither well defined nor universally agreed upon. Ultimately, the risk-management decision of what is an acceptable risk for a particular situation has to take account of cost–benefit analysis and public perception.

Risk assessment, being a scientifically based process, is designed to assess true risks to human health. However, the public's reaction to food safety is largely based on perceptions. Frequently, what the public perceives as unacceptable hazards in food and reacts emotively to is not necessarily proven as a major cause of foodborne disease. Nevertheless, issues surrounding these perceived hazards could bring about severe backlash on businesses, industries, and government by consumers and export markets. From a business viewpoint, the perceived risks are as real as the true food-safety risks. However, perceived risks are outside the domain of scientific food-safety risk assessment but may be dealt with as a commercial risk by other techniques.

RUM

L Fahrasmane and A Parfait, Institut National de la Recherche Agronomique, Petit-Bourg, French West Indies, Guadeloupe

Introduction

The term 'rum' is used to describe the distillates originating from the fermented products of sugarcane (*Saccharum* spp.), that is to say fresh juice, molasses (the thick brown liquid separated from raw sugar at the end of the sugar manufacturing process), and syrup obtained from sugarcane juice concentration (**Table 1**). The fermented liquid must be distilled under 96% ethanol by volume (Directive 89/1576/EEC).

Rum production has always been a way to use and value molasses. Thus, in the French West Indies islands, *de sucrerie* rum, obtained from molasses, is produced from distilleries attached to sugar plants. However, in the Caribbean French colonies, Guadeloupe and Martinique and also in Haiti, some small sugarcane planters who were disadvantaged, during

the first half of the eighteenth century, by the development of central sugar plants and a general reduction in sugar sales began to distil rum directly from the fresh juice of their harvest or from the syrup resulting from the juice concentration. This was how *agricole* rum was born. It is produced by independent distilleries, outside the sugar industry, using the raw material from farming.

Nowadays the world rum market is dominated by the light rums which are produced from molasses, in modern productive distilleries. Light rum is marketed white or aged, and drunk as an ingredient in long drinks. However, traditional rums are still produced and sold. These are characterized by a mixed fermentation involving alcohol-producing yeast strains and cofermenting bacteria. They are distilled at a lower ethanol content than the light rum (about 80% by volume) and are richer in aromatic compounds. Jamaican type (also known as heavy rum or *grand arôme*, is a typical example of these traditional products.

History and Uses

The British term 'rum' referred to the alcoholic liquors distilled from fermented sugarcane products, coming from the British colonies of the Caribbean. They were generally of a better quality than those produced in the French colonies, where they were referred to as tafia and guildive. Indeed, rum has had and still does have various names throughout the world, including some archaisms, such as kill-devil, the obsolete word rumbullion, guildive which is probably a French adaptation of kill-devil, tafia, grappe, arrack (Mauritius), and gavine (South Africa). Nowadays, it is rhum in French, aguardiente and ron (in Spanish-speaking Latin America), cachaça, pinga, aguardente (Brazil), clairin (Haitian traditional rum, with 30–35% alcohol content), toaka (Madagascar), and kana (Guinea-Bissau).

Although the cultivation of sugarcane and its transformation into sugar date back to time immemorial, rum production is more recent; it developed with sugar production in the Caribbean islands in colonial plantations in the seventeenth century. Every plantation had its distillery. Rum appeared when the world sugar production, which was only from sugarcane, was taken from the Mediterranean area to America. The increase in sugar production generated important molasses volumes. The European colonists discovered that they could take advantage by distilling fermented washes from the molasses and sugary wastes such as scum.

Among the first writers to mention rum was the father Du Tertre, who stayed in the French West Indies from 1640 to 1657. At much the same time, Robert Ligon in his *History of the Island of Barbados* (1657) described the preparation of a fermented beverage called punch. Father Labat, who arrived in the West Indies in 1694, described the elaboration of guildive in his *Nouveau voyage aux isles de l'Amérique* (*New Journey to the American Islands*; 1722).

In those days, rum was a byproduct of the sugar industry. The manufacturing process was simple: the fermentable sugar was seldom derived from cane juice but came from the scum that comprised the sugary impurities raised during juice boiling, and molasses rich in sucrose were drained from the sugar production process. These sugary resources, diluted – around 100 g l^{-1} of sugar – in water and/or distillation waste waters, were spontaneously fermented (Table 2). Then the fermented wash was single- or double-distilled in a pot still. The manufacturing process in use in the seventeenth and eighteenth centuries was diverse. The quality of the product was often poor, or frankly bad, because of the low microbial quality of the raw materials (scum, molasses, waste waters), the rudimentary condition of the fermentation process, and above all the poor resolving power of the distillation apparatus. Spirits were often derived from washes inside which acetic, butyric, and even putrid fermentation had occurred, and the pot stills were unable to provide the rectification to remove undesirable compounds. Moreover, the alcohol content was weak, often under 42% (by volume), especially in the products from the French colonies.

The phylloxera crisis in the nineteenth century had involved a high demand in alcoholic products including those from the rum distillery. In the meantime there was development of industrial processes with rational management and mass production. Pasteur's works on fermentation allowed microbial control in the washes. This evolution and new knowledge were applied in rum production where there was a chemical comprehension of distillery products and pursuit of productivity. During the second part of the nineteenth century appeared an untraditional process, which featured microbial control and bacteria elimination in the washes, a plant with voluminous fermentation vats, and a multistage column for distillation which involved a high level of rectification of the distillates.

Rum was first a drink for slaves and seamen. It was considered as a coarse drink, not appropriate for the palates of the upper classes. Admiral Penn, after he took Jamaica in 1655, instituted the daily rum ration distribution to his sailors. Admiral Vernon, who was nicknamed Old Grog – grog is a mixture of one portion of rum, two portions of water and some lemon juice – replaced the Admiral Penn ration, with grog in 1731. Rum was distributed daily to sailors of the British Royal Navy until recent times. In the West Indies the British blended rum with various foodstuffs, including tea, sugar, lemon, and cinnamon and named the cocktails punch. In the eighteenth century there were many rum liquors known by the name island liquor.

The British encouraged rum production from the beginning, because it was favorable for traffic with the North American Indians, and the slave trade on the African coast. Whisky production was low at that time. Barbados, Jamaica, and New England were colonies where rum production was developed. In 1765, two distilleries were situated in Liverpool, where they produced rum to supply ships bound for Africa.

From the eighteenth century, rum-based drinks became numerous. An important feature of rum utilization is its ready association with fruit aroma and vegetable extracts in the mixing of punch, cocktails, planteurs and, more recently, rum and cola; some mixes are sold ready-to-use. Rum has the distinction of being an excellent basic ingredient for composite drinks. The earliest English terms, punch and grog, are still largely used, although the beverages are rather different from those in the eighteenth century. Nowadays one can find, for example:

- curaçao from the Dutch West Indies, produced after soaking orange peel in rum: shrub is very similar to curaçao
- cocktails which are mixtures of rum with other liquids, mainly tropical fruit juices and spices: punch and planteur from the French West Indies are similar
- Alexandra is a sophisticated mixture of aged rum and cream
- in Brazil there is a variety of Batida, which is a mixture of fruit and cachaça
- daïquiri or daiquiri was created in 1898 by an American in Cuba. Originally it was a light rum like Bacardi mixed with lemon juice
- Cuba libre, one of the most popular drinks in North America, is a mixture of Coca-Cola and rum

Another very interesting feature of rum which is not often emphasized is its use in eaten products, confectioneries, icecreams, chocolate, and foods. For example, in France, more than 40% of marketed rum is used as an aromatic resource, in confectionery. Baba (sponge-cake) is one of the best-known confectioneries containing rum. Traditional rum and heavy rum are used to flavor various foods because both are rich in aromatic compound and can endure physical hard treatment, such as the high temperature encountered in food processing. Light rum, on the other hand, is poor in aromatic compounds and is not suitable as a flavoring agent in foodstuffs.

Manufacturing Process

The first stage of rum elaboration is preparation of the mash. The goal is to favor the alcoholic fermentation of sugars by yeasts, either occurring naturally or introduced in the fermentation media by the distiller. During fermentation there is also a production of heat which in small vats is quickly dissipated, but in larger vats may raise the temperature such that it kills the yeast. When fermentation is finished, the mash is distilled either in a pot still in continuous distillation columns, or in a multistage distillation column (Figure 1). This operation makes it possible to separate from the fermented media the volatile components and concentrate them in the distillate. The resulting raw rum is at a higher percentage in ethanol (around 80%) than the marketed products, so it is diluted before sale. It contains aromatic volatile compounds which distil together with the ethanol. These congeners are generally in small quantities (0.0001–0.001% of the ethanol, in weight). Depending on their proportion, they add significantly to the taste and aroma of the raw rum.

More than 95% of the rum produced in the world is derived from molasses and high-test molasses (HTM). Molasses is rich in sugar, and has a density comparable to honey: 1.4. It also contains nonsugar

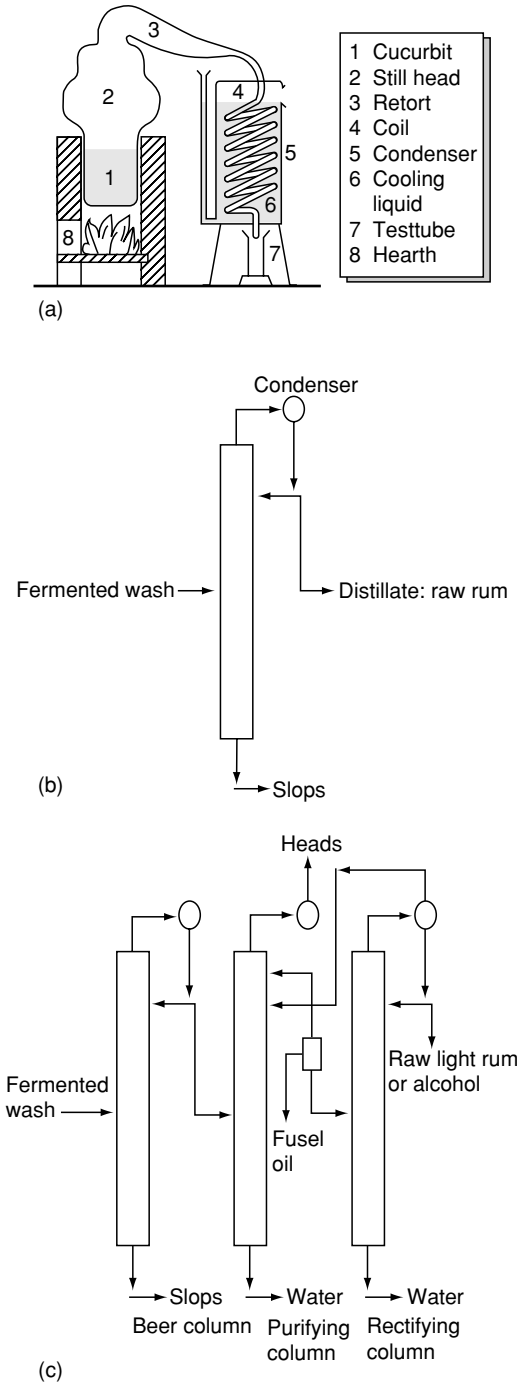

Figure 1 Rum distillation devices. (a) Intermittent pot still; (b) continuous single distillation column; (c) multistage column.

compounds such as minerals, organic acids, phenols, and others chemicals generated by the thermal treatment during sugar manufacturing.

Rum from sugarcane juice is a special feature of traditional production in the French West Indies.

Before the eighteenth century, the essential elements of rum production were:

- a mash comprising molasses and scum as the source of sugar, which was diluted with waste water (slops) and/or water in varying proportions (Table 2)
- in this mixture sugars were spontaneously fermented over a 7–15-day period by the abundant flora of *Schizosaccharomyces* yeast and various bacteria. Often, the molasses were introduced repeteadly, three times, to avoid fermentation failure
- the fermented washes were distilled in a pot still (Figure 1a) with double distillation. The kettle was manufactured of red copper, and a tap at the bottom was used to drain the spent liquor. The still head was also of red copper, sometimes tin-plated. The condenser was made from copper or pewter.

The rums obtained were between 41 and 45% ethanol content by volume. Developments in distillation engineering and microbiology were destined to improve these early processes dramatically.

During the eighteenth century, distillation equipment evolved, with the use of the retort, making it possible to obtain marketable spirit from a pot still without double distillation. In some devices the distillates were around 80% ethanol content. The continuous single distillation column (Figure 1b) was developed in the nineteenth century, in order to increase production. The distillates were also more consistent and the raw rums contained up to 90% ethanol – sometimes even 95%. The Creole, the Savalles, and the Barbet columns were typical of this period; the Barbet columns produced very aromatic distillates.

Multicolumn devices appeared during the nineteenth century (Figure 1c) and are used extensively today. The Coffey still was introduced for the distillation of grain whisky in Scotland and used largely in the British colonies. It produces distillates with 84–85% ethanol content. It initially comprised two columns: the analyzing column and the rectifying column, as used for grain whisky distillation. Today, multicolumn stills with three stages (beer, purifying, and rectifying columns) or even four columns are used for rum distillation.

The other great advance in rum production in the twentieth century concerned microbiology. In the early days, the spontaneous flora was used, and was often initiated with a natural starter by using a piece of wool soaked in washes and then carefully dried and kept to be introduced into the new fermentations. After Pasteur's studies of wine and beer fermentations, some researchers considered replacing the spontaneous or natural starter by pure fermentation using selected yeast strains. The aim was to improve

productivity and avoid bacterial contamination, since it was thought by some that the bacterial flora was detrimental to the flavor of the products. On the other hand some microbiologists, such as Allan and Ashby, believed that bacteria played an important part in producing the rum bouquet.

The application of pure fermentation involved modifications in fermentation management, in particular growth of starter cultures with selected yeast strains, and the use of antiseptics to limit bacterial presence and activity. The major change was fermentation by *Saccharomyces* yeast strains rather than *Schizosaccaromyces*. The result was an increase in yield but the quality of the products fell, through an increase in chemical neutrality. Roques, in 1927, was commissioned by the French Ministry of Agriculture to carry out a study which concluded that 'rums produced from pure and rapid fermentations are characterized by low levels of acid and ester, as well as relatively high contents in higher alcohols'. Most traditional rum producers consequently gave up the use of selected yeasts and decided that 'wild' fermentations gave the best results, producing rums with richer flavor.

At that time, which was the Prohibition period, light rum production was expanding in the greater West Indies and in the English-speaking lesser West Indies. Here rum was produced using modern plants and pure culture yeast. Under these conditions fermentations are rapid, the distillation is carried out with multistage devices, and the resulting distillates are low in aromatic compounds. These light rums formed the basis of the modern rum industry. However, traditional aromatic rums are still produced in the French West Indies and in Jamaica.

The distillery products are sold white (without aging), or after aging, generally in oak vats for many months.

Typology and Raw Rum Treatments

Rums, like many others alcoholic beverages, are often classified and labeled according to their geographical area or country of origin. However, this geographical classification does not necessarily correspond to the organoleptic properties of the spirit and, indeed, the US Federal Administration does not correlate the geographical designation with rum type.

From the analytical and sensory viewpoints, rums are most often described according to their aromatic intensity. This property largely relates to the microbial status of the fermentation and distillation equipment (Table 3).

Rum can be divided into four categories (Table 4): light, heavy, *de sucreride,* and *agricole*.

Table 3 Basic rum types and processing features

Raw material			
	Molasses		*Cane juice*
PF, MC Light	MF, PD, SC Heavy	MF, SC *de sucrerie*	MF, SC *Agricole*

PF, pure fermentation (yeast only);
MC, multistage column distillation;
MF, mixed fermentation (bacteria and yeast);
PD, pot still distillation;
SC, single-column distillation.

Table 4 Basic rum types: appellation, aspect, and post-distillation treatments

Not traditional	*Traditional*		
W, A, SC Light	W Heavy	W, A, SC *de sucrerie*	W, A, SC *Agricole*

W, white, a, aged; SC, straw-colored.

Light rum, of which Bacardi is the market leader, is the result of improvements in distillation engineering and fermentation flora control. Fermentation is rapid – 12–20 h duration – and uses cultured yeast with minimization of the bacterial flora by various means. In Cuba, rum with lightened features appeared around 1870. A gold medal was awarded to Don Facundo Bacardi, in 1876, at the international exhibition of Philadelphia for his light products. Similarly, a light rum or common was manufactured in Jamaica in 1882. In the French West Indies, traditional producers were not satisfied by the aromatic profile of the light rums and by the 1930s, they returned to traditional production processes. In modern light rum, the content of compounds other than ethanol (not alcohol: NA) is often under 60 g impurities per hectolitre (hl) of pure alcohol.

Traditional rums are a specialty of the French overseas territories: Guadeloupe, Martinique, and La Réunion. While part of this production is exported, the traditional products from Haiti and Brazil are solely consumed locally. The raw materials for traditional rums may be cane juice or molasses, giving respectively *agricole* rum and *de sucrerie* rum. The starting gravity is around 1035 for media from sugarcane juice, and 1060 for those from molasses. The production is on a cottage industry basis with small plants, because productivity is not a major goal. Length of fermentation is 20–48 h and features the presence and activity of a spontaneous bacterial flora that contributes to the aromatic properties of the product. The ethanol content of the final fermentation media is about between 3.5 and 8% by volume and the

marketed products have an aromatic content over 225 g Na hl^{-1} of pure alcohol.

Heavy rum or *grand arôme* (Wedderburn and Plummer in Jamaica) is molasses-based. The wash is diluted with prefermented distillery waste water (slops) instead of water. The wash containers are often wood-made. The fermentation is a true ecosystem, where only *Schizosaccharomyces* yeast strains are able to perform alcoholic fermentation; meanwhile there is important spontaneous bacterial activity. Length of fermentation is long: 7–15 days. Heavy rums, which are a peculiar form of traditional rums, are not used as a beverage, but as an ingredient of blends, and as an aromatic agent in confectionery and cooking. The content of aromatic compounds is very high compared to the other rums – generally between 800 and 1500 g NA hl^{-1} of pure alcohol. Rumverschnitt, or German rum, is a blend of potato alcohol with heavy rum, providing aromatic flavors.

Light rum and the traditional rums, heavy rum, *agricole*, and rum *de sucrerie*, are the four basic rum types. Depending on postdistillation treatments they will have various color and organoleptic properties (Table 4). There are three color categories that generally relate to the length of maturation; the longer the maturation period, the darker the color. However, in some raw rums coloration can be derived from added caramel and some aged rums may be treated to remove the color.

White rums are potable spirits sold without coloring. They are made in two ways:

- They can be obtained from raw rum which, after a short maturing period to eliminate the pungent highly volatile compounds, is diluted to the commercial strength.
- Alternatively, white rum is sometimes made from matured spirits that have been treated with activated charcoal, and mixed with sugarcane alcohol. The Cuban Havana Club Silver dry is one such product.

