All the ingredients, after they have been weighed or measured, are blended together to make a liquid mix. This mixture is then subjected to a heat treatment process, which in most countries is specified by legal requirements. This heat treatment renders the mix substantially free of vegetative microorganisms, killing all pathogens likely to be present. The ice cream mix is always homogenized, often as a step in the pasteurization process. The homogenizer is a complex piece of equipment and must be carefully cleaned and disinfected each time it is used, or the mix may be seriously contaminated. It is therefore suggested that homogenization of the ice cream mix is carried out before it is finally heat-treated, where possible. Then follow cooling and aging of the mix. After the aging period, the mix is passed to the freezer where it is subjected to considerable agitation and reduction in temperature, as well as incorporation of air. On leaving the freezer, the ice cream will normally be packaged (in family packs, individual retail packs, or other forms), frozen hard in wind tunnels at $-40\,^{\circ}C$ or in hardening rooms, and then kept at a temperature of about $-30\,^{\circ}C$ both until and during distribution. Some ice cream is sold directly from a dispensing freezer as 'soft-serve' ice cream in cones, or in various types of made-up desserts in restaurants and cafés, or from vehicles complete with their own electricity generation equipment.

The overall operation is relatively complex and each of the steps taken may have some influence on the microbiological quality of the final product. The processing methods or equipment may be responsible for wide variations in bacterial counts.

Ice cream mixes should not be kept for more than 1 h at a high temperature (more than $7\,^{\circ}C$) before being pasteurized, in order to avoid the proliferation of organisms carried in the ingredients. During pasteurization, time as well as temperature should be strictly observed in order to avoid on the one hand excessive heat treatment, which may lead to undesirable flavor changes, and on the other hand, to insure the destruction of pathogenic organisms and the adequate reduction of total bacterial numbers. Cooling of mixes to 0–$2\,^{\circ}C$ almost completely eliminates the possibility that microorganisms can grow in the mix. Cooling of mixes to such low temperatures is done efficiently in direct-expansion-type swept-surface heat exchangers. Such cold temperatures add several days to the shelf-life of mixes sold to other firms for freezing. The cooling must also be rapid and the mix must be kept at that low temperature until it is frozen, otherwise, any viable organisms may proliferate. This can lead to a product with a high microbial count and

possibly to a disease outbreak. The same danger exists if the cooling system fails during the aging of the mix. In this case, the mix must be discarded because, although a repasteurization will kill the organisms, it will not destroy possible toxins already present. Normally, the mix should be frozen within 24 h of heat treatment, as undue prolongation of storage may lead to proliferation of psychrotrophic organisms, with a serious risk of spoilage of the mix.

The incorporation of air into the ice cream mix during the freezing process may cause airborne contamination, so air must be admitted through filters to prevent the ingress of organisms. For some products, the ice cream is blended with water ice on leaving the freezer, and may be frozen on a stick or in a cone (single portions) and covered with a chocolate or flavored couverture, together with broken biscuits or nuts. Addition of ingredients to the pasteurized mix constitutes a critical control point in ice cream manufacture, because no further lethal process is given to the product. Therefore, it is important that all operations at this point be done in a sanitary manner and that ingredients be free of pathogenic microorganisms. The most likely pathogens to be encountered at this point are *Listeria monocytogenes* and *Salmonella*.

The packaging materials may occasionally cause trouble, but there should be no problem if they have been handled and stored under hygienic conditions.

In addition to careful operation of the equipment, proper cleaning and sanitizing of the plant and equipment are of great importance; therefore, special care is demanded. All plant equipment that comes into contact with ice cream or ice cream ingredients must be carefully cleaned and sanitized immediately after use; this is usually done at the end of each day's operation and before it is used again or it may even be necessary to clean the plant thoroughly before further processing during the same day. Not only is the processing equipment important, but ancillary equipment, in particular at the final sales point, must be kept in a satisfactory hygienic condition. Poor cleaning and sanitizing of the plant and equipment may lead to pockets of ice cream residues where intense proliferation occurs, which results in recontamination of the pasteurized mix with a large number of bacteria. For the ordinary soft-serve or dispensing freezer, manufacturers usually lay down strict cleaning routines which must be followed carefully. Isolation of *L. monocytogenes* from an ice cream plant shows that dangerous microorganisms are able to survive in the food-processing environment and improved and precisely targeted cleaning and disinfection practices are of great importance in the eradication of those microorganisms.

Clean surroundings are essential if equipment is to be kept in a hygienic condition. All rooms, especially toilets and locker rooms, must be kept as clean and sanitary as the area immediately surrounding the packaging equipment. Surrounding activities (e.g., sewerage plants, rubbish tips) often represent potential sources of contamination, and birds, rodents, and insects are very important vectors of such contamination. In addition to preventing access of pests to the process area, it is important that the factory yard is kept free of food waste, rubbish, and spilled material that might attract birds, rodents, and insects. All such material should be kept in lidded containers and removed on a daily basis. Pet animals, such as dogs and cats, similarly have no place in a food production factory.

Operations must be segregated to minimize the chances of pathogenic microorganisms being carried from raw materials to finished products. Persons handling raw milk or cream must not be allowed access to rooms where pasteurized products are exposed unless those persons have first changed their clothes completely and have disinfected themselves. Room air pressures should be maintained at successively higher levels, from the mix room to the processing room, to the freezing operation, and to the packaging operation. Thus, the flow of air will be away from the most critical area, i.e., the packaging room. The supply of hot and cold water must be unrestricted and facilities for disposal of both liquid and solid wastes must be adequate. All water that is used in food formulation, or will be used on (or could gain access to) food contact surfaces should be of potable quality and be stored in enclosed tanks and distributed in piping that is completely segregated from other pipe systems. Potable water may be derived from public mains supplies or other sources such as boreholes which must be protected against contamination by surface water or underground contamination from drains, seeping from farm or industrial tips, and similar potentially hazardous areas. Whatever its origin, the water should be routinely examined microbiologically at point of entry to the site and at the point of use, particularly if there is on-site storage.

The hygienic standards of the workforce are crucial to the ice cream manufacturer. No worker who has not been adequately taught the necessities of personal hygiene and approved practices should be allowed to perform tasks in the plant. Every employee must dress in a clean uniform, wear a hair restraint, wash and sanitize hands, disinfect footwear on entry to the process area, and refrain from touching any product contact surface without properly sanitizing the hands, or gloves if worn. Proper sanitary practices are essential to

the ice cream plant. No one should be allowed to enter the processing environment who is not familiar with the required sanitary procedures or who does not conform to the required dress and personal hygiene measures. Freedom from chronic contagious diseases should be confirmed yearly by medical examination. Provided that the preparation of ice cream is conducted in a closed processing cycle with modern industrial equipment of high hygiene standards, the opportunities for contamination by human contact are few.

Tests carried out during the production process should be indicative of the standard of hygiene.

Storage (Quality Deterioration)

Microorganisms are unable to grow in ice cream stored at correct temperatures, although many survive for extended periods. It is a perfect substrate for microbe development as far as its composition is concerned. It has all the essential components (sugar, proteins, water), oxygen, as well as a relatively high and suitable pH. High temperature is the only agent not available. If a rise in temperature does occur, all the conditions are in place for the development and proliferation of microbes that may exist. Microbiological considerations, therefore, primarily involve the elimination of vegetative pathogens by pasteurization and the prevention of recontamination due to insanitary processing and packaging, at all stages up to point of sale, the microbiological status of ingredients with particular reference to thermoduric organisms and preformed toxins, and the prevention of microbial growth before freezing.

Ice cream may be sold direct from the freezer as a soft-serve product, or it may be further reduced in temperature and frozen in wind tunnels at $-40\,^{\circ}C$ or in hardening rooms, to produce 'hard' ice cream, which will be stored at a temperature of about $-30\,^{\circ}C$ until it is sold. Deep-freezing stabilizes the microbial content of ice cream: microorganisms found in it no longer proliferate. Some sensitive species (Gram-negative) die and their populations decrease. Even if the period between freezing and final sale is several months, there will be little change, if any, in the microbial content of the ice cream. Extensive research has shown that both *Mycobacterium* and *Salmonella*, as well as many other less harmful but often more resistant types, can survive at the low temperature of storage for very long periods. They do not multiply provided that the temperature is low enough for the ice cream to remain hard; in effect, the microbial quality of ice cream is 'locked in' by the hardening process.

Problems of quality deterioration can appear when there is a delay between pasteurization and freezing, mainly a delay from heat treatment to cooling of the mix, or the aging of the mix at a temperature higher than $4\,^{\circ}C$ due to ignorance or failure of the freezing system. Spoilage can also occur, in cases of melting and refreezing of the product resulting from temperature fluctuations or failure of the freezing systems. Special care is needed with the mix for soft-serve ice cream that has to be transported, often for long distances, in trucks to retail soft-serve stores or stands where it is kept soft-frozen and dispensed to consumers. Both contamination and temperature abuse of the mix may easily occur. Furthermore, refrigeration space is usually limited, and adequate facilities for cleaning and sanitizing the freezer and the associated equipment are often lacking or are, at best, marginal.

Under these conditions, especially when inadequate practices have preceded storage, the ice cream is overloaded with microbes which lead to quality deterioration or even to cases of food poisoning. Reference is made in the Further Reading section to cases of food poisoning following the consumption of ice cream contaminated by microbes, such as *Staphylococcus, Salmonella, Shigella, Listeria*, and *Streptococcus* group A organisms. More serious cases may occur with homemade ice creams, where a combination of faulty practices, such as the use of raw milk, eggs contaminated with *Salmonella*, inadequate heat treatment, no rapid cooling following heat treatment, and contamination by infected persons give rise to products with high microbial loads, especially of pathogenic bacteria which can survive many months in contaminated ice creams. (*See* ***Listeria***: Properties and Occurrence; ***Shigella***; ***Staphylococcus***: Properties and Occurrence.)

Problems at Point of Sale

The largest proportion of microbiological problems with ice cream products, in general, is due to poor techniques of selling and serving at the final point of distribution. This plays a vital role in the microbiological load of ice cream. Even when the greatest care has been taken to produce an ice cream of the highest quality, it is still liable to contamination at the point of sale.

The method of sale has a major bearing on the level of contamination to which the product is subjected. Although much ice cream is retailed in its final packaging, a significant quantity is portioned from bulk packs at the point of sale.

Prepackaged ice cream that is sold in individual package is considered safer because it has to be handled only by the consumer in its wrapping and can be contaminated only by the consumer. Attention

must be paid to the right storage temperature without temperature variations or failure of the freezing system. Greater degrees of contamination may occur in ice cream which is portioned from bulk packs in restaurants or coffee shops, mobile vans (complete with their own electricity generation equipment), and kiosks. This process is the weak link from the hygiene viewpoint since many outlets have only limited facilities for hand washing and utensil sterilization. In order to minimize the possibility of contamination, the equipment (servers, wafer holders, and so on) has to be kept free of all residues of ice cream, which might otherwise melt and allow the growth of bacteria to recommence. Whenever possible, these items of equipment should be kept in running cold water. If they have to be kept in a jug of water, this water must be changed regularly to avoid it becoming a source of contaminating bacteria. The personal hygiene of the server is also important. Persons handling and serving food should be trained to live up to definite and rigid standards of personal hygiene. Hair, hands and fingernails, uniforms and shoes have to be clean. Soap, water, and single-service towels should be easily accessible.

Soft-serve ice cream sold directly from a dispensing freezer can become contaminated very easily unless stringent precautions are taken. The product is usually manufactured at the point of sale, which may be a specialist outlet or café, a nonfood outlet such as a gas (petrol) filling station, or a mobile outlet or kiosk. Soft-serve ice cream may be manufactured from a conventional mix produced on the premises, from an ultrahigh-temperature-processed, aseptically packaged mix, or from a spray-dried powder mix. Powdered mixes may be formulated for reconstitution in either hot or cold water. Hot-water mixes are preferable with respect to hygiene, but cold-water mixes are often considered more convenient. Attention must be paid to the reconstitution of the mixes; this must be done under satisfactory hygienic conditions to prevent the proliferation of *Salmonella*, which may survive if mixes are not prepared carefully.

Soft-serve ice cream freezers and ancillary equipment should be dismantled, cleaned, and sanitized daily. It must be recognized that maintenance of the necessary hygiene standards can be more difficult in an environment primarily concerned with retailing than in one wholly concerned with manufacturing. Particular difficulties may be encountered in outlets which are predominantly nonfood, such as filling stations, and those with inherently limited facilities, such as kiosks. The self-pasteurizing soft-serve freezer offers at least a partial solution. Such equipment is designed to heat the mix and machine surfaces in contact with the mix to an appropriate temperature and time before cooling rapidly to about 4 °C. It is usual to 'pasteurize' daily, usually at the end of the working day, and restrict full cleaning and sanitization to a weekly basis. It must be emphasized that self-pasteurizing freezers are not intended to process unpasteurized mix. Generally, special dispensing freezers should be kept in constant operation, and placed inside the shop with the taps facing the interior. In addition, they must not be directly exposed to the sun, dust, or flies.

Probably the most serious and dangerous sources of contamination are operation and serving. Many major food-poisoning outbreaks have been caused by human contamination. Cases of typhoid fever, including deaths, have been reported to be caused by ice cream contaminated by the manufacturer who was a urinary excretor of *Salmonella typhi*. There has been a case of *Shigella* dysentery caused by an ice cream that was accidentally touched by a monkey. Also, outbreaks involving salmonellae and staphylococci have been reported. The personal hygiene and habits of vendors at sale points are important. Education, in addition to medical inspection, is absolutely necessary and no employee must be allowed to work without full medical clearance.

Finally, birds, rodents, insects, and pet animals have no place at the retail selling point.

Many countries, recognizing the significance of ice cream in relation to public health, have legislated as to the conditions and methods to be used for heat treatment and subsequent storage and sale.

Introduction

Antibodies are a group of globular proteins called immunoglobulins (Ig), which are formed in response to the invasion of foreign substances in vertebrates. Igs are classified into five groups: IgA, IgG, IgE, IgD, and IgM. IgG, which has a molecular weight of 150 kDa and is composed of two heavy chains (50 kDa) and two light chains (25 kDa), is one of the most common serum Igs (80% of total Igs). Antibodies are capable of binding with foreign substances noncovalently with high affinity and, thus, to inactivate them.

Substances that induce the defensive action by producing antibodies in the host are called antigens, and are characterized by their immunogenicity and their antigenicity. Immunogenicity is the capability of a molecule to induce antibody formation. Thus, the term 'immunogens' specifically refers to those substances capable of inducing production of antibodies. The antigenicity, or antigenic specificity, however, is the characteristics/capabilities of the interaction of the antigen with antibodies. The interaction involves small sites, which are called 'antigenic determinants' or 'epitopes' on the surface of the antigen molecules.

In contrast to antigens, low-molecular-weight compounds (less than 2500 Da) are not immunogenic. These compounds are called haptens and can only become immunogenic after conjugation to a high-molecular-weight protein carrier.

Although it has been known for more than a century that vertebrates are capable of producing specific antibodies after invasion by foreign substances, the complexity of immunoreactions has only been revealed in the last two decades. With the advances in understanding of the mechanism of immunoreactions, the specific interaction between antibody and antigen/hapten has been used as the basis for several analytical techniques called immunoassays. These assays, which are characterized by their high sensitivity, specificity, and simplicity, were originally developed for the analysis of clinical samples. Recent development has led to the application of immunoassays for food and agricultural chemicals, including both normal and abnormal food components, additives and contaminants, as well as agricultural chemical residues.

In contrast to clinical samples, immunoassays for specific substances in foods and feeds are more

complicated because: (1) specific antibodies must first be raised against a wide range of food components and chemicals. Some are antigens, whereas others are nonimmunogenic haptens, most of which are lipid-soluble; (2) foods are very complex systems and sample matrices often interfere with the assay; (3) changes in physicochemical properties of food components/contaminants during processing of foods often complicate immunoassays because the antibody may not recognize the denatured species. Nevertheless, much progress has been made and numerous review articles on the immunoassay of food components/contaminants have appeared. The reader should consult these reviews for details.

Principles

All immunochemical techniques are based on the specific noncovalent interaction between antigens/haptens and specific antibodies. Earlier applications of immunochemical methods for analytical purposes were confined to the interaction between antibodies and high-molecular-weight antigens that led to the precipitation of the antigen–antibody complex for quantitation. However, precipitates are also not formed between antibody and haptens. Investigations in the last three decades have led to the development of more sensitive immunochemical methods. Thus, the term 'immunoassay' now also includes the modern immunochemical techniques which involve the use of labeled marker for the antigen or antibody and innovative approaches for the separation of free antigen and antigen–antibody complex. As a result of the development of new instruments and incorporation of label markers in the assay system, new innovative precipitation methods with high sensitivity are now also available.

For simplicity, the binding of antibody with a simple hapten, which has only one antigenic determinant site (univalent), is used to illustrate the antigen–antibody interaction. As shown in eqn (1), the interaction depends on the equilibrium or affinity constants ($K = k_a/k_d$), which is the ratio of the association (k_a) and dissociation rate constants (k_d) and the concentrations of the reactants, i.e. [antibody] and [antigen].

$$[\text{Antibody}] + [\text{Antigen}] \underset{k_d}{\overset{k_a}{\leftrightarrow}} [\text{Antibody–Antigen}]$$

In general, the K values for antibody–antigen interaction are in the range of 10^6–$10^9\,\text{l mol}^{-1}$, but they may vary from 10^3 to $10^{14}\,\text{l mol}^{-1}$. Antibody with a high K value is more preferable for the assay, but any reaction with a K value above $10^9\,\text{l mol}^{-1}$ would be feasible. For analytical purposes, either a labeled antigen or a labeled antibody marker is present in the system. With an adequate method to separate the antibody–antigen complex from the free antigen and antibody, as well as a sensitive method for detection of the markers in the free or bound form, the concentration of the analyte can readily be determined. In general, a standard curve is established and then used to calculate the concentration of unknown sample. Thus, it is critical to have a pure standard from a reliable source which should also be tested frequently for its stability.

Preparation of Immunochemical Reagents

As indicated above, an effective immunoassay depends on the availability of: (1) a specific antibody; (2) a sensitive marker antigen or antibody; and (3) an effective separation method. Methods for the preparation of marker antigen or antibody and methods for the separation of the free and bound species of antigen and antibody vary considerably with different immunochemical methods used. Approaches for the preparation of immunogen and antibody as well as methods for characterization of antibody can be generalized as follows.

Preparation of Immunogens

Antibodies against major food proteins and naturally occurring foodborne microbial toxins/contaminants have been produced and used in different types of immunoassays. High-molecular-weight substances such as proteins and polysaccharides can be used directly as immunogens. In general, well-characterized and pure immunogens are used for generating antibodies. With the development of monoclonal antibody technology, partially purified proteins or even crude cellular extracts from pathogenic bacteria have also been used successfully for immunization as long as an effective method in selecting specific hybridoma cell lines is available. Because of structural changes for some proteins and other macromolecules during food processing that alter the immunogenic site, purified proteins are not necessarily used to generate antibodies from components in food-related products. Rather, for determination of such materials in processed foods, specific antibodies must be raised for corresponding denatured proteins. Thus, depending on the specific components to be analyzed, one must consider selecting an immunogen which has comparable properties to that actually found in the food.

Haptens must first be conjugated to a protein/polypeptide carrier before immunization. Methods for

the conjugation of various low-molecular-weight naturally occurring toxins, including antibiotics, mycotoxins, phycotoxins (marine toxins), pesticides, and other agricultural chemicals, to protein carriers have been established. Proteins, including bovine serum albumin (BSA), modified BSA, and keyhole limpet hemocyanin, are most commonly used. In general, if the hapten has a reactive group such as a carboxylic or an amino group, it can be conjugated to the protein directly via one of the following approaches: water-soluble carbodiimide method, mixed anhydride method, condensation method in the presence of formaldehyde (Mannich reaction), cross-linking with glutaraldehyde, activated ester method through the formation of *N*-hydroxysuccinimide (NHS) esters, 1,1′-carbonylimidazole and m-maleimidobenzoyl-*N*-hydroxysuccinimide ester, and many other innovative methods. Derivatization is necessary if no reactive group is present. Before derivatization or conjugation, one must select appropriate strategies to insure that certain portions of the hapten molecule are exposed. Not only the amount of hapten conjugated to the protein molecule is important in determining the effectiveness of the conjugates as an immunogen, but also the position of the side chain in the hapten where conjugation is made, as well as the space between the hapten and protein molecule are critical. However, a conjugate containing a large amount of hapten may not necessarily be a better immunogen. Antibodies have been obtained from rabbits immunized with immunogen containing only 2 mol of hapten per mole of carrier protein. The optimum amount of hapten coupled to a protein that yields a good immunogen should be experimentally determined, but generally is in the range of 10–20 mol per mole of protein.

Rapid progress in cloning genes for many proteins/enzymes/toxins in food and agricultural commodities has led to another approach for the preparation of immunogens. By knowing the DNA sequence of a gene, the amino acid sequence for a specific gene product in which we are interested could be deduced. Through structural analysis, the highly immunogenic fragment in this protein could be identified and chemically synthesized. These peptides could then be conjugated to a branched-chain lysine to form a multiple-chain immunogenic polypeptide for immunization. Using this approach, it is possible to generate an antibody for a protein even before it is purified and characterized.

Preparation of Antibodies

Two approaches have been used for the production of antibodies. The classic method involves immunization of animals and then obtaining the antibodies from the sera of the immunized animals. Antibodies obtained by this approach are polyclonal antibodies (PAbs) because they are derived from different B lymphocyte clones. In this method, immunogens are mixed with adjuvant and then injected into animals, most commonly rabbits, intradermally or subcutaneously through the thigh or on the back at multiple sites. For production of a large quantity of antiserum, large animals such goats and horses are used. Other animals, such as pigs and mice, have also been used. Production of antibody has been optimized by immunization of chickens and then isolation of antibody from eggs.

The amount of immunogen used in the immunization varies considerably. In general, 1–2 mg protein is used for each rabbit. To avoid toxicity of some food-borne bacterial toxins, a smaller amount of toxins or toxoids are used in the initial immunization (e.g., 5 μg) and this is followed by a gradual increase in dose for subsequent booster injections. For haptens, 200–500 μg of conjugate is generally used in each injection. Although antiserum obtained from animals could be used directly in the immunoassay, simple purification such as ammonium sulfate precipitation is generally necessary. Further purification of antiserum through various chromatographic methods can improve the efficacy of immunoassays.

If the immunogen is highly immunogenic, antibody titers, as determined by different approaches such as immunodiffusion, radioimmunoassay (RIA) or enzyme immunoassay (EIA), usually start to increase at 4–7 weeks. Subsequent booster injections are generally performed once a month. Since PAbs are heterogeneous, it is advisable that the purified antigen be used in the titer determination. For haptens, a specific hapten-marker must be used. Use of inadequate antigen or hapten-markers usually fails to provide information regarding whether the immunogen and immunization protocols are effective.

Although production of PAbs is relatively simple and the affinity of Pabs is generally high, they are heterogeneous, and their supply is limited. With increasing demand for large amounts of antibodies with homogeneous properties for immunoassays, as well as advances in hybridoma technology, specific monoclonal antibodies (MAbs) for a number of food components and contaminants in foods have also been produced. In this method, spleen cells obtained from mice immunized with immunogen or hapten–protein conjugates are fused with myeloma cells, followed by propagation of the hybrid cells, and selection and characterization of the clones, as well as isolation and characterization of the antibody. Production of mAbs can either be carried out in tissue culture or in mice, in which ascites fluids are collected. Thus,

mAbs are derived from a single B lymphocyte clone and are immortal. Once a hybridoma cell line is obtained, there is an unlimited supply of homogeneous antibodies with unique properties. Similar to the production of PAbs, the key to success in obtaining a useful hybridoma cell line lies in the effectiveness of immunogens as well as the immunogen-marker or the hapten-marker. The importance of an effective immunoassay protocol in selecting the positive clones cannot be overemphasized. Many new stable hybridoma cell lines for production of antibodies against various food components, contaminants, naturally occurring toxicants, and agricultural residuals are now available. Rapid progress in molecular cloning of MAbs has also led to the application of this technology for the production of antibody important to agricultural and food scientists and several laboratories have succeeded in this regard.

Antiidiotype Antibodies

The development of immunochemical methods for agriculture and food analysis has led to a great demand for specific antibodies and related immunochemical reagents for the assay. An alternative approach for preparing immunochemical reagents is through generating antiidiotype antibodies (Ab2), which have gained wide application in diagnostic and therapeutic areas for large molecules. In the last few years, Ab2 against small-molecular-weight haptens, including insecticides, herbicides, hormones, mycotoxins, and phycotoxins, have been successfully developed. Some Ab2 have not only been shown effectively to mimic the biological functions of the haptens, but have also been used as the immunogen to generate antiantiidiotype antibodies (Ab3) with specificity similar to the original antibody (Ab1). Both Ab2 and Ab3 have been shown to be effective in immunoassays.

Characterization of Antibodies

Antibodies obtained from the above methods should be well-characterized before they are used in the immunoassay. In general, both the type of immunoglobulin and the specificity of the antibody to various analogs of the immunogen/hapten should be determined. The typing of immunoglobulin is generally done by using commercially available kits. Information on the immunoglobulin type is important in selecting adequate markers as well as an appropriate method for separation of free antigen or antibody from the antigen–antibody complex in the immunoassay. Information on the specificity will provide an accurate assessment as to whether structurally related compounds will interfere in the immunoassay. They could also be used to estimate the affinity of the antibody to the immunogen/hapten and its structurally related analogs.

The specificity of the antibody, usually expressed as the cross-reactivity of an antibody, is primarily determined by the type of immunogen that has been used. A minor change in the immunogen structure could generate a different antibody. Some antibodies are very specific, whilst others show a broad specificity. The apparent cross-reactivity of the antibody also varies with the type and concentrations of the marker antibody or antigen and the format used in the immunoassay. Thus, in addition to knowing the specificity of the antibodies generated by a specific immunogen, the conditions under which that specificity was determined should be stated. Preferably, the 'apparent cross-reactivity' should be reevaluated under the conditions that are to be used for the assay. The specificity of the polyclonal antibodies can be improved by removal of nonspecific antibodies through immunoabsorption.

For haptens, the site in the hapten molecule linking to the carrier protein is important. The degree of cross-reactivity of these antibodies with structural analogs of the hapten used in the conjugation should be determined. The accuracy of immunoassay of hapten in naturally contaminated samples is generally affected by both the specificity of the antibody and the possible presence of structurally related analogs of the hapten in the sample as well as by some substances with similar structures of the hapten.

Experimentally, the cross-reactivity of antibody is determined by an immunoassay where various structurally related analogs of immunogen/haptens at a wide range of concentrations are used to compete with the binding of the marker ligand with the antibody in the assay. The concentration at 50% inhibition (I_{50}) of the binding is generally used as the basis to calculate the relative cross-reactivity for each analog. A typical example of such a competitive RIA and enzyme-linked immunosorbent assay (ELISA) for aflatoxins is shown in Figure 1. The specificity of the antibody is generally documented with data describing antibody production and characterization for a particular immunogen.

Immunoassays other than RIA and EIA used in Food Analysis

With the availability of different antibodies against various food components and contaminants, many types of immunoassays have been developed. Before modern immunoassays such as RIA and EIA were developed, several classic methods, most of which are based on the precipitation of the immunocomplex, were used widely for the analysis of high-molecular-weight

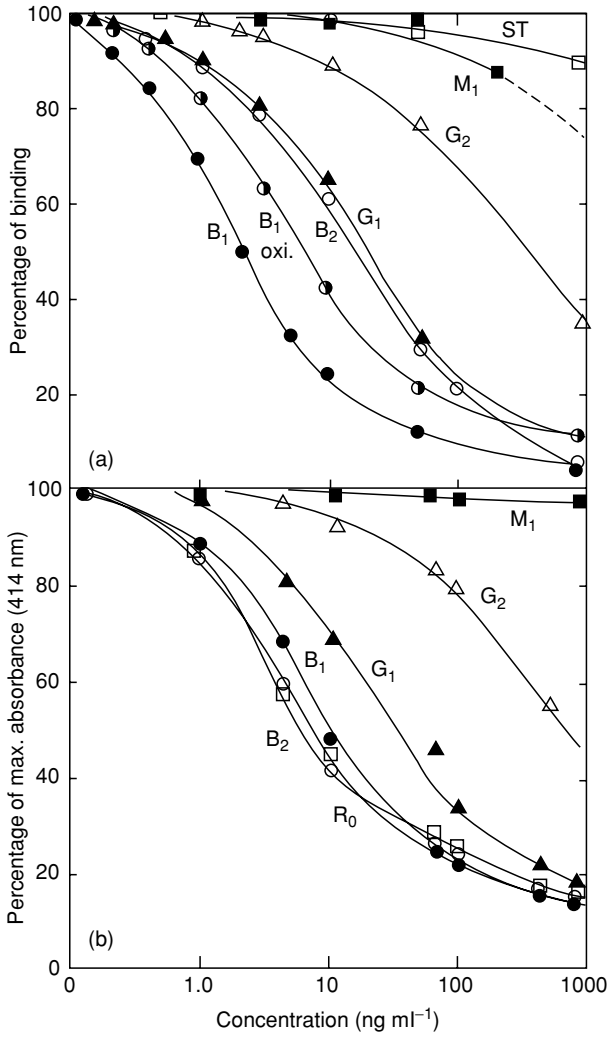

Figure 1 Cross-reactivity of polyclonal antibody against aflatoxin B_1 with various aflatoxins as determined by (a) radioimmunoassay and (b) enzyme-linked immunosorbent assay. immunogens. Considerable improvement has been made over the years to some of these methods. With the availability of new instruments and enhancement of the particle size, both the precision and sensitivity have been improved in recent years. Thus, they are still frequently used for the analysis of food constituents. Immunochemical methods other than RIA and ELISA in food analysis are briefly described here.

Precipitation

This method is based on the formation of precipitate as a result of antibody–antigen interaction. Several formats, which require several minutes to several days to perform and have a sensitivity range from 0.1 to 10 $\mu g\,ml^{-1}$, have been used.

Precipitation in solution or quantitative precipitin method In general, an aliquot of different concentrations of antigen or antibody is added to a series of tubes containing a constant amount of antibody or antigen. A precipitate is formed after incubation. The concentration of the unreacted antigen or antibody in the supernatant solution or the weight of the precipitate of the antigen–antibody aggregate is determined after centrifugation. Maximum precipitate is only formed at the equivalent zone where none of the reactants is at excess. This approach is very tedious and subject to error, and is not commonly used at present. Instead, turbidimeter and nephelometer are used in most laboratories. Recent developments have led to measuring the light-scattering effect of the particles instrumentally; the term 'light-scattering immunoassay' is used for this type of assay.

Methods based on simple diffusion of reactants and subsequent precipitation of immunocomplex in agar gel These methods, which are based on the formation of precipitin bands or lines in agar gel, were originally developed by Oudin and Ouchterlony. Three formats are generally used: simple gel diffusion, double diffusion, and radial immunodiffusion (RID).