Straw-colored rums are matured for several months in huge oak casks, during which time they adopt a light coloration, resulting from exchanges with the cask walls. The organoleptic properties of these products are halfway between white rum and aged rum.

Old rums are obtained after maturation in previously used oak barrels, of 170–650 liters capacity, generally for a period of 3 years. During the aging process, many changes occur in the raw spirit, which becomes darker, by leaching compounds from the barrel to the spirit. There are also changes to the organoleptic properties of the spirit, for example, oxidation and hydrolysis reactions involving lignin from the barrels, producing aromatic aldehydes. The very old rums are appreciated in much the same way as other matured spirits like malt whisky and brandy.

The ethanol content of rums varies from one product to another. The rum produced in the English-speaking Caribbean islands is often 43% by volume, but in the French-speaking islands it is 50% by volume. The aged products are generally lower in alcohol content than the white ones – between 37 and 45% by volume. However, there are products with very high ethanol content, such as Jack Iron (79% by volume) in Carriacou, Strong Rum (79% by volume) in Grenada, and Puncheon (75% by volume) in Trinidad. In western markets there are many distributor brands. Those distributors often use raw rum from the West Indies to elaborate their products.

Rum Market

Rum was the world's leading spirit in the 1980s with an annual volume of 9 500 000 hl of pure alcohol, while the annual volume of whisky and vodka respectively was of 9 000 000 hl of pure alcohol. Nowadays, after vodka and whisky, rum is the third spirit consumed through the world, with more than 80 million 9-liter cases sold in 1998. The US market leads, with a sales volume of 12 million cases, amounting to $1.5 billion, of which half is sold by Bacardi, followed by Captain Morgan, Castillo, and Havana Club. Bacardi, with $1840 million, was second in the list of top 100 spirit brands world retail sales value in 1995 after Stolichnaya vodka, which was first with $2090 million sales. The second rum brand was Captain Morgan which was 67th in this Top 100, with $290 million. The world's six leading rum brands ranked by retail value are shown in Table 5.

With regard to consumption, USA has the highest rate, followed by the Philippines, Mexico, India, Germany, Colombia, the Czech and Slovak republics, Venezuela, Canada, and France.

Table 5 The world's top rums in 1995

Rank	*Brand*	*Brand owner*	*Sales*[a]
1	Bacardi	Bacardi Martini	18.76
2	Tanduey	Tanduay Distillery	14.00
3	Captain Morgan	The Seagram Co.	1.90
4	Gran Reserva	Santa Teresa	1.40
5	Castillo	Bacardi Martini	1.34
6	Cacique	The Seagram Co.	1.25

[a]In millions of 9-liter cases.

Conclusions

Rum is a product steeped in history, pictures, and flavor, associated with seasonings and condiments. It is exceptional among spirits because of its range of products, uses, and variety of applications, as a beverage and as a flavor ingredient in foods.

Nowadays knowing about dietetics reveals that food value is not only nutritional. On an individual basis, food is also a source of pleasure and symbols. The composition of rum and its appreciation are plenty of elements to satisfy consumers' expectations.

The modern consumer search for local products opens a perspective for traditional foodstuffs which are vehicles of aroma.

On all alcoholic beverage packaging, in France, it is a legal obligation to display: *A consommer avec modération* (i.e., to be taken in moderation). Now, can I propose a toast?

RYE

M G Lindhauer and J Dreisoerner, Federal Centre for Cereal, Potato and Lipid Research, Detmold, Germany

Background

Botanically, the rye (*Secale cereale* L.) belongs to the family of grasses (Gramineae). The rye plant is characterized by a culm, ranging in length from 65 to 200 cm, depending on the cultivar. The 5–20-cm-long four-cornered ear consists of single spikelets covered by lemmas with long awns. The blue-green grains are 5–9 mm in length and can be easily removed from the spike when ripe. For cultivation, winter rye varieties are preferred, as they are normally higher yielding than summer rye cultivars.

Rye is thought to have originated around 8000 BC in south-west Asia, probably in the area of the present states of Turkey, Iraq, and Iran. From that area, rye spread out for centuries, although the exact route is not known. About the eighth century BC, farmers in Central Europe considered rye as a weed in wheat and barley crops, as it often exhibited a better growth performance and yields, obviously due to its drought resistance and ability to grow on poor soils, than the primary cereals. Because it is often a weed in older cereals, rye (together with oats) is also called a 'secondary cereal'.

Nowadays, rye is a specialty of the northern latitudes between 50 and 65° degrees latitude. Its main cultivation area is in the north-west part of the eastern hemisphere, roughly between the Ural mountains in the east and the North Sea in the west. During the sixteenth and seventeenth centuries, rye was eventually brought by European settlers from Central Europe to North America and western South America, and during the nineteenth century, it was introduced into Brazil, Argentina, Uruguay, Australia, and South Africa.

Agronomic Significance

Rye is a cereal with modest requirements in terms of soil, fertilization, and climate. Particularly on poor sandy soils, as in northern and north-western parts of Poland and Germany, which have a limited nutrient and water availability, and because of its relatively good winter hardness, rye has an overall better performance than other cereals and should not be replaced in the crop-rotation system. But as a result of hybrid breeding rye can now compete in yield formation even on more fertile soils.

The greatest rye producer used to be the former Soviet Union, producing 11–13 million tonnes per year. Now, this has been split into two main parts: Russian Federation 6–8 million tonnes and Belarus 3 million tonnes. The second highest producing country is Poland, with 5–6 million tonnes, followed by Germany, with 4–5 million tonnes. The Nordic and Baltic countries also have a specific tradition in rye utilization and are relatively small producers; yearly production fluctuates with the weather conditions at the time of sowing and the overwintering conditions.

Yield performance shows a broad range depending on the agricultural system, especially on the availability of resources like fertilizer, pesticides and high-yielding varieties, and on climatic conditions. Statistical data for 1999 show that Germany had the highest yield, with 57.9 dt ha^{-1} (decitons per hectare), followed by Switzerland (53.7 dt ha^{-1}) and Scandinavia (Sweden and Norway: 47.9 dt ha^{-1}; Denmark: 46.5 dt ha^{-1}). In major rye-producing countries like Russia, the yields were 13.5 dt ha^{-1}, and in Poland 23.1 dt ha^{-1}. For comparison, the average yields in North America were 20.6 dt ha^{-1} in 1999.

The most important diseases in rye are snow mold (*Microdochium nivale*), leaf rust (*Puccinia recondita*), powdery mildew (*Erysiphe graminis*), foot rot (*Pseudocercosporella herpotrichoides, Fusarium* ssp.), head blight (*Fusarium graminearum, F. culmorum, Microdochium nivale*) and ergot (*Claviceps purpurea*). This latter fungus is typical for cultivated grasses prefers to grow on rye. Instead of a rye kernel it is up to 2.5 cm long outside black violet and inside grayish white sclerotium develops in a spikelet and as such it is clearly visible in an infected ear in the field. During harvest it gets into the bulk grain. The sclerotia of Claviceps purpurea are known as ergot; they contain specific poisonous alkaloids, so-called ergot alkaloids, which cause different symptoms, from dizziness to cramps, resulting in neuronal disorders in the case of chronic poisoning. Since the ninth century, ergot poisoning has been implicated in several epidemics in central Europe during the Middle Ages. Today, ergot in rye is no longer a problem due to the use of efficient cleaning and sieving systems in flour mills preventing ergot from contaminating rye flour. The EU has specified a threshold value for ergot in flour of 0.05%.

Rye Breeding

For farmers, the most important objective is a stable grain yield. In this respect, much progress has been made during the past 20 years in hybrid rye breeding. Hybrid rye breeding started in 1970 at the University of Hohenheim, Germany. At present, 17 hybrid cultivars are registered on the official descriptive list of plant varieties in Germany occupying almost 60% of the total rye acreage in this country. Hybrids are characterized not only by higher yields but also by a higher resistance against preharvest sprouting. This is a phenomenon specifically more pronounced in rye than in other cereals, meaning that under wet weather conditions, the grains already start to germinate on the culm. Preharvest sprouting causes high harvest losses, as the flour prepared from such preharvest sprouted grain loses its baking performance and is no longer suitable for breadmaking.

As well as breadmaking quality, progress has been made in improving other important traits such as kernel weight, lodging resistance, and resistance against diseases (e.g., leaf rust). Hybrid varieties are also licensed and released in other member countries of the EU as well as in Poland. Hybrid rye breeding programs are also in progress in Russia and Australia. By crossing rye and wheat, a new cereal species, *Triticale* (from Triti*cum aestivum* and *Se*cale *cereale*), has been generated, which has replaced rye in some production areas.

Rye and Nutrition

In the food culture of several European countries such as Russia, the Baltic and Scandinavian countries, Polish and German rye besides wheat has a long tradition as a raw material for breadmaking and for the production of a variety of other different products. Although the total production of rye has diminished in recent years, its use as a human food increased slightly during the 1990s (Table 1). In 1990, the food consumption of rye in the world was about 8 million tonnes, which was about 35% of the total production.

Milling Products

There are many similarities between the milling of rye and wheat. In both cases, the same type of machinery with only slight modifications in the procedure is used. By using different equipment and milling techniques, a large variety of rye products can be obtained (Table 2).

During the milling process, the first machine flours contain after sifting mainly starch flour granules only (i.e., they have a low flour extraction grade), while the following flours with a higher extraction grade contain increasing amounts of bran and other fibrous material. The extraction rate is strongly correlated with the ash (mineral) content. The higher the amount of bran and fiber in the final flour, the higher the ash content. Wholegrain rye flour has an ash

Table 1 Rye product consumption in the world in some selected countries

content of about 2 g per 100 g, whereas the most frequently used flours for breadmaking have ash contents of about 1 g per 100 g (with an extraction rate of about 80%).

Breadmaking

Unlike wheat, the gluten protein of rye is able to form a three-dimensional network as basic structure of the dough rye proteins are less able to swell. This is also valid for rye starch. However, rye contains a large amount of nonstarch polysaccharides of high water binding capacity, i.e., swelling capacity. They are collectively called pentosans. Conditioned by sour dough – today, dough acidification steps are often undertaken instead – certain rye proteins are also able to swell. The soluble proteins, starch, and the pentosans cause the gas-holding capacity of rye flour during dough preparation. The swelling ability can be measured ('swelling index') and provides information on the dough-rising and gas-holding capacity. Other specific methods such as techniques using falling numbers and amylograms are available to predict the dough-forming suitability of rye flours. Pentosans, especially, are responsible for the higher shelf-life and freshness of rye breads than with wheat breads.

The most typical rye bread made from whole grains or wholemeal is that prepared with sour dough. In this method the main ingredients, flour, water, and starter culture, are mixed and fermented for about 8–18 h. During the fermentation period, the lactic acid bacteria and the sourdough yeasts grow, and as a result of the microbial activity and enzymatic reactions of the microflora, flavor precursors are synthesized. The main components formed are lactic and acetic acid. After fermentation, more flour, water, and other ingredients are mixed into the sourdough to make the dough. The dough is then left to rise for a short period, after which the breads are shaped, left to rise again, and baked.

Bread Types

The use of rye is mainly based on local traditional nutritional practices. Consequently, in those countries with significant rye production and consumption, a wide variety of different types of rye bread have been established. The flavor and structure of rye bread are quite different from those of wheat bread. They vary depending on the flour type, ingredients, dough preparation (type and amount of sourdough), baking conditions, and time, as well as the size and type of bread.

Traditional rye bread is the dark sour bread, popular in Finland, the Baltic states, Russia, Belarus, and Poland. This tradition has changed somewhat on its way to the West, for instance to Sweden, Denmark, or Germany. In Germany, the total consumption of rye bread is steadily decreasing, especially that of wholemeal rye bread. Mixtures of different amounts of wheat and rye flour are preferred.

In addition to the typical rye bread crispbreads, thin crispbreads, rye rolls and buns, rolls, buns, and breads containing wheat/rye mixtures and parbaked rye products enrich the variety of rye products, but in different amounts in individual countries.

The most typical rye bread in Finland, Denmark, Russia, and the Baltic countries is wholegrain bread made by the aid of sourdough. Crispbread originated from Sweden, and nowadays is eaten throughout the world but with a greater preference in the Nordic countries. There are three different types of rye crispbread: normal yeast-fermented, sourdough-fermented, and cold crispbread, the third being baked without yeast. The dough has the right texture from a foaming process in which air is incorporated into the cooled dough, which also leads to the almost white color of the finished bread. Crispbread has a long shelf-life owing to its very low water content (5–7%).

Other Rye Products

Different types of rye groats and flakes are available for baking, porridges, and breakfast cereals. These products are generally produced from whole-grain rye. In the Nordic countries, several new types of rye products have been developed, among which breakfast cereals have gained a certain popularity. Breakfast cereals with up to 55% rye are available; the rye of these products is flaked and precooked and sometimes even extruded to increase the crispiness and improve the taste. Table 3 lists the different types of rye products.

In the light of modern knowledge on the nutritional value of rye, much effort has been made in different rye-producing countries to invent attractive rye-based dishes to reverse decreasing consumption.

Chemical Composition

Table 4 compares the most frequent constituents in whole grains of rye, wheat, and oats. The outer layer of the endosperm, the aleurone layer, is rich in proteins, minerals, and vitamins, especially B-vitamins (cf. Table 5). Fat is mostly located in the germ, and starch in the central endosperm. Rye is essentially a good source of minerals, such as potassium, magnesium, zinc, manganese, and fluoride.

From Tables 4 and 5, it is clear that rye wholegrain or wholemeal is also an important source of dietary fiber. The dietary fiber content of typical rye bread is about three times higher than that of white wheat bread. Even at the same flour extraction rate, rye flour contains higher amounts of dietary fiber than the respective wheat flour.

Furthermore, rye grains contain significant amounts of lignans: 47 mg of secoisolari ciresinol (SECO) per 100 g and 65 mg of matairesinol (MAT) per 100 g, so-called phytoestrogens. Also, other phenolic compounds are present in rye, e.g., tannin and phytic acid. All constituents are considered bioactive compounds.

Table 3 Other rye products

'Maemmi' – a Finnish Easter pudding
'Kalakukko' – a rye-dough-covered baked dish containing ingredients like fish, meat, and/or vegetables

Health Benefits

Nutritionists worldwide recommended increased consumption of wholegrain products as a source of dietary fiber. Rye is an excellent raw material for healthy and tasty food with a high fiber content (Table 4). In cereals, fiber is mainly located in the outer cell layers of the kernels, especially in the bran. Wheat and rye have similar bran contents, but rye contains more cell wall within the endosperm and thus has a higher fiber content.

There are two main types of dietary fiber: soluble and insoluble. Water-insoluble dietary fiber includes,

among others, cellulose and lignin, whereas arabinoxylan and β-glucan are partly insoluble, partly soluble. Arabinoxylans, often subsumed under the term pentosans, are the main fiber component of rye.

In the classical understanding of dietary fiber, it is common knowledge that a recommended intake of 25–35 g of fiber per day reduces the risk of overweight and constipation. Dietary fiber increases the fecal volume and reduces the intestinal transit time.

Research results in recent years have provided good evidence that dietary fiber, especially soluble fiber, contributes to a number of health benefits, such as a reduced risk of heart disease, decreased serum cholesterol level, reduced risk of elevated blood glucose levels and diabetes, strengthening of the immune system, and protection against different kinds of cancer (e.g., colorectal cancer, breast cancer, etc.).

Besides dietary fiber, rye grain contains relatively high concentrations of lignans, which are converted to weakly estrogenic mammalian lignans in the colon. Such phytoestrogens affect sex hormone metabolism and function by influencing certain sex hormone metabolizing enzymes at the cellular level. In addition, they have a great number of other interesting biological activities, possibly making them anticarcinogenic compounds.

Animal Feed and Alcohol Production

Depending on the total rye production and consumption of rye as food in an individual country, varying amounts of rye between 30 and 80% are used for animal feed. There are, however, restrictions on the use of rye in animal feed.

Those components with beneficial effects on human health, the pentosans, create some problems in the digestion of monogastric animals such as pigs and poultry–young animals are much more affected than older animals, with symptoms of maldigestion, reduced growth, and weight increase. Therefore, much effort has been made to improve rye-based feed by adding specific enzymes and to find uses for feed to alluviate the apparent overproduction of rye in the EU and the rest of the world. One such use is the use of rye and rye products for feeding fish and crustaceans in specialized farms in Asia and elsewhere.

There is also a tradition of producing alcohol from rye. Famous brand names of such spirits exist in nearly all of the rye-growing countries, but the total amount of rye used for these is comparably small.

SACCHARIN

J F Lawrence, Health and Welfare Canada, Ontario, Canada

Introduction

Saccharin has been in use as an artificial sweetener for about 100 years. It was discovered accidentally by researchers at the Johns Hopkins University in 1879 during studies on the oxidation of *o*-toluene sulphonamide. Its structure is shown in Figure 1. It is not metabolized but is excreted unchanged by the human body and thus contributes no calories to the diet. The safety of the substance has been the subject of debate for many years, and the controversy continues with arguments both for and against its use as an artificial sweetener.

Sweetness

Saccharin is about 300–500 times as sweet as sucrose, depending upon its concentration and the type of food medium in which it is used. Compared with sucrose, it has a slow onset of sweetness that increases to a maximum and then persists. The major drawback of saccharin is its bitter metallic aftertaste, which is particularly evident at higher concentrations. Because of this, efforts have been made to mask the aftertaste by adding substances such as cream of tartar, lemon flavor, pectin, ribonucleotides, glycine, gentian root, and artificial sweeteners such as aspartame or cyclamate. Combinations of saccharin with aspartame or cyclamate have proved to be very successful for many applications. In these cases, it has been found that saccharin exerts a substantial synergistic effect on the sweetness of either aspartame or cyclamate. For example, a mixture of 20 mg of aspartame and 4 mg of saccharin is equal in sweetness to either 45 mg of aspartame or 35 mg of saccharin if used alone in a cup of coffee. Not only does saccharin exhibit a synergistic effect with aspartame, but it apparently improves the stability of the latter in acidic soft drinks, enabling extended storage of such products. Saccharin/cyclamate mixtures were widely accepted in the USA until the ban on cyclamate in 1969. At present, saccharin/aspartame concentrations are commonly used in the USA in diet soft drinks. In some European countries, saccharin/cyclamate combinations are still permitted.

Production, Physical, and Chemical Properties

Commercial production of saccharin has been carried out by two different chemical processes. The Remsen–Fahlberg method involves reaction of toluene with chlorosulfonic acid to produce *o*- and *p*-toluene sulfonyl chlorides. The *o*-isomer is separated and then treated with ammonia to form *o*-toluene sulfonamide. The last compound is oxidized to *o*-sulfamoyl benzoic acid, which, upon heating, cyclizes to saccharin.