Simple gel diffusion This method involves the use of a small tube (about 0.5×8 cm; Oudin tube) partially filled with agar containing antibody (occasionally antigen). The test solution is placed on top of the agar column. After antigen diffuses into the agar, a precipitation band is formed at the interface as a result of the antigen–antibody interaction.

Double diffusion (double immunodiffusion) This method involves the use of an agar gel plate (sometimes called an Ouchterlony plate) where cups or wells containing test antibody and antigen solutions are placed in such an order that the antigen and antibody solutions diffuse toward each other through the gel. Most commonly, the antibody well is placed in the center, with the antigen wells around it. After incubation, a band is formed between the antibody and test antigen solution. The intensity of the precipitin band is related to the concentration of the reactants. With appropriate arrangement of the wells for the antigen and antibody, the cross-reactivity of the antibody with structurally related antigen could also be determined. If the precipitin band of the antigen is completely connected with the band of the next well, these two antigens are identical. If they are partially connected to form a spur (arc) type of band, then they are partially identical. However, if both bands cross each other, these two antigens are not identical.

Radial immunodiffusion In this assay, antibody is distributed throughout the gel matrix. The test antigen is placed in wells punched into the gel. After incubation, the antigen is diffused into the gel to form an opaque zone where the immunocomplex occurs. The diameter or area of the circular zone is proportional to concentrations of the test solutions.

Combination of other separation methods with immunodiffusion and precipitation reaction One of the most common approaches is immunoelectrodiffusion (IED) or immunoelectrophoresis, which involves the separation of antigen electrophoretically, followed by immunodiffusion. In practice, a trough parallel to the direction of electrophoresis in a gel is cut immediately after the electrophoresis. The trough is then filled with specific antibody. After incubation, precipitin bands/arcs are formed in the gel.

Several variations of this method have been developed. For example, the IED or so-called 'rocket' immunoelectrophoresis method involves the combination of electrophoresis with RID. In this assay, the antibody is distributed in the gel and antigen or analyte is placed in the well at the end of the gel. Electrophoresis is carried out under conditions which do not permit the migration of antibody. After electrophoresis and diffusion, rocket-shaped precipitates are formed. The height of the rocket is generally related to the concentrations of the test solution. Other variations such as counterimmunoelectrophoresis or immunoosmophoresis, or electrosyneresis and zone immunoassay (ZIA), have been reported, but have not been widely used.

Agglutination Assay/Particle Immunoassay

The unique ability of immunoglobulin to agglutinate cells with multiple antigens has been used in an assay system to determine antigen through competition. Different from the precipitation methods, either an antigen or the corresponding antibody is attached to an inert particle via direct binding or covalent interaction, which serves as the label. Whereas both red blood cells (RBCs) and latex particles have been used for this purpose for some years, recent developments have led to the use of other particles. Thus, a general term of 'particle immunoassay' is also used for this type of assay.

Hemagglutination In hemagglutination (or hemagglutination inhibition assay, HIA, or passive hemagglutination assay, PHA), RBCs (generally sheep), which have been coated or coupled with antigen (thus called sensitized RBCs), are incubated with antibody and sample. After incubation, the degree of agglutination is determined. In this assay, antigen in the sample competes with the antigen coated on the RBCs for their interaction with antibody. Another variation of the HIA is reverse passive hemagglutination assay, in which the purified antibody is coupled to the RBCs. Agglutination is observed when antigen or sample extract is added to the system. Although HIA is relatively simple, food extracts often interfere with the assay and a large amount of antiserum is needed. Only semiquantitative information can be obtained.

Latex agglutination Instead of using sheep RBCs, latex particles coated with antigen have been used as the agglutinating agent in the antigen/antibody reaction. Both regular inhibition and reversed type of agglutination methods have been used.

Other particles and new intrumentation methods for particle counting Several other particles, including microcapsule gelatin, silicate, gold, and emulsified fluorocarbon, have also been introduced as labels in recent years. Among these, the microcapsule gelatin is used most often. Instruments to measure the agglutinated particles are now available and are termed 'particle-counting immunoassay'. Both photometric and light-scattering methods have also been used. The availability of sophisticated instruments has not only improved the sensitivity to a level in the subnanograms per milliliter, but has also led to an automated system that can handle large volumes of samples with good precision.

Other Immunochemical Approaches

Several other immunochemical methods that have gained wide applications in recent years are cited below. Immunoadsorption methods are based on temporary immobilization of immunocomplexes on a solid support; immunoaffinity chromatography is a means of removing undesirable antibodies from an immune serum using the corresponding antigens. Conversely, immunoaffinity chromatography is also used for retaining a given antigen from a complex matrix by using the antiantigen antibodies. Usually, the antigens or the antibodies are immobilized on a support and packed in a small column for immunoaffinity chromatography, which is then used in different types of immunoassays and automation. Some rapid-screening test kits are based on this principle and have gained wide applications. In addition to this technique for haptens, immunomagnetic beads have been used in affinity enrichment and isolation of pathogenic bacteria, including *Escherichia coli* O157:H7. The separation is quick and convenient, requires no elaborate equipment, and can be used instead of precultivation as a precursor for other tests to extract the

target organism. Another powerful immunochemical method is the Western blot, which involves the separation of food components electrophoretically, followed by transfer of the separated components on to nitrocellulose membrane and then staining immunochemically with either enzyme-labeled or radiolabeled antibody. Using a similar principle and in combination with microscopy, a rapid antibody-direct epifluorescent filter technique (antibody-DEFT) for screening of *E. coli* O157:H7 in beef at a level of 0.1 CFU g^{-1} was developed recently. The antibody-DEFT involved membrane filtration, fluorescent antibody staining, and epifluorescence microscopy and was accomplished in less than 1 h.

Radioimmunoassay and Enzyme Immunoassay

F S Chu, University of Wisconsin, Madison, WI, USA

Introduction

Immunochemical methods discussed in the previous article generally involve no labeled antigen or labeled antibody. Concentration of the antigen–antibody complex is estimated from the secondary reaction that leads to precipitation or agglutination. These methods are not sensitive, are subject to nonspecific interference, and are primarily used for analysis of high-molecular-weight proteins. However, the development of radioimmunoassay (RIA) of insulin by Yalow and her colleagues in the late 1950s has widened the scope of immunoassays. This method revolutionized the classic approaches by combining the unique properties of specific antibody–antigen interaction and the use of a radioactive labeled marker to monitor complex formation. Thus, RIA provides specificity, sensitivity, and simplicity, and can be used for analysis of both antigen and haptens. With the introduction of enzymes as markers in the assay, the sensitivity is further amplified. Using different labeled markers, a variety of immunoassays, including fluorescence immunoassay (FIA), time-resolved FIA, FIA polarization immunoassay, enzyme immunoassay (EIA), luminescent immunoassay (LIA), metalloimmunoassay (MIA), and viroimmunoassay (VIA) have been developed. Since RIA and EIA are most commonly used in food analysis, only these two and immunochemical biosenors or immunosensors, which have recently been developed, will be discussed in detail.

Radioimmunoassays

Principles

RIA involves the use of a radioactive marker in the assay, which competes with an analyte in the sample for binding to an antibody. For RIA of high-molecular-weight antigen, either the antigen or antibody molecules can be labeled. It is also common to use a radiolabeled second antibody, i.e., antibody against the primary antibody. In contrast, labeled hapten is typically used in RIA for low-molecular-weight substances. For simplicity, RIA is explained in eqns (1) and (2).

$$\text{Antibody} + \text{Antigen}^* \rightleftharpoons \text{Antibody} - \text{Antigen}^* + \text{Antigen}^* \quad (1)$$

$$\text{Antibody} + \text{Antigen}^* + \text{Analyte} \rightleftharpoons \text{Antibody}- \text{Antigen}^* + \text{Antibody} - \text{Analyte} + \text{Antigen}^* \quad (2)$$

At a constant amount of antibody and labeled antigen (denoted by an asterisk), the presence of analyte in the sample (eqn 2) will result in a decrease in radioactivity in the bound form and an increase in radioactivity in the free form because the analyte is also bound with antibody. In practice, antibody is incubated simultaneously with a solution of unknown sample or known standard, and a constant amount of labeled antigen or hapten. After separation of the free and bound forms, the radioactivity in those fractions is determined. The concentration of the substances to be analyzed in the unknown sample is determined by comparing the results to a standard curve, which is established by plotting the ratio of radioactivities in the bound fraction and free fraction versus the logarithm of the concentration of unlabeled standard analyte.

Although RIA is simple and sensitive, it is limited by the need for a marker with high specific radioactivity, instruments for measuring radioisotopes, and licenses for using radioactive materials and disposal of radioactive materials. Consequently, enzyme-linked immunosorbent assay (ELISA) has become more popular. Nevertheless, because the radioactive marker has the same structural features as the compound to be analyzed, RIA provides good accuracy and is an effective method in the initial phase for screening of antibodies.

Preparation of Radioactive Ligands

The specific activity of the radioactive ligand plays an essential role in the sensitivity of RIA in addition to the affinity constant of antibody and antigen interaction. Because of the availability of high-specificity radioactive iodine, immunoglobulin and protein antigen are generally labeled with ^{125}I. Reagents for iodination such as Bolton-Hunter reagent, chloramine T, iodo-gen, lactoperoxidase, and iodo-beads are commercially available. Thus, most laboratories can prepare their own labeled marker. Since the half-life of ^{125}I is short, iodinated markers generally should not be stored very long. For haptens such as mycotoxins or antibiotics, both tritiated and iodinated derivatives are used. Occasionally, ^{14}C-labeled compounds have also been used. Some high-specific-activity compounds are made commercially by a tritium exchange method. Reduction of a hapten with high-specific-activity-tritiated sodium borohydride is commonly used. For hapten containing hydroxyl groups, the secondary hydroxyl group is first oxidized and then reduced with tritiated sodium borohydride. Iodinated hapten markers are prepared by direct iodination or by iodination of hapten derivatives containing a linker such as tyrosine, histamine, tyramine, or others. For example, 3′-[^{125}I]tyramine-aflatoxin B_1-*O*-carboxymethyl oxime (2300 Ci nmol^{-1}) was used in the RIA of both aflatoxins B_1 and M_1 with high sensitivity (10 pg per assay).

Separation of Antigen–Antibody Complex from Free Antigen

To assess the amount of complex formation, effective methods for the separation of free and bound antigen/antibody must be established. Approaches for the separation of high-molecular-weight antigen and immunocomplex generally can also be used for RIA of hapten as well as for EIA; however, the converse is not always true.

Separation of hapten and hapten–antibody complex Methods such as equilibrium dialysis, ammonium sulfate precipitation, precipitation with organic solvent, polyethylene glycol 6000, membrane filtration, dextran-coated charcoal, and albumin-coated charcoal have been used. Except for the coated charcoal methods, all these methods are based on the separation of molecular weight.

Separation using solid-phase matrix In this approach, antibody is coated to a solid matrix such as polystyrene tubes/beads, microtiter plate, or modified nylon tubes or beads noncovalently, or conjugated to various matrices such as acetylbromocellulose, various types of sepharose gel or agarose gel, and controlled-size fine-particle magnetic gels. Separation is achieved by filtration or centrifugation after the reaction.

Separation using a secondary antibody or other reagents In this approach, a second antibody is added to the reaction mixture to separate the free antigen and immunocomplex. Although the formation of precipitate of the primary antibody with second antibody was used in earlier studies, a solid matrix coupled with the second antibody is now more commonly used. Because of their high affinity to immunoglobulin G (IgG), staphylococcal protein A and protein G coupled to a solid-phase matrix are also commonly used for separation in both hapten and macromolecule assays.

Enzyme Immunoassay

General Considerations and Assay Configurations

EIA is a general term for immunoassays involving use of an enzyme as a marker for the detection of

immunocomplex formation. Whereas the general principle of EIA is similar to RIA, there is an amplification system present in this assay, and thus it is more sensitive. Since no radioactive substances are used, the assays avoid the problems encountered in handling radioactivity. Enzyme labeling can be achieved by conjugation of the enzyme to an antigen or antibody via periodate oxidation with subsequent reductive alkylation method, cross-linking using glutaraldehyde or others. Some of the methods used in the conjugation of hapten to proteins can also be used. However, to avoid nonspecific interaction, methods for coupling of protein/hapten to enzyme should be different from the one that had been used for conjugating the hapten to protein for immunization purpose. Although horseradish peroxidase and alkaline phosphatase are the two enzymes most commonly used, others, such as glucose-6-phosphate dehydrogenase, coupled with oxidoreductase and luciferase, glucose oxidase, beta-galactosidase, urease, and others have also been employed.

Depending on whether or not the immunocomplex is separated from the free antigen, EIAs are further divided into two types. One type is a homogeneous system, which is based on the modification of enzyme activity occurring when antibody binds with the enzyme-labeled antigen/hapten in solution. No separation is necessary in this assay. One such type of this system, which is called enzyme mulitiplied immunoassay (EMIT), has been used for the analysis of some antibiotics and hormones in the clinical diagnosis area. Because modification of enzymatic activity is generally not significant, this system is not very sensitive ($\mu g\,ml^{-1}$ to $mg\,ml^{-1}$ range) and has not been widely used in food analysis.

The other is a heterogeneous system involving separation of free and bound antigen–antibody. In this system, either antigen or antibody is bound to the solid matrix noncovalently, or conjugated to it covalently. Unreacted antibody or antigen/hapten is simply removed by washing or centrifugation. The term 'enzyme-linked immunosorbent assay' (ELISA) is used for this type of assay. Solid phases such as microtiter plates, cellulose, nylon beads/tubes, nitrocellulose membrane, polystyrene tubes/balls, and modified magnetic beads have been used. In some cases, staphylococcal protein A or protein G is coated on the solid surface, entrapping the antibody for subsequent analysis. This method is further divided into two major types. One type is competitive ELISA, which can be used for the analysis of both hapten and macromolecule; the other is noncompetitive sandwich-type ELISA, which is only used for divalent and multivalent antigens.

Competitive ELISA

Depending on whether enzyme-labeled antigen or antibody is used or whether antigen or antigen is coated to the solid phase, several types of competitive ELISAs have been developed. Two major types, i.e., direct competitive ELISA (dC-ELISA) and indirect competitive ELISA (inC-ELISA), are used most commonly in food analysis.

Direct competitive ELISA In this assay, specific antibodies are first coated to a solid phase. The sample or standard solution of analyte is generally incubated simultaneously with enzyme–conjugate or incubated separately in two steps. The amount of enzyme bound to the plate is then determined by incubation with a chromogenic substrate solution. The resulting color/fluorescence, which is inversely proportional to the analyte concentration present in the sample, is then measured instrumentally or by visual comparison with the standards. A typical standard curve for dC-ELISA of aflatoxin is shown in Figure 1 of Immunoassay: Principles and general considerations. Excluding the time for sample preparation, the assay itself can generally be completed in 1–2 h. In general, dC-ELISA is approximately 10–100 times more sensitive than RIA when purified standard is used.

Indirect competitive ELISA (or double-antibody ELISA) In the inC-ELISA, an antigen or a hapten-protein (or polypeptide) conjugate (preferably with a carrier protein/polypeptide that is different from the original carrier protein) is coated to the solid phase, e.g., microtiter plate, to facilitate antibody capture. Antibody and analyte are then incubated together in the wells of the plate. The amount of antibody bound to the wells is then determined by reaction with a second antibody–enzyme complex such as goat anti-rabbit IgG–enzyme complex or goat antimouse-IgG (IgM)–enzyme complex and by subsequent reaction with substrate. Thus, analyte in the sample and antigen in the solid phase compete for the same antibody-binding site in the solution. The sensitivity of the in C-ELISA is comparable to or slightly better than the dC-ELISA, with the advantage that less antibody is required. In addition, it is not necessary to prepare an antigen/hapten–enzyme conjugate. The disadvantage of the method is that an additional incubation step is necessary for the assay and, thus, it requires longer analytical time (2–3 h).

Two modifications of the inC-ELISA have been made. One involves the conjugation of antibody, especially monoclonal antibody, to an enzyme; the conjugate is then used directly in the assay. Thus, this modification converts the inC-ELISA format to a direct assay. The second involves premixing

the antibody with a second antibody–enzyme conjugate. Both modifications have shortened assay time without sacrificing sensitivity. Because only small amounts of antibody are needed, inC-ELISA has been used extensively for screening hybridoma cultures for monoclonal antibody production.

Noncompetitive Sandwich Immunoassay (or Two-Site ELISA)

In this assay, the antibody is coated on to the solid phase, most commonly to the wells of a microtiter plate. The analyte is added and incubated for an appropriate time. After washing, enzyme-labeled antibody is added and incubated, followed by reaction with substrate to develop the color. Under optimal antibody and enzyme antibody concentrations, the color intensity is directly proportional to the concentration of analyte. Thus, it is not necessary to prepare an enzyme-labeled antigen in this assay. A number of modifications of this method have been made.

Monoclonal antibody-based sandwich assay In this assay, a monoclonal antibody (type 'a') is coated on the plate. The plate is sequentially incubated with analyte and another monoclonal antibody (type 'b') labeled with enzyme. The antibody–enzyme conjugate must recognize a different epitope on the analyte than does the antibody (type 'a') used to coat the plate. Determination of analyte–antibody–enzyme–complex is then made by incubation with substrate. With this format, one can select appropriate pairs of monoclonal antibodies for special analytical objectives.

Double-antibody sandwich assay In this assay, antibody originating from animal species 'a' (e.g., rabbit) is coated on to the plate. The plate is sequentially incubated with analyte and antibody against the same analyte from animal species 'b' (e.g., mice), followed by antibody against animal species 'b' (goat antimouse) labeled with enzyme, and then with substrate.

Quick Immunoscreening Tests

Based on the ELISA principle described above, a number of quick screening tests have been developed. For example, by adjustment of reagent concentrations, microtiter plate ELISA assay can be completed in less than 20 mins. Other approaches involve immobilizing the antibody on a paper disk or other membrane which is mounted either in a plastic card or in a plastic cup, or on the top of a plastic tube. In the 'dipstick' assay, antibody or antigen is coated on to a stick, which is then dipped in various reagents for subsequent reactions. Substrates leading to the formation of a water-insoluble chromogenic product are used in these assays. Most of these screening tests are very simple and easy to perform and take 10–15 min to complete. They are designed to provide semiquantitative information at certain cut-off concentrations for the substance in which one is interested. The immunoscreening tests have gained wide application for monitoring microbial toxins in foods and food contaminants such as mycotoxins in the field and versatile assay kits are commercially available.

New Developments and Biosensors:

Nonisotopic Labeling Other than with Enzymes

Among many new nonisotopic labeling systems developed in recently years, FIAs in which the immunoreactants are tagged with fluorescent probes are used most often. For example, in the so-called 'hit-and-run' assay for T-2 toxin, a T-2 toxin column was equilibrated with a fluorescein isothiocyanate (FITC)-labeled Fab fragment of IgG (anti-T-2 toxin). Samples containing T-2 toxin were injected into the column. The FITC-Fab that eluted together with the samples containing T-2 toxin was then determined in a standard flowthrough fluorometer. While fluorescein isothiocyanate (FITC) has been used most often for this purpose, a number of other high-quantum-efficiency reagents, such as the phycobiliproteins, which include phycoerythrins, phycocyanins, and allophycocyaninins, have gained wide applications in recent years. These reagents replace the enzyme as the markers in both the heterogeneous and homogeneous immunoassays.

Fluorescence-based substrate has also been used to improve the sensitivity. New instrumentation further led to the development of several unique FIAs. For example, the fluorescence polarization method can detect the antigen/antibody reaction in solution with good sensitivity in the homogeneous system (ng to μg ml^{-1} range). A time-resolved fluoroimmunoassay, which involves the use of europium ion (Eu)-labeled antibodies, has a sensitivity similar to most ELISAs for aflatoxin analysis (with an IC_{50} of 0.2 ng ml^{-1}). In the particle concentration FIA (PCFIA), the antigen/antibody is bound to the solid phase such as submicrometer polystyrene particles and the fluorescence-labeled reagent and analyte bind to the particle surface competitively. The sensitivity of this for both high-molecular-weight proteins and haptens reaches the ng and sub-ng range in each assay. Similar to FIA, both bioluminescent and chemiluminescent reagents have been used as the markers as well as enzyme substrates in different types of immunoassays.

Enhanced Amplifications Leading to more Sensitive and Ultrasensitive Immunoassays

The sensitivity of different immunoassays has also improved considerably by incorporation of various amplification systems in conjunction with EIA and RIA. Whereas biotin (BT) has been used commonly as a secondary label in systems in conjunction with labeled avidin (AV) or streptavidin, amplification with multiple labeling further improved the sensitivity. The power of amplification is well demonstrated in the ultrasensitive immunoassay where several steps of amplifications and solid-phase concentrations are involved. For example, in a noncompetitive IA of hapten, the hapten is first biotinylated and then reacted with antihapten IgG-coated solid phase. After washing, the bound hapten–BT is removed from the solid phase at pH 1.0. The eluted solution is adjusted to neutral pH, then reacted with antihapten-Fab'-enzyme conjugate, followed by incubation with AV (or streptavidin)-coated solid phase. After washing, the hapten-BT-antihapten-Fab'-enzyme-solid phase is reacted with the substrate. Although this involves many steps, the sensitivity of this system for the hapten reached to 10 attomoles (10^{-18} mol) per assay.

Automated Immunoassay and Development of Antigen/Antibody-Based Biosensors

Development of new sensitive immunoassays that require repeated precise handling of reagents as well as the demand for large numbers of samples for analysis have led to the establishment of automated immunoassay systems. Rapid progress on the antigen/antibody-based biosensors for the detection of various food components, toxins, and contaminants has also emerged. Only a few examples are cited here to show the dimension of this type of technology. A biosensor for a homogeneous immunoassay for T-2 toxin, which involves the use of liposomes and complement, was developed. A fiberoptic immunosensor has been demonstrated to be effective for several microbial toxins, including staphyloccocal enterotoxin B (SEB), T-2 toxins, and fumonisins, in foods. In the assay of hapten-related toxins, monoclonal antibodies are covalently bound to an optical fiber and an evanescent wave effect was utilized to excite the fluorescent-tagged toxin near the surface of the monoclonal antibody fiber as the tagged toxin bound to the fiber. In the presence of unlabeled toxin, it competes with the labeled toxin for binding with monoclonal antibody and results in a decrease in signal. Thus, it is also a competitive assay. For SEB, the sandwich system rather than the competitive format was used and an automated immunosensor detected 5 ng of SEB g^{-1} of cream in 10 min. In the automated particle-based immunosensor (API), the antigen or hapten–protein conjugate is coated on to the polymethylmethacrylate beads (98 μm), and this is then pumped into the 1.5-mm diameter glass capillary to serve as the flow cell within the final lens and trapped on a filter. The sample or calibrated standard solutions that had been incubated with antibodies were then allowed to pass through for a short period (120 s), followed immediately by FITC-labeled goat antirabbit antibody (120 s), and then finally washed with buffer to remove excess label. The fluorescence during each step of the reaction was recorded. Thus, this is a kinetic exclusion assay and can easily detect down to a level of 4 ng g^{-1} of sample (4 p.p.b.) for aflatoxin in 8 min. In a miniaturized ELISA, urease acts as an enzyme marker to produce a pH-shift that can be detected by the ion-sensitive field effect transistor. This system consisted of a flowthrough set-up with a pretreated activated fused silica capillary as a reaction cartridge to serve as a solid phase for the reversible inC-ELISA with a detection limit of 10 pg ml^{-1} for T-2 toxin. In the surface plasmon resonance (SPR) immunosensor, antibody is adsorbed on to a thin gold film substrate coupled to a glass prism. The output beam of a planar light-emitting diode is focused through the prism to excite SPR at the surface of the gold film. When a sample containing antigen/hapten is added to a cell on the outside of the gold film, the angular profile of reflected light intensity shifts. This changes the resonance angle and the reflected beam intensity at a selected angle, both of which are proportional to the antigen/hapten concentration. A detection limit of 50 ng ml^{-1} is obtained for the mycotoxin fumonisin with an analysis time under 10 min. A commercial electrochemiluminescence (ECL) sensor can detect 100 and 1000 of *Escherichia coli* O157 and *Salmonella typhimurium*, respectively, in 1 ml of pristine buffer (or 1000–2000 bacteria ml^{-1} of food samples) in less than 1 h.

Application of Immunoassays in Foods

Immunoassays for Normal Food Components and Adulteration in Foods

Whereas immunochemical methods have been established for most normal food components, one of the major applications of immunoassay in foods is to detect adulteration. This includes the detection of nonmeat proteins in meats and meats from different species. Combinations of electrophoresis with various classic methods, which provided only some qualitative information, were used in early investigations. Both RIA and ELISA are more commonly used at present. For example, RIA has been used to differentiate cattle

meat from sheep, donkey, pig, horse, and kangaroo at 5% contamination level. Various ELISA methods were used to detect albumin and immunoglobulins as a means of detecting blood residues in the muscles of various species. Sensitive RIAs and ELISAs for nonmeat proteins, including soybean proteins, cows' milk, avian egg white protein, wheat gluten, and other nonmeat proteins (legume, cotton seed, peanut, sunflower), have also been developed. These assays are specific and could be used to detect the presence of these proteins in meat products. Since heat treatment or acid hydrolysis can result in a change of protein structure, immunoassays for some of these proteins have also been developed by using antibodies against the denatured proteins and soluble proteins. Immunoassays have also been established for some antinutrients such as trypsin inhibitors, lectins, and allergens. The so-called radioallergosorbent inhibition test (RAST) involving the use of ^{125}I-labeled antihuman IgE, has been used for the detection of allergens in foods. Allergens in foods are also detected with double-antibody sandwich ELISA as well as dC-ELISA and inC-ELISA.

The application of immunoassay for quality control in food processing has also emerged. For example, immunoassays of certain forms of casein, lactoserum, α- and β-lactoalbumins, IgG, lactoferrin, and certain enzymes produced by psychrotropic bacteria in milk were used to determine quality of milk and dairy products. A sensitive ELISA method is also available to differentiate animal rennet and other rennet substitutes. Immunoassay of barley proteins and other soluble proteins and enzymes has been used by the beverage industry. Immunoassays of cortisol and corticosterone were used to monitor meat quality. An ELISA was established for insect myosin, which serves as an indicator for the presence of insects in foods.

Immunoassays for Naturally Occurring Contaminants and Toxins in Foods

Foodborne pathogens and toxins Immunochemical methods have been used for more than 30 years for the detection of foodborne pathogens and high-molecular-weight microbial toxins in foods. Different immunochemical methods for foodborne toxins, including staphylococcal enterotoxins, *Clostridium perfringens* type A enterotoxins, *C. botulinum* toxins, *Bacillus* enterotoxins, and *E. coli* toxins, have been developed. Immunoassays of these toxins in foods have moved from classical immunodiffusion and hemagglutination methods to modern RIA, and now, more commonly, to ELISA. Increasingly, monoclonal antibodies are used. The sensitivity of various types of RIA for the detection of staphylococcal enterotoxins is in the range of 1–5 ng ml^{-1} as compared to that of ELISA of 0.1–5 ng ml^{-1}. An EMIT assay using β-amylase with a sensitivity of 5 ng ml^{-1} has been developed for SEB. The ELISA sensitivities for the detection of botulinum toxin and *C. perfringens* type A toxin are in the range of 0.125–5 ng ml^{-1} and 0.5–500 ng ml^{-1}, respectively. Recent developments have led to more sensitive ELISA methods for monitoring important foodborne bacterial pathogens such as *Campylobacter jejuni, E. coli, Listeria, Salmonella*, and *Yersinina enterocolitica*.

During the last few years, many studies focused on the development of immunoassays for *E. coli* O157:H7. For example, a bead-ELISA with a sensitivity of about 200 pg ml^{-1} was developed for specific detection of the VT2 variant VT2e and a monoclonal antibody-based sandwich ELISA for VT1 and VT2. Using an antigen competition format, a solid-phase fluorescence-based immunoassay was developed. In this assay, a soft glass capillary tube served as the solid support, to which heat-killed *E. coli* O157:H7 were adsorbed. Polyclonal anti-*E. coli* O157:H7 antibody, conjugated with biotin, was used; the bound antigen–antibody complex was detected using avidin molecules labeled with a fluorescent cyanine dye Cy5. Anti-*E. coli* O157 antibody coated to the inexpensive macroporous polyester fabric Polymacron was used to capture *E. coli* O157 antigens for subsequent immunoenzymatic detection of the bacteria. In a rapid and inexpensive sandwich enzyme-linked receptor-based immunodot assay method, the purified glycosphingolipid digalactosylceramide (diGalCer) was used as in the solid-phase matrix to entrap for the assay.

Naturally occurring food toxicants Rapid progress on the development and application of immunoassay for low-molecular-weight naturally occurring toxins, contaminants, and agricultural residues in foods has also occurred during the last two decades. Both monoclonal and polyclonal antibodies against low-molecular-weight food toxins, including marine toxins (brevetoxin, palytoxin, okadaic acid, paralytic shellfish toxins, and ciguatoxins) and mycotoxins (aflatoxins, ochratoxin A, fumonisin, sterigmatocystin, trichothecenes, and zearalenone), are available. Various immunoassay formats have been developed. These methods are generally very simple and sensitive. For example, the lower limits of RIA and ELISA for purified mycotoxin standards are in the range of 0.05–0.5 ng and 2.5–5 pg in each assay, respectively. Because of the interference of sample matrix, the detection limits of most of the mycotoxins in foods/feed are generally about 1–5 p.p.b. for RIA and 0.05–0.5 p.p.b. for ELISA with no sample

clean-up treatment. The detection limits for other food contaminants by RIA and ELISA varied considerably, but generally are less sensitive than for mycotoxins.

Since immunoassays for these haptens in foods share some common problems, strategies to overcome these problems are discussed here. In general, the use of affinity purified antibody in combination with the use of good radioactive-labeled or enzyme-conjugate marker, or with other systems such as chemiluminescence, or amplification systems such as biotin-avidin, can improve the assay sensitivity. However, one of the major concerns is still interference by sample matrix. This problem is generally overcome by dilution of the sample to a range which does not affect the assay or by using sample extract in the preparation of the standard curve. Sample clean-up may sometimes be necessary. For example, the sensitivity of the RIA, dC-ELISA and inC-ELISA for mycotoxins in foods has improved after such treatment. The combination of using high-specific-activity radiolabeled compounds and clean-up samples has allowed the sensitivity for the detection of aflatoxin M_1 in tissues and milk to reach the $0.01\,ng\,g^{-1}$ level in both RIA and ELISA.