The Maumee process involves diazotization of methyl anthranylate with sodium nitrite in the presence of hydrochloric acid to form 2-carbomethoxybenzenesulfonyl chloride, which is converted to saccharin after amidation and acidification. The calcium or sodium salts of saccharin are produced by reaction of the respective hydroxides with saccharin.

Saccharin and its calcium or sodium salts are white crystalline powders with intensely sweet tastes. A dilute aqueous solution of saccharin is about 500 times sweeter than a solution with an equal concentration of sucrose, whereas the salts are about 300 times sweeter than a solution containing an equivalent weight of sucrose. The melting point of saccharin is 228.8–229.7 °C, whereas the salts decompose above 300 °C. The excellent stability of saccharin and its salts under normal food-processing makes it ideally suited technically as a noncaloric sweetener in many different products. It is unaffected, for example, by the heat processing required for jams, jellies, and canned fruits. The salts of saccharin are much more water soluble than saccharin (1 g of salts per 1.5 ml of water versus 1 g of saccharin

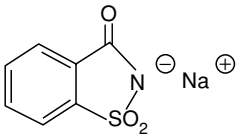

Figure 1 Structure of saccharin (sodium salt). Reproduced from Saccharin, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

per 290 ml of water). Aqueous solutions of sac charin are slightly acidic, whereas the calcium and sodium salts are neutral or slightly basic. They are very stable in aqueous solution over a wide pH range, although below pH 2.5 at elevated temperatures saccharin has a tendency to hydrolyze slowly to *o*-sulfamoyl benzoic acid and *o*-sulfobenzoic acid.

Food Uses

Because of its stability, saccharin (usually as its calcium or sodium salt) has been used in a wide variety of food products. These include carbonated and noncarbonated soft drink beverages, table-top sweeteners, dry beverage bases, canned fruits, gelatin desserts, cooked and instant puddings, salad dressings, jams, jellies, preserves, chewing gum, and baked goods. Typical amounts of sodium saccharin used in food products are, for example, 2.7 mg per ml of table-top sweetner, 0.32 mg per ml of carbonated soft drinks, 0.19 mg per ml of noncarbonated soft drinks, 0.9 mg per ml of jams and jellies and 2.2 mg per stick of chewing gum.

Nonfood uses of saccharin include applications in cosmetics such as toothpastes, mouthwashes, and lipstick, pharmaceuticals, such as coatings on pills, cattle feed, electroplating, and, in Japan, as an intermediate in the production of the rice blast fungicide, probenazole.

World commercial production of saccharin in 1900 was estimated to be about 190 tonnes. This increased more or less steadily up to the late 1970s, when world annual production reached approximately 5000 tonnes.

Metabolism and Safety

Many feeding studies with a variety of animal species have shown that saccharin is excreted unchanged. In rats, saccharin is excreted rapidly. However, there is some accumulation in the bladder, but the sweetener is completly cleared in 3 days after removal of saccharin from the diet. No metabolites have ever been detected. Studies have shown that the compound is not metabolized by liver microsomal enzymes, it is not genotoxic, and it does not bind to DNA after oral administration. The metabolic profiles of saccharin fed to dogs, rabbits, guinea-pigs, and hamsters are similar.

The greatest concern relating to metabolic effects of saccharin has been the uncertainty about its carcinogenicity to humans. Several early carcinogenicity studies in rats that included *in utero* exposure had indicated that feeding of saccharin may lead to bladder tumors. However, subsequent studies seem to indicate that it is not saccharin itself that causes the effects, but some other still unclear mechanism that operates in a dose-dependent fashion. Also, recent (1998) studies in monkeys have shown that saccharin is without carcinogenic effect on the primate urinary tract. A number of extensive epidemiological studies in humans have shown no association between saccharin consumption and urinary bladder cancer.

Regulatory Status

In 1972, because of the uncertainty of the safety of saccharin, the US Food and Drug Administration delisted saccharin and in 1977 proposed to ban its use in foods and beverages. However, public protest led congress to impose a moratorium on the ban, which has been extended up to the present. In Canada, saccharin was banned in 1978 for use in foods. However, it is permitted to be sold in pharmacies as a table-top sweetener. It is currently under review for other applications. In most other countries throughout the world, saccharin is permitted, although its use is restricted to varying degrees.

Analysis

A number of methods for the determination of saccharin in foods and pharmaceutical preparations have been reported. These include gas chromatography with flame ionization or electron capture detection, thin-layer chromatography, ultraviolet absorption spectrophotometry, and high-performance liquid chromatography (HPLC) with ultraviolet absorbance detection. The last technique is the most commonly used method at present, especially for the determination of saccharin in foods and beverages. For liquid samples, minimal sample preparation is required. The samples are filtered and perhaps diluted before being analyzed directly by HPLC. Solid foods are usually mixed with water, which extracts the saccharin. An aliquot of the aqueous extract is then directly analyzed by

HPLC. The sensitivity of the technique is more than adequate for the concentrations of saccharin normally encountered in foods. Saccharin has been incorporated into a multisweetener HPLC method.

SAGO PALM

J J Lal, Centre for Development of Science and Technology, Thrissur, Kerala, India

Introduction

The term sago means an edible starch extracted from the pith-like center of several Asian palms (including *Metroxylon sagu*) or sometimes of cycads. Palm is the common name for members of the plant family Palmae. Palmae is a large family and includes tropical trees, shrubs, and vines. Most members of this family are tree-like, characterized by a crown of compound leaves, and terminating in a tall, woody, unbranched stem. Natives adopt different techniques to separate sago from the stem.

Cycas revoluta

Cycas revoluta, popularly known as sago palm, is not a real palm but a cycad. It is a slow-growing, evergreen, long-lived, medium-sized palm-like plant. It is the most popular species in the genus *Cycas*. This plant is popularly known as King Sago. It is one of the cheapest and most readily available sources of food starch. It is a native of China and Japan and is widely grown as an ornamental plant in India. In combination with protein from sources such as fish and nuts, and vitamins from wild fruits, it forms a diet that has nourished communities in underdeveloped regions for many centuries. Even today it is a major energy food for many poor populations and is also a valuable famine food in these regions. The Japanese show special affinity for this plant and it plays an

important role in Japanese culture. The genus also occurs in the Malaysian region and South-east Asia, extending to Micronesia, Polynesia, Madagascar, and East Africa, and constitutes one of the oldest living plants on the earth. It plays an important role in the life of the locals as a source of cheap food in the form of sago and also plays a negative role by producing some toxins. These toxins are very strong and found in most parts of the plant. Consumption of the parts of the plant or even the processed flour from the plant has been implicated in a number of disease conditions.

Morphological and Anatomical Features

This attractive, ornamental tree is about 2 m in height and has branched stems with multiple heads. The plants grow in xerophytic areas like exposed slopes and other sunny places where water is scarce. It is hardy to $-9\,^{\circ}C$ and can also withstand high temperatures. It has a tuberous stem at a young age and rough, thick columnar stem in the adult stage and it is covered with an armour of thick, persistent leaf bases and at the apex with a crown of large compound leaves in apparent whorls. Once or twice a year, they produce a complete circle of new leaves which emerge all at once. The main rachis of the young leaves is in-curled and the leaflets are in-rolled, as in ferns. The general appearance of the plant is similar to that of a small palm and it is popularly known as cocopalm by the natives.

Internally the stem consists of an outer protective layer: the epidermis, large parenchymatous cortex, and large pith-containing thin-walled cells densely filled with starch or sago grains, numerous mucilage canals, and vascular bundles. Sago is the edible starch that can be extracted from the stem of cycads.

There are two types of leaves: scale leaves and foliage leaves. They are arranged in close spiral succession, alternating with each other. The scale leaves are brown, persistent, more numerous than foliage leaves, and play a protective role. The foliage leaves are large, 60 cm long, compound, and pinnately divided into more than 100 leaflets with a revolving margin, thus giving the plant its species name, *Cycas revoluta*. The midrib does not have veins and projects beyond the apex, ending in a spine. Petioles are thick and quadrangular in shape.

There is a taproot system which produces branches and some of the lateral roots become apogeotropic, growing vertically upward on the surface of the ground, where they branch repeatedly and form dichotomously branched coral-like masses, coralloid roots or corallorhiza that are inhabited by blue-green algae, *Anabaena cycadacearum*. This cyanophycean algae helps the plant to fix atmospheric nitrogen and increases the health and fertility of the soil. The surface of the coralloid roots is beset with lenticel-like apertures, suggesting their respiratory function.

Propagation

Sago palm is extensively propagated by vegetative methods by means of adventitious buds or bulbils, which are formed in the basal part of the stem as well as in the main trunk in mature plants. The plant is asexual (sporophyte) and dioecious in nature, i.e., the male and female structures, the cones, develop on separate plants. The male cones are borne singly and terminally on the main stem. Further apical growth of the stem is continued by the development of an axillary bud at the base of the cone and it becomes the new stem apex and therefore the stem of the male plant is sympodium. The male cone consists of a central woody axis bearing microsporophylls in a close and compact spiral. Each microsporophyl bears a large number of microsporangia, bearing microspores. There is no true, compact, and properly organized female cone.

The male gametophyte phase of the life cycle begins in the microsporangium and the pollen grain is considered to be an immature male gametophyte. The male gamete (sperm) develops inside the pollen grains. The large, top-shaped sperm ranges in size between 180 and 210 μm and it is visible to the naked eye. The megasporophylls arise spirally in acropetal succession and are loosely arranged on the stem like the ordinary crown of foliage leaves. The apical growing point of the female plant thus grows without any interruption and the stem in the female plant is monopodial. The megasporophylls are large, ranging from 15 to 20 cm in length. Each megasporophyl is divided into an upper broad leafy portion and a lower stalk-like portion and the ovules are borne laterally on the lower stalk-like portion: their number varies from two to 10. The female gametophyte develops inside the ovule.

The plant is generally believed to be wind-pollinated. After fertilization, the seeds develop over the summer and are ready to be removed in January or February. Mature seed is differentiated into an outer orange-red-colored fleshy layer, stony middle layer, and fleshy inner layer. Within these seed coats, there is a fleshy female prothalus, the endosperm, which functions as the food storage region of the seed. Seed will usually germinate in 3–6 months, but may require more than 3 years of growth to reach a small bulb-like structure.

Toxicity

Sago palm is known to be poisonous and sago separation includes careful processes to remove these toxins, before they are edible. Intake of sago before proper processing to remove toxins can cause vomiting, liver damage, and even death. Recent evidence indicates that the toxins have neurotoxic effects and now it is considered to be a slow poison.

It is remarkable that many indigenous people in different parts of the world have quite independently adopted different processing techniques. Fleshy seeds, leaves, unprocessed flour from stem pith, and pollen grains are considered to be toxic to livestock and to the population who live in proximity to these plants, and this has created interest in the pharmaceutical industry. The general symptoms of *Cycas* toxicity include diarrhea, headache, dizziness, vomiting, and mortality. The major toxic principle in sago palm poisoning is a glycoside named cycasin and other toxic glycosides include macrozamin, neocycasin, and an amino acid β-methylamino-L-alanine (BMAA). The active component of the glycosides is methylazoxyglycoside (MAM), which is formed by the cleavage of cycasin (glycosides) with the help of an enzyme, found in microbes in the gut. MAM is known to be hepatotoxic and carcinogenic. It causes apoptosis (programmed cell death) in the brain, thus reflecting a link between cycad ingestion and development of neurodegenerative disorders. BMAA is a nonprotein amino acid and its chemical structure shows similarities with beta-*N*-oxalylamino-L-alanine (BOAA), the neurotoxin from *Lathyrus sativus*. There are reports of incidence of amyotrophic lateral sclerosis (ALS) and parkinsonism dementia (PD) after *Cycas* ingestion. Cycasin and its aglycone MAM impair both rodent and human β-cell function, which may lead to the death of pancreatic islet cells, a very high prevalence of glucose intolerance, and diabetes mellitus.

Utilization of Sago Palm

Stem

Stem starch has been widely used as a food source. Pith and cortical cells contain a large amount of starch and yield sago grains and hence the plant is known as the sago palm. It has been estimated that a mature stem (i.e., beginning to flower) of about 1 m yields about 2 kg of sago. *Cycas* starch is a constituent of poor people's food and is used in times of food scarcity.

To separate the sago, the trunk of the plant is split and its pith-like center is chopped and ground into powder and the starch is removed. Before sago separation there is repeated washing, settling, and discarding of the water to eliminate the toxins. Ingestion of sago before proper washing leads to vomiting and dizziness. In Japan, the seeds and stems are often used to prepare wine. In Africa, to prepare bread from cycads, the central pith of the stem is taken in animal skin and buried in the ground for about 40–42 days until it is partially fermented. This fermented stem is ground up with water and is shaped into bread and baked. Crushed bark and seeds or megasporophyls, when mixed with coconut oil, are used in South. India as a poultice for sores and wounds. Since it contains a toxic glycoside, its constant use is said to cause intestinal disorders and it is considered to be genotoxic. Fiber obtained from the stems is used to make cloth and rope.

Leaves

The strong and leathery leaves keep their fresh green color long after being cut off from the plant and hence they are used as a nursery stock for funeral wreaths and church festivals under the name palm branches. The leaves are also used to decorate marriages and festivals. Leaves are used to make brooms and baskets, and to thatch huts. Leaf is also a source of fiber in the manufacture of cloth, ropes, and twines. Young fleshy leaves are used as vegetables. Consumption of leaves without proper detoxification is harmful and prolonged ingestion of leaves is toxic.

Roots

The roots are a source of sago and in Africa it is believed that burying the roots by a house could protect from lightning.

Seeds

Mature palms produce seeds in the female cones. A large plant may yield over 1000 seeds. Mature seeds are large and orange-red in color. The seeds attract animals, birds, rodents, and fruit-eating bats, which help seed dispersal. Intake of these seeds by domestic animals is toxic and leads to vomiting, dizziness, salivation, paralysis, and even death, but in wild animals, it is found to be nontoxic. To separate the sago, mature seeds are split open and the kernel is collected and sun-dried for 1 or 2 days. After thorough drying, the toxins are eliminated from the seeds by immersing it in water for 3–6 h: the water is stirred well and the foamy water is drained off. This washing process is repeated at least seven times for the total removal of toxins. Thereafter it is dried in sunlight and ground to prepare flour. Sago flour is pure white

in color and is similar to that of wheat or rice flour. Natives prepare bread, steam cakes, several indigenous dishes/sweets, and even wines. Preparations from the sago palm flour are considered to be an effective medicine to cure hemorrhoids (piles). It is also observed that pregnant women demand sago palm seed flour preparations as part of their pregnancy cravings, particularly if they were in the habit of consuming sago during their childhood days. Young seeds on boiling yield a decoction which is often used as a purgative.

Pollen Grains

Pollen grains formed inside the microsporophyls are considered to have medicinal properties. In India 'quacks' claim it as a folk medicine which has several health benefits, obtained from 'kailasam' (the place of Lord Shiva). It has been reported that pollen is heavily laden with cycasin and BMAA and is toxic.

Metroxylon Sagu

Metroxylon sagu is a true palm belonging to the order Arecales, family Palmae, and subfamily Calamoideae. It is commonly grown in wild swampy areas of Malaysia, Indonesia, and New Guinea. This palm grows between 10 °N and 10 °S latitudes and up to an elevation ranging from 700 to 1000 m. It is also found growing in dry lands. In certain regions of the world, this palm is a provider of staple food. Its tremendous utility favored its distribution from its place of origin to far-off distant places, including South-east Asia. It attains a natural height of 15 m. The stem is straight, stout, and without branches and has a unique crown of large pinnate leaves. The roots are unbranched and go straight down to the soil. Sago palm grows quickly and it dominates in tropical peat swamp rainforests, where other crop plants do not thrive. Sago palm is a kind of semiwild species but not a well-established crop plant. In the wild and in cultivation, sago palm is mostly propagated vegetatively through its suckers.

Sago palm is tolerant of highly acidic conditions (low pH) coupled with high concentration of metals in the soil like aluminum, iron, and manganese, which inhibit the growth of other plant species. It has the ability to grow abundantly in heavy clay soils, which inhibits the growth of other plant species. In wild conditions, a cluster of sago palms can be seen. Each sago cluster consists of several mature plants and suckers. People used to harvest the mature trunk, leaving the immature ones and suckers. Thus, there is a possibility for the continuous harvesting of mature palms at intervals, thereby sustaining sago production.

Individual suckers at first grow into a rosette of leaves. Then it produces a stout trunk. Sago palm reaches sexual maturity at about 12–15 years. It is a monocarpic plant – it flowers only once in its life and then dies. Insects help to pollinate the flowers. The fruits take about 1½–2 years to mature. Just before the onset of flowering, the palm is harvested to obtain maximum yield. During this stage, the palm converts its stored nutrients into starch, which accumulates in the trunk.

Edible starch is extracted from the pith-like center of sago palm when the tree is about 12 years old. During harvesting, the entire trunk is cut into pieces. The marrow of the stem is then chopped out as finely as possible and its starch is then washed out and separated from the cellulose. Starch separated from the stem is dried to yield sago meal.

Productivity of sago palm is four times that of paddy (*Oryza sativa*). A single sago palm yields about 150–300 kg sago. This starch is an important item in the diet in some parts of Eastern Asia. It is used in various food items and also to stiffen cloth material in the textile industry. Desiccated products made from sago starch can be stored for exceptionally long periods. Sago starch has a multitude of uses. Sago is widely used to produce sago pearls. Sago pearls can be boiled, either alone or mixed with other foods, and consumed directly as a carbohydrate source. Sago is also widely used, together with rice, corn, and potatoes, in the manufacture of noodles in Malaysia. It is also used for the production of monosodium glutamate, soft drinks, and various syrups. The other uses of sago include the manufacture of biodegradable plastics, ethanol, and citric acid. Sago meal is very digestible and hence it can be used to feed livestock, pigs, and even poultry.

In addition to the production of starch from the stem, the large and strong leaves are useful. Leaves are best for roof thatching, and for making bags, baskets, and cages. Leaves contain long fibers (1.69–3.59 mm) which have a high cellulose content. Hence, it is also useful for papermaking.

The sago beetle is one pest which attacks the sago palm. It bores into the trunks of the palms and lays its eggs inside. But the natives consume the larvae of these sago beetles as a highly esteemed delicacy. They consume it either raw or in cooked form. Thus, the pest attack has proved a boon to the local population. Unfortunately, however, apes and wild boars tend to damage palms at the young stage by digging up and eating young palms during the sucker stage.

SALAD CROPS

Contents

Dietary Importance

K Gupta and M K Rana, CCS Haryana Agricultural University, Haryana, India

Introduction

Vegetables that are normally consumed raw or uncooked are known as salad crops. They are seasonal, attractive in appearance, and are valued for their appetizing succulence, bulk, and nutritional importance in human diet. Advances in education and communication now mean that people have become health-conscious and aware of quality of food for their better health. Salad is becoming a popular addition in the routine food habits of masses of people all over the world. Salad vegetables consumed raw supply more nutrients compared to cooked ones. All salad vegetables are highly perishable in nature, and their natural fresh form, which is preferred by quality-conscious consumers, is rapidly lost. However, with improved packaging technology, refrigerated transportation systems, and advanced storage facilities, the demand for salad vegetables, especially celery, lettuce, and many others, is increasing day by day.

Types of Plant in the Salad Category

Since there is a vast number of salad vegetables grown and consumed in various parts of the world, it is essential that these must be so grouped that information on them can be accessed readily. They may be classified according to botanical traits, season of growth, edible part of the plant used, and suitability of the soil reaction for their successful cultivation (**Tables 1–3**.) However, as salad vegetables are consumed fresh, it may be pertinent to classify them particularly on the basis of edible portions consumed (**Table 2**).

Table 1 Names of salad crops in nine languages

English	*Danish*	*Dutch*	*French*	*German*	*Italian*	*Portuguese*	*Spanish*	*Swedish*
Artichoke	Artiskok	Artisjok	Artichauft	Artischocke	Carciofo	Alcachofra	Alcachofa	Kronartskocks

Nutritional and Dietary Significance

Salad vegetables, categorized as protective foods, are rich in the macro- and micronutrients and fiber that play a significant role in the maintenance of human health. In contrast, salad vegetables are relatively inexpensive. They are quite popular, easy to grow, ship well, and have a long period of harvest but short storage life. They are important for neutralizing the acids produced in the stomach during the course of digestion of meat, cheese, and other fatty foods. They are of value as roughage that helps to prevent constipation. A certain amount of bulky food is necessary for good health. Most salad vegetables, particularly the leaf types, such as celery, cabbage, Chinese cabbage, lettuce, parsley, and spinach, are characterized by a high water content and a relatively high percentage of cellulose or fiber because of their succulence and large bulk. The leafy and root salad crops ordinarily help in the digestion of highly concentrated foods (Tables 4–7.).

The carbohydrates of vegetables comprise starch and sugars, mainly sucrose, glucose, and fructose, which are easily available to the body and constitute the main source of energy. Vegetables also provide unsaturated lipids containing essential fatty acids such as linoleic, linolenic, and arachidonic acid, which are required for normal growth and maintenance of the body. Salad vegetables provide a variety of proteins to the human body.

Salad crops ranking highest in vitamin A are carrot, turnip greens, spinach, mustard, and dandelion (Tables 5–7.). Measured in levels of vitamins and minerals, artichokes rank seventh among the top vegetables. Spinach, kale, and collard contain high levels of vitamins and minerals, particularly vitamin A, calcium, phosphorus, and iron. A single serving meets the daily requirement of vitamin A and C and 13% of the total calcium requirement of an adult.

Beet crops and carrots are considered primarily as a source of carbohydrates, especially sugars. Carrot roots contribute a significant proportion of the daily requirement for vitamin A in US diets for adults, and in addition to vitamins and minerals they provide important dietary fiber.

Likewise, celery is also a good source of calcium, phosphorus, and iron, and is rich in carotene, the precursor of vitamin A, and in riboflavin, niacin, and thiamin. One hundred grams of celery contain protein 6.3 g, minerals 2.1 g, carbohydrates 1.6 g, and fiber 1.4 g.

The nutritive value of cactus is comparable to those of other popular fruits. They are rich in sugars (sucrose 0.2%, glucose 7.0%, fructose 4.8% of fresh fruit mass); vitamin C 22 mg; minerals (calcium 27.6 mg, magnesium 27.2 mg, sodium 0.8 mg potassium

Table 2 Botanical names, common names, and edible plant parts of vegetables/salad crops

Common name	*Botanical name*	*Family*	*Edible plant part*
Monocotyledony

European corn salad	*Valerianella locusta* (L.) Laterrade em. Betcke	Polygonaceae	Leaf

161 mg, phosphorus 15.4 mg, iron 1.5 mg $100\,g^{-1}$ edible part) and amino acids.

Chicory, chives, endive, kale, mustard, parsley leaves, spinach, spring onions, and turnip greens are excellent sources of vitamins A and C. Vitamin A ranges from 2500 to 14 000 IU and vitamin C from 30 to 180 mg per 100 g of the edible part (Table 7). The plain-leaf endive (escarole) and the dandelion (leaves) are highly rich in vitamin A (14 000 IU) and contain vitamin C 100 and 35 mg $100\,g^{-1}$ edible plant part, respectively. Sprouting broccoli is most nutritious amongst the cole crops, especially for calcium, iron, vitamins, and protein. As regards quality, kohlrabi is similar to red cabbage but superior to turnip and rutabaga as it has less bitter principle.

Parsley and watercress are good sources of iron, calcium, vitamins A and C, and riboflavin. Spinach,

amongst the highly nutritious salad vegetables, is the best source of vitamin A, providing 8100 IU $100\,g^{-1}$ edible part. This amount also provides vitamin C 51 mg and calcium 93 mg. Spinach is also a good source of iron, phosphorus, and potassium, with 3.1, 51, and 470 mg $100\,g^{-1}$ edible plant part, respectively. The quality of spinach is related to its bright green color, tenderness, and flavor.

Table 3 Classification based on life cycle and optimum temperature (season)

Cycle/vegetable	*Season*
Perennial	*Cool-season crops*
Artichoke	*Hardy*
Garlic	Asparagus
Tomato	Leek
Asparagus	Parsley
Dandelion	Rhubarb
Watercress	Turnip
Chicory	Cabbage
Onion	Dandelion
Rhubarb	Watercress
Chive	Garlic
	Onion
Biennial	Kohlrabi
Beet	Radish
Cabbage	
Celery	*Half-hardy*
Leek	Carrot
Parsley	Celeriac
Carrot	Fennel
Celeriac	Lettuce
Parsnip	Artichoke
Cauliflower	Beet
Florence fennel	Celery
Kohlrabi	Chicory
Turnip	Endive
Annual	*Warm-season crops*
Cucumber	Tender–tomato
Lettuce	Very tender – cucumber
Radish	
Endive	
Mustard	

Turnip greens are considered valuable in the diet primarily because of vitamin A and C contents and the minerals calcium and iron. Leafy green and yellow salad vegetables are important sources of vitamin A and vitamin C, and contain appreciable quantities of thiamin, niacin, and folic acid.

Industrial Use

The consistent availability of fresh and processed vegetables in the world market indicates the immense economic significance of the vegetable industry as a major segment of the agricultural economy. The dehydration of onions is done at industrial level in the USA, especially in California. Asparagus, tomatoes, lettuce, cucumber, and carrot are produced commercially and processed into different food products on an industrial scale. Some cauliflower, cabbage, rat-tailed radish, turnip, and carrot are stored, canned, and shipped. The commercial production of kale and spinach is confined along the East Coast and in California, respectively. Sauerkraut is the main processed product prepared from cabbage.

Chinese cabbage is fermented to produce the Korean dish kimchi, which includes either fermented Chinese cabbage or fermented radish along with hot peppers, garlic, and other ingredients. Commercial quantities of chives are sold to processors, and chopped leaves are mixed with cottage cheese or cream cheese for the retail market. Lettuce leaves are sometimes used as a substitute for tobacco in cigarettes. Certain species of cactus are used for making jam and syrups, alcoholic drinks, honey and cheese, and fruit juices, and soap is made from the leaves.

Celery has been used as a garnish and condiment in Europe, Egypt, and China since old times. Probably the plants used for these purposes were of the 'smallage' type, with hollow, narrow petioles. Presently

the celery seeds are used as a pleasant flavoring agent in tomato juice, sauces, soups, pickles, pastries, salads, and other savoury dishes.

Fennel (*Foeniculum vulgare*), a tall, hardy, aromatic perennial of the parsley family, is native to southern Europe, and the Mediterranean area, especially in the vicinity of the sea. Fennel is derived from the Roman *Foeniculum*, a variety of fragrant hay, and has been used as a condiment by the Chinese, Indians, and Egyptians since long ago. *F. vulgare* var. dulce Alef is cultivated in France for its young stems, which are used in salads, and for its seeds; young shoots are used as a vegetable and herb in Italy. The leaves are feathery green, finely divided, and there are golden yellow flowers. The fresh needle-shaped leaves are used to flavor fish sauces and to garnish mackerel.

Biological Properties

The medicinal significance of the above-mentioned salad vegetables in human life is briefly described below.

Asparagus shoots used as salad are useful to cleanse the bowels and to cure jaundice and other stomach disorders. The cactus may reduce sugar and cholesterol levels in human blood and its seeds are used in pharmaceuticals. Globe artichoke is known for its medicinal significance in reducing blood clotting and capillary resistance, and in neutralization of some acids. The juice extracted from globe artichokes is used as a remedial treatment of gastrointestinal disorders.

Chicory is used for the remedy of warts. The boiled leaves of dandelion are used as a diuretic and for liver, kidney, and urinary disorders. The extract taken from

In some cases, the analytical data relating to a given crop will appear to vary between articles. These differences may arise because of contrasts in experimental techniques and/or raw materials employed by the original authors, and hence no attempt has been made to standardize the available information.

spinach leaves is used to clean wounds and cure warts in the UK. According to documentary evidence in the literature, watercress has been used as a medicinal plant from the first to the nineteenth centuries; its principal use is as an antiscorbutic.

The plants of the Brassicaceae family have been claimed to possess cancer-preventive properties. Increased consumption of broccoli, particularly among women, appeared to improve survival against lung cancer. Broccoli may also play an important role in lowering the serum cholesterol levels. Plants of the Crucifereae family contain *S*-methylcysteine sulfoxide, which is principally responsible for reducing blood cholesterol levels in the body.

Sulforaphane, a substance isolated from broccoli and some other crucifers, helps to prevent the growth of tumors developed by cancer-causing toxin in mice. This may also have future applications in human cancer treatment. The discovery of antithyroid properties of cabbage causing goiter in rabbits and other studies have related the occurrence of endemic goiter in humans in Belgium, western China, and Canada and in animals to the consumption of rutabaga, turnip, cabbage, kale, rape, and other crucifers.

Researchers and breeders increasingly are concerned about the concentration of glucosinolates in cruciferous crops and their influence on humans and animals. Glucosinolates as such are not injurious, but their hydrolytic forms cause serious damage. When plant cells are crushed, the myrosinase (thioglucoside-glucohydrolase) enzyme becomes active and starts hydrolyzing the glucosinolates present in the cells into various breakdown products, such as isothiocyanates (mustard oils), thiocyanates, and nitrites. However, there is increasing evidence associating regular consumption of cabbage and other *Brassica* vegetables with the reduced incidence of some forms of cancer, probably due to the presence of glucosinolate-derived products.

Several claims have been made that celery seeds improve longevity and memory, eradicate skin wounds and cure leprosy. It has also been used in the UK for the treatment of rheumatism since the nineteenth century and is still used today as a nerve stimulant in India. In the Orient, celery is used as the medicine tranians; the boiled seed oil is inhaled as vapor to cure headaches.

In past centuries fennel has been involved in medicine as a carminative, stimulant, and stomachic, and

as a cure for asthma, earache, toothache, rheumatism, and cough. Even today it is being used as one of the principal ingredients of 'gripe water' given to small babies with digestive troubles and recommended by herbalists to obese persons to reduce their weight.

Leek and other vegetables of the genus *Allium* are known to have aphrodisiac, blood purification, and antithrombotic properties. The antibiotic effects of *Allium* are due to the occurrence of sulfur compounds, the bactericide being allicin. Onion has been prized for its medicinal significance since Gerarde. In the *Great Herbal* (1596) it was stated that 'the juice of onions snuffed up into the nose purges the head ... Forged with salt, rue and honey ... it is good against the biting of mad dogs ... Anointed upon a bald head in the sun brings up the hair again very speedily.' Onion and garlic are used as folk medicine to cure headaches, remove parasites, and for heart and circulatory disorders. In China, onion tea is taken to treat headache, cholera, fever, and dysentery.

Ancient Greek and Roman physicians used to cure jaundice, headaches, and fevers with extract of wild lettuce leaves. The extract for the treatment of cancers of the uterus, liver, and other tumors was also used. Unlike its close wild relatives, the cultivated form *Lactuca sativa* does not contain the bitter principles sesquiterpene lactones, lactucin, and lactupicrin, having sedative properties. The other form of lettuce, *L. virosa* L., is used in the pharmaceutical industry for manufacturing the drug lactucarium.

Rhubarb was prescribed in the literature for liver and stomach disorders and to eradicate ringworm. In Europe towards the end of the Middle Ages a huge demand for the purgative drug derived from its dried roots established a steady trade from central Asia.

Use in the Home as Raw or Industrially Processed Food

Freshness contributes prominently to crispiness and taste of the salads that are customarily consumed uncooked and in a raw state. A small fraction of salad vegetables is also processed to convert them into more delicious and durable food products. Ordinarily carrot, radish, turnip, cauliflower, cucumber, and chillies are used to make pickles in addition to their use in fresh salads. Celery, lettuce, onions, and tomatoes, the most popular and important salad vegetables, are available throughout the year. However, due to their medicinal importance in human diet, carrots, cabbage, lettuce, mustard, onion, rhubarb, spinach, and watercress are used as salad.

Artichoke is generally boiled or steamed before it is consumed. However, some people prefer to take it raw, when it is harvested at a young stage. The bottoms and hearts are canned, frozen, marinated, or kept in oil, and also used to produce pulp. Inulin, the carbohydrate stored in the Jerusalem artichoke tubers, on hydrolysis yields fructose, and is therefore recommended for diabetes mellitus.

Numerous cultivated forms of cabbage (*Brassica oleracia* var. capitata), with a wide range of features, are available in nature. One or another variety, e.g., Spring Green, January King, Savoy, Round-Headed, White Cabbage, and Red Cabbage, can be made available throughout the year. These are particularly used in the frozen-food industry and in prepared salad. Many types of Chinese cabbage are extremely important in the diets of Asians, used raw in salads, cooked as greens, or fermented and preserved for later use. Fermented Chinese cabbage or radish, along with hot pepper, garlic, and other ingredients, forms the popular Korean dish kimchi.

In Mexico, the USA, Chile, Brazil, Spain, Italy, Greece, and Northern Africa, certain genera of cactus form an important part of people's dietary requirements. The tender young pads of *Opuntia* and *Nopalea* species of cactus, known as Nopalitos, are extensively used as fresh green or salad vegetable and fruit in Mexico and Texas. With the excellent quality and flavor of fresh fruits, its young leaves serve as a nutritious vegetable and salad dish and immature fruits for making mock-gherkins.

Celery, chervil, leeks, and tomatoes are used to make delicious soups and stews. Rhubarb and tomatoes are also used in the preparation of sauces. Chervil, chicory, leeks, fringed-leaf endive, fennel leaves, and parsley are also used to flavor and garnish the food. Lettuce, cabbage, radish, turnip, and cucumber are industrially fermented to lettuce kraut, sauerkraut, sauerriipen, pawtsay, dill pickles, sour pickles, and salt stocks. These fermented products are relatively more appetizing, palatable, and flavorful than the unfermented ones.

Finely ground powder prepared from dried, roasted chicory roots is used as a substitute of coffee or in blends with coffee. Chicory and endive are grown as potherbs and their leaves are used to some extent only. Chives are used in salads or in omelets and other dishes. A close relative of the globe artichoke, a leafy plant known as cardoon is grown for its edible roots, or more often for its petioles, which may be used either as a cooked vegetable or eaten raw in salads.

Parsley, being appealing in flavor and taste, may be used both on and in most foodstuffs except sweets, as a seasoning and garnish in soups, salads, fish, meats, and vegetables. Its foliage is in greater demand than its seeds. In California, USA, West Germany, Belgium, Hungary, Canada, Spain, and France, industrial

dehydrated parsley flakes are produced on a commercial scale.

Toxic Substances

Asparagus contains saponins and cholinesterase inhibitors. Carrot roots hold carotatoxin, which causes neurotoxic symptoms. The leaves of rhubarb and sorrel have a high content of oxalic acid, which on ingestion reacts with soluble calcium and synthesizes insoluble calcium oxalate, and as a result inhibits the absorption of calcium. Hence, because of their toxicity, they should not be consumed in huge quantities. The glucosides present in rhubarb appear to cause strong irritation. White-colored oca tubers possess a slightly higher oxalic acid content.

Brassica plants possess cholinesterase enzyme inhibitors and a number of different goitrogens that cause goiter in humans. Various species of mustard contain glucosinolates, which are responsible for several digestive disorders. Parsley and celery contain psoralens and terpenoids, which cause dermatitis, whereas some species of parsley and celery also contain alkaloids and a cholinesterase enzyme inhibitor. Lettuce is known to be an accumulator of a nitrate form of nitrogen. Spinach contains oxalic acid and saponins, and also tends to accumulate high levels of nitrates, which may be reduced to nitrites. Nitrites may convert hemoglobin to methemoglobin, interfering with the normal transportation of oxygen in the blood.

Some species of cucumber have a high content of glycoalkaloid compounds, usually the glycosides (cucurbitacins), which contribute a bitter taste to the fruit, and their higher concentrations appear to be very toxic. Hot pepper contains a high amount of amide or resinoid capsaicin, which may sometimes cause gastric disorders and skin irritation.

The cultivated forms of vegetables are generally considered as safe if consumed appropriately, and have many alimentary benefits that contribute to the maintenance of health. However, excess ingestion of beneficial substances can produce harmful effects, whereas only low concentrations of some toxic compounds can be endured by the body. The important consideration is the dosage that makes the toxic compound effective to produce injurious effects, and where and how it acts in the body (Table 8).

Table 8 Toxins present in salad crops

Name of crop	*Toxins*
Artichoke	Grosshemin
Brown mustard	Progoitrin
Cabbage	Glucocapparin (progoitrin)
Cabbage leaves	Spirobrassinin
Celery	Xanthotoxin
Chicory	Cichoralexin
Cucumber	Cucurbitacin
Fennel	Anethole
Garden beet	Malonic acid
Hot pepper	Capsaicin
Lettuce	Lactucin, lactucopicrin
Mustard	Gluconasturtiin
Parsley	Malonic acid
Parsnip	Xanthotoxol
Rhubarb	Oxalic acid
Spinach	Coumestrol, histamine/oxalic acid

Leaf-types

K Gupta and M K Rana, CCS Haryana Agricultural University, Haryana, India

Introduction

Leafy salad vegetables are amongst the most important and universally used vegetable crops grown throughout the world, and are also available throughout the year. They are attractive in appearance and have value for their appetizing succulence, bulk, and nutrients. These vegetables mostly have crisp, tasty,

and tender edible leaves. Leafy salad vegetables are nutritionally important sources of protein, fiber, minerals, and vitamins. Their prominence as an important crop group has been heightened over several decades through awareness of consumers regarding nutritional and other obvious values they offer to the diet as fresh greens. As these crops have become a daily table staple, their acreage has expanded to a remarkable degree over the past few decades, making them an important segment of the agricultural and marketing industries, especially in the USA.