Other naturally occurring contaminants In addition to mycotoxins and phycotoxins, sensitive immunoassays have also been developed for many naturally occurring toxicants and contaminants, including DNA-adducts of psoralens, caffeine, naringin, limonin, and selected isoflavones. Sensitive ELISA ($ng\,g^{-1}$) for ergot alkaloids can detect about one sclerotium $20\,kg^{-1}$ of grain. Immunoassay for potato glycoalkaloids such as α-solanine, α-chaconine, and solasonine, and tomato glycoalkaloids such as α-tomatine, tomatidine (aglycon), and digitonin are also available. The sensitivity of these assays is in the $1–200\,ng\,g^{-1}$ range. Contaminants such as mercury ($100\,ng\,g^{-1}$ in scallops) and histamine ($10\,\mu g\,g^{-1}$ salmon) are now detectable by immunoassay.

Agricultural chemicals and residues and pesticides This is another area for which immunochemical methods have been established in the last two decades and have gained wide application. Immunoassays are available for almost all the important antibiotic residues that might be present in our foods. For example, β-lactone antibiotics such as ampicillin, cloxacillin, and penicillin G, in the range of $1–10\,ng\,g^{-1}$, could easily be measured in milk. The sensitivity for the detection of other antibiotics by immunoassay falls in a similar range. Likewise, immunoassays for many pesticides are available. The sensitivity for measuring ethyl parathion, diflubenzuron, and dieldrin in milk are around $5\,ng\,g^{-1}$. Less than $1\,ng\,g^{-1}$ of benomyl/carbendazim in fruits and vegetables could be determined by immunoassay. ELISA kits with a sensitivity in the range of $0.1–5\,ng\,ml^{-1}$ are available for alachlor, aldicarb, atrazine, carbaryl, carbendazim, carbofuran, cyanazine, 2,4-D, and metolachlor.

Concluding Remarks

The development of immunoassays for the detection of food components and contaminants has progressed rapidly in the last few years. Antibodies against almost all the important agricultural and food-related compounds are currently available. Sensitive, simple, and specific immunoassays have been established. Modern immunoassays such as RIA and ELISA are gradually replacing the classic immunodiffusion and agglutination methods for food analyses. These methods are very simple, sensitive, and specific. To avoid the use of radioactive compounds, ELISAs are more commonly used than RIA. The development of new labeling reagents and enhanced amplification systems in conjunction with solid-phase technology further improves the sensitivity and precision of different types of immunoassays, including those of precipitation and agglutination. With the availability of immunochemical reagents and sensitive instrumentation, automation of immunoassays has become a reality. Versatile immunoassay kits that can be used in the field are commercially available and are widely used for the detection of toxins and contaminants in foods. A number of immunoassay protocols have been adopted as first action by the Association of Official Analytical Chemists.

Whereas immunoassays have been used extensively for the analysis of contaminants/toxicants/residues in foods, applications of these methods for the analysis of food components and food adulteration are also merging. However, immunoassays for the control of food processing are not common. Future developments in the area of rapid test, automation, and immunosensors will certainly widen the scope of applications to some of these areas. As such methods are developed, more collaborative studies are needed to validate the efficacy of the protocol and assay kits. Since all immunoassays are based on the specific interaction of antibody with antigen, it is imperative for those who run immunoassays to have a clear understanding of the specificity of the antibody used in the assay as well as the purity and authenticity of the standards. Immunochemical methods, including affinity chromatography as a clean-up tool and immunoassay as a monitoring system for high-performance liquid chromatography, thin-layer chromatography, and electrophoresis have been used in

conjunction with other analytical methodologies. The innovative approaches have led to a new dimension in the immunochemical methods for food analysis. Unquestionably, immunoassays will be advanced to another new era in the new millennium and they will be used extensively in food and agriculture in the coming years. It will not be surprising to see immunoassay screening kits will some day reach the consumer level. Such progress will certainly not only provide safer foods to eat and a better environment in which to live, but will also enhance agricultural productivity by using these new technologies to improve crop quality and yield and enhance animal and plant health.

IMMUNOLOGY OF FOOD

K M Burghardt and F W Scott, Ottawa Health Research Institute, Ottawa, Canada

Introduction

The process of eating brings us into intimate contact with a wide variety of foods derived from plants and animals. These foods contain carbohydrates, proteins, lipids, micronutrient vitamins and minerals, dietary fiber, other nonnutrient chemicals, bacteria, fungi, viruses, environmental contaminants, food additives, and byproducts of processing and cooking. Food is the most important modifiable environmental exposure to which we are subjected. The aim of this chapter is to explore, in a selective manner, food components that have the potential to alter the activity of the immune system. The gut immune system is continously challenged by a wide spectrum of dietary macromolecules, their metabolic products, resident bacteria, and invading pathogens. Luminal antigens and other molecules are thus a source of information about our immediate environment. The main interaction between food and the immune system occurs in the gastrointestinal tract, the largest lymphoid organ in the body. We shall examine the arsenal of immune cells in the gut-associated lymphoid tissue (GALT), the defense mechanisms, and selected examples of immunomodulatory foods and food components that contribute to health or disease.

Dietary Modulation of the Immune System

Human milk provides optimal nutritional, immunological, physiological, and psychological benefit to a newborn child. At this vulnerable time when its immune system is ill equipped to protect itself, the baby relies on antiidiotypic antibodies and lymphocytes it received *in utero* and which it continues to acquire through mother's milk. Breast-fed infants have been reported to experience significantly fewer gastrointestinal, respiratory, urinary, and ear infections. Some studies have shown long-term enhanced

protection against *Haemophilus influenzae* type b infections, otitis media, diarrhea, respiratory tract infections, and wheezing bronchitis. Mother's milk provides an immediate boost for the young immune system because it delivers antibodies, cytokines, hormones, growth factors, and cells that promote the maturation of the intestinal mucosa as well as modulate immune responses. It contains factors that establish a normal, symbiotic microbial gut flora that protects the newborn from pathogenic bacteria. There is a debate whether infants at risk for development of atopy should be breast-fed because small amounts of food allergens have been detected in human breast milk. A prospective study of neonates identified prolonged (> 9 months) exclusive breast-feeding as the most likely risk factor for atopy by 2 years of age. In contrast, another study showed that supplementation with cows' milk prior to breast-feeding resulted in fewer cases of atopy by 18 months. Numerous other studies have examined this question, and it is yet to be established whether exposure to antigens acquired via the mother's milk induces oral tolerance or priming. Several confounding factors such as antigen dose, timing, and frequency of exposure contribute to the variable results obtained.

The type and quantity of essential fatty acids, such as linoleic acid (*n*-6), dictate the structure and function of the cell membrane. Long-chain and saturated fatty acids reduce fluidity, while short-chain and *cis*-unsaturated fatty acids increase membrane fluidity. Changes to membrane fluidity influence cellular permeability as well as reorganize the distribution and activity of membrane-associated enzymes and receptors. Consequently, this alters the presentation of membrane surface antigens, which affects cellular communication, migration, and immune stimulation.

Linoleic acid is a precursor of arachidonic acid (AA). AA serves as the starting material for eicosanoid synthesis. The membranes of lymphocytes and macrophages contain high concentrations of AA, > 25% of all esterified membrane fatty acids. Mitogens stimulate the release of AA from lymphocytes, which will be converted to eicosanoids by macrophages. Other stimuli that release AA from the cell membrane are reactive oxygen intermediates (ROI) and cytokines such as interleukin-1 (IL-1) and tumor necrosis factor (TNF). Eicosanoids are composed of two families of molecules, the prostanoids (prostaglandins and thromboxanes) and the leukotrienes (lipoxins and hydroxy acids). Release of these oxidation products has physiological and immunological consequences. Prostaglandins regulate immune responses such as IL-2 production, T-cell mitogenesis, and antibody production. Leukotrienes cause leukocyte infiltration, stimulate vascular permeability, and induce smooth-muscle contraction.

Linolenic acid, of the *n*-3 series, was reported to inhibit leukotriene B_4 synthesis and decrease inflammation. Linolenic acid is a precursor for eicosapentaenoic acid (EPA), which is structurally similar to AA, but has antiinflammatory effects. In fact, dietary supplementation with *n*-3 fatty acids increases the incorporation of EPA into the membrane with a proportional decrease in the amount of AA. EPA is metabolized to prostacyclins and thromboxanes which have a net antiinflammatory and antiaggregatory effect. Thus, the amount and type of essential fatty acids in the diet can regulate the type of eicosanoid synthesis. Furthermore, polyunsaturated fatty acids (PUFA) modulate immune responses by enhancing antibody production and decreasing cell-mediated responses, as demonstrated by a shift from T helper 1 (Th1) to Th2 responses that is consistent with IL-2 receptor inhibition. Incorporation of EPA, derived from dietary *n*-3, at the expense of AA reduces the level of PKC activation and thus decreases IL-2 receptor production. There is now considerable evidence that atherosclerosis is an inflammatory disease of the vascular system, the prevention of which involves not only the modification of serum lipids but also a decrease in inflammatory reactions with the endothelium. Dietary *n*-3 PUFA and vitamin E have received particular attention as protective agents.

Dietary fat is also important as a delivery vehicle for the lipid-soluble vitamins, D, E, A, and K. These lipophilic vitamins have immunomodulatory functions. Vitamin A, D, and β-carotene regulate leukocyte activity. Vitamin A controls the recruitment of cells to lymphocyte and macrophage lineages. Vitamin E has antioxidant properties that prevent excessive tissue damage by ROI during stress or infection. Since ROI are also involved in activation of proinflammatory gene expression (e.g., nuclear factor kappaB (NFκB)), antioxidant vitamins can inhibit the inflammatory cascade. These vitamins have been shown to scavenge free radicals that initiate lipid peroxidation. Lipid peroxidation in polymorphonuclear leukocytes, macrophages, and mast cells also releases AA.

Garlic has been used since the times of the early Egyptians as a medicinal herb. There are several biologically active ingredients, including protein fraction 4, diallyl disulfide, and *S*-allyl cysteine in garlic. *S*-allyl cysteine can inhibit activation of NFκB in neuroblastoma and melanoma cells. Thus, garlic is reported to inhibit directly tumor cell growth and may potentiate the immune system by stimulating macrophages, NK (nuclear killer cells), and killer cells, lymphokine-activated killer cells, and increasing production of

IL-2, TNF (tumor necrosis factor), and interferon-γ (IFN-γ). This could be considered an example of inducing a Th1 response that benefits the immune system fight against certain tumors. It is important to be aware that individual foods are unlikely by themselves to be 'magic bullets' that boost the immune response against cancer or regulate other complex chronic diseases. It is the aggregate effect of all dietary exposures that is important. There are several other examples of foods and food components that influence the immune response, including glutamine, arginine, nucleotides, probiotics, vitamins (e.g., vitamin D_3), minerals (e.g., zinc, iron, copper), and oligosaccharides (e.g., 1,3 β-glucans), to name a few.

Micronutrient Modulators of the Immune System

Nutrient status may determine the defense capacity of the immune system. Many vital relationships between trace elements such as zinc, iron, selenium, copper, and cellular function have been described. Most often these elements are an integral part of enzymatic reactions as cofactors and molecular scaffolds. Recently, micronutrients have been shown to regulate directly the immune system.

Zinc has catalytic, structural, and regulatory functions that are well described in cellular metabolism. Zinc deficiency also has immunological consequences, such as lymphopenia, poor cell- and antibody-mediated responses, adrenal hypertrophy, and thymic atrophy. When zinc becomes limiting, it is redistributed to vital organs such as the liver and diverted to the innate arm of the immune system. Zinc deficiency induces a chronic increase in glucocorticoid synthesis, a steroid which promotes apoptosis in precursor lymphoid cells. Thus myeloid cells such as macrophages and neutrophils are spared while lymphoid compartments are depleted. Although macrophages are spared from apoptosis, they are still sensitive to zinc availability. Macrophages isolated from zinc-deficient mice have a reduced capacity to phagocytose and generate an oxidative burst, likely due to the dependence of superoxide dismutase and certain phospholipases on zinc as a cofactor. Similar findings were shown in human monocytes. Clearly, zinc status can alter the choice of defense mechanisms of the immune system.

Iron is an essential trace element because it is part of heme compounds, hemoglobin and myoglobin, which are responsible for oxygen transport and storage, as well as being part of nonheme compounds, and acting as a cofactor for certain critical enzymes like mitochondrial aconitase and ribonucleotide reductase. Moreover, iron availability influences immune effector functions. In the event of chronic infection, iron uptake and storage are increased by proinflammatory cytokines to limit the availability of this essential cofactor to invading pathogens. Increased iron uptake and storage by activated macrophages and monocytes also serve to increase IFN-γ and TNF-α activity and thus enhance their cytotoxic effect. These cytokines also induce the production of nitric oxide, and can form iron–nitrosyl complexes and further decrease iron availability. The counter-effect of the diversion of iron traffic is a reduction in heme synthesis, which contributes to a reduced oxygen transport capacity and possibly chronic anemia. A case in point is anemia of chronic disease, whose pathogenesis has been linked to activated macrophages and monocytes.

Dietary selenium is covalently bound to methionine and cysteine and converted to selenide. Selenide provides an essential cofactor for the synthesis of selenoproteins such as glutathione peroxidases and type 1 iodothyronine deiodinase. Selenium has been exploited in rheumatoid arthritis therapy to reduce oxygen-derived free radicals that damage inflamed joints. Furthermore, selenium also has immunomodulatory properties. Selenium-deficient mice show decreased lymphocyte proliferation in response to mitogen. Selenium supplementation has been shown to enhance cell-mediated immune responses in clinical trials with elderly individuals or subjects receiving parenteral nutrition.

A copper deficit is associated with a small thymus, anemia, decreased antibody production, and neutropenia. In more extreme cases, severe copper deficiency compromises the number and function of neutrophils and macrophages. Individuals fed a copper-deficient diet exhibit reduced T-cell proliferation following mitogen stimulation, an effect that is attributed to decreased IL-2 production. Acquired immunity is also impaired in an animal model of marginal copper deficiency. Pregnant rats were placed on a marginally copper-deficient diet halfway through the gestation period. The rat pups showed reduced cell-mediated responses, yet they had normal copper status as determined by common indices: tissue copper, serum copper, and ceruloplasmin activity. This highlights the exquisite sensitivity of the immune system to nutrient deficiencies and the inherent difficulties in defining 'normal' nutrient requirement for optimum immune function.

How Luminal Antigens are Handled by the Gut Immune System

Nonspecific barriers, such as gastric acid, mucus, digestive enzymes, and peristalsis, as well as specific

immunological barriers, including secretory immunoglobulin A (sIgA) and sIgM, limit antigen access to the GALT. It is estimated that 1 out of 10^5 ingested antigens is absorbed intact by the gastrointestinal tract, which is in the order of microgram per liter quantities. Antigens that cross the gut epithelium are surveyed by immune cells and classified as harmless or harmful. The controlled manner by which luminal antigens gain entry to the GALT is depicted in Figure 1. Lymphoid follicles, called Peyer's patches, are overlaid by membranous epithelial cells (M cells) whose morphology is typified by a smooth apical surface, lack of glycocalyx, and deep invaginations of the basolateral membranes, particularly suited for antigen uptake and delivery to the closely associated lymphocytes and macrophages. Other lymphocytes and dendritic cells are scattered throughout the lamina propria in anticipation of antigens delivered through enterocytes. In healthy epithelia, the uptake of these macromolecules is through active vesicular transport. When the junctions between gut epithelial cells become less restrictive, permeability increases and additional lumen antigens can penetrate the lamina propria and activate resident immune cells. The immune response is based on multiple factors.

A dietary antigen that gains access to the GALT has the potential to induce systemic responses, such as active immune suppression (oral tolerance), immune priming, or it can prompt local immune responses such as the production of sIgA. Oral immune tolerance refers to the unresponsiveness of the immune system, specifically the hyporesponsiveness of mature lymphocytes in peripheral lymphoid tissue that stems from prior oral exposure to the antigen. Recent studies suggest $CD4^+$ Th cells are essential for the induction of oral tolerance because $CD8^+$ cytotoxic T lymphocyte knockout mice can still develop oral tolerance. Furthermore, $CD4^+$ T cells can transfer oral tolerance to a naive individual. Immune deviation from Th1 toward Th2, Th3, or regulatory Tr-1 cells has been proposed to favor normal production of IgA with diminished risk of immunopathology. The major mechanisms, likely acting in concert to establish and maintain tolerance, are clonal anergy (the lack of costimulatory molecules), clonal deletion, and suppression by cytokines such as TGF-β. This depends on the nature of the antigen, dose, maturity of the host immune system, nature of the flora in the digestive tract, and poorly understood host factors. Under certain conditions, the immune system is primed for further immune reaction instead of immune tolerance. Moreover, controversy regarding local immune responses to oral soluble food antigens is not fully resolved. Some suggest that IgA production and secretion accompany oral tolerance, while others contend that healthy individuals do not produce measurable quantities of food-IgA antibodies. Indeed, the decision to commit to any of these pathways is the result of a complex set of cellular interactions and the summation of many bidirectional messages (Figure 1).

Particulate or replicating antigens (e.g., bacteria) are primarily taken up by M cells and diverted to

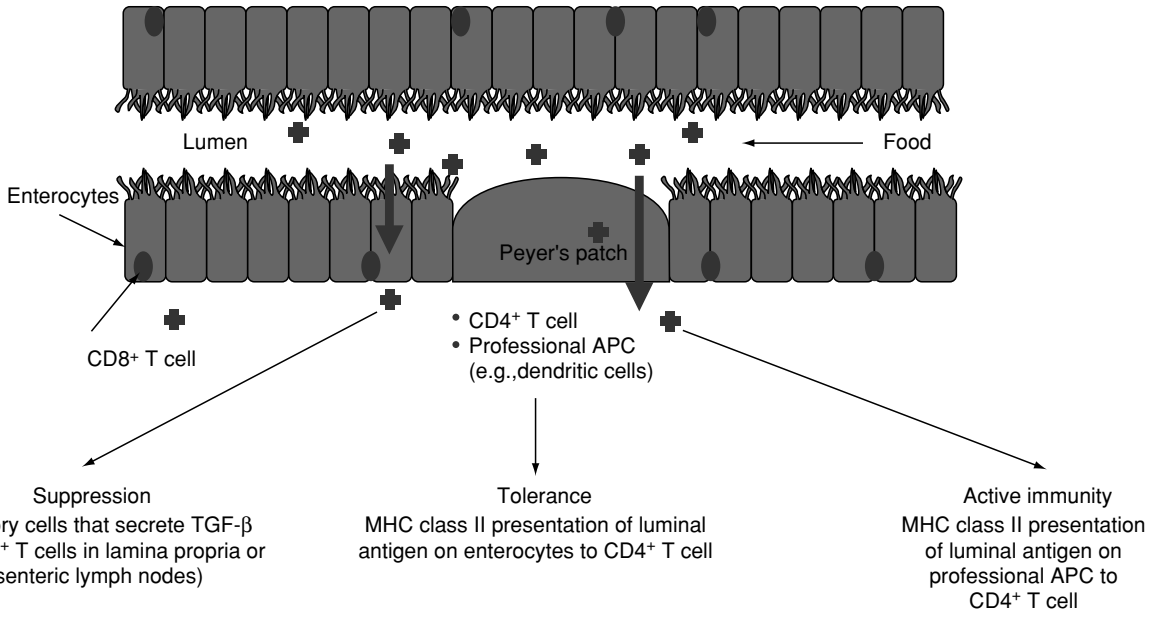

Figure 1 Routes of antigen transport and mechanisms of immune regulation in the gut. APC, aerobic plate count; TGF-β, transforming growth factor-β; MHC, major histocompatibility complex.

the immune cells of Peyer's patches where they will most likely prime the immune system for an assault on these foreign intruders. Most food antigens are digested in the intestinal lumen, which results in various tolerogenic forms of the antigen. The requirement for tolerance induction will depend on the antigenic mixture and its breakdown products. Most soluble antigens induce systemic tolerance.

Oral tolerance has been successfully induced through different regimens and doses of antigens. It has been suggested that a single high dose of antigen ($> 0.5\,mg\,g^{-1}$ body weight) will abrogate antibody, cytokine, and cell-mediated responses in naive individuals as a result of T-cell inactivation. Regulatory T cells are more likely to be activated following multiple low doses ($< 0.1\,mg\,g^{-1}$ body weight). In contrast, very low doses of antigen ($< 0.005\,mg\,g^{-1}$ body weight) were shown to prime systemic and local immune responses.

The age at first encounter with the antigen is an important determinant of the type of immune response that ensues – oral tolerance or immune priming. In general it has been observed that it is easier to tolerize young mice than adult mice. The mechanisms leading to oral tolerance also vary with age. Anergy and/or deletion may be predominant in the immature gut immune system, whereas in adults, regulatory mechanisms have been established and tolerance is more likely the result of active immune suppression. These characteristics of the neonatal immune system may be ascribed to the less restrictive absorption in the neonatal gut, less competent or 'immature' GALT, or differences in the regulation of neonatal lymphocyte responses. A breakdown or failure to establish oral tolerance results in various forms of food hypersensitivity.

Abnormal Immune Reactions to Food

In some individuals, ingestion of certain foods results in a disproportionate immune reaction or allergic reaction. Allergenic foods are commonly resistant to proteolysis, undergo posttranslational glycosylation, and may exhibit enzymatic activity. A distinction should be made between allergy, which is immune-mediated, and intolerance. Intolerance refers to a nonimmunologically mediated reaction stemming from abnormal metabolism (e.g., enzyme deficiency) or impaired excretion of a food constituent or product. Allergy or immediate type 1 hypersensitivity is usually the result of sufficient numbers of IgE molecules binding to some dietary macromolecules, thus initiating the complement cascade and inducing mast cell degranulation. The release of preformed immune mediators stored in the mast cells instigates the immediate onset of symptoms ranging from cutaneous, and gastrointestinal to respiratory, as well as systemic anaphylactic reactions. The severity of the allergic response is associated with the number of immune cells being activated. An allergen that is distributed by the circulatory system has the potential to stimulate a greater number of mast cells, releasing large quantities of immune mediators. Studies of intestinal biopsies have suggested that food allergy in animals and humans is characterized by an increased number of intraepithelial lymphocytes, mucosal mast cells, and eosinophils.

Food allergies and other inflammatory disorders of the intestine are associated with a dysfunction of the epithelial barrier. However, whether the epithelial barrier dysfunction predisposes an individual to allergic disease or is a consequence of a proinflammatory state is controversial. One hypothesis that has sought to explain food allergy suggests that excessive hygiene may be preventing the gut immune system from learning to differentiate between harmful and harmless macromolecules, leading to an inappropriate inflammatory response. Another theory suggests that exposure to high levels of antigen in childhood in individuals with an inherent dysfunction of the gut mucosa may promote allergic diseases. IgE cross-reactivity between food allergens and pathogens is another possible mechanism that may explain the observation that risk of allergy may be proportional to the rate of infection and vaccination. However, the pathogenesis of food hypersensitivity reactions remains unknown.

Diet–Gene Regulation

Food components can influence directly or indirectly the transcription of genes. A case in point is curcumin, which directly influences acute-phase immune responses. Curcumin, a component of turmeric powder from the rhizomes of the *Curcuma longa* L. plant, has antiinflammatory properties that stem from its capacity to inhibit the expression of proinflammatory genes. The transcription of these genes is regulated by NFκB, which in turn is regulated by an endogenous inhibitor called IκBa. Curcumin prevents the degradation of IκBa, which blocks NFκB from translocating to the nucleus to initiate transcription of κB-dependent genes such as TNF-α, IL-6, IL-8, Cox-2 (cyclooxygenase), and nitric oxide synthase. Similarly, some nutrients, such as vitamins A and D, fatty acids, sterols, and zinc, bind to regulatory elements of genes. For example, the metallothionein gene promoter requires the binding of zinc–protein complexes in order to initiate transcription. In addition to the metallothionein gene, 47 other potential zinc-regulated genes have

been identified, which underscores the complexity of nutrient–gene regulation.

In contrast, an indirect effect may be exerted by some nutrient metabolites through secondary metabolism. The effect of dietary fiber is a well-studied example of indirect gene modulation. Intestinal bacteria metabolize undigested fiber and release butyric acid. Although the protective action of butyric acid on colonocytes has not been fully elucidated, *in vitro* studies suggest that butyric acid may modulate gene expression by direct and indirect means. It may acetylate or phosphorylate histones in the nucleus, which would affect the binding of transcription factors to regulatory elements of genes. In particular, elevated butyrate has been shown to inhibit histone deacetylase, which results in the upregulation and secretion of IL-8, a potent chemotactic factor for neutrophils. In addition, butyrate could also act as an oxidative substrate, which would modulate cellular signaling networks via G-proteins. Investigation of these mechanisms may uncover new dietary treatments and better understanding of the progression of colorectal cancer. Moreover, butyrate-producing bacteria in the intestine can vary depending on the diet. Infants fed a casein-based formula predominantly excrete butyric acid and propionic acid, in contrast to breast-fed infants whose stool contains mostly acetic acid. Thus, the presence of butyrate can relay signals to the mucosal immune system, providing vital information about luminal contents and events.

Expression of genes for proteins involved in antigen presentation, namely major histocompatibility complex (MHC) class II molecules and the invariant chain Ii on enterocytes, are also regulated by diet. In mice, prolonged exposure to dams' milk delayed the expression of MHC class II and Ii molecules, suggesting that early oral dosing of antigens could modify the level of antigen presentation. Furthermore, the appearance of MHC class II and Ii molecules was delayed in mice fed an elemental diet composed of synthetic amino acids and fats as compared to littermates fed standard cereal-based rodent diets. Thus, gene expression in intestinal epithelial cells can be manipulated via the presence of specific dietary proteins in the gut lumen.

The complexity of nutrient–gene interactions involves not only interaction with the genome and gene transcription but also affects posttranscriptional events. The regulatory factors involved in posttranscriptional control may be the dietary components themselves, metabolites, or changes in hormones, making it difficult to distinguish the regulatory pathway. There are some examples of nutritional modifications where the regulatory sequences that are targeted are from 3′ and 5′ untranslated regions (UTR) of mRNA that bind specific proteins, a process that in turn regulates polyadenylation, translation, localization, and stability of mRNA. It may be possible in the future to define nutrient–gene interactions in order to tailor dietary requirements to individuals with different disease risk profiles.

Immunonutrition

Lessons learned from studying the immunomodulatory potential of individual nutrients in patients undergoing surgery or recovering from various tissue damage have led to the development of a therapeutic approach called immunonutrition. These special enteral diets are formulated with components that have been shown to enhance or preserve host immune reactions, or suppress exaggerated inflammatory responses, with the aim of decreasing the morbidity and mortality of critically ill patients. Immune-enhancing enteral diets have been assessed in 12 prospective, randomized clinical trials. Although these studies show a strong and statistically significant benefit to most patients, the ideal composition of such a diet still needs to be established. Furthermore, a better definition of the type of patient who would benefit most from immunonutrition is needed before this therapy is widely adopted.

Autoimmunity

Nutrition-based therapies of autoimmune disease are a novel approach that exploits the immunomodulatory nature of certain foods. For example, vitamins have been reported to act as immune regulators in multiple sclerosis. 1,25-Dihydroxy vitamin D_3 supplementation of mice with experimental autoimmune encephalomyelitis (EAE), a murine model of multiple sclerosis, prevented the progression of the disease, while withdrawal caused regression to multiple sclerosis-like symptoms. Nutrition-based therapy using gamma-linolenic acid (18:3*n*-6) supplementation has also reduced the signs and symptoms of disease activity in rheumatoid arthritis. Similarly, dietary modification has been shown significantly to inhibit the development of diabetes in both rodent models of spontaneous autoimmune diabetes, BioBreeding rats and nonobese diabetic (NOD) mice. It was shown that hydrolyzed casein diets had less diabetes-inducing potential than cereal-based diets. Of particular interest, it was also observed that early oral exposure to antigens from known diabetes-promoting diets delayed and inhibited development of diabetes in about one-third of neonates. The identity of the immunomodulatory agent(s) in the diet is currently being investigated.

In other inflammatory disorders of the human intestine, such as celiac disease, ulcerative colitis, and Crohn's disease, a cytokine imbalance may trigger and potentiate the destructive process. In the case of celiac disease, the gut immune system is sensitized to certain wheat peptides. Upon ingestion of wheat, individuals with certain disease-risk haplotypes, particularly the antigen-presenting molecules human leukocyte antigen (HLA)-DQ2 and HLA-DQ8, may display gliadin proteins in a conformation that is recognized by lamina propria T cells. Once activated, these T cells could initiate a destructive inflammatory process that releases the endomysial autoantigen, tissue transglutaminase, and thus potentiates the immune attack and atrophy of intestinal villi. When wheat proteins are eliminated from the diet, the immune attack stops and the symptoms disappear. Of note, is the observation that celiac disease predisposes individuals to other autoimmune disorders such as type 1 diabetes, dermatitis herpetiformis, autoimmune thyroiditis, collagen diseases, autoimmune alopecia, and autoimmune hepatitis. This correlation is stronger in cases of long-term undiagnosed and untreated celiac disease, further suggesting that the GALT is an important site for immune regulation and potential stimulation of autoreactive cells.

New Technologies

New approaches are being explored to assess the immunomodulatory nature of food components. For instance, genomic analysis using microarray chip technology can detect differences in the level of transcription of genes. Alternatively, protein mixtures can be characterized using two-dimensional electrophoresis and mass spectrometry to obtain amino acid sequences of proteins that can be matched with those in existing databases. This approach can be combined with immunoblotting using sera from susceptible individuals or specific monoclonal antibodies. Such proteomic analysis has been used to characterize wheat allergens in baker's asthma. Since there is debate over the risks of toxins, allergens, and other chemical hazards stemming from new food production and processing technologies, these modern tools may be invaluable in food safety assessment. These may also serve as predictive tools for predicting risk of food immunogenicity and allergenicity.

Transgenic plants are being examined as vehicles for vaccine delivery. A case in point is transgenic lettuce plants expressing hepatitis B virus surface antigens that were ingested by human volunteers and resulted in a specific serum-IgG response to the plant-produced viral proteins. Other examples include genetically modified potatoes expressing Norwalk virus capsid protein or autoantigen for autoimmune therapy. Transgenic plants may serve as an inexpensive alternative to fermentation systems for production of antigens. They may also avoid costly purification processes because the subject ingests directly the modified plant. Oral vaccination with bioengineered plants is currently being evaluated for long-term safety, effectiveness, and cost-effectiveness. Transgenic tobacco plants containing the autoantigen GAD-65 (glutamic acid decarboxylase-65) were fed to diabetes-prone NOD mice and this treatment prevented animals from developing diabetes. These data open the possibility of using bioengineered plants as vehicles for the delivery of molecules that may be tolerogenic.