Nearly all vegetables can be consumed raw, but few of them are commonly referred to as salad crops, of which only a few are considered as leafy salad vegetables based on the criterion that their leaves alone are consumed. Leafy salad crops are defined as those crops from which leaves and associated parts are harvested for use as raw vegetables. Their succulent leaves and petioles are susceptible to damage by pests, poor production and handling systems, and environmental extremes over which growers have little or no control.

There are four major leafy salad crops – celery (*Apium graveolens*), chicory (*Cichorium intybus*), endive (*Cichorium endivia* L.) and lettuce (*Lactuca sativa* L.) – and other lesser vegetables used primarily for salads, flavoring, or garnishing the foods. The latter include Brussels sprouts (*Brassica oleracea* var. gemmifera), cabbage (*B. oleracea* var. capitata), Chinese cabbage (*B. pekinensis*), chervil (*Anthriscus cerefolium*), dill (*Anethum graveolens*), garden cress (*Lepidium sativum*), mustard (*B. juncea*), parsley (*Petroselinum crispum*), spinach (*Spinacia oleracea*), and watercress (*Rorippa nasturtium-aquaticum*). Most salad crops thrive best during cooler and moist seasons, and do not tolerate hot weather conditions.

Global Distribution, Commercial Importance, and Varieties

Brussels sprouts (*B. oleracea* var. gemmifera) are similar to cabbage when prepared as salad for table purposes. This crop has been grown around Brussels and Belgium for hundreds of years and is an important vegetable in Europe, particularly in England. Out of Europe it is not important, although it is widely grown in Australia and California.

Improved Long Island, Catskill, Early Morn Dwarf Improved, and Friither Zwerg Kvik are important varieties belonging to the dwarf type. Bedfordshire, Cambridge no. 1, 3, and 5, Irish Elegance, and Sherradian are some of the important cultivars grown in England and Ireland. Early cultivars such as Breda (Netherlands), Weibulls Rapid (Sweden), and Wilhelmsburg (Germany) have light green sprouts. Late hardy cultivars include Red Vein, Hild's Idea, DeRoshy Amager, and Polarstjernen.

Cabbage is one of the most important and oldest recorded vegetables, cultivated throughout the world. The word cabbage (*B. oleracea* var. capitata L.) is probably derived from the French word cobbache meaning head, and the name *Brassica* from the Celtic name bresic for cabbage. Cabbage was mentioned in the early literature and was probably in general use as early as 2000 or 2500 BC. In 1987, the total area under cabbage crop was 1 682 000 ha with a production of 38 132 000 tonnes. Asia has the largest production area (811 000 ha) followed by the former Soviet Union (420 000 ha) and Europe (296 000 ha).

Cabbage and Chinese cabbage (*B. pekinensis* and *B. chinensis*) are annual potherbs grown as salad vegetables. In China they have been cultivated since the fifth century and were introduced to the USA in the late nineteenth century. In the USA, Chinese cabbage is grown throughout the year in California, Florida, and Hawaii. The importance of Chinese cabbage is also increasing in European countries, notably the UK, France, and Germany. The most popular varieties are Chihili and Wong Bok, grown in the USA. Two more or less distinct species are grown: petsai (*B. pekinensis*) and pak choi (*B. chinensis*). Shantung Cabbage, Chefoo Cabbage, Pekin Cabbage, Chou De Chine and Celery Cabbage are the known varieties of Chinese cabbage.

Celery (*Apium graveolens*) is an herb, widely cultivated for its edible swollen leaf petioles. Green and white varieties are available. Celeriac is a variety of celery (*A. graveolens* var. rapaceum) with an edible tuberous base to the stems. Celery was first cultivated as a medicinal crop as early as 400 BC in Egypt and in the Roman Empire. The Greeks used it to make a celery wine called selinites. Crowns made of celery stems and leaves were awarded to winners of athletic games at the Isthmus of Corinth.

Chicory (*Cichorium intybus* L.), a member of the family Compositae (Asteraceae), is an important perennial salad vegetable. It is native to Europe and Asia, and may have originated from the Mediterranean region. Chicory is also known as French endive, witloof, witloof chicory, and succory. The first mention of chicory cultivation was in 1616 in Germany. The blanched cluster of leaves (head) called witloof chicory, which has a delicate flavor, is widely used in France, Belgium, and The Netherlands. The dried, roasted, and ground roots are also used as a coffee substitute or in blends with coffee.

Radichetta and Rosso de Verona are the important chicory cultivars in the USA and Italy, respectively. Penninck, Christaens, Mueninck, and Van Espen are Belgian cultivars, while Normato, Malina, Bubbal

Blank, and Slusia Meilof are Dutch cultivars. Flambor, Bergere, and Zoom are chicory hybrids. Tardivo and Mitado are the best cultivars for forcing, giving highest yield and best quality produce. Best forcing varieties under hydroponic system in terms of yield and quality are Tardivo, Mitado, Nunhems 825-76 and Nunhems 820-76, Zoom, Alvaro, and Barola. For very early forcing, Daliva, Arnova, Zoom, Mitiva, and Wivro are the outstanding cultivars.

Chervil is native to Europe and has finely divided pinnate leaves. It was cultivated in England in 1597 and in America by 1806. The origin of salad chervil (*Anthriscus cerefolium* L.) lies in the region of south-eastern Europe and western Asia. Cress is also known as pepper grass or garden cress, and is grown as a salad crop all over the world. A native of Iran and Europe, it spread from Persia to India, Egypt, and Greece. It was mentioned by Xenophobe in 400 BC, and has been cultivated in England since 1548. In the USA it is cultivated and also grows wild. Four types of cress are cultivated: common, curled, broad-leaved, and golden cultivars. Chervil may also be used as a garnish, in soups or as a cooked vegetable.

Endive (*Chichorium endivia* L.), belonging to the family Compositae (Asteraceae), is an annual or biennial popular salad vegetable in Europe. Its popularity has also increased in the USA. It is believed to be a native of Egypt or India. It is indigenous to eastern Mediterranean areas and may have originated from a cross between *C. intybus* and *C. pumitum*. The Egyptians used it at a very early period. During the thirteenth century, it reached northern Europe. It was noted in the USA in 1806. Endive is an important market garden crop in Florida, USA. Its cultivation began in England in 1686 and in France in 1826. Endive is classified into two general groups: (1) the curled or fringe-leafed cultivars, and (2) the broad-leaved cultivars. The Green Curled Ruffic, Deep Heart Fringed, Green Curled Pancalier, and White Curled are curled or fringe-leafed types. Varieties representing the Broad-Leaved class are broad-leaved Batavian, Full-Heart, Batavian or Escarole and Florida Deep Heart.

Kale (*B. oleracea* var. acephala) is a nonheading type of cabbage and belongs to the family Cruciferae (Brassicaceae). It is a hardy food and a fodder crop. It can tolerate temperatures as low as $-15\,^{\circ}C$ as well as high temperatures. There are various types of kale, but curly-leafed types are grown for human consumption. Cultivation of kale probably began seven millennia ago; the Greeks grew them as early as 600 BC. Kale varieties have been classified as Marrow-Stem Kale, Leafy Kale, Thousand-Head Kale, and Curly Kale. The most popular varieties of kale in the USA are Dwarf Blue Scotch and Dwarf Green Scotch.

Lettuce, an annual and a most popular cool-season leafy salad vegetable of great commercial importance, belongs to the tribe Cicoreae and family Compositae. The cultivated lettuce (*Lactuca sativa* L.) is related to wild lettuce (*L. scariola*), a common weed in the USA. Heading lettuce is a relatively recent cultivated crop, being first described as cabbage lettuce in 1543. It is grown throughout temperate, tropical, and subtropical climates. Both cultivated and wild lettuce species are native of Europe and Asia, and have been in cultivation for the last 2500 years. Evidence from tomb paintings indicates that it was cultivated before 4500 BC. In India, the Portuguese and the British introduced it during the sixteenth century. The crop spread throughout the Mediterranean region during the Greek and Roman era and from there to the rest of Europe. It was recorded as being cultivated in the New World by 1494. Lettuce is known as green gold in California, the most important vegetable-producing state in the USA.

Lettuce production and consumption have increased several-fold over the last two decades throughout temperate countries. However, in tropical and subtropical countries, its popularity is still confined to urban populations. Lettuce ranks sixth in acreage and third in value among 22 principal vegetables. World lettuce production is estimated at about 3 million tonnes and it is grown on more than 300 000 ha. Lettuce is grown in all continents, but the greatest consumers and producers are the USA (91 000 ha, of which 60 000 ha are in California) and Europe (total European Community area 80 000 ha). Lettuce is also grown in large areas of south-eastern Australia, Japan, China, Israel, northern Mexico, Chile, Argentina, Brazil, and Peru. The value of the US crop is nearly $800 million and in the UK lettuce is the single most valuable vegetable crop, with a value of £78 million. It is widely used in all salad preparations, and has a somewhat bizarre use as a substitute for tobacco.

Four types of lettuce – head-type (*Lactuca sativa* L. var. capitata), leaf-type (*L. sativa* L. var. crispa), cos-type (*L. sativa* L. var. longifolia), and asparagus lettuce or stem-type (*L. sativa* L. var. asparagina) are grown in the USA. The crisp head-type is the most popular and is extensively grown in the USA. About 70% of US crisp head lettuce is produced commercially in California, 16% in Arizona, and the rest in several other states. The American type has recently become increasingly popular in the UK and Spain. Crisp head lettuce is often called Iceberg lettuce, when marketed as a trimmed overwrapped head. However, this is somewhat misleading since there is

a crisp head cultivar called iceberg, which is unsuitable for iceberg production. Butter head and cos (Romaine) are popular in northern and southern Europe. Leaf lettuce is grown mainly in Mediterranean areas and also in South America. Stem lettuce is cultivated mainly in the orient.

One hundred and fifty distinct varieties have been reported, of which 20–25 are commercially important. They have been classified into three general classes:

1. Butter head varieties:
   (a) Bunching varieties
   (b) Cabbage heading varieties
2. Crisp head varieties:
   (a) Bunching varieties
   (b) Cabbage heading varieties
3. Cos-type varieties:
   (a) Lanceolate-leaved varieties
   (b) Lobed-leaved varieties
   (c) Spatulate-leaved varieties

The crisp head class includes most of the important commercial varieties, of which New York 515 and Imperial 44, 152, 456, 615, and 847 are the most popular. Great Lakes and Penn Lakes are other important crisp head varieties: the former has several strains. Big Boston, White Boston, May King, Salamander, and Wayahead are the common varieties of butter head type, but they are of relatively little commercial importance. Black-Seeded Simpson, Early-Curled Simpson, Grand Rapids, and Slow Bolt are the main varieties of leaf or bunching lettuce. Paris White (White Cos) and Dark Green are the cos-type varieties.

Cultivars include Sea Green, Empress Calsweet, Green Ice, Cabrillo, Cal K-60, Calmaria, Chaparral, Mesaverde, Morangold, Morgangourd, and Royal Oak Leaf. In India Great Lakes (head-type) and Chinese yellow (loose-leaf-type) are commonly grown cultivars. Imperial 859 and Slow Bolt are also improved cultivars of lettuce, and the Indian Agricultural Research Institute, New Delhi, has released all four cultivars.

Mustard (*B. juncea* or *B. alba*) is a member of the cabbage family. It is used both as a salad ingredient and as a green vegetable. There are several species of mustard used for spice, flavoring, oil seeds, green fodder, manure, and greens or salad. In addition to being grown for its seeds, white mustard may be grown as a salad plant, cover crop, and green manure. It is principally an oilseed crop, but is commonly grown as a leafy vegetable in northern parts of India, China, and tropical and subtropical regions. All the *Brassicas* are native to central Asia and the Himalayas, with secondary centers in India and eastern China. The commercially important white mustard (*Sinapsis alba*), brown mustard (*B. nigra*), and Ethiopian mustard (*B. corinata*) are grown all over the world for various uses. They are particularly common in the USA, Canada, the UK, and most countries of Europe, India, China, and the South-east Asian countries. In the USA, mustard for salads and greens is grown in Texas, California, Florida, Georgia, Louisiana, and Mississippi. There are two principal salad or greens cultivars, namely Florida (broad leaf) and Southern Giant (curled leaf), which are grown in the USA. Varieties Ford Hook Fancy, Ostrich Plume, and Southern Giant are the popular varieties of *B. juncea* grown in the USA.

Parsley (*Petroselinum crispum* Mill.), a biennial or short-lived perennial cool-season crop, is native to the Mediterranean region and Europe. Parsley is popular as a garnish for salads, sandwiches, and cooked dishes; as flavoring for soups and pasta, and as a salad ingredient – only in small amount owing to its pungent flavor. The Hamburg type is used mainly in soups and stews. The swollen root of turnip-rooted parsley is eaten as a cooked vegetable. It was popular in early times among the Greeks and Romans. It is valued as an aid to digestion and in suppressing odors of onion and wine. It has been in cultivation for over 2000 years. Parsley is produced commercially in Texas, California, New Jersey, Florida, and New York. Parsley was introduced into England from Sardinia in 1548 and into America by 1806.

Five types of parsley varieties – plain-leafed, celery-leafed or Neapolitan, curled, fern-leafed, and turnip-root types – are available. The curled type is most common but plain and turnip-root types are also grown in the USA. The best-known varieties are Moss, Extra Double Curled, Fern-Leafed, Curled Dwarf, Ever Green, Extra Triple Curled, Plain, and Dark Green Italian. Morgo was developed in Sweden, and Hamburg is a turnip-rooted variety.

Spinach (*Spinacia oleracea* L.) belongs to the family Chenopodiaceae. The name spinach is derived from the Spanish word espinaca. Spinach is annual for leaf production and biennial for seed production. It is the most important potherb or green vegetable grown throughout the world and is used raw in salads or mixed with other salad vegetables. Its leaves and tender shoots are consumed fresh or processed and canned. Spinach is native to central Asia, most probably Iran (Persia). Spinach cultivation developed during the Greek and Roman civilizations about 2000 years ago. It was introduced and known in China as early as the seventh century (647 AD). Arabs introduced spinach into North Africa and therefrom the Moors introduced it into Spain in the eleventh

century and into America in 1806. The crop was known in Germany in the thirteenth century and elsewhere in Europe in 1552. Spinach is of two types: prickly-seeded and smooth-seeded.

The major commercial areas for growing spinach are California, mostly in Ventura country; the Winter Garden region of the lower Rio Grande Valley of Texas; Maryland, New Jersey, and Colorado. California contributes one-third of the total spinach produced for industrial processing. One hundred and twenty-one spinach varieties obtained from American and European sources were tested and it was concluded that only five distinct varieties exist. Varieties were classified into Savoy leaf and flat leaf types, instead of the original four groups – Norfolk or Bloomsdale, round-leafed, thick-leafed, and prickly-leafed. Juliana, Virginia Savoy, Old Dominion, Hollandia, Viroflag, Amsterdam Giant, King of Denmark, and Nobel are important varieties of these two classes. The varieties Viro flag, Fruremona, and Wiremona are good for processing. Beltsville Arlington (Virginia), Beltsville (Maryland), Winter Haven (Texas), and Davis (California) are long-standing varieties in different countries; many hybrids are also available.

Watercress, a unique perennial salad vegetable having worldwide distribution, commonly grows in flowing water as a wild or cultivated crop. It is believed to be a native of the eastern Mediterranean and Europe. It grows wild in streams in the cool regions of the world, but is also found growing wild above 1500 m in the Himalayas of Nepal and hilly areas of the USA. Most production is in Virginia, Maryland, Pennsylvania, and California. It was used as a medicinal plant in AD 77 as it has antiscorbutic properties. In Europe, watercress formed one of the tributes to the high Kings of Erin (Ireland) during the Dark Ages. The first large-scale cultivation of watercress is suggested to have been in southern Germany, near Erfurt, around 1750. It was grown in England for the first time in 1808 and in France in 1811 where large-scale cultivation was started to supply the markets of London and Paris.

Watercress is cropped for its side stems and leaves. It has a hot mustard/radish-like flavor and pungent taste, and is generally used in mixed salads, as a garnish, in sandwiches and soups. Seedlings with the hypocotyl and green cotyledons are cut and used in the UK for salads and sandwiches. Its elongated shoot with vigorous basal branching produces a sward crop. Repeated cutting leads to increased branching and as many as 10 crops a year may be harvested. For commercial outdoor cultivation it is planted in beds covered with slowly flowing clean water. There are two main cultivars: Green Cress, which is diploid, and fertile, and Brown Cress or Winter Cress, which is triploid and sterile. Cress (*Lepidium sativum* L. f. Cruciferae) is a much-branched annual with linear leaves. The Moss Curled (curled) variety is branching, dark green, and with a mild, but distinct flavor.

Features of the Edible Parts

In Brussels sprouts, instead of a single head at the top of the stem, miniature heads are born in the axils of leaves distributed all along a tall stem, which is crowned with a cluster of loose leaves. The dwarf varieties of Brussels sprouts have short stems, mostly less than 50 cm long. In dwarf cultivars sprouts are of medium size and the distance between sprouts is small. Tall late hardy cultivars are preferred for a long growing season. Early cultivars have light green sprouts. The small solid heads 5–7 cm in diameter are tender and delicious.

Michihili, the most common improved variety of Chinese cabbage, is uniform in size and heading. The heads are usually 46 cm long and 10 cm thick, and cylindrical in shape with a tapered tip. The outer foliage is dark green, the inner leaves are blanched, and the midrib is white and broad. The old Chinese cultivar, Won Bok, has light green leaves. The petsai, which resembles the cos lettuce, produces a much larger, elongated and compact head; the leaves are slightly wrinkled, green, thin, and much veined. The midrib is broad and light in color. Another variety, pakchoi, resembles Swiss chard in its growth habit. The leaves are long, dark green, and oblong or oval, and do not form a solid head.

In the case of Radichetta chicory, the leaves are dark green, narrow, and notched, and the Italian cultivar is a red, nonforcing type.

Endive is a plant with numerous radical leaves, which are smooth, lobed, more or less deeply cut and spreading into a rosette; the stem is hollow, from 50 cm to over 1 m high, ribbed and branching. Endive grows as a loose head of leaves, which are usually strongly ruffled and serrated. The outermost leaves are green and bitter in taste, but the inner leaves are light green to whitish in color.

Kale is closely related to the wild cabbage, and most of its forms bear a rosette of leaves at the top of the stem. Its tender young leaves are used for salad. It also produces edible inflorescence like cauliflower and broccoli.