Summary

The nutrition recommendations that are currently suggested by government agencies and health professionals are based on epidemiological studies of discrete populations. The weakness of these studies is that they do not take into account our inherent biochemical and genetic individuality, as was already recognized in 1956 by Williams. The food we eat brings us into direct contact with a complex mixture of nutrients, nonnutrients, toxins, microbes, and molecules that are similar to those that make up our own bodies. Many of these have biological activity that can modify host immune system reactivity. This multitude of food components can alter the nutritional milieu, provide antigens that must be dealt with, act as modifiers of lymphoid cell membranes, alter the balance of immune regulatory (or other) cell compounds such as growth factors, hormones, metabolites, cytokines, chemokines, inflammatory mediators, or interact directly with the genes that are important controllers of the immune response. We are at a stage when new tools for high-throughput screening and analysis of gene and protein expression are providing opportunities for understanding complex interactions among food, genes, and proteins. These technologies and our increasing ability to categorize and comprehend the large amounts of information they generate will permit new insights into the mechanisms by which our exposure to hundreds of chemicals from foods affects our immune systems. This will eventually permit us to understand the range of immune system reactivity and how it is influenced by foods we eat as well as other environmental factors. The advent of genome and proteome exploration may yield information that will permit nutrition-based therapies designed for individuals.

INBORN ERRORS OF METABOLISM

Overview

K de Meer, Vrije Universiteit Medical Center, Amsterdam, The Netherlands

Scope

In clinical medicine and food science, metabolic disorders form a small but important field. Removal of nutrients which can have a critical effect on development of toxic crises or irreversible detrimental effect on organ function is a potentially simple and sometimes life-saving treatment. Simple measures, such as avoidance of prolonged fasting, can be very effective in selected cases. Special diets and costly supplements are necessary in others. Although inborn errors of metabolism are collectively numerous, most disorders are individually rare. Clinical presentation can vary substantially over the spectrum of inborn errors of metabolism and patients can be seen at any age by pediatricians, neurologists, cardiologists, immunologists, hepatologists, dermatologists, and gynecologists. There is no common single test to screen for the whole group of diseases. Collaboration between specialized clinicians and biochemists, metabolic laboratories, and the food industry is required for adequate procedures in the diagnostic work-up and for proper treatment.

Much expert and scientific information on individual genetic variation in relation to human disease is available online (**Table 1**). This article offers a

Table 1 Inborn errors of metabolism: online information sources

OMIM (Johns Hopkins University, Baltimore)

Extensive information on clinical and molecular topics of inborn errors of metabolism and other inherited diseases is available from www.ncbi.nlm.nih.gov in the Online Mendelian Inheritance in Man (OMIM) library. It combines the human gene map with a morbidity map. The OMIM database assigns a code (MIM) number, gives the locus symbol, and provides a complete list of clinical phenotypes for each disease entity. Experts also describe the clinical picture. OMIM provides a morbidity search machine for differential diagnosis on the basis of clinical symptoms and signs. At present, the number of gene loci with an associated clinical disease entity exceed 1700, and more than 2250 human phenotypes have been mapped on the genome. In more than 70% of these disease phenotypes, the molecular basis has been defined. The National Center of Biomedical Information (NCBI) website of the National Library of Medicine at the National Institute of Health also hosts the medical scientific literature (PubMed) and human genome (GenBank) library databases. Together these resources provide an intertwined and up-to-date online source for practitioners and scientists

HUGO Mutation Database Initiative (University of Melbourne)

The website ariel.ucs.unimelb.edu.au/~cotton/mdi.htm provides a list of locus-specific databases according to gene designation, available from university and research institute sources around the world. Connected by the MIM number of each locus, the information from OMIM is only one click away. The drawback is that the visitor should already know the locus lettercode prior to starting up the link. HUGO also lists patient information sites. Information on nonhuman genetic variation is also available

conceptual approach to the field, and describes a selection of diseases in which nutritional intervention is possible.

Genetics and Inborn Errors of Metabolism

Inherited metabolic diseases cause structural changes or metabolic derangements in the body. The term 'inborn error of metabolism' was presented by John Garrow in 1906 in a lecture about alcaptonuria, in which he also hypothesized the theory of one gene, one protein as its cause. Although the concept of inborn error of metabolism implies that a deficiency of a single enzyme is present, the term has also come into use to describe inherited disorders in proteins not involved in metabolism. Mutated genes and their translation products, proteins, can cause derangements during body and tissue formation, and can also be present as abnormal structural proteins and diminished enzyme activity in a wide range of processes. Autosomal recessive inheritance is the most common form of inheritance encountered in inborn errors of metabolism, but not all affected individuals necessarily have symptoms and other inheritance patterns are all but rare.

Mutations in the estimated 30 000 human genes can in principle cause a very large number of diseases. More than 2200 disease loci are now known. In the human genome, mutations in a number of genes are not compatible with survival at the time the embryo develops. In some cases the same mutation in an allele is known to be causally related to more than one disease. Within one disease the same genotype can be associated with more than one phenotypical presentation. Given the magnitude of the human genome, and the multitude of possible mutations and phenotypic disease states, it is not possible to recognize all inborn errors of metabolism by neonatal screening. Apart from dedicated neonatal screening for the more frequent and treatable disorders, simple methods using clinical diagnosis and targeted laboratory investigations are needed to identify the inborn error of metabolism in an individual patient.

From a pathophysiological point of view, the metabolic disorders can be divided into a number of groups that can be used to facilitate diagnostic decision making, including the initial differential diagnosis by the general practitioner and specialist. Specialists in pediatrics, internal medicine, neurology, clinical chemistry, and genetics collaborate in the clinical field of metabolic diseases for establishing the diagnosis on the level of the protein or gene, and to provide treatment and genetic counseling. The focus of this chapter is on inborn errors of metabolism in which nutritional modulation is an important, and in some cases the only, is of treatment. They are summarized in Table 2.

Not all inborn errors of metabolism with nutritional consequences are covered in this article. Familial hyperlipidemias are, also in terms of numbers of patients, a very important group of inborn errors of metabolism, and are dealt with elsewhere in this encyclopedia. Some inborn errors of metabolism in which food components play a role, notably glucose-6-phosphate dehydrogenase deficiency, in which fava beans can trigger symptoms, and porphyrias in which low carbohydrate intake can aggravate symptoms, are not further explored here.

Pathophysiology

Metabolic disorders can be divided into groups, according to the pathophysiological mechanism that is involved.

Table 2 Selected metabolic disorders for which nutritional therapy is used

Amino acid disorders	
Phenylketonuria	Protein restriction, tyrosine and docosa-hexanoic acid supplementation
Tyrosinemia type I and II	Protein restriction, NTBC in type I
Maple syrup urine disease	Valine, leucine, isoleucine restriction, and thiamin supplementation
Urea cycle defects	Protein restriction, arginine and sodium benzoate and phenylacetate supplementation
Homocysteinuria (CBS-deficiency)	Methionine restriction, vitamin B_6, and betaine supplementation
Isovaleric acidemia	Leucine restriction, glycine and carnitine supplementation
Serine synthesis defect (3-PGDHD)	Serine and glycine supplementation
Hartnup disease	High-protein, nicotinamide supplementation
Carbohydrate disorders	
GSD type I and III	High carbohydrate/low fat and cholesterol
Galactosemia	Galactose (and lactose) restriction
Hereditary fructose intolerance	Fructose restriction
Glucose-galactose malabsorption	High fructose/low glucose-galactose
Congenital disorder of glycosylation Ib	Mannose supplementation
Organic acidemias and acidurias	
Propionic acidemia	Protein restriction, avoidance of dehydration, Inhibition of colonic flora with metronidazole
Methyl malonic acidemia	Protein restriction, vitamin B_{12} supplementation
Multiple acyl coenzyme A dehydrogenase deficiency	Fat restriction, riboflavin and carnitine supplementation
Glutaric aciduria type I	Lysine restriction, riboflavin supplementation
Fatty acid oxidation and ketolysis defects	
β-Ketothiolase deficiency	Low protein, avoid fasting
MCAD, LCAD, LCHAD deficiency	Low fat, avoid fasting, ± carnitine
Mitochondrial disorders	
Respiratory-chain disorders	Increased energy need in early life
Pyruvate dehydrogenase deficiency	High fat/low carbohydrate and thiamin
Micronutrient disorders	
Biotinidase deficiency	Biotin supplementation
Vitamin B_6-dependent epilepsy	Vitamin B_6 supplementation
Transcobalamin II deficiency	Vitamin B_{12} supplementation
Immerslund-Grsbeck disease	Vitamin B_{12} supplementation
Hereditary folate malabsorption	Folate supplementation
Methylene tetrahydrofolate reductase deficiency	Folate supplementation
Acrodermatitis enterohepatica	Zinc supplementation
Wilson disease	Zinc supplementation

NTBC, nitro-trifluoro-methylbenzoyl-cyclohexanedione; CBS, cystathionine β-synthase: homozygous patients cannot metabolize homocysteine which is formed after transmethylation of methionine; 3-PGDHD, 3-phosphoglycerate dehydrogenase deficiency: the enzyme block prevents the biosynthesis of serine; GSD, glycogen storage disease; MCAD, medium-chain acyl coenzyme A dehydrogenase; LCAD, long-chain acyl coenzyme A dehydrogenase; LCHAD, long-chain hydroxy acyl coenzyme A dehydrogenase: these mitochondrial enzymes form part of the oxidation of fatty acids.

Group 1 is comprised of disorders characterized by the disturbed synthesis or catabolism of complex molecules. Symptoms are not related to food intake, and are permanent, progressive, and independent of intercurrent infections. Lysosomal storage disease, peroxisomal disorders, α_1-antitrypsin deficiency, and congenital disorders of glycosylation are in this group. With some notable exceptions, nutritional therapy is not effective in these disorders.

Group 2 includes all disorders of intermediate metabolism. Because multiple enzymes are involved in the metabolism between macronutrients and end products, these disorders lead to accumulation of toxic compounds proximal to the metabolic block. There can be progressive or acute intoxication due to these compounds, and intercurrent infections or excessive intake of foods can lead to a metabolic crisis. A symptom-free interval is characteristic. Late onset or an intermittent clinical presentation is typical. Aminoacidemias, most organic acidurias, urea cycle defects, and sugar intolerances belong to this group.

Group 3 consists of inborn errors involved in intermediate metabolism which is directly related with cellular energy transfer. Enzyme defects can affect the supply with macromolecules involved in energy production as well as the transfer of energy by molecules in the matrix and in the inner membrane respiratory chain system within the mitochondria. Glycogen storage diseases, gluconeogenesis defects, defects in pyruvate carboxylase and dehydrogenase,

fatty acid oxidation defects, and mitochondrial respiratory chain disorders are present in this group.

Group 4 is comprised of diseases in which disturbances are present in: (1) membrane transport; (2) intracellular signaling; or (3) critical developmental periods. Defects of transmembrane transporters for carbohydrates, amino acids, and lipids in the intestine are suspected by clinical observation (diarrhea, failure to thrive) and absorption studies. Similarly, defects can be present in tubular reabsorption in the kidney. Other clinical entities are related to disturbed transport of metals (e.g., of copper, such as Menkes and Wilson disease). New insights have been developed that complex compounds, produced in specialized metabolic tissues and necessary for specialized functions in the brain, must undergo a critical step in transport over the cell membrane for proper function. Similarly, with respect to intracellular signaling functions, the assembly or metabolism of complex compounds in the central nervous system and other organs can be deranged. Defects of intracellular membrane transport comprise another group of newly recognized disorders. The transport defects generally result in the dysfunction of one or more affected organs (e.g., diarrhea in carbohydrate malabsorption, liver failure and brain dysfunction by copper storage in Wilson disease, brain dysfunction in creatine transporter deficiency, X-linked nonspecific mental retardation, and abnormal neurotransmitter synthesis) or deficiency syndromes (due to malabsorption).

Recently, insights in developmental biology led to the discovery that certain compounds (e.g., cholesterol) with known functions during extrauterine life are critical for developmental gene description in the embryo (e.g., absence of 7-dehydrocholsterol biosynthesis causes Smith–Lemli–Opitz syndrome, characterized by dysmorphic features and severe mental retardation). Developments in molecular biology and the genome project, human genetics, and clinical chemistry enable discovery of the etiology and pathophysiology of newly recognized disorders with a range of clinical presentations.

Clinical and Laboratory Expertise in Diagnosis

Children with inborn errors of metabolism may present with one or more of a large variety of symptoms and signs. Although most Mendelian phenotypes are expressed early in life, adult presentations are recognized in increasing numbers. The patient history, clinical assessment (for color, odor, hepatomegaly, neurological abnormalities, including hypotonia, and dysmorphic features), and immediate laboratory investigations are necessary for initial judgment in terms of the pathophysiology group and index of suspicion for an inborn error of metabolism. A full medical and genetic family history is important and should include the circumstances of any stillbirth, sudden infant death, unusual death in childhood or early adulthood, and information on consanguinity between the parents.

Blood investigations should include routine hematology and electrolytes (search for anion gap), glucose, creatinine, liver enzymes, bilirubin, ammonia, calcium, phosphate, lactate, pyruvate, ketone bodies (3-hydroxy- and ketobutyrate), fatty acids, uric acid, blood-gas analysis, and prothrombin time. Urinalysis should include acetone, reducing substances, pH, sulfite, electrolytes, and uric acid. Further investigation may comprise lumbar puncture, chest X-ray, and cardiac and central nervous system function studies. Further laboratory and other investigations are guided by the pathophysiological group, abnormalities in the routine investigations, and suspicion of an individual disorder.

The metabolic laboratory is specialized in the investigation of body fluids in the search of abnormal metabolites which are present in many inborn errors of metabolism. Apart from the routine investigations mentioned above, liquid, gas, and thin-layer chromatography are performed on plasma, urine and cerebrospinal fluid, and mass spectrometry, electrophoresis and spectrometric analysis techniques are other methods available for investigation. The use and distribution of these techniques in the investigation of patients suspected of an inborn error of metabolism are depicted in **Figure 1**.

A systematic description of the metabolites and abnormalities frequently observed in inborn errors of metabolism is beyond the scope of this overview. In practice, the inborn errors in which laboratory abnormalities are found are grouped using three different conceptual approaches. Grouping takes place by: (1) the main laboratory abnormality in a body fluid (e.g., aminoacidemia or organic aciduria) as a result of the enzyme defect; (2) the cell organelle where the abnormality is located (e.g., lysosomal storage disease, perixisomal disorder); and (3) the abnormal structural molecule (e.g., defect of purine metabolism, mucopolysacharidosis, or congenital disorder of glycosylation). **Figure 2** shows the distribution of diagnosis of inborn error of metabolism based on records in one laboratory of metabolic diseases where both regional and international patient investigations take place.

The diagnosis system of an inborn error of metabolism is eventually based on the enzyme nomenclature, the MIM number (Mendelian inheritance in

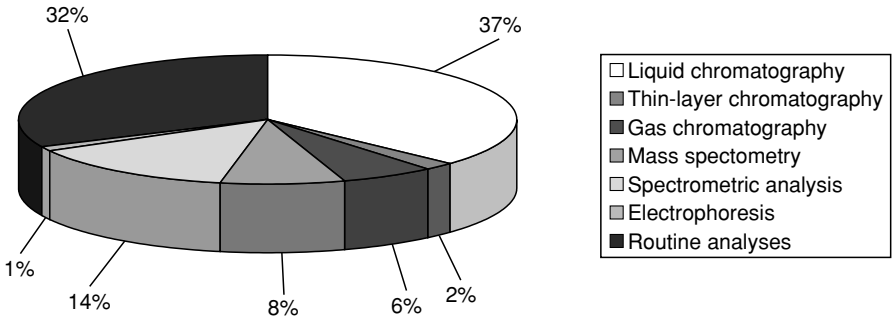

Figure 1 (see color plate 99) Laboratory analyses performed in body fluids of 2150 patients investigated over a period of 5 years in the laboratory for metabolic diseases of the Vrije Universiteit Medical Center in Amsterdam. Investigations were performed in whole blood, plasma, urine, amniotic fluid, and cerebrospinal fluid.

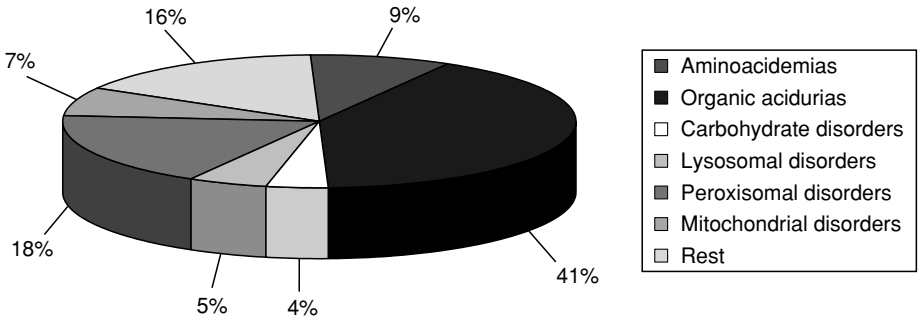

Figure 2 (see color plate 100) Frequency distribution according to diagnostic group in 263 patients newly identified with an inborn error of metabolism over a period of 5 years in the Laboratory for Metabolic Diseases of the Vrije Universiteit Medical Center in Amsterdam. Fatty acid oxidation defects included in organic acidurias.

man, formerly the McKusick number) for each disease entity, and the mutations linked with the clinical entities in the OMIM database (Online Mendelian inheritance in man: Table 1). Enzyme diagnosis, using leukocytes, cultured fibroblasts, or biopsies from chorionic villi or other affected tissue, is increasingly used to confirm the diagnosis. DNA diagnosis is also developed for an increasing number of inborn errors.

In the following paragraphs, some important disorders and clinical problems are presented, to illustrate the interactions between nutrition and inborn errors of metabolism.

Amino Acid Disorders (Group 2 Pathophysiology)

Amino acids are the building blocks of body protein and are mainly derived from the diet. Ingested protein is absorbed almost completely. Amino acids which become available in the body, in excess of the needs for protein synthesis and growth, are eventually oxidized through several pathways. For the nonessential amino acids there are also pathways of biosynthesis. Some of these pathways are shared between two or more amino acids, and others are unique to one amino acid. Inborn errors of metabolism are known for each amino acid. Here we discuss two of the most frequently encountered aminoacidemias.

Hyperphenylalaninemia

Phenylalanine is an essential amino acid. It is normally degraded via the tyrosine pathway. To enter the tyrosine pathway, phenylalanine is converted into tyrosine by the enzyme phenylalanine hydroxylase, which has tetrahydrobiopterin as a cofactor. Deficiency of the enzyme or of its cofactor causes accumulation of phenylalanine in the body fluids and tissues. Hyperphenylalaninemia is present, and detection in plasma is a reliable way of establishing the suspected diagnosis.

Classic phenylketonuria (PKU) is caused by the deficiency of the enzyme phenylalanine hydroxylase. In the first weeks after birth patients have no symptoms, although in the neonatal period vomiting can be an early symptom. Mental retardation is the major abnormality in untreated patients, with an estimated loss of about 50 IQ points by the end of the first year

of life. Untreated patients develop behavioral and neurological abnormalities, including hypertonicity and athetosis, and 25% of patients develop epilepsy. On clinical examination they have an unpleasant smell, probably due to the accumulation of abnormal metabolites of phenylalanine such as phenylacetic acid (which has a musky odor). Microcephaly and growth retardation are common. If protein and phenylalanine restriction is instituted early after birth, the patients remain free of these symptom. Special PKU infant formulas are available, but careful follow-up of the patient's physical growth and development is needed and regular measurement of phenylalanine plasma levels are mandatory in order to prevent under- and overtreatment. Metabolic derangement can take place under catabolic conditions, e.g., during infections.

Proper treatment requires early detection. Mass newborn screening for PKU became effective when Guthrie developed a bacterial inhibition assay which could be done on dried blood collected on paper obtained after a heel puncture during the second half of the first week of life.

About one in 50 patients with hyperphenylalaninemia have a defect in one of the enzymes necessary for the synthesis or recycling of the cofactor tetrahydrobiopterin. If undetected and treated as PKU, these patients show normalized phenylalanine plasma levels but develop severe neurological symptoms. The reason is that tetrahydrobiopterin is a cofactor for other hydroxylases, involved not only in hydroxylation of phenylalanine but also of tyrosine and tryptophan. The latter two are involved in the biosynthesis of the neurotransmitters dopamine and serotinin. For this reason all neonates with hyperphenylalaninemia are required to undergo tests for deficiency of the cofactor. Treatment of these patients requires protein restriction and supplementation with tetrahydrobiopterin (because they also have nonclassical PKU), and supplementation of L-dopa and 5-hydroxytryptophan (because the supplemented cofactor does not cross the blood–brain barrier).

Research has demonstrated that *in vivo* hydroxylation in children with PKU can be so low that patients may suffer from the effects of a diminished availability of the metabolic product of phenylalanine hydroxylase, tyrosine. Tyrosine is an essential amino acid required for physical growth but also a precursor for dopamine biosynthesis. Tyrosine supplementation thus is required in some patients with PKU.

PKU is one of the more common inborn errors of metabolism and this autosomal recessive disease is a major cause of preventable hereditary mental retardation and neurological debilitation in the population. Neonatal screening programs have saved thousands of patients who would otherwise have spent their life in asylums. Nowadays, many adult patients cease the diet and report no psychological or neurological problems. None the less, new problems have emerged in the management of these patients. Pregnancies in mothers with PKU who no longer use the low-phenylalanine diet are complicated by spontaneous abortions, and their living offspring are often mentally retarded and show microcephaly or congenital heart disease. It has become clear that women with PKU who are of child-bearing age should start a low-phenylalanine diet before conception and should be closely monitored for their phenylalanine blood levels before and during pregnancy. Also, deficiency of *n*-6 polyunsaturated fatty acids has been described in patients with PKU (and supplementation has been advocated). The complications during pregnancy and of polyunsaturated fatty acid synthesis demonstrate one of the concepts of group 2 pathophysiology, i.e., that metabolites accumulating proximal to the metabolic block can cause derangements in distant organs and metabolic pathways.

Tyrosinemia Type 1

Tyrosine is likewise an essential amino acid derived from ingested protein. Excess tyrosine is oxidized. Several inborn errors of metabolism in the degradative pathway are known. Deficiency of fumarylacetoacetate hydroxylase causes type 1 tyrosinemia, and has an acute or chronic clinical manifestation. The acute form presents in infancy, and comprises most reported cases. Some symptoms resemble that of PKU with failure to thrive, developmental delay, and vomiting, but hepatic manifestations with organ enlargement, jaundice, and bleeding tendency are common findings as well. Apart from elevated tyrosine, elevated methionine is also found in many patients. Hypoproteinema and low prothrombin are often present. Many patients develop end-stage hepatic failure in childhood and die unless appropriate therapy is started. Patients with the chronic form also present with failure to thrive and development delay, but generally not during the first year of life. Cirrhosis (which can be associated with acute liver failure during catabolic episodes), renal tubular dysfunction, and vitamin D-resistant rickets are often found. Acute episodes of polyneuropathy may complicate the disease. In the long term, a substantial proportion of patients with type 1 tyrosinemia develop hepatic adenoma, and over time hepatocellular carcinoma can develop in these lesions. The wide spectrum of organ pathology, including malignant disease in tyrosinemia, demonstrates the effect of toxic substances that accumulate due to the inability to catabolize tyrosine. Although dietary restriction of tyrosine and

methionine has been advocated over the years, many patients have shown progression of hepatorenal and hematological symptoms and developed malignant liver disease under this treatment regimen. Liver transplantation is a cure for patients with liver cirrhosis or (solitary) tumors, as the donor liver provides the patients with a normally functioning liver, including normal activity of the deficient enzyme. Liver transplantation has a high risk of acute and chronic complications and thus is only an option for patients with severe liver disease. Since 1994 a promising new pharmacological therapy has been successful in reducing morbidity and liver complications: nitrotrifluoro-methylbenzoyl-cyclohexanedione (NTBC), an inhibitor of *p*-hydroxyphenylpyruvate dioxygenase, prevents the formation of (cytotoxic and carcinogenic) metabolites distal of this enzyme and proximal of the inborn error. Although the elevated tyrosine levels do not disappear during NTBC therapy, and tyrosine and methionine restriction remain necessary, this treatment appears remarkably effective. Patient follow-up of this treatment has been less than 10 years at present. There is hope that the long-term life-threatening complications such as liver failure, bleeding disorders and tumor induction are preventable with NTBC.

Table 3 Metabolic causes of hypoglycemia in childhood

Decreased production of glucose
Decreased release of glucose from the liver
Glycogen synthase deficiency
Glucose-6-phosphate deficiency (GSD type Ia or Ib)
Amylo-1,6-glucosidase deficiency (GSD type III)
Galactose-1-phosphate deficiency (galactosemia)
Fructose-1-phosphate aldolase deficiency (hereditary fructose intolerance)
Decreased rate of gluconeogenesis
Pyruvate carboxylase deficiency
Phosphoenolpyruvate carboxylase deficiency
Fructose-1,6-diphosphatase deficiency
Glycerokinase deficiency
Decreased availability of alternative fuels, resulting in increased use or decreased conservation of glucose
Impaired oxidation of fatty acids
Medium-chain acyl-coenzyme A dehydrogenase deficiency
Long-chain acyl-coenzyme A dehydrogenase deficiency
Carnitine acyltransferase I deficiency
Multiple acyl coenzyme A dehydrogenase deficiency
Impaired synthesis or use of ketones
β-Ketothiolase deficiency
Hydroxymethylglutaryl coenzyme A lyase deficiency
Decreased fat stores
Prematurity
Malnutrition

GSD, glycogen storage disease.
Other metabolic disturbances resulting in hypoglycemia are toxic (exposure to ethanol or salicylate), endocrine (hyperinsulinemia, growth hormone deficiency, cortisol deficiency), hyperleucinemia, and a self-limiting ketotic hypoglycemia.

Energy Disturbance (Group 3 Pathophysiology)

Hypoglycemia

A low blood sugar level is potentially dangerous (for central nervous system function) and can be life-threatening. Some organs (the heart, the brain) have a high energy expenditure while using only a limited selection of metabolic fuels. For the brain the balance between energy supply and expenditure is the most critical because glucose and ketone bodies (and, under certain conditions, lactate) are its only energy substrates and the specific energy demand is high. Energy stores in the neural cells are very low and rapidly consumed. Although hypoglycemia can be caused by nonmetabolic disorders it is a hallmark symptom for a large number of inborn errors of metabolism, particularly those of intermediate carbohydrate and triacylglycerol metabolism (Table 3).

Symptoms can be present within hours after birth (and, in the case of low liver stores, even within minutes). The time of presentation after the last meal is indicative of the relevant group of disorders, with glycogen storage disease, gluconeogenesis defects, and fatty acid oxidation defects and impaired availability of ketones successively being the most probable cause when a wider gap is reported between the time of the last meal and the presentation of the hypoglycemia. For the diagnosis of the inborn error, and for the differential diagnosis, including endocrine disorders, blood and urine sampling at the time of the hypoglycemic crisis is essential. In life-threatening situations such as coma, treatment prevails over the complete collection of samples for the diagnostic work-up. Some abnormalities may still be present in blood and urine even hours after intravenous administration of glucose and restoration of the blood glucose level to the normal range. In some disorders symptoms can develop only months or even years after birth. The clinical spectrum is wide, with liver enlargement present in some (e.g., glycogen storage type I and III, hereditary fructose intolerance) but not all disorders and toxic crises present in some (e.g., coma and severe liver function abnormalities in medium-chain acyl-coenzyme A dehydrogenase deficiency) but not all disorders. Hyperlipidemia, granulocyte dysfunction, hyperuricacidemia and gout, hyperlactatemia and osteoporosis, liver adenomas, and pancreatitis are complications in just one of these disorders (glycogen storage disease type I). Cataracts with or without liver dysfunction are seen in galactosemia. This illustrates that virtually any organ

system can be affected in the wide spectrum of disorders encountered as the cause of a decreased blood level of just one metabolite, glucose.

A systematic overview of the spectrum of disease and complications of inborn errors of metabolism causing hypoglycemia cannot be further pursued here. Treatment depends on the cause, and ranges from strict avoidance of certain foods (e.g., galactose and lactose in galactosemia) to continuous drip-feeding (e.g., in glycogen storage disease type I). Avoidance of prolonged fasting is important in a large proportion of disorders. Early diagnosis is essential to prevent brain damage and other irreversible organ failure. Thus recurrent or severe hypoglycemia should bear a high degree of suspicion of a metabolic cause.

Elevated Resting Energy Expenditure

Mitochondrial respiratory chain enzyme defects are associated with myopathy and failure to thrive in early life in mildly affected patients and severe multiorgan involvement, including brain damage and early death in other patients. The failure to thrive in infants with the disease can result from neurological impairment (vomiting, difficulty with swallowing) but also elevated energy expenditure is often found. The pathophysiology of the increased resting energy expenditure is of conceptual interest for this overview on human inborn errors and nutrition. The mitochondrial respiratory chain is comprised of five enzyme complexes which together drive the process of oxidative phosphorylation and maintain the proton gradient through which adenosine triphosphate (ATP) production is maintained. Complex I, III, and IV have proton-pumping capacity, and the efficiency of the protons (with eventually energy transfer to ATP, P) pumped and coupled electron flow through the respiratory chain to oxygen (O) can be expressed as the P/O ratio. In normal mitochondria the ratio is about 1.75 for reduced nicotinamide adenine dinucleotide (NADH)-linked substrates and 2.75 for reduced flavin adenine dinucleolide (FADH)-linked substrates. However, in patients with deficiency of complex I, II, or III, the respiratory chain is substantially less efficient as one proton (ATP) less is produced by the electron's energy transfer between complex I and V. Adaptive changes, including a higher adenosine diphosphate (ADP) concentration (a known stimulus of oxidative phosphorylation activity) and higher resting oxygen consumption are present in many patients. To find out whether, and to what extent, this pathophysiological mechanism is present in an individual patient diagnosed with a respiratory chain defect indirect calorimetry can be useful. Therapy exists in high-energy feedings, and growth monitoring is important. This is particularly important during infancy when energy demands and growth rates are already high and patients depend on food offered by the mother. In later life many patients expend less energy due to muscle fatigue and lower physical activity levels, and the balance between total daily energy expenditure and energy intake is more easily maintained.

Lipids and Essential Fatty Acid Deficiency

In the affluent world and in poor parts of the world, nonhereditary causes of insufficient essential fatty acid status prevail and are worldwide much more frequent than hereditary causes. Disturbance of *n*-6 and *n*-3 polyunsaturated fatty acid status is caused by a number of inborn errors. The most frequent ones are shown in Table 4. Single-enzyme deficiencies in the metabolic pathways of *n*-6 and *n*-3 polyunsaturated fatty acid synthesis and oxidation are extremely rare, probably because essential fatty acids from food and the interconnections between the *n*-6 and *n*-3 desaturase pathways provide alternative provisions and overflow routes for affected metabolites. These rare patients are not reviewed here or included in Table 4.

Table 4 Causes of essential fatty acid deficiency

Mechanism and disease state	*Affected gene(s)*
Hereditary causes	
Intestinal malabsorption	
Abetalipoproteinemia	MTTP
Hypobetalipoproteinemia	Apolipoprotein B
Anderson disease	?
Exocrine pancreas insufficiency	
Cystic fibrosis	CFTR
Shwachman syndrome	Mapped to 7p11-q11
Pearson syndrome	Mitochondrial DNA deletions
Deranged metabolism of polyunsaturated fatty acids	
Decreased synthesis of docosahexanoic acid	
Phenylketonuria	PAH
Zellweger syndrome	PEX
Decreased inhibition of leukotriene B_4	
Sjögren–Larsson syndrome	FALDH
Nonhereditary causes	None
Malnutrition	
Fat-free diet	
Parenteral nutrition without essential fatty acid supplementation	

MTTP, microsomal triglyceride transfer protein; CFTR, cystic fibrosis transmembrane conductance regulator; PAH, phenylalanine hydroxylase; PEX, peroxin, involved in peroxisome biogenesis; FALDH, microsomal fatty aldehyde dehydrogenase.

In patients with disorders in which the assembly of peroxisomes is deficient (mutations in PEX protein complementation groups, e.g., Zellweger syndrome), deficiency of some essential fatty acids has been documented. Enzymes required for the oxidation of very-long-chain fatty acids (including arachidonic acid) and in the synthesis of some polyunsaturated compounds are located in the peroxisome and these are absent or have a very low activity in these patients.

PKU is a single-enzyme disease in phenylalanine hydroxylation in which low essential fatty acid status has been found. It is associated with neuropathy in some patients. Circulating abnormal metabolites affect the synthesis of *n*-6 (arachidonic acid) and *n*-3 (docosahexanoic acid) fatty acids.

Secondary deficiency of essential fatty acids has been found in relatively rare disorders causing lipid malabsorption (transport defects, group 4 pathophysiology) and hereditary exocrine pancreas insufficiency. In the latter group, cystic fibrosis is the most frequently encountered disorder. Sjögren–Larsson syndrome (in which microsomal conversion of medium- and long-chain fatty aldehydes to their carboxylic acids is defective) causes a unique inactivation in leukotriene B_4 inhibition. Patients have elevated leukotriene levels and inflammatory skin changes. Symptoms of essential fatty acid deficiency in other patients are nonspecific and range from dermatitis to severe failure to thrive. Diagnosis is often delayed. Treatment of exocrine pancreas insufficiency by pancreas enzyme supplementation often corrects the essential fatty acid profile. In other disorders skin ointments (on the basis of vegetable oil rich in polyunsaturated fatty acids) are a treatment option. The course of several severe and fatal disorders, such as abetaliproteinema or Zellweger syndrome (in which oral supplementation is given), is not clearly altered by such treatment however.

Milk Formulas

D Hileti-Telfer, The Hospitals for Sick Children, London, UK

Background

Until the early 1900s, there was no alternative to human breast milk for feeding newborn infants. Consequently, over 80% of infants were breast-fed. If a mother was unable to breast-feed her baby, a wet nurse had to be found, or diluted cow's milk had to be given. The 1940s marked a major turning point in the history of infant feeding in the UK, with an increasing proportion of babies being bottle-fed. A number of social, economic, and practical factors contributed to this radical change in infant feeding practices. The major influence was the introduction of the Welfare Food Scheme during World War II. This allowed mothers and children to have free or subsidized National Dried Milk (NDM) at a time when cows' milk was rationed. Inevitably, the use of NDM spread to infants and escalated as social attitudes gradually changed towards women working outside the home.

Unfortunately, NDM and most commercial infant formulas available over the succeeding years were not

adapted to meet the specific nutritional and physiological needs of newborn infants. Excess concentrations of sodium, chloride, phosphorus, and calcium caused many problems, including hypernatremic dehydration, neonatal tetany, and even death in some infants. It is only recently, with advances in food technology, that infant formulas have been developed, providing an acceptable alternative to human milk.

Need for Infant Formulas

Humans are the only mammals who have attempted to feed their young on something other than their own milk. It is now recognized that suitable infant formulas must be made available for infants whose mothers choose not to breast-feed or are unable to establish lactation, or where breast-feeding is contraindicated owing to a medical condition, such as galactosemia and congenital alactasia.

Despite the well-documented advantages of breast-feeding, many women choose not to breast-feed. The UK Office of National Statistics (ONS) 1995 Infant Feeding Survey showed that 39% of mothers gave infant formula from birth, and by 6 weeks, 62% of infants were exclusively bottle-fed. One of the main differences between the ONS surveys of 1990 and 1995 was the decrease in the use of cow's milk at 8 months from 42% in 1990 to 16% in 1995 owing to the continued use of milk formulas.

In the UK, mothers who are carriers of the human immunodeficiency virus (HIV) are discouraged from breast-feeding, as the virus can be passed to an infant via the breast milk. Breast-feeding by HIV mothers is not, however, discouraged in less developed countries such as sub-Saharan Africa, where safe preparation and provision of infant formulas cannot be ensured. Maternal medication can also be found in breast milk. Even low doses of some drugs need to be avoided during lactation, including those that are radioactive, cause allergy or bleeding disorders, are poorly metabolized by the newborn, or inhibit lactation. The relative risks of drugs that pass into the breast milk are reviewed annually in the British National Formulary. If a suitable alternative drug is not available, a mother would need to use an infant formula.

Compositional Guidelines

The composition of all infant formulas in the UK comply with the guidelines of the COMA report 'Artificial Feeds for the Young Infant' and the legal requirements of 'The Infant Formula and Follow-on Formula Regulations 1995'. The 1995 regulations implement the European Commission Directives 91/321/EEC and Council Directive 92/52/EEC, and represent the first mandatory controls on composition and marketing of infant and follow-on formulas. They set upper and lower limits for the concentration of most nutrients in a reconstituted feed (Table 1).

In setting these, the normal physiology of young infants and biological availability of nutrients were considered, but the composition of mature human milk provided the main reference standard. Currently, 10 infant formulas based on cows' milk are available in the UK.

Types of Infant Formulas

Infant formulas should provide the sole source of nutrition during the first few months of life. Although manufacturers can now simulate the nutrient composition of mature breast milk, they are unable to reproduce other aspects such as its enzyme content or immunological properties. Normal infant formulas are manufactured from cows' milk, but this requires substantial alteration to parallel the composition of breast milk (Table 2). These modifications are a reduction in protein and minerals, an increase in carbohydrate, and the addition of vitamins and trace elements. Extra iron and zinc need to be added, owing to their poor absorption from cow's milk. Vitamin activity may be lost during the manufacturing process or on storage, and this must be compensated for.

The other adaptions made to cows' milk are to improve its absorptive characteristics, which is achieved by altering the casein:whey ratio and fat blend.

The protein in cow's milk is predominantly casein, with a whey:casein ratio of 20:80. Two categories of infant formulas are produced: whey-dominant and casein-dominant. The newborn infant more readily absorbs whey protein. Whey-based milks are a mixture of demineralized whey and a small amount of skimmed milk, which achieves a whey:casein ratio similar to breast milk (60:40). The use of whey proteins alters the amino acid pattern, making it closer to human milk. In addition, demineralization of the whey reduces the sodium, potassium, and phosphate contents.

Casein-dominant milks are manufactured using skimmed milk and in a few, full-cream milk as the protein source. Their whey:casein ratio is the same as cows' milk. Although substantially modified during manufacture, the levels of sodium, phosphorus and potassium are usually higher than in whey-dominant milks.

In recent years, studies have indicated that young infants may have an impaired ability to synthesize taurine and carnitine, and a dietary source is therefore required. Carnitine is necessary for the transport of long-chain fatty acids into the mitochondria, where they undergo β-oxidation. Artificial formulas based on cows' milk contain adequate amounts of carnitine, without the need for fortification. Taurine has a major role in the conjugation of bile acids, which is essential for fat absorption, and it may be involved in retinal, cardiac, and central nervous system function. Cows' milk contains a low concentration of taurine. Infant formulas are now fortified with taurine to a level similar to that found in breast milk (3.3–5.2 g per 100 ml).

The carbohydrate present in cows' milk and human milk is lactose. Extra carbohydrate must be added to cows' milk to equate with human milk. This is usually added in the form of lactose, but maltodextrins and occasionally amylose are used in casein-dominant milks. Lactose enhances calcium absorption and helps to inhibit the growth of gut pathogens by fermentation in the colon. Lactose and maltodextrins are efficiently digested and absorbed by the young infant, but the situation with amylose is less clear. Sucrose is rarely used in infant formulas, as it would make the feed very sweet compared with breast milk, and it is also more cariogenic. Glucose and other monosaccharides are avoided, as they would significantly increase the feed osmolality.

The concentrations of fat in mature breast milk and cows' milk are similar. However, the chemical composition, in terms of degree of saturation, chain length, and configuration of fatty acids on the triglyceride molecule is different. These differences influence fat absorption. Short and medium-chain fatty acids are more efficiently absorbed than saturated fatty acids of the same chain length. In both milks, palmitic acid is the most common saturated fatty

Table 2 Comparison between cow's milk and mature human milk

	Cow's milk (per 100 ml)	*Mature human milk (per 100 ml)*
Energy (kcal)	66	69
(kJ)	275	289
Carbohydrate (g)	4.8	7.2
Protein (g)	3.2	1.3
Fat (g)	3.9	4.1
Sodium (mmol)	2.4	0.6
Potassium (mmol)	3.6	1.5
Calcium (mmol)	2.9	0.9
Phosphorus (mmol)	3.0	0.5
Zinc (μmol)	6.1	4.6
Iron (μmol)	0.9	1.3
Vitamin D (μg)	0.03	0.04
Vitamin C (mg)	1.0	4
Vitamin B_1 (mg)	0.04	0.02
Vitamin B_2 (mg)	0.17	0.03
Nicotinic acid (mg)	0.1	0.2
Vitamin E (mg)	0.09	0.34
Vitamin A (μg)	52	58

Data from Holland B, Welch AA, Unwin ID *et al*. (1991) *McCance and Widdowson's The Composition of Foods*, 5th edn. Cambridge: Royal Society of Chemistry.

acid. In human milk, palmitic acid is mainly in the 2 position on the triglyceride molecule, and this is absorbed more easily than palmitic acid in the 1 and 3 positions, as found in cows' milk.

No single fat source can adequately reflect the characteristics of the fat profile in mature breast milk, so a blend is used. Most manufacturers use a mixture of vegetable oils.

The fat source must also provide the essential fatty acids linoleic (C18:2, ω-6) and α-linolenic acid (C18:3, ω-3). Current research suggests that a balance between these two fatty acids is necessary, as excess linoleic acid suppresses the formation of α-linolenic acid derivatives. A ratio of 5:1 of ω-6:ω-3, as occurs in breast milk, is being suggested. However, there is a need for more short- and long-term studies before the optimum ratio and its effects on growth are evaluated. Not all infant formulas provide a ratio of 5:1.

Linoleic and α-linolenic acid are the precursors of the very-long-chain (C20–C22) polyunsaturated fatty acids (LCPUFA), arachidonic and docosahexaenoic acid. LCPUFA are involved in the neural and vascular development of the fetus and neonate and are present in human milk. Recently, there has been much interest in the possible benefits of the addition of LCPUFA to infant formulas. A recent systematic review concluded that ω-3 LCPUFA increases the early visual maturation in preterm infants, but no long-term benefit has been shown for preterm infants receiving formula supplemented with LCPUFA. However, another systematic review prepared by the same author, examining the effect of LCPUFA supplementation in term infants, concluded that there is little evidence that it confers any benefit on visual or cognitive development. Currently, some, but not all, infant formulas are supplemented with LCPUFA.

Nucleotides, a component of the nonprotein nitrogen in human milk, may be important for normal immune function. Nucleotides can also be synthesized endogenously. Nucleotide nitrogen accounts for 0.1–0.15% of the total nitrogen content of human milk, but is present in much smaller concentrations in cows' milk-based formulas. Supplementation of infant formulas with nucleotides seems to be beneficial in clinical trials, although further research is needed before routine nucleotide supplementation of infant formulas can be considered.

Since 1984, a further range of formulas have been manufactured known as 'follow-on' milks. These are based on cows' milk and are intended for use from 6 months of age in the UK, as part of mixed feeding. They are not suitable as a replacement for either breast milk or infant formulas before this age.

'Follow-on' milks have a higher protein and iron content than infant formulas, but the energy density is similar. The main 1995 compositional guidelines for infant and 'follow-on' formulas set by the European Commission Directives 91/321/EEC and 92/52/EEC are shown in Table 1. The iron, calcium, and sodium contents are higher than in infant formulas. Generally, all brands are supplemented with the full range of vitamins and minerals.

Soya infant formulas are manufactured from soya protein isolate and used for infants on cows' milk-free diet. Their carbohydrate source is a glucose polymer, and the protein is derived from soy. They are supplemented with methionine, carnitine, minerals, vitamins, and trace elements, so that the available nutrients are similar to those in human milk (Table 1).

Production

Advances in food technology since the early 1960s have enabled manufacturers to produce infant formulas that are in line with present scientific knowledge about infants' nutritional requirements.

Infant formulas are typically composed of the following: skimmed milk, demineralized whey (in whey-dominant formulas only), a carbohydrate source, fat blend, and vitamins and minerals. Each raw material undergoes stringent quality-control checks on arrival at the factory and throughout all stages of manufacture. These tests are for nutritional composition, purity, microbiological safety, and physical properties. The manufacturing process and the cleaning of the manufacturing plant are partially or fully automated.

Production methods vary, but all aim to blend the raw ingredients together to produce a safe, homogeneous, and stable powder or liquid. A typical example of an infant formula manufacture is as follows:

Pasteurized skimmed milk is bought in as liquid or powder. On arrival, the liquid milk is usually repasteurized by heating to 72 °C for 15 s, which destroys about 90% of all microorganisms present. Throughout the manufacturing process, the product is repasteurized several times. Whey is purchased in a demineralized form or is demineralized on site. The technique of demineralization, which was perfected in the 1960s, was a major advance in infant formula production and is performed by electrodialysis, ultrafiltration, or ion exchange. The repasteurized skimmed milk and demineralized whey are mixed with the carbohydrate source, vitamin premix, minerals, and the fat blend. The minerals required will vary, depending on their concentration in other raw materials. The fat-soluble vitamins are usually added to the fat prior to this process.

The bulk ingredients usually undergo centrifugal clarification, to remove small particle matter, and

then homogenization to ensure that all the particles are uniform in the final product. The liquid infant formula is further subjected to two heat processes: pasteurization and heating to a suitable temperature for spray-drying. Spray-drying produces a powder that will reconstitute easily into solution. Some companies use additional wetting and drying cycles to form granules, which, they claim, are easier to measure and dissolve.

In the UK, powdered infant formulas are packaged in a protected atmosphere using an inert gas to help remove the oxygen, thus reducing any oxidation of the powder. On the packing production line, the cans (already sealed at one end) are inverted and subjected to intense blower and vacuum systems to remove any contamination. A machine drops the measuring scoop into the can, prior to filling with powder. Air is then removed from the pack and replaced with an inert gas mixture, and the container is sealed. Foil sachets are filled in a similar manner. The shelf-life is 2–3 years for sealed tins and 15 months for sachets; when opened, tins need to be used within 4 weeks, and foil sachets within 2 weeks.

Several companies produce ready-to-feed (RTF) infant formulas for community and hospital use. Glass bottles (100 ml) are produced for hospital use and laminated cartons (250 and 1000 ml) for home use. The major ingredients are the same as those used in powdered infant formula production. For the production of RTF bottles, the liquid is produced using water that has been ultrafiltered or deionized to remove all mineral elements. The feed is then repasteurized and decanted into bottles, capped, and sealed. Finally, the bottles undergo terminal sterilization in a rotary autoclave.

For the production of RTF cartons, milk is subjected to UHT sterilization. This quick, high-temperature process (typically 142 °C for 2 s) aims to retain flavor (by reducing caramelization) and allows an extended shelf-life. The cartons are multilaminate, composed of polyethylene, aluminum, and cardboard layers. The base is heat-treated and the packs sterilized internally by hot hydrogen peroxide, before being aseptically filled with milk. The manufacturers recommend that opened 250-ml cartons are used within 24 h, and opened 1000-ml cartons are used within 48 h. The quality checks on these products are extensive, possibly more so than those performed on powders, with up to 5% of the final product destructively tested.

Preparation

In response to the 1974 government recommendation, reconstitution of infant formula in the UK was standardized, requiring only the addition of water. Previously, feed reconstitution was not uniform, which sometimes resulted in over- or underconcentration of feeds. Nowadays, the dilution is always one level scoop of powder added to 30 ml (1 fl. oz.) of water. Scoops from different brands are not interchangeable. However, the relative risk from using the wrong scoop is minimal, unless a scoop for granulated powder is used for measuring nongranulated powder (or vice versa).

Freshly boiled water that has been allowed to cool should be used to reconstitute infant formulas. Domestic softened water, or water repeatedly boiled, is unsuitable, owing to unacceptably high levels of certain minerals. Water filters remove organic compounds, chlorine, and pesticides from water. The resulting water may not be microbiologically safe once the chlorine has been removed, and must therefore be boiled prior to use in feed preparation. Some bottled waters have an unacceptably high sodium content; only those that contain 20 mg of sodium per liter or less, should be used for reconstituting infant formulas. They will also require boiling before use, as they are not sterile.

Immediately before preparing feeds, hands and work surfaces need to be thoroughly washed. Written and pictorial instructions for reconstituting milk powders are given on all infant feed packaging. The first stage is to measure the cooled, boiled water into a graduated milk bottle. The optimum temperature for the water is usually about 50 °C, as this achieves the best dissolution, but specific instructions are given for each formula. The powder is heaped naturally, not compressed, into a scoop and leveled off with the straight edge of a clean knife or spatula. The appropriate number of scoops are added to the water, the cap replaced, and the bottle shaken to achieve thorough mixing of the feed. This can be fed to the infant or kept refrigerated for a maximum of 24 h. Feeds can be warmed by standing the bottle in a jug of hot water. Microwave ovens should not be used for this purpose, as they may result in uneven heating and risk scalding the baby. The temperature of warmed feeds can be checked by testing a few drops on the inside of the wrist.

Sterilization

Bottle-fed babies do not have the same degree of immunological protection as those that are breast-fed, and so strict attention to hygiene practices is vital during feed preparation.

Used bottles and equipment should be thoroughly washed in warm, soapy water, using a bottle brush, if necessary, to remove all traces of milk, then rinsed in

cold water and sterilized. Sterilization is most commonly performed by the addition of sterilizing tablets or liquid to water to produce a hypochlorite sterilizing solution. All bottles and equipment, except metallic objects, need to be completely immersed for the time specified by the manufacturer. To ensure complete sterilization, the bottles should not contain any air bubbles or milk residues. A fresh solution must be made every 24 h.

Alternatively, items can be disinfected by boiling for 20 min in a lidded saucepan kept exclusively for this purpose. Again, the bottles must be fully submerged and free of air bubbles. Teats need only be boiled for 5 min.

Steam sterilization at home is a fairly recent innovation, relying on moist heat as the means of disinfection. Several companies now produce simple electric steam sterilization units. Steam is generated by the addition of a small amount of water on to a heated base-plate; the water gradually turns to steam, sterilizing the bottle surfaces. The machine automatically switches off on completion of its 6–12-min cycle. A temperature in excess of 98 °C is achieved for 3 min. This conforms with the current UK Department of Health standards for equipment used for disinfection: 80 °C for a minimum of 1 min. Microwave ovens are not effective for sterilizing equipment.

Marketing

The Infant Formula and Follow-on Formula Regulations regulates the marketing of milk formulas. Before this was adopted, manufacturers adhered to the Food Manufacturers' Federation code of practice. This was a voluntary code compiled by the infant formula manufacturers in consultation with the Ministry of Agriculture, Fisheries and Food and the Department of Health and was based on the International Code of Marketing of Breast Milk Substitutes. The main recommendations of the code are as follows: advertising of infant formulas should be restricted to publications, which are distributed by health care professionals; all packaging and advertisements should clearly state the superiority of breast-feeding; the provision of free samples of formulas to mothers should be prohibited; and maternity hospitals should not promote the use of infant formula. Furthermore, in 1989, the UK government advised that RTF infant formulas should no longer be subsidized for National Health Service hospitals as the availability of these cheap products undermined breast-feeding practices. These are now purchased at a price decided by national contract. The WHO code is endorsed by most industrialized countries, but it is not universally implemented.

Weaning Foods

A M Fehily, Tinuviel Software, Warrington, UK

Introduction

Weaning is the name given to the process by which infants progress from a diet composed only of breast milk or infant formula milk to a family diet containing a wide variety of foods. This is necessary to insure that nutrient intakes continue to be adequate for healthy growth and development throughout childhood.

Infants vary in the age at which they are ready for weaning. Advice from medical experts is that the majority of infants should not be given solid foods before 4 months of age and that a mixed diet should be offered by 6 months of age. Ideal first foods are rice- or maize-based cereals, fruit, vegetables, and potatoes. The range of foods offered can then be gradually increased, such that by the age of 1 year the diet should be mixed and varied. (*See* **Infants**: Weaning.)

This article discusses the types of foods used during weaning, special diet considerations, the nutrient composition of weaning foods, legislation requirements for the composition of commercial weaning foods, and methods of preparation of weaning foods.

Consistency and Taste

At the start of weaning, foods should be of a very smooth, thin consistency such that they can be sucked from a spoon. The food needs to be sufficiently liquid for the infant to transfer it to the back of the mouth for swallowing, but not so runny that it becomes unmanageable. Foods should be of small particle size and have a bland flavor. At this stage, the aim is to introduce the infant to a wide variety of tastes.

As weaning progresses, the infant is introduced to an increasing variety of foods, providing a range of tastes and textures. Once the infant has become used to taking food from a spoon, puréed foods of a thicker consistency can be introduced, and later foods with small soft lumps and soft finger foods. From about 1 year of age, most infants will be enjoying a regular pattern of meals and snacks made up of family foods.

Types of Foods

During weaning the infant is introduced to a wide variety of foods. In this way, the eventual diet is more likely to provide all the nutrients needed for continued healthy growth and development. A few foods are worthy of special mention and these are discussed below.

Cows' Milk

The UK Department of Health recommends that whole cows' milk should not be used as the main milk drink for infants under the age of 1 year. This is because the main drink makes a major contribution to overall nutrient intakes of infants and cows' milk is not a good enough source of iron or zinc.

The Department of Health advises that semi-skimmed milk should not be used as the main milk drink before 2 years of age and that skimmed milk should not be used as the main milk drink before 5 years of age. This is because milk provides a significant proportion of a child's energy intake, and if skimmed or semiskimmed milk is used as the main drink it may be difficult to insure that total daily energy intake is sufficient.

This advice only applies to the use of these milks as the main drink. It does not apply to the small amounts of milk used in composite dishes. Milk and dairy products are a very important part of a young child's diet, providing an excellent source of protein and calcium. The use of milk and milk products as part of the weaning diet helps to accustom the infant to this important group of foods.

Eggs

For infants, eggs should be thoroughly cooked until the white and yolk are solid.

Meat and Fish

Meat, especially poultry, should be thoroughly cooked. For meat and fish, care needs to be taken to insure that no traces of bone remain in the food.

Nuts and Seeds

For infants and young children, nuts and seeds should be finely ground and not whole, to prevent choking.

Where there is a family history of allergy, the Department of Health advises that peanuts and peanut products should be avoided for the first 3 years.

Honey

It has been recommended that honey should not be given to children under 1 year of age. This is because honey is a known source of certain bacterial spores

(*Clostridium botulinum*). In older children and adults, the natural gut flora suppresses the growth of these spores. However, an infant's gut flora may not adequately suppress the growth of these spores.

Salt

Salt (sodium chloride) is the major source of sodium in the diet of older children and adults. However, infants are less efficient than adults in excreting an excess of sodium in the diet. This is because their kidneys are not fully mature. Salt should therefore not be added to baby foods.

In the UK, commercial baby foods have no added salt. However, many foods intended for older children and adults contain added salt and are therefore not suitable for infants.

Sugar

Frequent consumption of sugary foods can increase the risk of tooth decay.

Sugar should only be added to baby foods where this is necessary to provide an acceptable flavor, and the amount added kept to the minimum required. For example, a dessert such as chocolate pudding would taste bitter if no sugar were added.

Many foods contain sugars which are naturally present, e.g., fruits, fruit juices, vegetables, and milk. Both added sugar (table sugar or sucrose) and sugars naturally present in foods such as fruits and fruit juices can increase the risk of tooth decay if care is not taken in use of these foods. Frequent consumption of these foods should be avoided. Good dental hygiene is also very important: tooth cleaning should start as soon as teeth appear.

Additives

Foods intended for older children and adults may contain additives such as artificial colors, preservatives, artificial flavors, and sweeteners. Such foods are unsuitable for infants. These additives are not used in commercial baby foods.

There are some additives legally permitted for use in weaning foods within the European Union (EU). For example, natural flavorings such as vanilla are sometimes used. Certain emulsifiers may be used where needed to insure complete dispersion of oils and fats.

Modified starches are sometimes used to insure that products have the right consistency. These cross-linked amylopectin starches are used in preference to native starches as they perform better in the manufacturing process and do not lose their thickening properties. The amount used is small and the starch is easily digestible by the infant.

Special Diets

The Department of Health advises that where there is a family history of atopy or gluten enteropathy, mothers should be encouraged to breast-feed for 6 months or longer. Weaning before 4 months should particularly be discouraged and the introduction of foods traditionally regarded as allergenic, for example cows' milk and egg, should be delayed until 6 months at the earliest. For peanuts and peanut products, advice is that, where there is a family history of allergy, these should be avoided for the first 3 years.

For the vast majority of infants, where there is no family history of allergy, there is no need to restrict the weaning diet.

It is important to note that the avoidance of any food increases the risk that the infant may not get enough of all the nutrients he or she needs for healthy growth and development. Thus, if it is necessary to exclude any food from an infant's diet, it is essential that expert nutritional advice is obtained from a state-registered dietitian.

For infants being weaned on to a vegetarian diet, care needs to be taken to insure that the quantity and quality of protein are adequate and that energy intake is adequate. Special care also needs to be taken to avoid iron deficiency.

If using commercial baby foods, it is usually easy to identify products suitable for a milk-free, egg-free, gluten-free, or vegetarian diet, as labels of suitable products often carry a statement to this effect.

Nutrient Composition

The nutrient requirements of infants differ from those of older children and adults and are high relative to body size. (*See* **Infants**: Nutritional Requirements.)

A healthy diet recommended for older children and adults, i.e., low in fat and saturates and high in fiber, is not appropriate for infants.

Weaning accustoms the infant to a wide range of tastes and textures. As solid foods form an increasing part of the diet, the diet becomes varied and the nutrient density increases. This helps to insure continuing adequate nutrient intakes for healthy growth and development.

At the start of weaning, the nutrient composition of the foods is not very important as the amounts of foods consumed are small. As weaning progresses and solid foods make a larger contribution to overall nutrient intake, the nutrient composition of weaning foods becomes more important. Nevertheless, milk continues to make a substantial contribution to overall nutrient intake throughout early childhood.

Energy and Protein

An adequate energy intake is essential for healthy growth and development. If energy intake is inadequate, dietary protein may be broken down by the body and used to supply energy instead of being used for growth.

An adequate intake of protein, with a proper balance of essential amino acids, should also be insured during weaning. The protein content of the diet needs to be sufficient to support the fast growth rate of the infant, but not so much as to put a strain on the excretory capacity of the infant's immature kidneys. If the diet is restricted for any reason, care needs to be taken to insure that a variety of foods is offered at each meal, providing a mixture of protein sources.

All foods provide energy, the best sources being milk, rice, pasta, potatoes, bread, meat, poultry, fish, eggs, cheese, beans, and lentils. The main sources of protein in the diet are meat, poultry, fish, milk, cheese, eggs, cereals, beans, peas, and lentils.

Carbohydrate

Carbohydrate includes starch and sugars and these are important sources of energy. Sugars also enhance the palatability of the diet.

Starch is found in foods such as rice, pasta, potatoes, and bread. Apart from table sugar (sucrose), sugars are naturally present in many foods such as fruits, fruit juices, vegetables, and milk. Fruits, fruit juices, and vegetables contain fructose, glucose, and sucrose. Milk contains lactose.

Care needs to be taken in the use of sugary foods, whether the sugar is added or is naturally present in foods such as fruits and fruit juices, to minimize the risk of tooth decay. Frequent consumption of these foods should be avoided and good dental hygiene is essential.

Fruit juices and other sugary drinks should not be allowed to remain in the mouth for long periods. In the UK, the labels of fruit juices and similar drinks intended for infants carry advice supported by the British Dental Association to insure appropriate use of these drinks:

- Always follow the manufacturer's instructions on usage and dilution
- Serve only at meal times and keep drinking times short
- Never leave infants alone with any drink
- Never use drinks on a dummy or as a comforter
- Ideally serve from a spoon, trainer cup, or beaker, but not from a bottle
- Do not give at bedtime or during the night.

Fat

For adults, a healthy diet is one that is low in fat. This is not true for infants. Fat is an important source of energy in an infant's diet. If total fat intake is low, it can be difficult to insure that energy intake is adequate for healthy growth and development.

Fat is also an important source of essential fatty acids and of fat-soluble vitamins (A and D). Essential fatty acids are necessary for growth and for maintaining the skin in a healthy condition. Vitamin A is essential for vision and for healthy skin. Vitamin D helps the body to absorb calcium, which is essential for healthy bones.

Vitamins and Minerals

One of the best ways of insuring that an infant's intake of vitamins and minerals is adequate is to offer a wide variety of foods.

Two nutrients are worthy of special note: iron and vitamin C. Infants have high iron requirements and it can be difficult to insure that intake is sufficient. Iron deficiency results in anemia and may also result in impaired mental and physical development. The effects of deficiency may be long-lasting.

Iron is better absorbed from meat and meat products, particularly red meat (heme iron), than from vegetable sources (nonheme iron). Some components of the diet bind to iron and thereby hinder iron absorption: phytic acid from cereals, legumes, and other vegetables; phosphoproteins in cows' milk and egg yolk; tannin in tea; and polyphenols in spinach and coffee. Vitamin C, on the other hand, improves the absorption of iron from the diet. Vitamin C also enhances the absorption of other minerals from the diet – zinc and copper. Protein also helps to improve iron absorption, by reducing the inhibitory effect of phytic acid.

Foods containing iron, particularly heme iron and foods containing vitamin C, are therefore important components of a weaning diet. Meat, eggs, beans, lentils, peas, bread, and dark green vegetables provide the main sources of iron in the diet. Fruits, vegetables, and fruit juices provide vitamin C. Some commercial weaning foods have added iron and many have added vitamin C.

Fiber

Fiber is an important part of a healthy diet for adults. This is not the case for infants. A high-fiber bran cereal, for example, would not be appropriate for infants. This is because fiber makes the diet more bulky. If the fiber content of the diet is high, the infant may feel full after eating fewer calories. It may therefore be difficult for

him or her to obtain sufficient energy to insure healthy growth and development.