Lettuce forms a rosette of large, longish leaves, which are somewhat spoon-shaped and more or less undulated/toothed at the edges. From the center of the rosette springs a nearly cylindrical stem, which narrows very rapidly and branches at about one-third of its height. It is furnished with clasping

leaves, which encircle the stem and become narrower as they approach the top. There are six morphological types of lettuce: crisp head, butter head, cos, leaf, stem, and Latin, depending on changes in leaf shape and development of the heading character.

Crisp head-type lettuces have unbranched stems, which generally remain less than 30 cm long, owing to the growth being arrested at an early stage. As the growing point continues to form leaf primordia, a rosette of sessile leaves arises. The first leaf unfolds normally, and can reach a length of over 30 cm. After some time, other leaves are produced which unfold only partially and form a layer, embracing the laterally formed leaves that do not expand. This continuous segregation and growth of young leaves develops a head. Crisp head cultivars are usually large, heavy, brittle-textured and tightly folded with green outer and white or yellowish inner leaves.

Butter head comprises heads of very soft, buttery, textured crumpled leaves, which have less prominent veins and midribs than in crisp head types. The variety Imperial has relatively soft textured light to medium green leaves with serrated or wavy edges. The leaves of Great Lakes are brittle with ruffled margins, and are bright green to yellow with prominent ribs. Leaves of Empire are light green, deeply serrated and crisp, while the heads are often slightly elongated or conical. Butter head varieties are sometimes referred to as cabbage lettuce. Their broad oily, soft-textured, crumpled leaves form relatively small, loose heads. There are a number of other cultivars, which vary in size, color (including red), and appearance.

Leaf lettuce primarily produces a rosette of leaves and has no heading tendency. Like butter head lettuce, it forms a loose head, but the leaves are elongated, resembling those of cos lettuce.

Cos (Romaine) lettuce has elongated heads of long leaves with heavy midribs. The outer leaves are coarse and tough in appearance and dark green, but the inner leaves are fine-textured and light green. The eating quality of cos lettuce is good and it is very popular in southern Europe and the Mediterranean region.

Stem lettuce is sold as Celtuce in the USA; the stems are peeled and used as salad or cooked vegetable.

Latin lettuce leaves are somewhat elongated, but more leathery than Romaine. It is very different in appearance from other types of lettuce, having a thickened, elongated stem, which is peeled and used as salad or cooked vegetable.

Mustard leaves are very strongly flavored and pungent. The inner younger leaves are milder and are best suited for salad. The basal rosette leaves of mustard vary in form, while the stem leaves are mostly entire. Leaves are large, broadening towards the apex, and have smooth or curled margins. Florida Broad Leaf is a vigorous, large, and erect plant with large, thick, broad, oval leaves with toothed margins. Southern Giant (curled leaf) is large and upright with large, wide leaves and curly leaf margins.

Parsley is a rosette of divided leaves on a short stem. The curled-leaf-type is most common and attractive. Its three subtypes – double-curled (moss curled), evergreen, and triple-curled – are distinguished by the degree of leaf curling, coarseness of the leaf, and plant growth habit. Moss curled (double-curled) has a stem about 30 cm tall with vigorous, compact and very dark green leaves, which are finely cut, deeply curled, and frost-resistant. Leaves of evergreen type are coarsely cut, while extra triple-curled leaves are finely cut and very closely curled. The triple-curled variety has slightly shorter leaves, which are closely curled. The leaves of the variety Paramount are tall, very uniform, triple-curled, and a very dark green color. The plain leaf parsley (Dark Green Italian) has deeply cut leaves but no curling or fringing. Plain-leaved types include plain (singles) and have flat leaves. The leaves of the Dark Green Italian cultivar are heavy and glossy green.

Spinach, in general, produces rosettes of fleshy leaves, which may be crinkled (Savoy) or smooth in the vegetative phase. The leaves are ovate, rounded or triangular, succulent, and borne on a short stem. In the second stage of growth, the stem elongates, producing a seed stalk with narrow, pointed leaves. The shape, size, and color may differ and be characteristic of a varietal group. Varieties used for processing have large, smooth, dark, or medium green leaves with a semierect or spreading habit.

The watercress plant has three parts: first is an aerial stem portion with an apex, and leaves with no roots projecting above the water; second is a stem portion beneath the flowing water, which has foliage and a system of adventitious roots that arise from the leaf axils and remain free in water; and third is the normal roots. Watercress leaves are pinnately compound with three to 11 leaflets, rounded or oblong, and slightly fleshy with smooth margins.

Chemical and Nutritional Composition

Brassica vegetables have isothiocyanates, thiocyanates, and nitrites as major sources of their characteristic flavor, i.e., pungent aroma and bitter taste. Brussels sprouts are rich in vitamin A and ascorbic acid and contain appreciable amounts of riboflavin, niacin, calcium, and iron. Kale, being a rich source of

vitamin C, carotenoids, and calcium, ranks high among the greens in nutritive value.

Cabbage is rich in vitamin C and high in minerals and proteins. Chinese cabbage provides 25 mg vitamin C, 240 IU equivalents of vitamin A, and moderate amounts of calcium, iron, phosphorus, and potassium per 100 g of raw product. The cold-hardy varieties possess higher soluble sugar content. The sugar to dietary fiber ratio and soluble protein content are related to flavor quality.

The fringed-leaf endive is quite an ornamental potherb and is more popular as a salad vegetable than the broad-leaf type which is used mainly unblanched in stews and soups. Curly endive provides 81 mg calcium, 3300 IU equivalents of vitamin A and 10 mg vitamin C as well as moderate amounts of phosphorus, potassium, and iron per 100 g edible part. Escarole has 14 000 IU equivalents of vitamin A and vitamin C 100 mg $100\,g^{-1}$ edible part. All endives contain moderate amounts of minerals. Chicory is rich in vitamins containing 1400 IU equivalents of vitamin A and vitamin C 100 mg $100\,g^{-1}$ edible part.

Lettuce, rated as fourth, behind tomato, citrus and potato on overall consumption basis, ranks 26th on a nutritional scale. Butter head lettuce, producing a large number of green leaves, is more nutritious than the crisp head type. Cos and leaf lettuces are still more nutritious, mainly because of their high carotenoids (1900 IU vitamin A equivalents) and vitamin C (18 mg) content per 100 g fresh weight. Crisp head lettuce supplies 6 mg ascorbic acid, 330 IU equivalents of vitamin A and calcium 20 mg $100\,g^{-1}$ fresh weight. However, butter head lettuce contributes 8 mg ascorbic acid, 970 IU equivalents of vitamin A and calcium 35 mg $100\,g^{-1}$ fresh weight. Other nutrients like phosphorus, iron, sodium, and potassium, are present in varying amounts in the different lettuce types. Although lettuce has a very high water content (94–95%), it can still prove a useful source of minerals. Leaf texture, color, crispness, taste, flavor, and resistance to early bolting are considered the quality characters.

The young inner leaves of mustard that are tender and mild in taste are consumed as salad. Mustard greens are highly nutritious. A 100-g serving of cooked mustard contains 48 mg vitamin C, 5800 IU equivalents of vitamin A, 138 mg calcium and moderate amounts of other elements.

Healthy parsley leaves with their familiar agreeable flavor are an excellent source of carotenoids, vitamin C, and iodine, a good source of potassium, and a moderate source of iron, sodium, and phosphorus. However, its contribution to the diet is negligible. Parsley per 100 g edible part contains 8500 IU equivalents of vitamin A, 172 mg vitamin C, and 203 mg calcium. (*See* **Fatty Acids**: *Trans*-fatty Acids: Health Effects.)

Spinach is the best vegetable source of provitamin A, providing 8100 IU equivalents per 100 g edible part, and it also contains 51 mg vitamin C and 93 mg calcium. Spinach is a good source of iron (3.1 mg), phosphorus (51 mg), and potassium (470 mg). However, the calcium is said to be unavailable due to the presence of oxalic acid, forming calcium oxalate. It may also contain appreciable amounts of nitrate and nitrite, which are injurious to human health. (*See* **Minerals – Dietary Importance; Nitrates and Nitrites.**)

Raw watercress leaves and stews supply 79 mg ascorbic acid, 4900 IU equivalents of vitamin A, calcium 151 mg per 100 g edible part and moderate to large amounts of other elements.

Postharvest Handling and Storage

Baskets are used to pick and carry Brussels sprouts to the packing houses. The individual boxes are overwrapped with a transparent film. Film packaging is useful in preventing moisture loss because the transpiration rate of Brussels sprouts is relatively high. The 0 °C temperature coupled with 95–98% relative humidity are optimum storage conditions for Brussels sprouts to keep them in marketable condition for about 3–5 weeks. The sprouts can be stored for a longer period at -2 °C temperature. A controlled atmosphere, having 2.5–5.0% O_2 and 5–7.5% CO_2, maintains the quality of Brussels sprouts held at 5 or 10 °C but not at 0 °C. Oxygen levels below 1% can cause internal discoloration.

Cabbage heads are usually harvested with a knife or sickle, retaining few leaves below the head intact to provide a kind of protection. For prolonged storage sufficient care is taken to prevent injuries due to bruising. The healthy heads are packed in perforated polyethylene bags and stored at low temperature immediately after harvest. Refrigeration at 1.6 °C or lower and low relative humidity is required to check the storage disorders. The lower the temperature, the longer will be the storage life, but severe freezing damages the quality. Solid heads are comparatively more prone to freezing injury than merely firm heads. A temperature of 0 °C with 98% relative humidity is advocated for storage up to 6 months.

All cole crops should be stored free from ethylene to avoid premature senescence and tissue injury. Prevention of excessive moisture loss is essential during the course of storage. The major advantages of controlled-atmosphere storage include slight reductions in weight loss and retardation of general senescence,

such as yellowing, toughening, and loss of the flavor of cabbage. White cabbage stores well in 5% O_2 plus 2.5–5% CO_2. However, if O_2 is maintained near zero or CO_2 at 15% or higher for 1 month or longer, there is discoloration of internal leaves, even though the external leaves of cabbage may remain normal. Some varieties which are stored for off-season marketing can be maintained in an acceptable condition for 2–3 months, and up to 6 months with the use of modified-atmosphere storage (1% O_2 and 5% CO_2 at 0–1 °C and 98–100% relative humidity). (*See* **Packaging**: Packaging of Solids; **Storage Stability**: Parameters Affecting Storage Stability.)

Chinese cabbage is harvested by hand at leaf base; the outer diseased or damaged leaves are trimmed off and packed in flat baskets, boxes, and crates of various sizes. The head should be packed loosely and preferably upright in crates. The produce can be stored for several weeks at 0 °C temperature and 95% relative humidity. However, at this temperature with 98% relative humidity, the Chinese cabbage can be kept in marketable condition for about 4–6 months. Proper spacing should be maintained in between containers for air circulation in storage. A low concentration of oxygen has been reported to be beneficial in prolonging the storage life of Chinese cabbage.

The compact, brightly colored and marketable size heads of chicory are harvested by cutting the plants from the base, and their damaged or diseased leaves are trimmed. Such heads, after washing and vacuum cooling or hydrocooling to 0 °C temperature, are packed in layers in wire-bound crates or cartons or baskets for transit. The smaller package is much desirable. The heads are stored for 2–3 weeks at 0 °C temperature and 90–95% relative humidity. Chicory can be stored for a longer period with crushed ice in and around the package.

Endive and escarole are not adapted to long storage and even at 0 °C temperature they cannot be kept satisfactorily for more than 2–3 weeks. Vacuum cooling or hydrocooling can be helpful in retaining their fresh appearance. The relative humidity in rooms, where endive or escarole is kept, should be maintained above 95% to avoid wilting. They can be kept somewhat longer if stored with crushed ice in or around the packages.

Lettuce is harvested as soon as its plants reach an acceptable size and firmness; harvesting should be completed before the leaves become tough in texture and bitter in taste, and prior to the emergence of seed stalk. The lettuce grown for market is allowed to grow to its full size and develop a solid head while, for home consumption it is often harvested before the head is well developed. The heads are hand-cut just below the lowest leaf; loose and damaged leaves are removed, and the produce is washed prior to packaging.

Generally three types of market preparation – naked pack, source-wrapped, and bulk pack – are adopted:

1. Naked pack: the heads are cut, trimmed, and packed in two tiers (12 heads each) in cardboard boxes.
2. Source-wrapped: after being cut and trimmed, the heads are wrapped, heat-sealed, and placed 24 per carton.
3. Bulk pack: cut heads, collected in bulk containers, are transported to a central packing house where they are cored, shredded, washed, and cooled immediately after harvest. Cooling is predominantly done by a vacuum method, particularly for head lettuce shipped to distant markets. To aid vacuum cooling, clean water is sprinkled on lettuce heads prior to carton closure if they are dry and warmer than 25 °C. Refrigerated trucks are used for the shipment of lettuce.

For long storage lettuce should be packed in perforated plastic films, used either as individual head wraps, or in carton or crates with liners to maintain a high humidity around the lettuce. To save on space and weight, trim two 'wrapper' leaves before packing, rather than keeping all five to six leaves, as extra wrapper leaves are not required to maintain quality. When lettuce reaches the market, wrapper leaves are removed and discarded to improve the appearance. Removal of wrapper leaves at harvest and wrapping the heads with plastic film reduces the amount of injury sustained by lettuce during packing.

Polyethylene-lined (0.04 mm thick) packaging checks lettuce leaf rot by 30–40% compared with open polyethylene bags. Mechanical injury is the major cause of quality loss and waste in unwrapped lettuce. Packaging of Romaine lettuce in unsealed polyethylene-lined packaging, in spite of high relative humidity, markedly decreases the rate of decay during storage. This beneficial effect of packaging is due to the high CO_2 and low O_2 levels in the package as a result of respiration. Lettuce should be precooled to − 1 °C just after harvest and stored at 0 °C temperature and 98–100% relative humidity. The rate of general deterioration at 15 °C is observed to be about 2.5 times higher than that at 0 °C.

Lettuce, being highly perishable, deteriorates quickly. The respiration rate increases rapidly and storage life decreases concomitantly as storage temperature increases from 0 to 25 °C. Leaf lettuce respires at about twice the rate of head lettuce. Lettuce can be stored for 3–4 weeks at about 0 °C, which is

twice a long as at 3–4 °C, if it is brought in good condition at the storage facility. Lettuce is easily damaged by freezing, therefore, storage room temperature must be kept above the highest freezing point (− 0.2 °C) of lettuce.

A limited use of controlled-atmosphere storage with about 1.5% CO_2 and 3–5% O_2 has been recommended for storing lettuce in good condition. This atmosphere prevents russet spotting and butt discoloration. High CO_2 (above 2.5%) and low O_2 (below 1%) levels in storage atmosphere are injurious to lettuce. Thus the problems of russet spotting, bacterial soft rot, and carbon dioxide injury causing serious losses can be checked. Kinetin application delays chlorophyl loss and slows down the increase in abscissic acid content. Two days prior to harvest a combined application of GA_3 10 ppm and the cytokinin isopentenyl-adenine 0.1 ppm delays lettuce senescence most effectively.

Small bundles of mustard greens are made after discarding the old and diseased leaves. It is handled like other greens at 0 °C temperature and commonly shipped with inpackage and top ice to maintain freshness. Vitamin content and quality are retained so long as wilting is prevented. Due to high rates of respiration, kale is prone to rapid desiccation, therefore provision of rapid cooling, low temperature, and high-humidity storage conditions is important until the commodity is consumed.

Harvesting of parsley, cutting outer and larger leaves only, extends over a long period of time. The loosely packed or bunched leaves are washed thoroughly before packing in crates or bushel baskets. Crushed ice is usually placed in the package, and shipment to distant markets is made under refrigeration. Much of the crop goes into the institutional trade (restaurants and hotels) and for dehydration. At 0 °C temperature and high humidity parsley can be stored up to 2 months.

Harvesting of spinach usually begins when the plants have attained five to six leaves and continues until before the seed stalks emerge. The plants are cut just close to the soil surface for market, while for processing purposes about 5 cm above the soil surface allows regrowth. Harvesting should be done only during the cooler parts of the day to minimize wilting. The crop should not be cut immediately after rain or heavy dew since the leaves, being at their full turgor, are injured easily. Yellow and diseased leaves are removed, and the produce is handled gently to prevent bruising. As washing in tanks usually results in injury to the leaves, spraying with water on a moving belt is desirable. Round bushel baskets, hampers, and crates are used to pack spinach, and crushed ice is generally placed in the containers when refrigerated trucks are used for long shipments.

Wilting of spinach on account of rapid air movement and low humidity makes it less attractive and causes loss of ascorbic acid content; however, this is of much less significance than unfavorable temperatures. From packaging till its final retail sale continuous refrigeration near 0 °C is generally recommended. Spinach can be hydrocooled or vacuum-cooled equally well. In case of hydrocooling, to remove excess water, it should be centrifuged for about 3 min. Chlorinated water (100 p.p.m.), if used for washing or cooling, avoids bacterial build-up on the produce. Spinach remains usable up to 24 days at 1.6 °C, 7 days at 10 °C, or 2–2.5 days at 18 °C. In spinach stored at 20 °C for 6 days the chlorophyl and ascorbic acid contents decrease greatly and yellowing increases. CO_2-enriched atmosphere (10% CO_2) retards yellowing of spinach and keeps the product in good quality for about 3 weeks at 5 °C. Thus, controlled-atmosphere storage extends the shelf-life of spinach by about 1 week at 5 °C.

The top 15 cm watercress shoots are harvested. Watercress is a highly perishable crop and needs prompt handling after harvesting. Improper handling of watercress will result in loss of its color and the leaves become slimy. It should be precooled by either hydrocooling or vacuum cooling. It is bunched and usually packed in alternate layers with flake ice and kept cool during shipment by spraying with cold water and/or ice. Watercress packed in waxed cartons with top ice holds up well for 2–3 weeks at 0 °C with high (95–100%) relative humidity. A similar storage life is possible using permeable polyethylene crate liners and package icing to minimize wilting. Naked bunches of watercress are highly perishable, even at 0 °C, and may be kept for 3–4 days. The use of polyethylene film liners may be justified to prevent moisture loss under some circumstances.

Other Types of Salad Crops

K Gupta and M K Rana, CCS Haryana Agricultural University, Hisar, Haryana, India

Introduction

Of all the leaf-stem types of salad crops, celery (*Apium graveolens*) is the most important. The other crops of this group are: American wintergreen (*Gaultheria procumbens* L.), asparagus (*Asparagus officinalis*), baby corn (*Zea mays* var. crassa), broccoli (*Brassica oleracea* var. *italica*), dandelion (*Taraxacium officinale* Wig.), florence fennel (*Foeniculum officinale* D.C.), globe artichoke (*Cynara scolymus* L.), kohlrabi (*Brassica oleracea* var. gongylodes), oca (*Oxalis tuberosa* Molina), and parsnip (*Pastinaca sativa* L.). These crops are consumed in different forms, especially in temperate countries.