Commercial Weaning Foods

A wide variety of commercial weaning foods is available. Weaning foods in cans and jars are available either as homogeneous purées for young infants (4–6 months of age), or preparations with larger particle size for older infants (from about 7 months of age). A wide range of dried weaning foods is also available, some intended for infants from about 4 months of age and others intended for infants from about 7 months of age.

Types of product available include baby rice cereal, breakfast recipes, savoury recipes, desserts, rusks, and drinks. Breakfast recipes are composed mainly of fruits and cereals. Savoury varieties are composite dishes containing ingredients such as meats, fish, vegetables, and cereals. Dessert varieties consist of fruits, dairy products, and cereals. Available drinks include pure fruit juices with added vitamin C and purified water with a hint of fruit flavor.

Within the EU, there is legislation governing the composition and labeling of processed cereal-based foods and baby foods for infants and young children, i.e., foods intended for children up to 3 years of age. Details of the compositional requirements are presented in Tables 1 and 2. Some companies also have their own additional nutritional guidelines for weaning foods to insure that these foods help mothers to provide a varied and nutritionally balanced diet for their babies.

Certain vitamins and minerals may be added to weaning foods, either to fortify the foods and thus help insure that an infant's nutrients intakes are adequate, or to restore losses which occur during processing. Manufacturers take professional advice when deciding on the levels of vitamins or minerals to add. There is also legislation within the EU setting down the maximum levels which may be present in foods intended for infants and young children where vitamins and minerals are added.

With regard to pesticide residues, EU legislation is more strict for weaning foods than for foods intended for older children and adults. Foods intended for infants and young children may not contain pesticide residues greater than 0.01 mg kg^{-1}, which in practice is the minimum detectable level.

The labels of commercial baby foods provide information on the ingredients, nutrient composition, and suitability for certain special diets. Nutrition information is given per 100 g for energy, protein, fat, and carbohydrate, although many companies also given information on the sugars, saturates, fiber, and sodium contents and provide data per serving as well as per 100 g.

Methods of Preparation

Commercially Made Weaning Foods

Commercially made weaning foods are produced by a variety of methods, some of which are described below.

Cereal-based foods For cereal-based foods, all the ingredients are mixed together with water to produce a liquid paste which is pregelatinized and dried using a roller drier. The dried flakes are then milled to the required particle size and the product then packed.

When using baby rice or other baby cereals at home, one teaspoon of the cereal should be measured into a clean bowl and mixed with one tablespoon of the infant's usual milk. The amount can be increased as necessary.

For baked cereal-based foods, such as rusks, fat and water are added to the dry ingredients and mixed to form a dough. This is converted into a continuous sheet or ribbon which is then cut, shaped and baked in a traveling-band oven, and the product then packed.

When using rusks at home, the back of a spoon should be used to crush a small piece of rusk in a bowl and then mixed with the infant's usual milk, or cooled previously boiled water, to a creamy consistency.

Dried foods For other dried weaning foods, dried ingredients are blended, mixed with water, and cooked on a roller drier to produce flakes. These are reduced to the required particle size and then packed.

When using dried weaning foods at home, the required amount of food should be measured into a clean bowl with a dry spoon. The feeding table presented on the pack should be used as a guide on the quantities to offer. The required amount of warm, previously boiled water should then be added and mixed thoroughly. For some foods intended for older infants, it may be necessary to add hot water to rehydrate the food. If so, then the food must be left to cool before feeding to the infant.

Foods in cans and jars Ready-to-feed weaning foods in cans and jars are produced as follows. Ingredients are prepared and weighed, then mixed with water. Starches, when used, are premixed with water to insure complete dispersion before addition to the main batch. Cooking of the mixture is effected via a steam jacket surrounding the cooking vessel, or via direct steam injection of the mixture. The cooked

Table 1 Composition of processed cereal-based foods for infants and young children: requirements of European Union legislation[a]

Type of product	*Compositional requirements*
Simple cereals which are or have to be reconstituted with milk or other appropriate nutritious liquids	Carbohydrate: the amount of added carbohydrate from sucrose, fructose, or glucose shall not exceed 1.8 g 100 kJ^{-1} (7.5 g 100 kcal^{-1}). The amount of added fructose shall not exceed 0.9 g 100 kJ^{-1} (3.75 g 100 kcal^{-1}) Fat: content shall not exceed 0.8 g 100 kJ^{-1} (3.3 g 100 kcal^{-1}) Sodium: content may not exceed 25 mg 100 kJ^{-1} (100 mg 100 kcal^{-1}) Thiamin: content shall not be less than 25 μg 100 kJ^{-1} (100 μg 100 kcal^{-1}) Vitamin A: if added, vitamin A content shall be a minimum of 14 μg RE 100 kJ^{-1} (60 μg RE 100 kcal^{-1}) and a maximum of 43 μg RE 100 kJ^{-1} (180 μg RE 100 kcal^{-1}) Vitamin D: if added, vitamin D content shall be a minimum of 0.25 μg 100 kJ^{-1} (1 μg 100 kcal^{-1}) and a maximum of 0.75 μg 100 kJ^{-1} (3 μg 100 kcal^{-1})
Cereals with an added high-protein food which are or have to be reconstituted with water or other protein-free liquid	Protein: content shall not exceed 1.3 g 100 kJ^{-1} (5.5 g 100 kcal^{-1}). The added protein shall not be less than 0.48 g 100 kJ^{-1} (2 g 100 kcal^{-1}). There is an additional requirement to insure high quality of the added protein Carbohydrate: the amount of added carbohydrate from sucrose, fructose, or glucose shall not exceed 1.2 g 100 kJ^{-1} (5 g 100 kcal^{-1}). The amount of added fructose shall not exceed 0.6 g 100 kJ^{-1} (2.5 g 100 kcal^{-1}) Fat: content shall not exceed 1.1 g 100 kJ^{-1} (4.5 g 100 kcal^{-1}) Sodium: content may not exceed 25 mg 100 kJ^{-1} (100 mg 100 kcal^{-1}) Calcium: shall not be less than 20 mg 100 kJ^{-1} (80 mg 100 kcal^{-1}) Thiamin: content shall not be less than 25 μg 100 kJ^{-1} (100 μg 100 kcal^{-1}) Vitamin A: content shall be a minimum of 14 μg RE 100 kJ^{-1} (60 μg RE 100 kcal^{-1}) and a maximum of 43 μg RE 100 kJ^{-1} (180 μg RE 100 kcal^{-1} Vitamin D: content shall be a minimum of 0.25 μg 100 kJ^{-1} (1 μg 100 kcal^{-1}) and a maximum of 0.75 μg 100 kJ^{-1} (3 μg 100 kcal^{-1})
Pastas which are to be used after cooking in boiling water or other appropriate liquids	Sodium: content may not exceed 25 mg 100 kJ^{-1} (100 mg 100 kcal^{-1}) Thiamin: content shall not be less than 25 μg 100 kJ^{-1} (100 μg 100 kcal^{-1}) Vitamin A: if added, vitamin A content shall be a minimum of 14 μg RE 100 kJ^{-1} (60 μg RE 100 kcal^{-1}) and a maximum of 43 μg RE 100 kJ^{-1} (180 μg RE 100 kcal^{-1}) Vitamin D: if added, vitamin D content shall be a minimum of 0.25 μg 100 kJ^{-1} (1 μg 100 kcal^{-1}) and a maximum of 0.75 μg 100 kJ^{-1} (3 μg 100 kcal^{-1})
Rusks and biscuits which are to be used either directly or, after pulverization, with the addition of water, milk, or other suitable liquids	Protein: protein content shall not exceed 1.3 g 100 kJ^{-1} (5.5 g 100 kcal^{-1}). For biscuits made with the addition of a high-protein food, and presented as such, the added protein shall not be less than 0.36 g 100 kJ^{-1} (1.5 g 100 kcal^{-1}). There is an additional requirement to insure high quality of the added protein Carbohydrate: the amount of added carbohydrate from sucrose, fructose, or glucose shall not exceed 1.8 g 100 kJ^{-1} (7.5 g 100 kcal^{-1}). The amount of added fructose shall not exceed 0.9 g 100 kJ^{-1} (3.75 g 100 kcal^{-1}) Fat: content shall not exceed 0.8 g 100 kJ^{-1} (3.3 g 100 kcal^{-1}) Sodium: content may not exceed 25 mg 100 kJ^{-1} (100 mg 100 kcal^{-1}) Calcium: for products manufactured with the addition of milk, and presented as such, the amount of calcium shall not be less than 12 mg 100 kJ^{-1} (50 mg 100 kcal^{-1}) Thiamin: content shall not be less than 25 μg 100 kJ^{-1} (100 μg 100 kcal^{-1}) Vitamin A: if added, vitamin A content shall be a minimum of 14 μg RE 100 kJ^{-1} (60 μg RE 100 kcal^{-1}) and a maximum of 43 μg RE 100 kJ^{-1} (180 μg RE 100 kcal^{-1}) Vitamin D: if added, vitamin D content shall be a minimum of 0.25 μg 100 kJ^{-1} (1 μg 100 kcal^{-1}) and a maximum of 0.75 μg 100 kJ^{-1} (3 μg 100 kcal^{-1})

[a]Commission Directive 96/5/EC, as amended.

The amount of cereal and/or starchy root shall not be less than 25% of the final mixture on a dry weight-for-weight basis. RE, retinol equivalents.

food is then reduced to the appropriate particle size, and hot-filled into cans or jars which are then sealed. The cans or jars are then heat-treated in pressure cookers, using a temperature–time–pressure regime, depending upon the type of product being processed. Finally the cans or jars are cooled and then labeled.

Ready-to-feed weaning foods in cans or jars do not need further cooking at home, and can be safely fed to infants without heating them up. If it is desired to heat the food, the required amount should be removed from the can or jar and placed in a clean cup or small bowl. This should be stood in a saucepan or bowl of hot water and covered. The food becomes lukewarm and ready to serve in a few minutes. The food should be stirred and the temperature tested with another spoon before feeding.

Any remaining unwarmed food should be removed from the can or jar, placed in a clean container, covered and stored in the refrigerator for up to 48 h.

Table 2 Composition of baby foods for infants and young children: requirements of European Union legislation[a]

Type of product	*Compositional requirements*
Meat, fish, or other traditional source of protein are the only ingredients mentioned in the name of the product	Protein: The named meat, fish, or other traditional source of protein shall constitute not less than 40% by weight of the product Each named meat, fish, or other traditional source of protein shall constitute not less than 25% by weight of the total named protein sources Protein from the named sources shall not be less than 1.7 g 100 kJ^{-1} (7 g 100 kcal^{-1}) Fat: If meat or cheese are the only ingredients mentioned in the name of the product, or are mentioned first, total fat content should not exceed 1.4 g 100 kJ^{-1} (6 g 100 kcal^{-1}) Sodium: If cheese is the only ingredient mentioned in the name of the product, sodium content shall not be more than 70 mg 100 kJ^{-1} (300 mg 100 kcal^{-1}). For other products, sodium content should be either not more than 48 mg 100 kJ^{-1} (200 mg 100 kcal^{-1}) or not more than 200 mg 100 g^{-1} Vitamin A and vitamin D: may not be added
Meat, fish, or other traditional source of protein is mentioned first in the name of the product	Protein: The named meat, fish, or other traditional source of protein shall constitute not less than 10% by weight of the product Each named meat, fish, or other traditional source of protein shall constitute not less than 25% by weight of the total named protein sources Protein from the named sources shall not be less than 1 g 100 kJ^{-1} (4 g 100 kcal^{-1}) Fat: Content should not exceed 1.1 g 100 kJ^{-1} (4.5 g 100 kcal^{-1}) Sodium: Content should be either not more than 48 mg 100 kJ^{-1} (200 mg 100 kcal^{-1}) or not more than 200 mg 100 g^{-1} Vitamin A and vitamin D: may not be added
Meat, fish, or other traditional source of protein is mentioned, but not first, in the name of the product	Protein: The named meat, fish, or other traditional source of protein shall constitute not less than 8% by weight of the product Each named meat, fish, or other traditional source of protein shall constitute not less than 25% by weight of the total named protein sources Protein from the named sources shall not be less than 0.5 g 100 kJ^{-1} (2.2 g 100 kcal^{-1}) Total protein shall not be less than 0.7 g 100 kJ^{-1} (3 g 100 kcal^{-1}) If cheese is mentioned in the name, protein from dairy sources shall not be less than 0.5 g 100 kJ^{-1} (2.2 g 100 kcal^{-1}); total protein shall not be less than 0.7 g 100 kJ^{-1} (3 g 100 kcal^{-1}) Fat: Content should not exceed 1.1 g 100 kJ^{-1} (4.5 g 100 kcal^{-1}) Sodium: Content should be either not more than 48 mg 100 kJ^{-1} (200 mg 100 kcal^{-1}) or not more than 200 mg 100 g^{-1} Vitamin A and vitamin D: May not be added
Product is designated as a meal, but meat, fish, or other traditional source of protein not mentioned in the product name	Protein: Total protein shall not be less than 0.7 g 100 kJ^{-1} (3 g 100 kcal^{-1}) Fat: Content should not exceed 1.1 g 100 kJ^{-1} (4.5 g 100 kcal^{-1}) Sodium: Content should be either not more than 48 mg 100 kJ^{-1} (200 mg 100 kcal^{-1}) or not more than 200 mg 100 g^{-1} Vitamin A and vitamin D: May not be added
Fruit-only dishes	Carbohydrate: Shall not exceed 20 g 100 g^{-1} Fat: Content should not exceed 1.1 g 100 kJ^{-1} (4.5 g 100 kcal^{-1}) Sodium: Content should be either not more than 48 mg 100 kJ^{-1} (200 mg 100 kcal^{-1}) or not more than 200 mg 100 g^{-1} Vitamin A and vitamin D: May not be added
Desserts and puddings	Protein: If a dairy product is the first or only ingredient mentioned in the product name, protein from dairy sources must be at least 0.5 g 100 kJ^{-1} (2.2 g 100 kcal^{-1}) Carbohydrate: Shall not exceed 25 g 100 g^{-1} Fat: Content should not exceed 1.1 g 100 kJ^{-1} (4.5 g 100 kcal^{-1}) Sodium: Content should be either not more than 48 mg 100 kJ^{-1} (200 mg 100 kcal^{-1}) or not more than 200 mg 100 g^{-1}
Drinks	Carbohydrate: Vegetable juices and drinks based on them: shall not exceed 10 g 100 ml^{-1} Fruit juices, nectars and drinks based on them: shall not exceed 15 g 100 ml^{-1} Other nonmilk-based drinks: shall not exceed 5 g 100 g^{-1} Fat: Content should not exceed 1.1 g 100 kJ^{-1} (4.5 g 100 kcal^{-1}) Vitamin C: Fruit/vegetable juices – content should be at least 6 mg 100 kJ^{-1} (25 mg 100 kcal^{-1}) or at least 25 mg 100 g^{-1} Vitamin A: Vegetable juices – content should be at least 25 μg RE 100 kJ^{-1} (100 μg RE 100 kcal^{-1}). May not be added to other foods Vitamin D: May not be added

[a]Commission Directive 96/5/EC, as amended. RE, retinol equivalents.

Homemade Weaning Foods

Preparing weaning foods at home is largely a matter of adapting normal cooking processes. If a meal is being cooked for other members of the family, it is usually possible for a suitable weaning food to be prepared from the same basic ingredients.

Preparation of homemade weaning foods usually involves omission of certain ingredients, such as chilli peppers, garlic, ginger, and other spicy ingredients, which might irritate the infant's digestive tract. Salt should not be added during cooking.

Grilling, baking, poaching, or boiling are all suitable cooking methods, but frying with added fat is not recommended. When the food has been cooked, it is necessary to reduce it to a suitable consistency, according to the infant's stage of development. Many hand and electrical gadgets are available for this purpose.

Using a microwave oven is not recommended to heat foods for infants as microwaves can cause uneven heating and food could burn an infant's mouth. However, if a microwave is used to heat foods for infants, the manufacturer's instructions must be followed exactly. The food should always be stirred to insure an even distribution of heat and the temperature checked before the food is fed to an infant.

Weaning Foods in Developing Countries

The first foods added to the diet are generally staple foods. These might include cereals and tubers such as maize, rice, millet, or sweet potato. In China, the staple of the diet is rice, whereas semolina is used in India. In Kenya, the infant diet is based on maize and in Nepal on soya, wheat, and maize.

The simplest recipe for weaning foods is one which has only two ingredients, for example a cereal or root mixed with a legume. Other foods can be added to this basic mix to make a complete meal. Such recipes are known as multimixes and consist of four basic ingredients:

1. A staple as the main ingredient – preferably a cereal.
2. A protein supplement from a plant or animal food – beans, groundnuts, meat, milk, chicken, fish, eggs, etc.
3. A vitamin and mineral supplement – a vegetable and/or fruit.
4. An energy supplement – fat, oil, or sugar to increase the energy concentration of the mix.

Hygiene

Since infants are particularly susceptible to infection during the first year of life, special care must be taken to avoid introducing a source of infection via weaning foods. The scrupulous washing of hands and all equipment used in the home preparation of food is essential. Plastic or glass items, such as plates, spoons, and mugs, can be sterilized chemically, but metal utensils must be boiled.

All weaning food manufacturers have very strict specifications to insure the safety of their products. Cleanliness is maintained in the manufacturing environment with rigorous standards of hygiene.

INFANTS

Contents

Nutritional Requirements

J Morgan, University of Surrey, Guildford, Surrey, UK

Introduction

For the purposes of this article, infants are defined as aged from birth to 12 months.

For many years estimating energy and nutrient requirements in infancy has relied on data derived from feeding studies and growth patterns of healthy full-term wholly breast-fed infants. Thus requirements in infancy were based on food intake data. However, more direct evidence for requirements (for example, energy expenditure data) has provided more direct data on needs. Thus, recent national and international committees have reflected this knowledge when proposing the best estimate of infant nutrient requirements and reference intakes.

Individual Variation in Food Intake

The wide individual variation in energy and nutrient intakes at any age has been recognized for 40 years. At 1 year of age there are infants at the upper end of the range consuming twice as much food as those at the lower end – some infants at 6 months are consuming energy intakes equivalent to those of young women (Table 1). The phenomenon of the variation in food intake (and hence nutrient requirement) highlights the need to distinguish between the terms 'requirement' and 'recommended intake.'

The effect of gender is well recognized: On average, boys have a greater intake of energy than girls. The US *Recommended Dietary Allowances* report (1989) provides an average energy allowance (AEA) for energy requirements from birth to 10 years which does not distinguish between sexes for energy requirements. However, other authorities, such as the UK Department of Health, do distinguish between the sexes with regard to energy requirements.

In young infants the nutrient requirement for growth itself is substantial, representing up to 30% of the energy requirement, but there exists a large variation within the normal range on the rate of growth and probably also in the composition of the tissue laid down.

The 'average' composition of human milk has been used as a basis for estimating requirements and also for calculating the composition of infant milk formulae. It is as well to remember, however, that the composition of human milk varies, from mother to mother, and from day to day. It depends on the stage of lactation and on the mother's diet (particularly the content of polyunsaturated fatty acids). As well as providing nutritional substances, milk contains several growth factors, including epidermal growth factors, insulin, and insulin-like growth factor (IGF-1). The physiological importance of these substances has not yet been established.

Table 1 Energy intake of boys and girls, illustrating average intake and maximum and minimum values

Requirement for Energy

Recently, recommendations for energy have been given as the estimated average energy requirement (EAR) – about half the population will usually need more than the EAR and half less. A recommendation for an energy intake that is adequate for all infants could result in obesity in those infants who have lower than average requirements, therefore the EAR reflects the estimated average energy requirement.

Energy requirements for infancy should be estimated from data on energy expenditure. The 1985 World Health Organization (WHO) / Food and Agriculture Organization report on energy requirements in humans based its recommendations for infants on the observed intake of healthy infants growing normally. It is recognized, however, that observed and desired energy intake may differ, and that a better estimate of energy needs is provided by energy expenditure. The available database on energy expenditure in infants has greatly expanded since 1985, thanks in large part to the application of the doubly-labeled water technique. This noninvasive method permits a reliable quantification of total daily expenditure in infants under normal conditions of everyday life. There are now thousands of data points on energy expenditure in infants obtained with this method. In addition, new data on growth and energy intake of exclusively breast-fed infants became available. Taken together, these data on intake, growth, and energy expenditure suggest that the actual energy requirements for breast-fed infants may be 10–40% lower than the 1985 estimates. One explanation for the overestimation of the previous recommendation may be first, that the data set of observed intakes included a large proportion of formula-fed infants, who consume higher amounts of energy than breast-fed infants, and second, that the reference standard for desirable growth is also based largely on a population of predominantly formula-fed infants.

The fact that healthy, exclusively breast-fed infants grow at a slower rate than the current reference standards is the subject of ongoing research. There is evidence, however, that these infants are no different than infants consuming more energy and growing at a faster rate in terms of morbidity, sleep patterns, or physical activity.

As a result of these studies, efforts are under way to develop a growth reference chart for exclusively breast-fed infants, which presumably would reflect a more physiological growth pattern than that of formula-fed infants.

Dietary reference values (DRV) for infants (males and females) from reports published under the auspices of UK, USA, and European committees are given in Table 2.

Requirement for Protein

Estimates of protein requirements for young infants are based on milk intake data. The WHO, the National Research Council, and the Department of Health have utilized this method.

Table 3 shows the reported intake of protein in human milk-fed male and female babies between birth and 4 months. Assumptions have been made regarding the protein content of milk (and complementary foods after 4 months) and the figure of 1.15 g of protein per 100 ml (for milk) is generally accepted. Because of the high quality and easy digestibility of human milk protein, few infants fed human milk develop protein deficiency.

In estimating protein requirements from 6 to 12 months, the WHO Committee used the factorial approach. A gray area of knowledge exists for protein requirements between 4 and 6 months of age. Estimates of protein requirements have been extrapolated from energy requirements, i.e., 1040 ml of breast milk per day is needed to fulfill the theoretical energy needs, and hence protein requirements, of male

Table 2 Dietary reference values for energy for males and females

Age (years)	*UK EAR (kcal/MJ day^{-1})*	*USA AEA (kcal/MJ day^{-1})*	*EU EAR (kcal/MJ day^{-1})*
Males

infants aged 5–6 months. This approach is obviously not ideal.

Table 4 outlines the dietary reference values for protein (g day^{-1}) for the period 0–12 months from various reports. A major point of issue when estimating requirements is the variation in protein needs for growth. The uncertainty related to this factor has resulted in the addition of 50% to the theoretical nitrogen accretion in the calculation of protein requirements. In fact, adjustment by 50% may even be too small. This is obviously an area where research is urgently needed, i.e., to investigate the daily variation in growth rate and the constraints in storage of essential amino acids to be available when maximum growth occurs. To adjust for interindividual variation in growth and maintenance, a factor of 12.5% has been incorporated. A theoretical basis for calculating the variability of protein requirement for growth does not exist. Work by Fomon indicates that over a period of 1 month children vary in their average daily rate of growth, with a coefficient of variation of 37%. This variation in weight gain is much greater than the variability in protein intake.

Human milk contains characteristic nitrogen-containing components. In fact, 25% of the nitrogen is derived from nonprotein sources: free amino acids, small peptides, amino sugars, creatine, creatinine, and glycolipids. The content of free taurine is 30–40 times higher in human milk compared with cows' milk. Although the nutritional or biochemical role of some of these substances is not fully understood, their presence, like that of the growth-promoting factors previously mentioned, should not be dismissed.

The specific amino acid requirements of infants are of interest. It appears that, beside the eight essential amino acids, three other amino acids (cysteine, taurine, and histidine) are essential in the postnatal period. This has implications for one aspect of infant feeding – the provision of total nutrition by intravenous (IV) feeding. Only recently have amino acid preparations for IV nutrition been tailored to the requirements of infants, including an appropriate amino acid profile.

Requirements for Fats

In the broadest sense, infants have a requirement for fats to provide energy, to provide essential fatty acids, to facilitate the absorption of the fat-soluble vitamins A, E, and D, and as a precursor of structural lipids and eicosanoids. Triacylglycerols in human milk contain more than 150 different fatty acids, but the origin and role of many of these are largely unknown. The average intake of fat can be calculated for breast-fed infants if the fat content of the breast milk is known (Table 5).

The specific requirements of long-chain polyunsaturated fatty acids (PUFA) and cholesterol in infants are not often considered. Infants have specific requirements for PUFA. In the 1950s and 1970s there were reports of deficiency in long-chain fatty acids in premature infants fed parenterally with no lipid source, and in full-term infants fed on formula devoid of linoleic acid. Human milk contains on average 7.2 g of linoleic acid per 100 g total fatty acids or 285 mg per 100 ml, i.e., 3.7% of total energy. The DRV report panel recommended that for infants and young children: 'linoleic acid should provide at least 1 per cent of total energy and alpha linolenic acid at least 0.2 per cent of total energy.'

Table 5 Average daily intake of fat by breast-fed infants aged 0–4 months

Age (months)	*Breast milk consumed (ml)*	*Weight (kg)*	*Average fat intake*[a]	
			(g)	*(g/kg day^{-1})*
Boys				
0–1	719	3.8	30	8
1–2	795	4.75	33	7
2–3	848	5.6	36	6
3–4	822	6.35	35	5
Girls				
0–1	661	3.6	28	8
1–2	731	4.35	30	7
2–3	780	5.05	32	6
3–4	756	5.7	32	5

[a]Fat content of breast milk 4.2 g per 100 ml.

Human milk is relatively rich in cholesterol, providing an average 16 mg l^{-1}. The existence of this sterol in breast milk is indicative of a biological role, although no authority to date has made recommendations on desirable intakes in infants not receiving human milk.

Several studies have suggested a specific role for certain PUFA in visual development. Eicosapentaenoic acid and docosapentaenoic acid have been evaluated in term and preterm infants; these fatty acids are found in high concentration in human milk, but they have not been added to infant formulae until recently. The requirement for them may be higher in preterm infants, but their contribution to visual development of the full-term healthy infant is not fully documented at this point. Several commercial infant formulae, however, are now fortified with eicosapentaenoic acid.

Requirement for Carbohydrate

Eighty percent of the total carbohydrate in human milk is a sugar, lactose (approximately 7 g per 100 ml of human milk). In early infancy, when the diet consists wholly of milk, about 40% of the energy intake is derived from lactose.

As the diet of the infant becomes more varied, the carbohydrate content also varies. Table 6 provides detailed information on the carbohydrate contribution of foods given to infants. After about 4–6 months human milk or infant milk formulae alone cannot meet an infant's energy and other nutrient requirements (notably iron). It is important to remember that infants are not miniature adults and that they have their own specific nutrient needs. There is evidence, however, that dietary guidelines for adults are being inappropriately applied to infants. There is a particular concern regarding the provision of nonstarch polysaccharides (NSP) and also the use of low-fat products in the diet of young children. The UK panel recommended in 1991 that children should have proportionally lower NSP intakes than adults, and that consumption should not be at the expense of energy-rich foods. However, no specific guidelines were given regarding safe intakes for NSP for infants.

Table 6 Average carbohydrate content of several foods for infants

Food	*Carbohydrate (% energy)*
Human milk	37
Cows' milk	29
Strained meat	1
Strained fruits	96
Strained desserts	89
Strained vegetables	80
Strained soups and dinners	56
Strained high-meat dinners	29

Requirement for Vitamins and Minerals

In the UK, supplementation of vitamins is recommended for breast-fed infants and young children from 6 months to 5 years unless the child's diet is diverse and plentiful. The daily dose of five vitamin drops provides 7 μg of vitamin D, 200 μg of vitamin A, and 20 mg of vitamin C.

Requirement for Vitamin A

Dietary requirements for vitamin A in infants have been usually based on and extrapolated from intakes calculated from values obtained from a wholly breast-fed infant receiving milk from a well-nourished mother. The breast milk from women living in the USA and Europe contains 40–70 μg of retinol per 100 ml milk and between 20 and 40 μg of carotenoids per 100 ml of milk. Assuming milk is consumed at 750 ml per day (and the concentration of retinol is 40 μg per 100 ml), the infant would receive about 300 mg of retinol per day. After taking into account factors such as individual variation in retinol content of milk, the US committee (NRC 1989) recommend an intake of 350 μg day^{-1} up to 1 year. The UK recommendations (DoH 1991) are set at 350 μg of retinol equivalents per day. In developing countries, vitamin A deficiency is uncommon in the first year of life. A drastic fall in the vitamin A content of milk has to be preceded by the exhaustion of the mother's stores of this vitamin.

Requirement for Vitamin D

Only small amounts of vitamin D are secreted in human breast milk, which indicates that a dietary source of this substance is teleologically unimportant; the major source of vitamin D is the action of ultraviolet (UV) light on the skin. The amount of exposure to UV light will differ from infant to infant. Because of this uncertainty, and to safeguard against lack of exposure to sunlight in the UK, the reference nutrient intake (RNI) is 8.5 μg of vitamin D per day (from food or supplements) from 0 to 6 months, and 7 μg day^{-1} from 7 to 12 months. The US recommended dietary allowance (RDA) is set at 7.5 μg day^{-1} for infants from birth to 6 months of age, and 10 μg day^{-1} from 6 months onwards because of increased body mass. The European 'safe range' from 0 to 3 years is 10–25 mg day^{-1}.

Thus, three authorities recommend a target intake for vitamin D, although there is no doubt that healthy,

wholly breast-fed infants who are exposed to sunlight do not require oral supplementation. Vitamin D deficiency in the material diet, lack of sunlight, adverse social or environmental factors, and infant prematurity indicate the need for supplementation.

Excessive intake of vitamin D is potentially harmful: only five times the RNI (45 μg day^{-1}) has been reported to be associated with hypervitaminosis in young children.

Requirement for Ascorbic Acid (Vitamin C)

Scurvy occurs primarily in infants fed diets consisting exclusively of cows' milk; as this mode of feeding is very uncommon, scurvy is rare in infants under 1 year of age. There are reports that infants receiving as little as 7 mg of vitamin C per day are protected from scurvy. Human milk contains approximately 4 mg of vitamin C (ascorbic acid and dehydroascorbic acid) per 100 ml. An infant receiving 750 ml of human milk per day will receive in the order of 30 mg of vitamin C. The UK recommends a daily intake of 25 mg of vitamin C up to 12 months; the USA recommends a daily intake of 30 mg and 35 mg of vitamin C from 0 to 6 months and 7 months to 1 year of age respectively.

Requirement for Iron

A normal healthy fetus stores iron in the last trimester of pregnancy. Because of this, a full-term infant can maintain satisfactory hemoglobin levels, without any other sources of iron, for about the first 4–6 months of life. Breast milk is noticeably low in iron – 76 μg 100 ml^{-1}. However, because the iron is well absorbed (50–70%, compared with 10–30% from cows' milk), and because an infant has hepatic hemoglobin stores, a dietary source is unnecessary. After 4–6 months of age, and in nonbreast-fed infants from birth, a dietary iron source is needed. Infant milk formulae and many infant food products contain added iron, thus insuring an appropriate dietary intake; in addition food commodities such as red meat can be included to provide a source of bioavailable iron. Dietary reference values for iron differ from country to country. At ages 4–6 months the UK value is 4.3 mg day^{-1}, the USA RDA is 6.0 mg day^{-1}, and the WHO recommendation is 8.5 mg day^{-1}.