Global Distribution, Commercial Importance, and Varieties

American wintergreen (*Gaultheria procumbens* L.) belongs to the family, Ericaceae, and *Gaultheria* was named after Dr. Gaultheria, a physician from Quebec in about 1750. It is commonly consumed as salad crop for its tender leaves and stem in America and Western countries, as well as Asia to Australia.

Asparagus (*Asparagus officinalis*) is native to Europe and Asia, and it is the young shoots that are the edible parts. There are green and purple varieties of asparagus. Forcing the plants with the exclusion of light produces white spears, which are very popular in Europe. The green variety of asparagus is the one commonly canned and is most popular in the UK.

Baby corn (*Zea mays* var. rugosa or sacchorata), a form of maize, is an ancient crop, as revealed from cob remnants, dating back to about 5000 BC, found at the Tehuacan cave excavations in Mexico. Domestication is estimated to have begun about that time. Baby corn is quite nutritious and is the most popular salad vegetable in United States and Western countries, where its tender ears, canned in 2% citric acid, are imported from developing countries, mainly from Thailand. It is an ingredient of vegetable biryani, mixed vegetables, Chinese food preparations, etc. Soup, crispy vegetable salad, and pickles made from baby corn are other value-added delicacies in big hotels and airlines. In addition to significant nutrition, baby corn imparts diversity to meals because of its texture and flavor. The recognized cultivars of baby corn in India are Prakash, Golden Baby, and Composite Kesari.

Broccoli (*Brassica oleracea* var. italica), a rapidly developing floral vegetable, is usually harvested when the curd is compact and immature. The name broccoli refers to the young shoots that develop in some species of genus *Brassica* ('brocco' is an Italian word for 'shoot'). In the United States, it is also known as Italian broccoli, suggesting its Italian origin. Its peduncle, basically a stem, is consumed raw as salad. The broccoli, believed to be the ancestor of cauliflower, is a vegetable of the highest quality and of commercial importance in USA as it is the favorite vegetable of Americans. Broccoli was one of the top vegetables exported from the USA in 1995. Broccoli and asparagus accounted for about 90% of the $102.6 million of exported vegetables from the USA to Japan in 1994. A large part of the US production goes to the freezing industry. The top broccoli-producing states in 1992 were California, Arizona, and Texas.

Broccoli is gradually becoming a popular vegetable in other parts of the world. Italian Green Sprouting and Calabrese are the most popular varieties of broccoli. The early and medium-maturing strains of Italian Green Sprouting, Midway, Green Mountain, and Grand Central, are dark bluish green in color and produce large compact heads and many lateral shoots after the central head is cut. The cultivar De Cicco, the main winter broccoli grown in Texas, is light green in color and produces abundant lateral shoots.

Celery (*Apium graveolens* L.) belongs to the family Apiaceae (Umbelliferae), and comprises three distinct cultivated varieties that are grown in different parts of the world for different economic purposes. These varieties are classified below, according to the botanical parts of the plant consumed.

1. *Apium graveolens* var. dulce, common name 'celery:' the plants of celery develop succulent, solid petioles that are used mostly raw as salad.
2. *Apium graveolens* var. rapaceum, common name 'celeriac' or 'root celery.' It is characterized by the development of enlarged hypocotyl or root tissue. It is consumed mostly cooked in stews and soups or grated on salad.
3. *Apium graveolens* var. secalinum, common name 'smallage' or 'leaf celery:' the plants have leafy, slender, and often hollow petioles. Its leaves are used as a condiment garnish and for medicinal purposes.

The genus *Apium* is spread world-wide, particularly in the Mediterranean basin, Australia, New Zealand, South Africa, and South America. Among 14 species, *Apium graveolens* is the only cultivated type. The Mediterranean basin is considered to be the center of its origin. Argentina and Chile are the countries richest in *Apium* species. Celery is important in Europe and America. Its habitat extends from Sweden southwards to Algeria, Egypt, and Ethiopia and in Asia from the Caucasus (Bluchistan) to the mountains of India. Wild celery can be found in damp or marshy areas of different European countries, Egypt, and parts of Asia. It was first used as a medicinal plant and as a food in AD 1500. Homer's '*Odyssey*' mentions salinon (celery) grown in 850 BC, but this early form, later called 'smallage,' was a leafy plant, quite pungent and bitter, and used exclusively for medicines.

Celery was demonstrated as a true vegetable in Italy in the sixteenth century. At that time, the first reports of the three horticultural varieties, 'celery,' 'celeriac,' and 'smallage,' appeared. Selection for solid and succulent petioles resulted in 'celery' types, whereas, selection for enlarged hypocotyls gave rise to 'celeriac' types.

Fresh use of celery began in the eighteenth century, and its use as a vegetable in the USA was recorded in 1806. It is used in mixed salads or as an appetizer, in which case, it is often stuffed with cream cheese or peanut butter. In the USA, a large part of the celery crop is consumed in the raw state, but considerable quantities are used in vegetable juices, soups, and stews and as cooked vegetables.

In the eighteenth century, two varieties of solid-stem Italian celery available in France were 'Solid Celery' and 'Striped Rose.' In 1875, Chemin selected a line known as 'Solid Golden White Celery,' which became the variety 'Paris Golden Yellow Self-Blanching.' In 1884, Pascal selected a green celery line from this variety, which was known in the seed trade as 'Pascal Celery.' In 1887, both the varieties were introduced to North America under the names of 'White Plume' for the self-blanching type and 'Giant Pascal' for the green type.

The word 'dandelion' comes from the French 'Dent de Lion' meaning 'lion's tooth' and reflects the jagged shape of the leaf. Previously, it was considered a noxious weed, but now, cultivated dandelion has been developed from the wild species (*Taraxacum officinale*), a member of the Compositae family. It is a great favorite in Europe, and to a lesser extent, in the USA. Its leaves are used raw in salads or cooked as greens. The flowers can be fermented to produce wine. The roots, similar to those of chicory, may be used as a coffee substitute.

Fennel is produced commercially in the USA, but most of its seed is imported from India, Argentina, and Bulgaria. Volatile oil (anethole constituent) of fennel seeds is an adaptable flavoring agent used in the manufacture of pickles, perfumes, soaps, liquors, cough drops, and chicory candy.

Florence fennel (*Foeniculum officinale*) is also a leaf-stem type salad crop. It is a native of southern Europe and resembles wild fennel. The type 'Carosella' (*Foeniculum piperitum*, D.C.), extensively used in Naples and scarcely known anywhere else, is a species very closely related to *F. officinale*. The plant is used while running to bloom. The fresh and tender stems, available only from the end of March until June, are served raw and still enclosed in the expanded leaf stalks; Italian fennel (*F. dulce*), a short-lived perennial also called finnochio, is cultivated as an annual. The base of its leaves becomes enlarged and bulb-like and, when blanched, has the texture of celery being primarily used for flavoring.

Globe artichoke (*Cynara scolymus* L.), belonging to family Asteraceae (Compositae) in tribe *Cynarae*, is named so as to distinguish it from the Jerusalem artichoke (*Helianthus tuberosus*). It is an important vegetable in Mediterranean countries, where 90% of the world artichoke crop is produced. Italy, Spain, France, and Argentina are the main producers. *Cyanara cardunculus* L. var. sylvestris Lam (the wild cardoon) is widely spread in the western Mediterranean basin (Spain, Morocco, Algeria, Tunisia, and Sicily). *C. sibthorpiana* Boiss and Heldr is located in the central part (the Peloponnese, Aegean Islands, and Cyrenaica), and *C. syiaca* Boiss is found in the eastern part (Palestine).

Kohlrabi (*Brassica oleracca* var. gongylodes), belonging to the family Cruciferae (Brassicaceae), is a biennial herbaceous swollen bulb-like stem vegetable grown as an annual. Writers in ancient Rome had described kohlrabi, which was developed in northern Europe in the fifteenth century. It is a minor crop grown in temperate countries and in some subtropical areas. The tubers or swollen stems, which develop above the ground, may be due to secondary growth in thickness. The tuber is harvested before it becomes tough or woody.

Oca (*Oxalis tuberosa* Molina) belongs to the family Oxaliolaceae. It is an ancient crop cultivated by preColumbian people and in the Andean highlands. Commercial production occurs in Mexico, Central America, and the South Island of New Zealand.

Parsnip (*Pastinaca sativa* L.) belongs to Umbelliferae (Apiaceae) family. It is a native biennial of Europe and Western Asia and is cultivated for its large, fleshy taproots and also for its leaves. It was introduced to the West Indies in 1564 but grows well in the tropics only at high altitudes. The Romans and Greeks used it for medicinal purposes and food in ancient times.

Rhubarb (*Rheum* spp.) is a very early and high-yielding vegetable crop, well suited for cultivation in climatically cool regions. The UK, The Netherlands, Germany, the Nordic countries, Canada, and the USA are the main cultivation regions for rhubarb. It is a minor commercial crop plant but very common in gardens. Rhubarb (*Rheum rhaponticum*) is a long-lived perennial plant, with edible stalks, and was originally native to Siberia.

Morphology of Edible Parts

American wintergreen plants are erect, or prostrate, with creeping stems, giving rise to erect branches (15 cm high and leafy at the top). The lower leaves are alternate and serrated with short petioles, but the top leaves are oval, 2.5–5 cm long, apiculate, glaucous, and shining above. The flowers are solitary or in racemes or panicles, and scarlet-colored.

The edible portion of asparagus is the spear that develops from the crown. Green asparagus, which is the greater portion of the crop, is cut 2.5–5 cm below the soil surface. Asparagus spears are usually harvested before excessive elongation occurs to keep the tenderness. The spears are harvested when the tip is about to emerge or just protrudes through the soil surface.

Baby corn is a herbaceous monocotyledon and warm season annual. Plants are monoecious with male flowers borne as the terminal inflorescence (tassels) on the main stem, and female flowers borne separately as lateral inflorescence (ears) developing at the leaf axils. Plants produce one or more ears. Baby corn is the young ear of maize plant harvested before fertilization when the silks have just emerged. The stem-like, dehusked, light yellow-colored, and tender ears of baby corn are used in salads.

The broccoli plant forms a kind of head consisting of green buds and thick fleshy flower stalks. The terminal head is rather loose and green in color, and the flower stalks are longer than those of cauliflower. The internodes are long, and the plant produces axillary flowering shoots in addition to the terminal inflorescence. The color of the flower buds forming the edible portion varies from white to green, depending on the cultivar. The inflorescence comprises fully differentiated flower buds, although it is considered to be a good-quality vegetable if these reach the open stage. The sprouts in the leaf axils develop strongly, especially after removal of the terminal head. The terminal head and the sprouts with bud clusters may be used in salads but also as a cooked vegetable.

The celery plant is characterized by enlarged, tender, edible petioles or leaf stalks. The petioles are broad, with sheathing bases. Celery is a biennial; however, a few strains and related wild species are cultivated as annuals. The plants start bolting (producing seed stalks) when exposed to cold temperatures for a longer time, which makes them unmarketable. The most common form bears five to 12 thick petioles in a tight bunch. A less popular form is turnip-rooted celery, known as celeriac (var. rapaceum). This is a biennial and is grown in the cool season, but it is also sensitive to prolonged cold temperatures. In the first year, the plant normally produces a tight cluster of petioles and leaves attached to a very compressed stem. Celery leaves are divided and pinnate with almost triangular toothed leaflets, which are smooth and dark green in color. Celery has a broad, furrowed, and concave leaf stalk. In the second year, the stem becomes furrowed and branched. Early vegetative growth is characterized by a fair amount of spreading, but leaves arising from the apex of the short stem form compact and elongated heads. The root system of celery is fibrous and spreads with many feeder roots close to the soil surface. The plant bears compound clusters (umbels) of small, white, perfect flowers with five petals and five stamens. The seed, which is actually a fruit formed from two compressed carpels enclosing the actual seed, is very small.

Dandelion produces deeply toothed leaves in a basal tuft and bears a single, composite, yellow flower on a hollow stalk. The cultivated forms of dandelion produce larger leaves than the weedy forms. Improved cultivars, mostly of French origin,

are tender, less bitter, slightly greener and larger than the wild types.

Florence fennel is an annual, very distinct, low-growing and thickened plant with a very stout stem that has joints very close to the base. The leaves are very finely cut and are of a glaucous green color. The leaf stalks are very broad, of a whitish green hue, and overlap one another at the base of the stem, forming a kind of head that varies in size; the inside is white and sweet. The height of the plant, even when grown for seed does not exceed 60–75 cm. The broad umbel with stout, stiff rays bears greenish flowers. The seed, twice as long as it is wide, is flat on one side and convex on the other and marked by five thick yellowish ribs that occupy almost the entire surface of the skin.

In globe artichoke, the edible part is the young capitulum, which is harvested when it is still in rapid growth. The enlarged receptacle (bottom) and the tender, thickened bases of the bracts are eaten. If the capitulum is picked at an early stage, all of the 'heart' can be eaten after removal of the tough outer bracts. The part of the stem just below the young head is edible. In the case of the Jerusalem artichoke, the underground tubers, which are oblong or extremely elongated and weigh 80–120 g, are eaten.

Kohlrabi (*Brassica oleracea* var. gongylodes) is often called turnip-rooted cabbage and is closely related to cabbage. The stem, which is the edible part, is greatly enlarged immediately above ground. It is an excellent vegetable if used before it becomes woody, tough, and stringy. The most popular varieties of kohlrabi in India are White Vienna, Green Vienna, Purple Vienna, and Earliest Ear Furt.

The compact, bushy growth of oca (perennial) is between 20 and 30 cm in height. Tubers can be eaten immediately after harvest, but their flavor is better when exposed to the sun in order to reduce bitterness. Oca is consumed after boiling, baking, frying, or pickling and can also be eaten uncooked. Leaves and young shoots are eaten in salads or as cooked vegetables.

Chemical and Nutritional Composition

Artichoke has interesting nutritional characteristics related to its high content of phenolic compounds, flavonoids, inulin, fiber, and mineral salts. The phenolic compounds are mainly derivatives of caffeic acid. Extracts containing cynarin (1,5-dicatteoyl quinic acid) have some effects on hepatobiliary disease, hyperlipidemia, and cholesterol metabolism. The pharmaceutical industry mainly uses the leaves.

Baby corn is a good source of pro-vitamin A. Celery is an important source of minerals and vitamins. Celery leaves also contain higher levels of vitamin C, carotene, and essential oils. The shape, color, crispness, pithiness, stringiness, ribbiness, petiole cracking, and flavor contribute to the quality of stalk and petioles. Celery is quite popular in the Western world due to its low fat content (0.6 g per 100 g of edible parts.) The composition varies at different stages of maturity; reducing and total sugars show a marked decline in the leaf blades but an increased concentration in the petiole from harvest until the end of storage. Nitrogen increases in leaf blades and petioles towards the end of storage.

Little information is available regarding the nutritional/chemical composition of Florence fennel and American wintergreen vegetables. However, it is reported that dandelion leaves are an excellent source of provitamin A (14 000 IU), vitamin C (35 mg) and calcium (187 mg) per 100 g of edible parts.

The nutritional qualities of oca tubers, with 85% carbohydrate (on a dry-weight basis) are comparable to potato, also presenting starch of good quality. (*See* **Ascorbic Acid**: Properties and Determination; **Calcium**: Properties and Determination; **Carotenoids**: Occurrence, Properties and Determination; **Retinol**: Properties and Determination; **Starch**: Structure, Properties, and Determination.)

Postharvest Handling and Storage

Asparagus loses its freshness and quality quickly after harvest; it is desirable to market or process it as soon as possible. Cooling of the spears soon after harvest helps in maintaining quality and improves its marketability considerably. Hydrocooling is the best way to reduce the temperature of asparagus spears rapidly. Chlorine is usually added in water used for cooling to minimize the bacterial population. The spears should be kept at a low temperature, as high temperatures result in the synthesis of more ethylene and rapid senescence. The losses in tenderness, flavor, vitamin C, and reducing and total sugars are also pronounced at higher temperatures. In addition to general deterioration, spear elongation and development of decay take place at moderately high temperatures. An increased rate of fiber development is directly correlated with spear length and age, and also with high postharvest temperatures.

Asparagus is packed either in plastic film bags or in boxes or crates without bunching. When the loose-pack method is adopted, the butts are cut off, and spears are laid in boxes lined with oily paper with a layer of wet moss placed in the bottom. Packing only spears with tightly closed tips can extend the postharvest life of asparagus. The packaging of asparagus in film bags maintains the marketability, edible, and

nutritional qualities by reducing moisture loss, preventing fiber formation, and decreasing the loss of ascorbic acid, respectively. However, impermeable film bags can produce off-flavors due to anaerobic decomposition. Such packaging would lead to uncontrolled accumulation of CO_2 and depletion of O_2 with possible damage to the product. The film must be adequately permeable to exchange these gases and to dissipate the respiratory heat.

Asparagus spears must not be placed horizontally, as their tips are negatively geotropic and turn upward. Containers with wide bases and narrow tops should always be used to accommodate the long tapered spears. To prevent desiccation, particularly at butt ends, a high humidity is essential; this can be achieved by placing the butts of asparagus on wet pads. Another way to maintain a high relative humidity inside the package is to pack spears in perforated films. Since spears continue to elongate after harvest, therefore, headspace should be provided in packaging to avoid tip damage.

Asparagus can be stored successfully for about 3 weeks at 2 °C, but high-quality asparagus can be maintained in good condition only for 10–14 days under such conditions. Fresh asparagus is highly perishable and deteriorates rapidly at temperature above 5 °C. Storage at 0 °C, coupled with 95% relative humidity, is generally recommended to prolong the marketable life of asparagus for about 3–4 weeks, but asparagus suffers from cold damage if it is held longer at this temperature. The recommended handling temperature is 2 °C along with a relative humidity greater than 95%. Chilling damage occurs with prolonged holding at temperatures lower than 2 °C. Rapid sorting, packing, and storage at 0–6 °C and 90% relative humidity help maintain a high quality.

Controlled-atmosphere storage of asparagus reduces postharvest deterioration and prevents the development of off-flavors, water loss, chlorophyll loss, and toughening. Exposure of spears to $7 \pm 2\%$ CO_2 for 24 h retards bacterial rots. No cold damage is observed at 1.7 °C and 15% CO_2 concentration. Controlled-atmosphere storage of asparagus helps to reduce decay, retardation or even reversal of toughening, retention of a more desirable color, sugar, organic acids and soluble proteins than spears stored in air. The shelf-life of several leafy vegetables including asparagus has been reported to be doubled by immersing the cut ends or dipping the vegetables in solutions of cycocel (CCC).

Broccoli is harvested shortly before the buds begin to open while their heads remain compact and cut to a length of about 20–25 cm. The axillary shoots, as they develop, are cut at a similar stage to that of the central head. Harvested broccoli heads are further trimmed to a length of approximately 15 cm, and bunches weighing about 700 g are tied together for packaging. Bunches are further packed in crates holding 28–30 bunches. The respiration rate of freshly harvested broccoli is very high in comparison with that of asparagus, spinach, or sweetcorn. Hence, to reduce the respiration rate rapidly, broccoli must be cooled soon after harvest and stored at a low temperature and O_2-free environment in order to prolong the shelf-life. Broccoli should be hydrocooled to 4.4 °C or packed in ice immediately after harvest and kept at 0 °C to maintain a good marketable condition. Film wraps can be useful in maintaining a high relative humidity and extending the storage life.

There is no definite stage of maturity at which celery should be harvested for a satisfactory quality. Celery plants are cut off just below the soil surface. Since the plants wilt easily, they should be moved quickly from the field to the packing house for preparatory operations like stripping to remove suckers and diseased or damaged leaves, precooling, sorting, washing, grading, and packaging prior to marketing. Celery is generally hydrocooled or vacuum-cooled. If ice is used in crates or waxed cartons, it is advisable to store celery at around 0 °C to avoid decay. To avoid wilting, packaging in ventilated wraps is advantageous. Box or crate liners should have about one hole per square foot. Celery can be stored at a temperature of 0–0.6 °C and 90–95% relative humidity for about 8 weeks. Trenching in the field or storing celery in the pits is practiced in the fall when there is a danger of freezing before the crop is harvested, but usually for only a short period of time. An O_2 level less than 5% slightly retards yellowing of celery, and a CO_2 level above 2.5% may be damaging in controlled-atmosphere storage. Therefore, all wraps must be perforated to avoid potentially dangerous accumulation of CO_2 or reductions in O_2 below 1%. Celery in storage absorbs foreign flavors, and so it should be kept away from the odors of other products.

Dandelion plants are trimmed, washed, and stored in containers at 0 °C and 90–95% relative humidity to preserve their quality.

Florence fennel plants are harvested just above the taproot. The upper petiole and leaf blades are trimmed relatively close to the bulb. Fennel has a good postharvest life if stored at 0 °C and high relative humidity.

Globe artichoke flower buds need to be handled carefully to avoid bruising and desiccation, as physical injury can accelerate decay as much as a 10 °C rise in temperature. The harvested buds are placed into suitable containers for transport to the packing house, where they are graded according to their size

and quality. Artichoke buds must be precooled as quickly as possible to retain their quality after harvest. Wilting of artichoke can be prevented by hydrocooling or by washing the bracts in cool water. Globe artichoke is then packed in different layers in paper-lined boxes of different sizes followed by immediate cold storage. Frosts can injure artichoke buds in the field, but in the USA, an industry promotional program effectively markets frost-affected buds, unless damaged severely, claiming that they are 'winter kissed' and, therefore, taste better.

The storage life of globe artichoke is related to its initial quality, since injured and decaying buds at harvest deteriorate 1.5 times more rapidly than sound buds, especially when they are held at 4.4 °C or above. Holding artichoke below 4.4 °C can effectively prevent decay. Storage at a temperature of 0–2 °C and a relative humidity of 95% can help maintain a good quality for about 10 days. A temperature of around 0 °C for prolonged storage and 1.7–2.8 °C for normal marketing periods is satisfactory.

Kohlrabi tubers can be stored in a good condition for 2–3 months at a low temperature (0 °C) and high relative humidity (98–100%) since a high humidity is essential to prevent shrivelling and toughening. Packaging in perforated film can be used to reduce moisture loss. Kohlrabi with attached leaves at 0 °C has a storage life of only 2 weeks.

Parsnip is harvested either by ploughing or hand-digging. The roots are usually lifted after removing the foliage. Harvests are delayed until low temperatures or frosts occur because the root quality is improved under such conditions. With the advancement of root maturity, starch starts converting into sugars, and this is accelerated by cold exposure. Parsnip can be stored in the field unless freezing is severe. Roots also store well at a temperature of 0 °C and relative humidity greater than 90%. A high humidity is required to extend the postharvest life because roots desiccate easily. Like carrots, if parsnip roots are exposed to ethylene during storage, they become bitter. Oca's storage characteristics are relatively good if properly cured, and moisture loss is minimized.

Root, Bulb, and Tuber Crops

K Gupta, G Talwar, V Jain, K Dhawan and S Jain, CCS Haryana Agricultural University, Haryana, India

Introduction

Root crops and bulbs (radish, carrot, beets, onion, garlic, etc.) are being consumed (raw or cooked along with other vegetables) increasingly for salad, have prominent fleshy, marketable, underground edible structures, generally have a long storage life, are economically important, and used and grown worldwide for market as well as domestic consumption. Most root crops are hardy to frost. Radish and turnip are susceptible to heat injury.

Edible, underground salad crops are classified as:

1. Enlarged taproot: beet, carrot, radish, salsify, turnip, parsnip, celeriac, rutabaga.
2. Tubers: ahipa, potato beans, Chinese artichoke, coleus potato, Jerusalem artichoke, jicama.
3. Bulbs: onion, leek, garlic, shallot.

Root salad is eaten raw as an appetizer, served as a side dish. Root salad has natural inherent energy and affects our bodies. Root crops tend to give coldness, warmth, and strength to the body, make the body alkaline-acidic (**Table 1**), and are used for different therapeutic applications. Their names are given in different languages in **Table 2**. Carrot and radish can be dipped in sauce and eaten as an appetizer. Some salads are used in cooking to add flavor. Garlic has a distinct flavor that adds to the taste of many meat and vegetable dishes. Leek and onion are also used to add flavor to soups and stews.

Table 1 Commonly used vegetables/salad, their energies, flavor, organs, and therapeutic applications, according to the traditional Chinese concept of food and nutrition

Name	*Energy/taste*	*Organs*	*Therapeutic conditions*
Beet	Neutral: sweet	Spleen	Nourishes fluids; rheumatic pains, congested chest, poor energy circulation
Carrot	Neutral: sweet	Lung, spleen	Diuretic and digestive, improves eyes, removes swellings and tumors, indigestion, cough, dysentery, difficult urination, skin eruptions, chronic diarrhea
Garlic	Warm: pungent	Lungs, stomach, spleen	Warms, expels cold, promotes energy, circulation, destroys worms, kills parasites, arthritis, cold, abdominal pain, edema, diarrhea, dysentery, whooping cough
Onion	Warm: pungent	Lungs, stomach	Diuretic, expectorant, external application for *Trichomonas vaginalis* and ulcers, common cold, headache, constipation, cold, abdominal pain, dysentery, dysuria, mastitis, nasal congestion, facial edema
Radish (seed)	Cool: sweet, pungent	Lungs, stomach	Detoxifies, promotes digestion, eliminates hot mucus discharge, expels cold; abdominal swelling due to indigestion, laryngitis due to continual cough with mucus discharge, vomiting of blood, nose bleeding, dysentery, headache, bloating, hoarseness, diabetes

Table 2 Names of root salads in different languages

Bulb crops	Garlic	da suan	ail, a. ordi-Naire, a. blane	knoblauch	aglio, a. domestico	ninniku	cesnok	ajo ajo comun
	Leek	jiu cong	poireau, Porreau	porree	porro porretta	liiki	luk porkej	ajo porro a. puerro
	Onion	yang cong	oignon	speisezwiebel, Kiichenzwiebel,	cipolla	tam an egi	luk repcatyj	cebolla

Nutritive Composition

Raw root salad crops and bulbs provide varying amounts of water, carbohydrates, minerals, and vitamins (Tables 3, 4 and 5). Carrot, rutabaga, and coleus are high in vitamin A and are within the reach of most consumers.

Root and Tuber

Ahipa: *Pachyrhizus ahipa* (Wedd.) Parodi

Potato beans: *P. tuberosus* (Lam) Sprengel

Other names: ajipa, ashipa, frijol chuncho, Central American tambeans.

Table 3 Chemical composition of root salad crops (per 100 gm fresh weight basis)

Crop	*Energy (Cal.)*	*Water (%)*	*Proteins (g)*	*Fats (g)*	*Carbohydrates (g)*	*Dietary fiber (g)*	*Total ash (g)*
Arracacha	104	73.0	0.8	0.20	24.9	0.60	1.10
Beet root	43	87	1.6	0.1	9.9	0.9	0.97

IU = 0.3 μg Vitamin A alcohol.

Ahipa and potato beans belong to family Fabaceae (Leguminoseae) and have long trailing vines. Ahipa is native to the south-western Amazon, near Bolivia or northern Argentina. Production and consumption are restricted to Bolivia and Peru. Potato beans are widely adaptated to tropical, subtropical, and temperate regions and resemble yam beans which are native to South America. *P. ahipa* vines are shorter than those of *P. tuberosus*. Leaves are entire and rhomboidal ovate in shape. To enhance root enlargement, developing flowers are removed. The roots of *P. ahipa* are smaller and mature earlier than those of *P. tuberosus*. Potato bean roots have a succulent, crispy, white interior. Swollen tubers are like roots, and are mainly eaten raw for salad: all other plant parts are toxic. Only tuberous roots are harvested. The thin, pale yellow skin does little to prevent desiccation; the root is commonly left in the ground until needed.

Arracacha: *Arracacia xanthorrhiza*

Other names: apio, Peruvian carrot, Peruvian parsnip, mandioquina-salsa, zanahoria, racacha.

Arracacha belongs to the family Apiaceae (Umbellifereae), and is a dicotyledonous perennial which is a

native of the Andean highlands from Venezuela to Bolivia. It is considered to be important as the white potato in some areas of the Andes. It is the preferred staple food of much of South America and is very popular in southern and central Brazil, where it is grown commercially. Wild types have been found in Peru and considerable diversity is found in Ecuador.

Arracacha is similar to carrot and celery, and has a mild carrot or celery-like flavor. Enlarged, fleshy, lateral roots resemble white carrots; the flesh is yellowish and a ring of cambium tissue is purple. The cultivars can vary in color, from white (blanca), to cream yellow (amarilla) and orange-purple (morada). Productive plants develop several (as many as 10) lateral carrot-sized roots clustered around the main rootstock. Root length typically ranges from 5 to 25 cm with diameter from 2 to 6 cm. The yield ranges between 5 and 15 t ha^{-1}. Dark green, purple-tinged petioles resemble celery and are eaten raw or cooked. Roots must be cooked and are commonly fried, boiled, or baked. They have an unusual taste, resembling a mixture of celery, carrot, and parsnips, roast chestnut combined with celery and carrot flavor. Starch content varies from 10 to 25%. This vegetable is easily digestible and is often prepared for infants and elderly.

Beet: *Beta vulgaris* subsp. Rubra

Beet is a fairly hardy biennial, which belongs to the family Chenopodiaceae. It is grown primarily for roots and has been cultivated as a potherb or green throughout recorded history. It is an important home garden and market vegetable crop and is also grown for shipping to distant marketplaces and for processing. Beets are believed to be native to the Mediterranean area of Europe and North Africa and North America.

The major producers of sugar beets are Russia, France, the USA, Germany, Poland, and Italy. Most commercial production of beet is for processing and this was an $8 million industry in 1997.

Four general classes of beetroot varieties are reported which are oblate or top-shaded, oval, half-long and long conical. Only varieties belonging to the root oblate class are of commercial importance. Based on red or yellow color, each class can be subdivided into varieties that also differ in form, earliness, and vigor, as shown in Table 6.

Beet is a good source of carbohydrates (sugar). It contain two pigments; the deep red color is beta-cyanin and beta-xanthin is a yellow pigment.

Freezing, drying, or canning can preserve beets. Uniform dark red color without zones or rings and tender flesh free of fiber are desirable processing qualities. Beets to be dehydrated are harvested at slightly later stage of maturity than those used for canning. Detroit Dark Red and Cylindra are the best varieties for canning and pickling. Beets are also added to soups and beet juice is used for coloring in many different products, as a primary ingredient of borscht (a Russian stock soup).

The best storage temperature for beets is nearly freezing point, 0 °C (32 °F) with 95° humidity. Topped beets store well for 3–5 months.

Carrot: *Daucus carota* sp. sativus (Hoffm.), (2*n* = 18)

Carrot is a biennial, belonging to the family Apiaceae, and is an important vegetable for its fleshy edible,

colorful roots. It varies in colour from white, yellow, orange, light purple, deep red to deep violet. It is widely grown in spring, summer, and fall in temperate countries and during the winter in tropical and subtropical regions.

Afghanistan is considered a center of origin, because the greatest diversity of wild types is found there. South-west Asia and eastern Mediterranean regions are considered to be secondary centers of diversity of wild type and domestication. Purple and yellow carrot variants were introduced into Europe, then to India, China, and Japan.

Carrot production for the fresh market increased from $355 million to $441 million in the year 1997. The market for processing carrots is considerably smaller than the fresh market, with a production value of $37.5 million in 1997. In the USA 99 000 acres of carrot is grown for fresh-market sales, of which 70 900 acres of carrot is grown in California. The total area for processing carrots in the USA is 23 800 acres.

Carrots may be grouped into two types: (1) temperate or European cultivars, which are biennial, orange in color and uniform in thickness with a small core; and (2) tropical or Asiatic cultivars, which are annual, red in color, more juicy, and have a bigger core and a heavier top. The most important bunching varieties of carrot in the USA are Imperator, Gold Spike, and Gold Pak, which have long slender roots with a good smooth exterior whereas the varieties Red Cored Chantenay, Royal Chantenay, and Autumn King are good colored and popular for processing. Nantes is a good home garden variety.

Some important and commonly grown varieties of carrot in India are Amsterdam, Barlikuner, Chantenay, Royal Chantenay, Delattya, Honey Sweet, Karotina, Pusa Kesser, Pusa Meghalli, Rubica, and Pusa Yamadagni.

Carrot is one of the most nutritious vegetables consumed both raw and processed. Gazraila is a sweet dish prepared by cooking shredded carrot in milk and sugar and is much liked in North India.

Carrots are low in calories and are an excellent source (ranging from 41 to 475 $\mu g\,g^{-1}$ fresh weight) of β-carotene, a precursor of vitamin A, which is good for eyesight. A serving size of 78 g carrot has only 35 cal and 2 g dietary fiber, along with 270% of the recommended dietary allowance (RDA) of vitamin A, 10% of the RDA of vitamin C, and 2% of the RDA for calcium. Carrot roots are a rich source of carotenoids, which contains different types of carotene, i.e., β-carotene (45–80%), α-carotene (15–40%), γ-carotene (2–10%) and others (3–6%). Thiamin, riboflavin, niacin, folic acid, and vitamin C are also present in appreciable amounts in carrot roots.

Some volatile constituents are also present, such as α-pinene, camphene, β-pinene, myrcene, α-terpinene, *p*-cymene, limonene, γ-terpinene, terpinolene, caryophyllene, β-bisabolene, γ-bisalolene, heptenol, dedocenal, myristicin, and falacarinol in stem-distilled oil of carrots.

The flavor of carrots is influenced by free sugars glucose, fructose, and sucrose, which contribute to sweetness; volatile mono and sesquiterpenoids, which contribute to harshness, 2-nonenal, which imparts a cooked flavor; isocoumarin and other phenolic compounds, which impart bitterness; 2-methyoxy-3 butypyrazine, which contributes to the carrot aroma; free amino acids, which contribute to the delicate flavor; and ionones, which impart a floral off-flavor. Carrot roots contain several times more sucrose than glucose or fructose.

Carrots are a versatile vegetable that can be served alone, raw or cooked, or, in combination with meats, baked, fried, sautéed, and pickled. A small portion of total production is used for making the fermented product kanji, an appetizing drink.

Carrots are processed into products such as canned carrots, dehydrated carrots, juice, beverages, candy, preserves, and halva. Carrot leaves are used to extract protein. Carrot tops and roots are fed to animals to increase milk yield and used in the preparation of poultry feed.

Carrots possess many medicinal properties and are used in ayurvedic medicine. Carrot is considered a

popular remedy for jaundice. Its juice has diuretic and nitrogen-balancing properties, and thus has been found to be effective for the elimination of uric acid. β-carotene acts as a free radical-trapping agent and a singlet oxygen quencher in biological systems. β-carotene has been reported to reduce the risk of cancer of the lungs, cervix, easophagus, and stomach, and cataract formation. Carrot extract has antioxidant properties. The combination of carrot and orange juice was found to reduce the oxidation of low-density lipoproteins in habitual cigarette smokers. Carrot seeds have been reported to possess antifertility activity in female albino rats.

Carrots are harvested when the roots are 2–2.5 cm in diameter. Fall carrots, if mulched in certain areas, can be left in the ground all winter and harvested as needed. After harvest, prompt cooling to 5 °C or below extends the storage life of carrot roots. Mature roots can be stored for 7–9 months at 0–1 °C temperature coupled with 90–100% relative humidity.

Chinese artichoke: *Stachys affinis* Bunge

Other names: Chryorogi, Japanese artichoke, knot root, kon loh (China).

The Chinese artichoke is a perennial herb, belonging to the Lamiceae (Labiateae) family, and is grown for its tubers (cylindrical) while constricted internodal segments, appearing bead-like on a square-shaped stem, and petiolated ovate leaves form an opposite pair on the stem. Flowers are white or pink. The tubers are usually pickled, and are a popular food in China and Japan and are also eaten fried or fresh in salads. Much of the carbohydrate (about 60%) is the tetrasaccharide, i.e., stachyose. Tubers are dug, washed, and eaten fresh or after cooking. They are commonly stored in damp sand.

Coleus potatoes: *Coleus parviflorus* (Chinese potato)

Other names: Sudan or Hausa potato (*Solenostemon rotundifolius* (Poir), J.K. Morton: *Coleus rotundifolius*, Livingston; kaffir or hausa potato: *Pleetranthus esculantus* (N.E. Br.).

The coleus potato is native to southern India. It is commonly called kourka and is also grown in tropical and subtropical regions of Asia, Sri Lanka, and Africa. The plant is an annual, belong to the Lamiaceae (Labiatae), family. It has simple leaves with serrate margins, oppositely attached to a succulent, square-shaped stem. Clusters of white-fleshed, small, round, brown or black starchy tubers are present at the base of the primary stem. Leaves can be used for flavoring. Tubers are eaten raw or cooked, pickled, and eaten as condiments in India. Leaves and roots have an aromatic flavor, and contain about 11–20% carbohydrate and 1–5% proteins. Harvest should not be delayed, as quality declines with overmaturity. It is stored well in cool, well-ventilated conditions.

Jerusalem artichoke: *Helianthus tuberosus* L. (2*n* = 102)

Other names: girasole, topinambour, and sunchoke. Jerusalem artichoke.

The Jerusalem artichoke is a herbaceous perennial plant, cropped as an annual, belonging to the Asteraceae (Compositae) family. Plants can be found growing wild from Kansas north to Minnesota and as far east as Nova Scotia in Canada and central USA. The Jerusalem artichoke is endemic to North America. Native American Indians were utilizing the tubers long before European colonization. It is not an artichoke: derived from the Italian, *girasole articocco*, it tastes like a globe artichoke, *Cynara scolymus*.