Requirement for Calcium

Adequate mineralization of the skeleton occurs in breast-fed infants receiving an intake of calcium as low as 200–300 mg day^{-1}. The most important factor governing calcium absorption is the degree of skeletal mineralization, mediated by a feedback mechanism, controlled by synthesis of 1,25-dihydroxycholecalciferol (a derivative of vitamin D). Others factors include a high dietary lactose content, the composition and structure of dietary fat, and a low buffering effect – all provided by human milk. Approximately 66% of calcium intake is absorbed. Although the requirement of calcium is probably 250 mg day^{-1}, the recommended intake is usually set in the region of 500 mg day^{-1}. The safety margin is necessary to allow for a variance in the absorption rate and to allow for individual variation in requirement.

Conclusion

An infant is not a small adult. During the first year of life, in particular, the infant has specific requirements related to physiology. As these requirements are becoming more fully understood, so more completely are we able to meet the requirement by adjusting infant milk formula. There are still gaps in our knowledge and these have been highlighted.

Breast- and Bottle-feeding

S Flack and V Shaw, Great Ormond Street Hospital for Sick Children, London, UK

Introduction

Breast milk is recognized as the best source of nutrition for healthy infants. It is species specific. Optimum infant nutrition from breast milk is dependent on adequate volume and mother's good health and nutritional status. The practice of demand feeding helps ensure adequate milk supply is maintained. Insufficient supply may be corrected by encouraging more frequent feeds or expressing milk. The infant's suckling and milk removal stimulate increased breast milk production.

Breast milk composition is not standard. It is influenced by maternal diet and by the mother's nutritional status. It changes during the course of lactation to meet the requirements of the developing infant. Milk shows diurnal variation; it varies from mother to mother, day to day, and even during a feed. At the initiation of a feed the milk has a low fat content (fore milk) and this increases up to fourfold during the feed (hind milk), to facilitate satiety.

The major change in breast milk composition occurs as the colostrum, the initial milk produced, changes to mature milk. Milk can be considered mature at about day 10 postpartum (Table 1).

The use of term pooled human milk as a sole source of nutrition for preterm infants remains controversial. It is recognized that early preterm mother's milk is more nutrient dense than term milk and is therefore more suitable for the premature infant's requirements. However, additional energy and nutrient fortification may be necessary.

Colostrum

This is the milk produced in the first few days after birth. It is compositionally distinctive from mature human milk (Table 1). It contains a higher concentration of protein, vitamin A, vitamin B_{12}, sodium, and some trace minerals. Initial colostrum has a high sodium content (60 mmol l^{-1}), which decreases rapidly as the paracellular pathways close. Much of the protein is present as secretory immunoglobulin A (sIgA) which functions to protect the gut from infection. It has a lower fat content than mature breast milk and, therefore, a lower energy content – 236 kJ (56 kcal) per 100 g.

Mature Human Milk

Energy

The energy value of mature human milk is quoted as 289 kJ (69 kcal) per 100 g in standard food tables in the UK. It is accepted that this is an average value, as milk composition is variable. Advances in technology have led to new estimates of its energy content. Doubly labeled water analysis has shown the metabolizable energy content of breast milk to be 2219 kJ (530 kcal) per liter at 6 weeks and 2428 kJ (580 kcal) per liter at 3 months. The clinical significance of this finding is unknown. Infant formulas are manufactured to provide a similar energy content to that of breast milk and contain approximately 2805 kJ (670 kcal) per liter; this has lead to speculation that infants receiving formula may be being overfed.

Protein

Protein in human milk is not homogeneous. It is traditionally subdivided into two main groups: casein and whey. Varying figures exist in the literature for total whey and casein content at different stages of lactation. The concentration of whey protein decreases during lactation. Some work suggests that the casein to whey ratio is 10:90 in colostrum, changing to a ratio of 45:55 in mature milk. Other literature suggests that whey proteins continue to represent about two-thirds of the protein in mature breast

Table 1 Comparison of the composition of colostrum and mature human milk

Nutrient per 100 g	*Colostrum*	*Mature human milk*

milk. The whey fraction's major components are α-lactalbumin, lactoferrin, and sIgA. The concentration of sIgA is approximately $9\,g\,l^{-1}$ in colostrum, falling to $1–2\,g\,l^{-1}$ in mature milk, representing about 10% of the protein. sIgA acts against enteric and respiratory immunogens. Lactoferrin also has an antibacterial affect. Its binding of free iron inhibits bacterial growth, enhances iron absorption, and stimulates proliferation of the mucosa. Casein and α-lactalbumin supply the essential amino acids.

Breast milk also contains nonprotein nitrogen, e.g., urea, nucleotides, and free amino acids such as taurine. Some of these constituents are believed to be important in the development of the infant. Taurine is the end product of methionine and cystine metabolism, but is considered a conditionally essential amino acid in infants. It is required for retinal development and digestion. It may also be protective against oxidative cellular injuries.

Fat

Fat is the main energy source in human milk, contributing 54% of the total energy in mature milk. The amount of fat and fatty acid composition in breast milk is variable and affected by maternal diet, nutritional status, and starvation (by the catabolism of her adipose tissue). It provides the essential fatty acids, i.e., linoleic (C_{18}:2*n*-6) and α-linolenic (C_{18}:3*n*-3) acids, contains long-chain polyunsaturated fatty acids (LCPs), and is a carrier for the fat-soluble vitamins (A, D, E, and K) and prostaglandins. The two principal functions of LCPs are as structural components of membranes and as the precursors of the biologically active eicosanoids.

Fatty acid composition also changes during the course of lactation. These changes can be linked to the requirements for neonatal brain development. Initial rapid cell division requirements are different from that of myelination.

Breast milk contains a form of inactive lipase, which is activated by bile salts in the duodenum and aids fat absorption in the infant. This is important, as pancreatic lipase secretion and bile salt conjugation are inefficient in the newborn.

Carbohydrate

Lactose, a disaccharide composed of glucose and galactose, is the main carbohydrate in human milk. It constitutes approximately 80% of the total carbohydrate. Oligosaccharides are also present in both colostrum and mature milk. The concentration of oligosaccharides in breast milk decreases as colostrum changes to mature milk. Oligosaccharides and lactose promote the growth of bifidus flora in the gut. Unabsorbed lactose is converted by intestinal microflora to lactic acid, creating an acidic pH which inhibits the growth of many pathogens and helps to protect the breast-fed infant from gastrointestinal infections. The additional benefit of this low pH is its effect on calcium. It increases the solubility of calcium and hence its absorption.

Vitamins and Minerals

Vitamin requirements can usually be met by adequate volume of breast milk from a well-nourished mother. Maternal diet influences the concentrations of most vitamins in human milk. Cases of clinical deficiencies of vitamins B_{12}, D, and K have been observed. Clinical rickets is rare but may occur in breast-fed infants, usually related to the infant or mother having limited exposure to sunlight. In the UK vitamin D supplements are recommended if there is concern about maternal diet or the infant's exposure to sunlight. Vitamin B_{12} is only found in animal products, therefore there have been case reports of deficiency (megaloblastic anemia) in breast-fed infants of vegan mothers. Breast milk has a low vitamin K content. Hemorrhagic disease occurs in approximately 2% of breast-fed infants. Additional vitamin K supplements are required during the period of exclusive breast-feeding. In the UK it is usually given intramuscularly at birth.

Breast milk provides all the major minerals and trace elements known to be essential for healthy infants in sufficient quantities for at least the first 4 months. The levels of calcium, phosphorus, and iron are low, but their bioavailability from human milk is excellent. However by 6 months additional iron and zinc supplements may be necessary; these requirements will be met by a balanced weaning diet.

Water

Mature human milk is 87% water. The fluid intake of an exclusively breast-fed infant will always be adequate provided demand feeding is practised. Additional water supplements are unnecessary even in very hot climates.

Nutritional Value of Cows' Milk and Infant Formula

Unmodified cows' milk is not a suitable feed for infants. It has a high renal solute load, inadequate vitamin and mineral profile, and is poorly absorbed. Infant formula is manufactured from modified cows' milk as a substitute for human breast milk. Available formulas in the UK conform to European Community compositional guidelines. These formulas may be nutritionally adequate but they lack the human anti-infective, humoral, and cellular factors found in breast milk.

Advantages of Breast-Feeding

There are numerous advantages of breast-feeding, including nutritional, emotional, physiological, and economic factors. Breast-feeding guarantees regular close contact between mother and child, promoting the emotional bonding process.

Many of the nutritional advantages of breast milk have already been discussed. In summary, milk from a healthy mother provides all the nutrients in an appropriate and easily absorbable form to meet the requirements of the infant.

Additionally, this feeding method is cheap, safe, and offers anti-infective advantages. Cross-infection from adults to the infant may be reduced; as only the mother is able to breast-feed, the number of adults handling the child may be reduced. Breast-feeding is convenient, as the milk will always be available at the correct temperature and ready to feed. The mother does not need to buy equipment, sterilize bottles and teats, or prepare infant formula in hygienic conditions. Many constituents in human breast milk stimulate the development of the infant's own immunity. Through the milk the mother is able to transfer to her infant antibodies (IgA) which are specific antigens against their environment. This fills the 'immunity gap' whilst the infant's immune system develops and its gut epithelial cells mature to be able to produce IgA. Other important defenses include macrophages (ingest foreign particles), lactoferrin (bacteriostatic), milk leukocytes (phagocytosis of bacteria, viruses, and fungi) and lysozyme (bactericidal and anti-inflammatory activity). Whilst the baby's own immune system matures, these bioactive milk constituents act synergistically to provide a passive immunological support system for the infant.

Epidemiological evidence suggests that breast-feeding has a protective effect against diarrhea, respiratory infections, necrotizing enterocolitis, and otitis media. Research has recently focused on possible links between infant feeding practice and chronic illness such as Crohn's disease and childhood lymphoma in later life. The American Academy of Pediatrics reviewed feeding method and incidence of type 1 insulin-dependent diabetes mellitus (IDDM). It recommended breast-feeding as the main source of infant nutrition and avoidance of intact cows' milk protein in the first year of life if there is a strong family history of IDDM.

The role of breast-feeding in protecting the infant against the development of atopic and allergic disorders in later life is controversial. Further research is needed in this area. It is hypothesized that the immunological factors in breast milk may protect the infant from absorbing intact allergens. Breast-feeding results in delayed exposure to many allergenic compounds in foods. However, components of the mother's diet may be passed to the infant via breast milk. The role of maternal exclusion diets in exclusive breast-feeding for high-risk infants is also controversial. Allergy to peanut is potentially life-threatening and for this reason, in the UK, the Committee on Toxicity of Chemicals in Food, Consumer Products and the Environment has suggested that pregnant and lactating women should avoid peanuts if they themselves, the father, or any sibling of the baby is atopic.

Enhanced cognitive development is associated with breast-feeding. The role of LCPs in breast milk and infant development has been the subject of recent research. Docosahexaenoic acid (DHA) (C_{22}:6*n*-3) and arachidonic acid (C_{20}:4*n*-6) are considered essential nutrients in early infancy. Dietary DHA appears to be essential for optimal membrane function in the nervous system and thus cognitive development in premature infants. Many infant formulas now contain added LCPs but other constituents of breast milk, e.g., growth factor, hormones, and choline, may additionally aid brain maturation.

Malnutrition can result from either the overconcentration or overdilution of infant formulas. There is no risk of this with breast milk. Breast-feeding is linked with child survival in developing countries due to its protective effect against diarrheal illness, environmental factors (e.g., lack of clean water supply), and economic factors (e.g., expense of buying adequate volumes of infant formulas).

It is known that breast-feeding has advantages for maternal health. Breast-feeding stimulates contraction of the uterus. It is associated with weight loss and thus a more rapid return to prepregnancy weight. Some epidemiological evidence suggests a link between extended lactation and reduced risk of premenopausal breast, ovarian, and endometrial cancers.

Lactation produces hormonal changes which suppress fertility. At the population level, this lactational amenorrhea enables prolonged birth spacing. Additionally, in some societies there are taboos against sexual intercourse during the period of lactation. Breast-feeding therefore has a major contraceptive effect.

Reasons for Bottle-Feeding

There are few contraindications to breast-feeding; the main reasons are related to the health and medication requirements of the mother. Maternal medication usage may prevent breast-feeding. Most drugs can be transmitted to the infant via breast milk. Drugs may cause toxicity in the infant, e.g., ergotamine, and others inhibit the suckling reflex, e.g., phenobarbitone.

The *British National Formulary* is an important resource for health professionals to check the suitability of a medicine for breast-feeding women. UK recommendations are that only essential medications should be prescribed to breast-feeding mothers.

There are certain medical conditions in the baby where breast-feeding is contraindicated: galactosemia, long-chain fatty acid oxidation disorders, and glucose-galactose malabsorption.

Breast-feeding is known to protect against bacterial infections. Certain viruses however can be transmitted from mother to infant in breast milk. The largest global health problem is related to human immunodeficiency virus (HIV) transmission via breast milk. The rate of vertical transmission from mother to infant in human milk is between 5 and 15%. In England and Wales the incidence of vertically transmitted HIV infection is increasing. In the UK the current recommendation is that mothers who are HIV-positive, or in a high-risk category but unsure of their serological status, should not breast-feed. Experts argue that if antenatal HIV testing was more widespread, there would be an opportunity to counsel against breast-feeding and insure early diagnosis and treatment of infected children.

In the UK bottle-feeding is a safe alternative to breast-feeding. In developing countries with high infant mortality rates the situation is very different. The known protective effect of breast-feeding against gastrointestinal infection is very important. It has been estimated that bottle-fed infants are 14 times more likely to die from diarrheal diseases and four times more likely to die from pneumonia than exclusively breast-fed infants. In these countries the risk of vertical HIV transmission needs to be weighed against the risk of gastrointestinal infection caused by inadequate water supply and sanitation. The United Nations has recently issued a new directive stating that all women should be informed of the risk of vertical transmission via breast milk due to the escalating problem of HIV. It recommends the decision to breast-feed should be made by the mother due to the diversity of situations in developing countries.

There remain concerns that women who do not breast-feed in developing countries may be stigmatized, and there are concerns over the safety of alternative feeds. Previously, infant deaths in developing countries resulted from the problems of mixing infant formulas in unsuitable environments. Recently it has been hypothesized that rates of HIV transmission are affected by mastitis infection and vitamin A deficiency in pregnancy. A 1994 study of HIV-infected women in Malawi found that 32% of those who were vitamin A-deficient during pregnancy had passed HIV on to their infants. In contrast, only 3% with adequate vitamin A levels did so. If health strategies are implemented to alter these states, breast-feeding may be a recommended feeding method for infants of HIV-infected women in the future.

In the UK women's choice of feeding method is influenced by social and cultural factors. The Office for National Statistics identifies that 94% of mothers have decided on feeding method antenatally. They identified that 36% of the mothers surveyed in the UK intended to bottle-feed. Reasons for planning to bottle-feed included disliking the idea of breast-feeding and embarrassment associated with breast-feeding. In western societies taboos continue to be associated with breast-feeding in public. The other major reason for choosing to bottle-feed is that the mother is not the sole feeder of the child, so other people can help with the feeding.

Current Practices

Breast-feeding in developing countries remains almost universal. It remains common in Africa for most infants to be breast-fed into the second year of life. As these countries become more urbanized, breast-feeding trends alter. Generally, women in rural areas are more likely to breast-feed than their urban counterparts. This change may reflect the availability of infant formula, limited support networks, and variations of maternal employment patterns. The wealthiest and most highly educated in developing countries are less likely to breast-feed. The converse is true in developed countries. Immigrants' feeding choice is affected by the norm in both their country of origin and resident country.

In the UK, government policy consistently supports the promotion of breast-feeding. Since the 1970s infant feeding practices have been surveyed and results analyzed, leading to Department of Health initiatives to promote breast-feeding, e.g., National Breastfeeding Awareness Week. This has been an annual event since 1993. In 1995, the Office for National Statistics survey reported an increased incidence of breast-feeding (**Table 2**). The composition of the sample population contained more mothers aged over 30 from nonmanual social class groups and with higher education levels. Each of these factors is associated with increased incidence of breast-feeding. When the results are standardized for the age and level of education, no increase in breast-feeding incidence in England and Wales is demonstrated. In Northern Ireland, however, standardized rates increased from 36% in 1990 to 41% in 1995.

The World Health Organization recommends exclusive breast-feeding for at least 6 months. A reduced

incidence of gastrointestinal infection is associated with breast-feeding for a minimum of 13 weeks. Results for the UK in 1995 showed that 20% of women had stopped breast-feeding at 2 weeks postpartum and 60% by the age of 4 months (Table 3). Initiatives are clearly needed to improve the duration of breast-feeding.

Reasons for stopping breast-feeding included 'insufficient milk.' This may be related to anxiety and lack of professional support and advice. Establishing breast-feeding is no longer instinctive in developed countries. Painful breasts, baby not suckling, not liking breast-feeding, and length of time taken to feed were other common reasons for cessation of breast-feeding.

The mother's experience of breast-feeding in hospital influences its duration. The giving of infant formula complementary feeds continues to exert a strong effect on the length of breast-feeding. In 1995, 34% of mothers whose infants received a bottle in hospital stopped breast-feeding within the first 2 weeks postpartum. Delays in first holding the baby significantly affected the likelihood of establishing breast-feeding. Only 51% of mothers who were separated from their baby for more than 12 h successfully initiated breast-feeding. These issues are being tackled by educating all health care professionals and the adoption of UNICEF's Baby Friendly Hospital Initiative. Between the 1990 and 1995 Office of National Statistics surveys, an increase in the number of babies kept at the mother's side at all times and the reduction in the number of breast-fed babies offered bottled formula during their hospital stay were seen. This is an encouraging trend.

Education and Advice

The 1995 Office of National Statistics survey showed that nearly all mothers (99%) had antenatal checkups and approximately 70% of new mothers attended antenatal classes. These are ideal opportunities in which to offer advice about feeding methods. The survey also showed that either a midwife or nurse gave 86% of new mothers help and advice at their first breast-feed in hospital. During their hospital admission, 35% of breast-feeding mothers experienced difficulties. The majority of these women (82%) received help and advice from health professionals and this has been shown to influence feeding duration. As about one-third of first-time mothers leave hospital within 48 h, access to professional support is restricted and potentially the declining lengths of hospital postpartum stay may impact on initiation and duration of breast-feeding.

After discharge from hospital, the mother is supported at home for the first 10 days by the midwife. Care is then transferred to the health visitor. Additionally several voluntary organizations can offer support on breast-feeding; these include the National Childbirth Trust, La Leche League and the Association of Breastfeeding Mothers.

Weaning

A MacDonald, The Children's Hospital, Birmingham, UK

Introduction

The term 'weaning' comes from the word 'wenian,' which means 'to accustom.' It is a gradual process through which an infant moves from total dependence on milk to eating normal family meals. The most widely used definition is the process of introducing semisolid food into the infant's diet in addition to milk. Definitions of weaning vary from country to country and include 'the process of expanding the diet to include food and drinks other than breast or infant formula,' 'cease to be suckled,' or 'complete discontinuation of breast-feeding.' As many of the foods initially introduced are not truly solid, the German word 'beiokost' is sometimes used to refer to these foods as a group.

History of Weaning

In ancient Egyptian and Babylonian times, the common age of weaning was 3 years. In the sixteenth and seventeenth century, pap (mixtures of flour, water, and sometimes milk) and panada (a broth of bread, flour, meat or lentils, and sometimes milk) were described as infant foods in the literature. Weaning was quite a dangerous time when started in early infancy, and Queen Anne is said to have lost 18 children from spoon-feeding and wet nursing. The infant food industry started in 1867. By the latter part of the nineteenth century, there was a more cautious approach to solid-food introduction. It was widely recommended that vegetables, particularly green, were not given to infants before 2–3 years of age, although cereals and custards were commonly introduced by 4 months. The situation changed again in the early part of the twentieth century with the trend towards earlier weaning in developed countries. This continued in the UK until the 1970s and 1980s, although the latest Office of National Statistics (ONS) report would suggest that more parents are delaying the introduction of solids until at least 3 months of age.

Why Wean?

There are four important reasons for weaning. These are:

- If an infant is still unweaned by 6 months, the intake of energy is likely to be inadequate. Infants double their birth weight in the first 4–5 months of life (DOH, 1994), and breast or formula milk can no longer meet energy needs. Late weaning is associated with a failure to thrive in infants.
- Breast milk provides little iron and vitamin D. In the later stages of lactation, zinc and copper concentrations also begin to fall. However, the bioavailability of nutrients in breast milk is good, and no other foods are usually needed until the age of 4 months, providing the mother is taking a good mixed diet. In addition, for the first 4 months, the full-term infant relies on iron stores to help meet requirements. Sooner or later, these stores will be depleted, and iron-deficiency anemia will occur unless there is a supply from the weaning diet. Formula milk contains higher quantities of iron, vitamin D, zinc, and copper, but with a different bioavailability than breast milk, but for other reasons, it is still recommended that solids be introduced by 6 months.
- There are important developmental reasons for introducing solid food. The neuromuscular coordination needed to eat solid foods develops during

Table 1 Developmental changes relevant to weaning

4 months
Can maintain posture if supported in a chair
5 months
Can take soft, puréed food from a spoon, form a bolus, and swallow it
Can hold objects and put them to their mouths to suck
6 months – 8 months
Teeth begin to erupt
Sits without support
Can chew
Can hand feed items like biscuits
Learns to shut mouth, turn head, and indicate feed refusal
9–12 months
Can sit easily
Attempts to use spoon
Indicates and understands 'no'
Pincer grasp of small objects

the early months of life. At 4 months, most infants can put objects to their mouths, take soft foods from a spoon, from a bolus and swallow (Table 1). From about 5 months, teeth begin to erupt, and infants are able to chew. Feeding behavior therefore proceeds from sucking to biting and chewing. Chewing improves the mouth and tongue coordination, which is important for speech development. Introduction of different tastes and textures promotes biting and chewing skills. However, if introduction of solids is delayed beyond 6 months, the weaning process becomes more difficult. Infants are less receptive to new tastes, and it is more difficult to teach older infants to chew. From 7 months of age, infants learn to shut their mouths, turn their heads, and refuse to feed.

- The fourth reason is to provide a variety of tastes and flavors. This will enable the infant to eventually accept and enjoy normal family meals.

When to Wean?

The ideal time to introduce solids will vary between infants and differ between cultures. In traditional societies, it is still practice for infants to be almost entirely breast-fed for the first year of life. In many Western countries, particularly Europe and North America, it is recommended that 'the majority of infants should not be given solids before the age of four months but a mixed diet should be offered by the age of six months'. Early weaning is discouraged for a number of reasons:

- Poor muscular coordination. Before 3 months of age, infants have poor head control, and back support is weak, so it is difficult to hold infants in a position where they can be fed and can swallow semisolid food.
- The kidney is immature and may not be able to cope with a higher renal solute load, and this could lead to higher plasma concentrations of sodium and urea if there is insufficient water available for their excretion.
- The gastrointestinal tract is immature, intestinal and pancreatic enzyme production is not fully developed, and the gut is more permeable to some of the foreign proteins introduced with food, thus increasing the risk of allergic reactions.
- Early weaning in the developing countries has been associated with a poorer growth velocity than in infants who are exclusively breast-fed. This is probably associated with the lower energy density of the cereal-based gruel offered, resulting from the addition of extra water to produce a food of suitable consistency. Also, iron bioavailability from cereal-based gruel is low. Another major problem is that contaminated weaning foods causes infection and diarrhea. This, in turn, increases nutritional requirements but often reduces an infant's appetite and overall nutritional intake.
- Solid feeding before 15 weeks is associated with increased wheeze during the first seven years of life. There is also evidence that early exposure to solids is associated with an increased risk of eczema. In a group of children studied until the age of 10 years, it has been reported that infants given solids during the first 4 months were 1.6 times more likely to develop eczema than infants not given solids before 4 months.
- There is evidence that early introduction of solids is associated with increased body fat and weight in childhood.
- There is some suggestion that early introduction of gluten in solids may contribute to a higher incidence of coeliac disease. In Glasgow, for example, records indicate that increased numbers of children were admitted to hospital with celiac disease and were diagnosed earlier during 1958–1965 and 1966–1973 than during 1950–1957. Cereals containing gluten were also introduced earlier in Glasgow during 1958–1963, and 91% of infants were given gluten by 3 months of age in 1965.

In Western countries, there is still a trend towards early weaning. The ONS survey reported that 55% of infants had been given solids by 3 months and 91% by 4 months. Babies of Asian origin in the UK were given solids slightly later than white babies, but 90% still had solids by 4 months.

Nutritional Requirements of the Weaning Infant

In the early months of infancy, the nutrient intake is derived almost totally from human or infant formula,

but in later months, the diet becomes more diverse with the introduction of solid foods. In ensuring that the provision of all nutrients is met for infants, a careful selection of solid foods given in the appropriate amount is required.

Energy

Energy should be provided in adequate quantities throughout infancy to provide fuel for the basal metabolic rate (BMR), growth, and physical activity. The amount of energy required per kilogram of body weight declines gradually, owing to a decreasing growth rate and BMR, even though the energy requirements for activity will increase as the infant becomes older.

The UK estimated average requirements (EAR) for energy are given in Table 2. These are based on results of studies using the doubly labelled water technique of measurement that reflects the total energy expenditure in free living infants and children with additions made for the energy value of new tissue deposited during normal growth.

Despite the introduction of solids, milk still needs to provide a significant proportion of the total energy intake throughout the first year of life. Fat contributes 50% of the energy in breast and infant formula milk and is the main source of energy in infants less than 6 months of age. It still continues to be important in childhood, and infants over 6 months of age will still need 500–600 ml of milk daily. From studies estimating the nutrient intake of older infants, solids contributed 52, 57, and 64% of the total energy intake at between 7 and 8 months, 9 and 10 months, and 11 and 12 months, respectively, whilst milk made up the rest of the energy deficit.

However, adequate energy from weaning foods should be assured, and the energy density of weaning foods is important. If it is high in carbohydrate and low in fat, the food will be very bulky, and it may be difficult for the infant to eat sufficient quantities to meet their energy needs. Failure to thrive, which is a common problem in developing countries, may result.

Protein

Protein is a crucial determinant of linear growth; it provides nitrogen and essential amino acids for synthesis of body tissue. The DOH (1994) recommends an adequate intake of protein with a proper balance of essential amino acids during weaning (Table 3). The protein/energy ratio is also important, and it is recommended that infants between 6 and 9 months have an intake of not less than 1.74 g of protein per 100 kcal. In developed countries, there should be few problems in achieving an adequate energy/protein ratio, but in developing countries, if weaning foods such as rice and maize are supplemented with oil to improve energy density, this would significantly reduce the energy/protein ratio below the minimum safe ratio.

Vitamins and Minerals (Table 4)

Vitamin A This is required for growth, normal development, and differentiation of tissues. The 1988 FAO/WHO Expert Group considered that a daily intake of 350 μg retinol equivalents would meet the needs of all healthy infants and allow the building and maintaining of sufficient liver stores.

Vitamin D This has an important metabolic role in the control of calcium homeostasis and deposition of calcium in bones and teeth. There are two main forms of vitamin D: cholecalciferol, formed by the action of sunlight on 7-dehydrocholesterol, which occurs naturally in the skin of man, and ergocalciferol, a synthetic source of vitamin D. Weaning infants are vulnerable to poor vitamin D status. Weaning diets are generally low in vitamin D, and breast milk contains little vitamin D. Infant formula is fortified with vitamin D, and provided adequate amounts are consumed, infants fed these products are unlikely to become depleted. In the UK, it is recommended that

Table 2 Estimated average requirements for energy during weaning (DOH, 1991)

Age (months)	*Energy requirement (kcal kg^{-1} day^{-1})*
3	100
6	95
9	95
12	95

Table 3 Reference nutrient intake for protein during weaning (DOH, 1991)

Age (months)	*Protein (g^{-1} kg^{-1} day^{-1})*
4–6	1.6
7–9	1.6
10–12	1.5

Table 4 Reference nutrient intake for vitamins and minerals during weaning (DOH, 1991)

Nutrient	*Age*		
	0–3 months	*4–6 months*	*7–12 months*
Vitamin A (μg)	350	350	350
Vitamin D (μg)	9	9	7
Vitamin C (mg)	25	25	25
Calcium (mg)	525	525	525
Iron (mg)	1.7	4.3	7.8
Zinc (mg)	4.0	4.0	5.0

vitamin supplements including vitamin D be given to breast-fed infants from the age of 6 months and to formula-fed infants when the volume of milk decreases below 500 ml daily.

Iron This is an important nutrient during weaning, which is necessary for the structure of the heme part of hemoglobin, as well a component of myoglobin and many enzymes. For breast-fed infants, after the age of 6 months, the amount of iron from breast milk is insufficient to meet increasing needs. Therefore, adequate intakes of iron, from heme (meat) and non-heme sources (cereals, pulses, and vegetables), should be encouraged with foods rich in vitamin C to aid absorption. Furthermore, the absorption of iron from breast milk is greater if breast feeds are given separately from solid food as inhibitors in the food bind the iron from breast milk in unabsorbable complexes. Formula milks in the UK are fortified with iron, and providing infants are taking over 500 ml daily, they are at less risk of iron-deficiency anemia. However, it is still important that iron-rich weaning foods be encouraged.

Zinc This is a component of several mammalian enzymes and is active in many metabolic pathways. Zinc deficiency may limit growth and may be a vulnerable nutrient during the weaning period. In the UK, there is evidence that the average daily intake of zinc is below the reference nutrient intake. Although meat and meat products are the richest sources of zinc, these foods provided only 10% of the dietary zinc intake.

Which Foods Should be Given?

Initial foods should be semisolid and have a smooth consistency and bland taste, and suitable first foods are cereal, such as baby rice or puréed home cooked rice, mashed potato, custard, plain (unsweetened) yogurt and puréed fruit, and vegetables. This should then progress to puréed meat, pulses, and a wider variety of cereals. In many parts of the world, the first food to be introduced is traditionally a cereal. In western European cultures, a commercially prepared infant cereal containing added vitamins and minerals is commonly the first food. In developing countries, the local staple cereal is more likely to be given, and this may include cereals such as corn, barley, oatmeal, millet, sweet potato, cassava, rice, plantain, yam, arrowroot, potato, or sago. These are mixed to a porridge or paste with milk or water.

Between the age of 6 and 12 months, the texture of foods given should gradually progress from semisolid to soft family foods. From the age of 6 months, minced or mashed food with soft finger foods can be encouraged. Meat should be coarsely puréed; wholemeal cereals or instant oat cereal can be given in addition to well-cooked egg. Suitable finger foods include soft fruits, e.g., banana and melon, cheese fingers, soft cooked carrot and fingers of toast, chappatti, and pitta bread.

From the age of 10 months, foods such as meat should be minced or finely chopped. Cooked vegetables need only be chopped, and pasta dishes with small shaped pasta can be given. Finger foods are particularly important at every meal to encourage the infant to participate in self-feeding.

Commercial Versus Home-made Family Weaning Foods

Homemade family weaning foods The use of appropriately home-made foods is encouraged, and in the UK, about 40% of infants are given some home-made weaning foods. They have several advantages: (1) they accustom an infant to the taste of adult-based food; (2) they are cheap and easy to prepare; (3) wastage is low; and (4) meat-based Halal weaning foods can be prepared for Muslim infants. Unfortunately, analysis of home-made weaning foods from the UK has revealed that some meals contain low amounts of energy, iron, and zinc but high amounts of nonstarch polysaccharides, protein, and sodium. Intakes of iron are also lower in infants receiving mainly family foods. Typical home-made foods given to a group of 6- to 8-month-old infants from a deprived inner city area in the UK were mashed potato, tinned spaghetti, and baked beans. However, breast or infant formula milk or cereal can be added to home-made weaning foods to the improve energy and nutrient density.

Commercial baby foods In the developed world, commercial weaning foods (tins, jars, and packet foods) are popular, especially cereals, ready meals, and desserts. They may be fortified with extra vitamins and minerals, and contain no added salt. Even with commercial baby foods, there are some cultural differences concerning manufactured foods given to infants. The Italians prefer individual constituents, i.e., a meat dish to which pasta can be added, whereas the British prefer composite sweet and savory dishes.

The Codex Alimentarius Commission (WHO/FAO) has set compositional standards for baby foods. In 1996, the European Commission issued a directive on processed cereal-based foods and baby foods for infants and young children (96/5/EC); it was amended in 1999. The regulations prescribe manufacturing, compositional and labelling requirements

and prohibit the sale of any processed cereal-based food or baby food, unless it complies with the regulations. The UK government has also published an expert report on additives in food specially prepared for infants and young children, which recommended that additives should only be used when there is a strong justification on technological grounds.

Although not essential, most mothers in developed countries use commercially produced weaning foods at some stage because they are so convenient. In the early stages of weaning, dried products can be made up in small quantities, so avoiding waste. However, commercial weaning foods are relatively expensive, there is a limited range of vegetarian foods, and there is a tendency for some parents to keep infants on strained varieties for prolonged periods of time, which may contribute to the delayed acceptance of more lumpy food.

Foods Avoided During Weaning

Salt

In the West, it is widely recommended that salt should not be added either to weaning foods during the cooking process or to the food at the table, as the developing kidney is unable to excrete large sodium intakes. Excessive sodium intake in young infants is associated with hypernatremia. In addition, there is some concern that a high salt intake in infancy and childhood may cause hypertension in later life; the evidence for this is unconvincing.

Sugar

It is recommended in North America and Europe that sugar should be kept to a minimum and should not be added to foods during preparation. The preference for sweet foods and drinks has been demonstrated even in preterm infants. To avoid encouraging the taste for sweet foods and to reduce the risk of dental caries, sugar should be avoided as much as possible. Even so, in the UK, it is common to introduce sugar-based foods early in the diet. In the MAFF survey looking at infant feeding practices between 6 and 12 months, 62% had been given sweets and chocolate, 70% received biscuits, and 45% of mothers gave milk-based dishes sweetened with sugar.

Gluten

There are many disputes about the best time to introduce gluten into the diet. Delayed introduction is associated with an increased age of onset, although there are those who maintain that it decreases the incidence. Challacombe *et al.* (1997) suggest that later introduction of gluten, increased use of gluten-free foods for weaning, and increased incidence of breast-feeding are associated with a decreasing incidence of celiac disease and transient gluten intolerance. However, in Sweden, a doubling of the gluten content of commercial baby foods was associated with an increased incidence of celiac disease from 1.7 children per 100 live births during 1978–1982 to 3.5 per 1000 thereafter. This occurred in spite of an increased prevalence and duration of breast-feeding and the delay in the introduction of dietary gluten from 4 to 6 months. Gluten-sensitive individuals who are breast-fed and who are introduced to gluten relatively late may not present clinically during weaning, although the disorder is still thought to manifest at an older age, and the cumulative prevalence is unaffected. Therefore, to prevent celiac disease developing at least during the early weaning period, when the infant is particularly vulnerable nutritionally, it is recommended by most health professionals that cereals given to infants under 6 months should be gluten-free.

Food Allergens

Infants are most vulnerable to the initiation of food allergy in the first months of life, and the risk of food allergy is greatly increased by family history of atopic disease such as eczema and asthma. When there is a strong family history of allergy, mothers should be encouraged to breast-feed for 6 months or longer. Weaning should be particularly discouraged before 4 months, and foods traditionally regarded as allergenic (e.g., cows' milk, soya protein, gluten, eggs, fish, and nuts) should not be introduced until 6 months of age at the earliest. In the UK, a working group for the Committee on Toxicity of Chemicals in Food, Consumer Products, and the Environment recommended that peanuts or peanut products should be avoided until 3 years of age in all children with a parent or sibling with an atopic disease.

Suitable Milks During Weaning

Breast milk This should be encouraged, but from 6 months of age, breast milk cannot supply the requirements for several micronutrients, including iron, copper, zinc, and vitamin D. Dietary sources should be given either as part of the weaning diet or as specific supplements, e.g., vitamin D supplements.

Infant formula Providing it is iron-fortified, it should be continued until the age of 1 year. It is a particularly good source of vitamin D, and infant formula sold in the UK is also rich in iron. Providing that a volume of 500 ml daily is taken, there should be no need to give extra vitamin supplements.

Follow-on formula This is intended for older infants over the age of 6 months. It is based on modified cows' milk. It contains less protein, calcium, and phosphorus than cows' milk but more than standard infant formula. Most follow-on formula contains almost double the iron and 45% more vitamin C than standard infant formula. It can provide a useful drink for older infants if breast-feeding has been stopped or the volume of standard infant formula is less than 400 ml daily. However, follow-on formula should not replace breast milk or standard infant formula if the volume of either is adequate.

Whole cow's milk This is not suitable for infants under 1 year as the main drink. It is low in iron, vitamin C, and vitamin D. It may be used in small quantities in the preparation of solid foods.

Goat's and sheep's milks These are low in iron, vitamin D, and folic acid and should not be given to infants under 1 year of age. Although these milks may be perceived as less allergenic or else providing special nourishment, none of these claims have been substantiated.

Problems Associated with Weaning

Iron-deficiency Anemia

Iron-deficiency anemia in later infancy and the toddler years is common throughout the world, and simple dietary iron deficiency is the most common cause. In the UK, it is particularly frequent in ethnic and socio-economically deprived toddlers, and 4–28% of older infants have been reported to have iron-deficiency anemia. It can cause psychomotor delay, apathy, irritability, reduced attention span, pallor, decreased resistance to infection, reduced exercise capacity, and poor appetite. It is associated with prolonged use of breast-feeding, early introduction of whole cow's milk and inadequate dietary iron during weaning. There have been many initiatives to try and reduce the prevalence of iron-deficiency anemia in the Western world. These include screening, health education, iron fortification of food and extension of the use of iron-rich infant formula. Although large-scale dietary education has failed to reduce iron-deficiency anemia in the UK (Child *et al*., 1997), programs to provide supplemented food containing iron to target groups have been shown to be successful in the USA. In addition, in the UK, a project extending the use of iron-fortified follow-on formula beyond 1 year significantly reduced the prevalence of iron-deficiency anemia.

Rickets

Prolonged deficiency of vitamin D can result in rickets. The main symptoms include skeletal deformity, delayed dentition, bone pain, muscle weakness, hypocalcemia, misery, and failure to thrive or short stature. Children under 3 years are particularly vulnerable to a poor vitamin D status because of demands resulting from the high rate at which calcium is being laid down in the bone. Although it is uncommon in Europe and North America, new cases are still being reported particularly in northern climates (Gessner *et al*., 1997) and immigrant children (Brundvand and Nordshus, 1996). In the UK, low-serum 25-hydroxycholecalciferol concentrations have been noted in 20% of Bangladeshi, 34% of Pakistani, and 25% of Indian 2-year-old children living in England (Lawson and Thomas, 1999). Low 25-hydroxy vitamin D levels have been noted in the winter in British children not taking vitamin D supplements.

Rickets is commonly reported in some hot climates. In a recent Nigerian study, overt rickets was found in 2.4% of households. Factors in hot climates such as increasing urbanization and the tendency of mothers and their young children to avoid exposure to sunlight, either by remaining indoors or in the shade or by covering the skin, must all contribute to a decreased endogenous synthesis of vitamin D, in combination with a poor vitamin D or calcium intake. In western countries, prolonged breast-feeding by mothers of poor vitamin D status, early introduction of whole cows' milk, poor weaning sources of vitamin D, little exposure to sunlight, and even the use of sunscreen are contributing factors.

Vitamin A Deficiency

In the developing world, vitamin A deficiency is one of the most common causes of blindness in children, particularly in the Middle east, the Indian subcontinent, and South-east Asia. It causes xerophalmia, keratomalacia, and eventually blindness. This is due to reduced infant stores of vitamin A due to maternal deficiency, low vitamin A-containing breast milk, and weaning diets low in preformed retinol from animal food. Vitamin A deficiency is often accompanied by protein-energy malnutrition. Vitamin A supplements, even in the absence of clinical overt deficiency, reduce child mortality.

Weaning Practices in Developing Countries

The weaning infant is potentially at risk in developing countries, and many nutritional problems arise with

the introduction of solids. The need to introduce nonmilk food sources with only the availability of rather crude preservation processes, poor hygiene, sanitation, and inadequate water supplies introduces the risks of gastrointestinal and parasitic infection because of the heavy contamination of foodstuffs with infecting organisms. In rural Bangladesh, a significant association has been found between the frequency of isolation of *Escherichia coli* in the weaning foods and *E. coli* diarrhea in the infants consuming them, and there can be little doubt that food plays an important role in the epidemiology of diarrhea in young children. The effects of infection lead to anorexia and pyrexia with increased metabolic requirements, and this can only serve to exacerbate any effects of a poor nutritional intake. In addition, many infants have been breast-fed for prolonged periods of time without weaning solids, and when they are introduced, it is probably a low-energy-density, cereal-based gruel that may be given only once or twice a day. The continued effects of deteriorating nutritional status and infection may lead to protein-energy malnutrition.

Feeding Problems

E M E Poskitt, Department of Public Health Nutrition, London School of Hygiene and Tropical Medicine, UK

Introduction

Nutrition is of great importance in infancy. Infants are entirely dependent on others for their nutrition and carers may have difficulty recognizing their needs. This dependence and infants' high nutritional requirements for growth and development make malnutrition a relatively common problem. Prolonged malnutrition can impair both somatic growth and brain development.

Failure to Thrive

Failure to thrive (**Figure 1**) is failure to gain in height and weight at the expected rates (determined from recognized growth data). The causes are numerous (**Table 1**) but if the precipitating causes can be successfully treated, failure to thrive is followed by accelerated or 'catch-up' growth (**Figure 1a**), provided extra food meets the nutritional needs of accelerated growth. Without extra nutrients, catch-up growth is likely to be incomplete. Affected infants may then resume normal growth rates, but along lower growth centiles than previously (**Figure 1b**).

Some children with growth below the third centile or ≈ -2SD weight-for-age or below (outside the recognized 'normal' range) may be labeled as failure-to-thrive although growing at more or less normal rates for age. They may have been low-weight for gestational age at birth and always small (**Figure 1c**). These constitutionally small children may show delayed bone age, delayed adolescence, and sometimes late catch-up to more normal adult size.

Careful dietary histories should indicate which infants are failing to thrive because of inadequate intakes, inappropriately constituted feeds, or inappropriate weaning practices. Average milk or formula intakes are 150 ml kg^{-1} day^{-1} (441 kJ kg^{-1} day^{-1}) for full-term normal infants. Around 6–8 weeks of age intakes often stabilize despite continuing

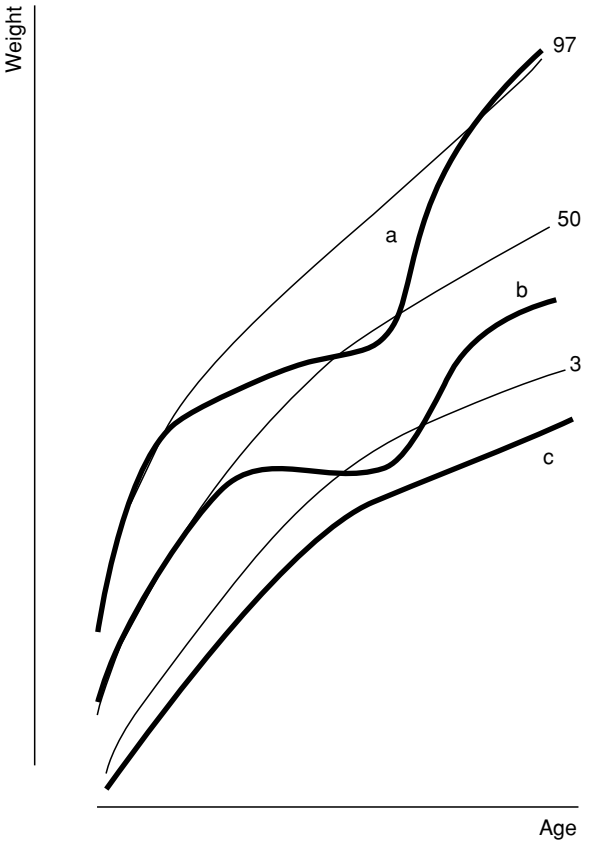

Figure 1 Weight of children with (a) failure to thrive and complete catch-up growth; (b) failure to thrive and failure of complete catch-up growth; and (c) constitutional small size plotted against the 3rd, 50th, and 97th weight-for-age centiles.

Table 1 Classification of nutritional problems associated with failure to thrive

Basic problem	*Examples*
Inadequate intake	Poverty; famine; ignorance of nutrient needs
	Vomiting: all causes
	Feeding problems, including neurological damage
	Anorexia
Increased losses	Protein-losing enteropathy
	Glycosuria; proteinuria
	Exfoliative skin conditions
	Suppuration
Failure to absorb food	Cystic fibrosis
	Gluten-sensitive enteropathy
	Giardiasis
	Lactose intolerance
Failure to utilize food	Inborn errors of metabolism
	Endocrine problems
	Micronutrient deficiencies, e.g., zinc
	Chronic renal failure
	Emotional deprivation
Increased requirements	Small-for-dates and premature infants
	Catch-up growth
	Congenital heart disease: left-to-right shunt

increases in weight and intakes $kg^{-1}\,day^{-1}$ thus decrease.

It may be difficult to assess the adequacy of milk intake in breast-fed infants. Normal growth velocities and general contentment after feeding suggest intakes are adequate. If there is concern, weighing infants in clean diapers prior to breast-feeding and then weighing them again after feeding without diaper change provides some indication of the weight, and thus the volume, of milk consumed. This test weighing must be for all feeds over 24 h since infants may consume large feeds early in the morning and in the evening, but relatively small amounts at other times of day.

When breast milk output seems insufficient for an infant's needs, improving maternal nutrition and increasing the frequency of suckling may improve milk secretion. Current recommendations are that infants should be exclusively breast-fed until at least 4 months of age and preferably until 6 months of age. Usually breast-feeding failure arises because of inappropriate feeding practices (e.g., infrequent suckling, especially in early lactation, or incorrect positioning and failure by the infant to latch on). Advice on feeding technique may resolve the problems. However, mothers who are sick or very malnourished may sometimes fail to produce sufficient milk to support normal infant growth. The decision whether to continue struggling to increase breast milk production, to introduce infant formula feeds, or to introduce weaning foods early is determined by individual circumstances such as the age of the child and cause of breast-feeding failure. Failure to thrive without evidence of nutritional inadequacy, or secondary to persistent anorexia and vomiting, requires urgent medical investigation.

Occasionally failure to thrive occurs without evidence of clinical disease or nutritional inadequacy. Children with such nonorganic failure to thrive may eat well, sometimes excessively, but grow poorly. Typically they are apathetic, showing little social interaction, although some are restless and inattentive. Developmental delay, particularly in social and cognitive skills, is common. These children come from home environments of social and/or emotional deprivation. Environmental stress and lack of love inhibit normal growth. Changing the home environment without necessarily changing the diet can induce accelerated growth giving a dramatically improved effect – confirming the diagnosis.

Vomiting

Most normal infants vomit occasionally and some vomit frequently. Probably the most common cause of persistent vomiting in infancy is laxity of the gastroesophageal sphincter. The sphincter is the spiral muscular area, 2–3 cm in length, at the lower end of the esophagus. Sphincter competence is related to the length of intraabdominal sphincter (which increases with age) and to intragastric pressure. Competence tends to be poor at birth but improves after the first 2 weeks of life, regardless of gestational age. The fluid diets of young infants and the high volumes of liquid needed to meet nutritional requirements produce gastric distension, high intraabdominal tension, and easy regurgitation. Thickening feeds to increase resistance to regurgitation, feeding smaller feeds more frequently, and raising the head end of the cot help reduce gastric distension and regurgitation. As infants grow, consume more solid food and adopt an upright posture, reflux ceases to be a problem.

Feeding problems, including gastroesophageal reflux, are common in children with neurological handicap. Failure to thrive can be severe and may improve with intragastric feeding through gastrostomy, but this exacerbates gastroesophageal reflux. Surgical fundoplication is usually performed, prior to gastrostomy, to control reflux.

Vomiting can be a symptom of serious gastrointestinal or parenteral disorder. When infants vomit and fail to thrive, vomit bile or blood, or vomit to the extent of causing dehydration, medical investigation is required urgently.

Diarrhea

Diarrhea is an increase in total stool output, usually from increase in water content, volume, and frequency of stools. The color, consistency, and frequency of stools vary widely both between different infants and in the same infant on different occasions. Exclusively breast-fed infants tend to have frequent watery yellow stools. Formula-fed infants have less frequent, greenish, drier-looking stools.

In infancy diarrhea is commonly part of either a specific gastrointestinal or a generalized (usually viral) infection. Infectious diarrhea has an acute onset but is usually short-lived and associated with other signs of infection: pyrexia, vomiting, anorexia, and general malaise. Weight loss from anorexia and dehydration are common. Weight recovery is generally rapid and complete. Acute diarrhea has little effect on long-term weight-for-age and even less impact on long-term height-for-age. However, chronic diarrhea and significant growth faltering are common with some gastrointestinal infections (especially rotavirus, *Giardia lamblia*, and *Entamoeba histolytica*).

Malnutrition causes profound changes to gastrointestinal mucosal structure and function. This predisposes malnourished children to severe diarrheal infection and high mortality from diarrheal illness.

All diarrhea should be managed with extra fluids, usually in the form of oral rehydration solution (ORS). ORS suitable for most infant diarrhea has lower sodium and chloride content than that intended for rehydration in adults.

Diarrhea which is persistent and associated with failure to thrive, dehydration, bleeding or other obvious illness, requires medical investigation.

Toddler diarrhea

Some young children persistently pass watery stools or have bouts of loose watery stools alternating with episodes of constipation without evidence of infection, malnutrition, or other ill health. The diarrhea stools are typically voluminous and watery with bits of undigested food in them, indicating the visible bean husks, tomato skins, and other vegetable matter present, although less obviously so, in normally formed stools. Children with toddler diarrhea are active and thriving but their parents are usually very concerned.

Toddler diarrhea has no recognized specific pathology and probably has many causes. Whole-gut transit time is reduced but there is no evidence of abnormal duodenal or jejunal secretion, nor of malabsorption. Minor infection may set off bouts of diarrhea and in some children there is a family history of response to stress with diarrhea. Poor hygiene and low-grade infection associated with constant pacifier (dummy) sucking and prolonged bottle-feeding may contribute to the problem.

Many affected children have high intakes of sweetened fruit juices and/or low intakes of dietary fat. High fluid intakes with high simple carbohydrate content encourage rapid intestinal transit which overwhelms small intestinal function, so sugars reach the large intestine unabsorbed. These and their fermentation products in the colon stimulate osmotic diarrhea. Reducing fluid intakes, particularly of sweetened juices and carbonated drinks, reduces the symptoms in some toddlers. Changing to more adult diets with higher concentrations of complex carbohydrates and fats can also reduce diarrhea. Lipids in the ileum slow duodenal and jejunal transit time (the ileal brake) and may modulate mucosal contact time and the absorption of intestinal luminal contents. Graduating to cup-feeding usually results in less excessive fluid intakes and, particularly if pacifiers are avoided, encourages more hygienic feeding practices.

Toddler diarrhea usually resolves as children move on to more mature diets and develop continence. It is unusual after the age of 6 years.

Micronutrient Deficiencies

Significant micronutrient deficiencies, other than for iron, are rare in normal-weight, full-term healthy infants in developed countries. Vitamin D deficiency rickets can be a problem in low-birth-weight (LBW) infants and noncaucasian infants. In developing countries low levels of vitamin A are associated with high morbidity and mortality from diarrheal diseases, respiratory infections, and measles. Iodine deficiency is also common. Many countries now have supplementation programs to prevent vitamin A and iodine deficiency.

Iron Deficiency

The human fetus has high hemoglobin levels to accommodate low oxygen tension *in utero*. After birth, in response to the high oxygen tension in the extrauterine environment, the bone marrow becomes relatively quiescent and hemoglobin levels decline. Eventually (usually at 4–6 weeks of age) the bone marrow becomes more active again but by then infants have grown and their blood volumes have expanded. Hemoglobin levels remain below adult levels, at 11–12 g dl^{-1}, until late childhood.

Where infants are small and growing very rapidly (e.g., premature and small-for-dates infants), with initially low total blood volume and low total body iron, the need for iron for new blood formation may soon exceed the iron stored, so anemia results. Once body weight has doubled, all infants are at risk of iron deficiency since, without good external sources of

Table 2 Classification of problems predisposing to iron deficiency in childhood

Basic nutritional problem	*Example*
Inadequate intake	Early introduction to cows' milk
	Prolonged exclusive breast-feeding
	Poor quality of weaning diet
	Strict vegetarian diet
Increased losses	Bleeding disorders
	Reflux esophagitis
Failure to absorb	Celiac disease
	Pyrexia
	Iron in ferric form
	High-phytate diet
Failure to utilize	Chronic infection
	Hypothyroidism
	Riboflavin deficiency
Increased requirements	Rapid growth: low-birth-weight infants
	Catch-up growth

iron, iron stores of the body will be distributed over twice the blood volume, and hemoglobin levels will have halved. However, iron supplementation should probably be avoided in exclusively breast-fed infants unless they show clinical evidence of deficiency, since lactoferrin is a major immunological component of breast milk. It binds iron in the small intestine, speeding absorption and inhibiting multiplication of iron-dependent bacterial pathogens. Iron fortification of infant formulas reduces the prevalence of severe iron deficiency in nonbreast-fed infants.

Iron sufficiency is important. **Table 2** lists some factors predisposing to iron-deficiency anemia. The frequency of iron-deficiency problems is an indication of the small margin of safety between requirements for iron and the quantity of iron young children are likely to ingest and absorb from their diets. Low-grade iron deficiency can impair growth rates, intellectual function, and the immunological response to infection. In countries where malaria is common, anemia resulting from iron deficiency puts infants at great risk of life-threatening severe malarial anemia.

Vitamin D Deficiency: Rickets

Rickets used to be common in weanlings. The Clean Air Act (1956) probably did as much to reduce rickets in the UK as any medical intervention, since vitamin D metabolites are predominantly derived from irradiation of 7-dehydrocholesterol in the skin by sunlight of wavelength around 300 nm.

Rickets is still seen in the UK in newborn Asian infants and mothers. The mothers have both inadequate absorption of dietary vitamin D and inadequate skin synthesis of endogenous vitamin D because of indoor habits and clothing cover when out of doors. Low calcium absorption due to low dietary intake and the high phytate content of traditional flours exacerbates the need for vitamin D to optimize calcium absorption from the small intestine. Skin pigmentation increases the need for sunlight exposure when levels of ultraviolet light of appropriate wavelength are low (e.g., winter in northern latitudes).

Infants born to vitamin D-deficient mothers may present with hypocalcemic tetany and convulsions soon after birth or with rickets in the weaning period. The incidence of rickets in Asian children is diminishing in the UK as Asian women in this country adopt lifestyles more suited to northern latitudes and their need for vitamin D supplementation is better recognized. However, signs of vitamin D deficiency in mothers and children are widely reported from the Middle East where there is plenty of sunshine of vitamin D synthesizing wavelength, but little social opportunity for women and children to expose their bodies to the sunlight.

Vegetarian Diets in Infancy

Infants weaned on to vegetarian diets may become deficient in a variety of nutrients. If diets include eggs and milk, it is not difficult to achieve dietary requirements, particularly if breast milk or infant formula is continued as a milk source beyond the first year of life. Milk usually provides a substantial proportion of riboflavin, calcium, and total energy intake in weanling children. Infant formula can provide a fairly absorbable dietary source of iron which may otherwise be deficient.

Vegetarian diets tend to be of low energy density because of high-fiber and low-fat content. Children should be fed frequently (at least four times a day) to enable them to consume the volumes of food necessary to meet nutrient needs. No vegetable protein contains the full range of essential amino acids so diets should include a variety of protein sources (e.g., beans, lentils, cereals, dark green leaves, soya and homogenized nut products).

It is difficult to achieve adequate nutrition in very young children with vegan, macrobiotic, and other strict vegetarian diets. These diets are not recommended for infants unless there is close pediatric dietetic supervision.

Low-birth-weight Infants

The problems of both premature and LBW for gestational age (small-for-dates or SFD) infants are similar, although the greater immaturity of the premature infants' gastrointestinal tracts and of other organs makes the nutrition of the former more difficult than that of the latter. In both groups there is a need for more nutrients per unit of body weight to cope

with the rapid growth to parallel intrauterine growth in premature infants and catch-up growth in SFD infants. The small stomach volumes of LBW infants restrict the volumes which can be fed at any one time without causing apnea, vomiting, or necrotizing enterocolitis. Respiratory problems in premature infants may also restrict the amount of enteral food tolerated. Thus there is a conflict between increased (proportionate to body weight) nutrient needs, especially for protein, calcium, phosphate, fluid, and energy, and the amounts of food that can be administered safely. Even when LBW infants are fed parenterally there are restrictions on the fluid volumes, and thus the quantity of nutrients, that can be given safely. The high demands for growth and development, particularly for the brain, lead to deficiencies of some nutrients which are usually synthesized by the body. This critical nutrient status applies to the long-chain polyunsaturated fatty acids, docosahexaenoic and arachidonic acids, and possibly also carnitine, nucleotides, and other nutrients. For this reason breast milk, which has high levels of these nutrients, may have advantages over infant formulas for the nutrition of LBW infants, if supplemented with energy to meet the high requirements of these infants. However, manufacturers, aware of the physiological needs of LBW infants, are gradually developing formulas which aim to meet these special needs.

Table 3 lists the problems of LBW infants which are discussed elsewhere. LBW infants should be supplemented at least with vitamins A, C, D, and folate over the first year of life. Iron supplementation in the neonatal period risks encouraging bacterial infection and damage by free iron radicals, since iron stores are replete following temporary bone marrow inactivity associated with high hemoglobin levels at birth. However, iron supplementation is advisable in formula-fed infants after the first 4 weeks. Iron supplements should probably not be given at all to wholly breast-fed infants unless they show hematological evidence of iron deficiency, since free iron in the gastrointestinal tract can counteract the protective effects of lactoferrin.

Table 3 Nutritional problems of low-birth-weight infants

Problem	*Precipitating factors*
Immediate hypoglycemia	Limited liver glycogen Delay in mobilizing fat stores Problems with supplying nutrition
Immediate hypocalcemia	Loss of high calcium flux across placenta Immaturity of calcium homeostasis Occasionally maternal vitamin D deficiency
Later poor growth	Low energy density of breast milk Poor tolerance of other energy/nutrient-dense feeds Poor fat absorption by immature infants Increased needs due to bronchopulmonary dysplasia
Bone disease of prematurity	Substrate deficiency, especially phosphate Renal calcium loss from acidosis and/or diuretics Vitamin D, protein, or copper deficiency
Anemia	Vitamin E deficiency increasing early hemolysis Folate deficiency Iron deficiency

Allergy

Cows' Milk Protein Intolerance (CMPI)

Food allergies, particularly CMPI, are frequently diagnosed in infants. True CMPI affects between 1.5% and 5% of the population of western Europe. In families with a strong atopic history the incidence may be much higher. Cows' milk protein intolerance most commonly develops in children under 2 months of age, although it may develop at a later age after gastrointestinal surgery, malnutrition, or gastrointestinal infection.

Children with diarrhea and/or blood loss in association with CMPI may show villous atrophy and increased inflammatory cell infiltrations on jejunal biopsy, or acute colitis on sigmoidoscopy. Those with respiratory symptoms may present with pulmonary hemosiderosis which resolves on removal of all cows' milk-containing products from the diet. However, for most children, manifestations of CMPI are varied and nonspecific.

Infants who vomit, have diarrhea, have a rash, or cry a lot, are liable to be diagnosed as CMPI. They are put on to commercial cows' milk-free formulas and may seem to improve. Improvements may have been coincidental or as a result of mothers feeling reassured that 'something was being done.'

Commercial cows' milk protein-free formulas are also lactose-free. Excluding formula and cows' milk products from the diet does not distinguish between CMPI and lactose intolerance. Children with lactose intolerance commonly have a preceding history of gastrointestinal infection, surgery, or malnutrition. They have loose stools, weight loss, and abdominal distension. Stools are acid and contain reducing substances. Thus, if infants' stools show $pH > 5.1$ and have no reducing substances in them and symptoms resolve on cows' milk protein-free diet but recur when milk protein is reintroduced, CMPI is likely.

Where the child's symptoms have been dramatic (e.g., angioneurotic edema; profuse life-threatening

diarrhea), challenging the diagnosis of CMPI by reintroduction of milk and milk products can be dangerous. Children should only be challenged with milk under hospital supervision and even then with great care.

The particular elements of the cows' milk protein causing allergenic responses vary. At least 18 components that can induce antibody formation have been identified. When purified protein fractions are used as challenges, β-lactoglobulin levels and casein produce symptoms in over 60% of affected individuals. Antibodies to cows' milk protein are widespread and neither their presence, nor their levels in the blood, correlate well with reactions to cows' milk.

Breast-fed infants often show circulating cows' milk protein antibodies. Changing from breast-feeding to cows' milk formula feeding can, very rarely, precipitate dramatic anaphylactic symptoms of angioneurotic edema with acute and very dangerous swelling of tissues around the neck and airway. Relevant proteins from the cows' milk consumed by the mother are thought to be transferred to affected infants either across the placenta or in breast milk, causing sensitization. The infants are then desensitized by the small amounts of antigen in maternal milk but are overwhelmed when confronted with a large load of antigen from formula feeding.

The management of CMPI involves removal of all cows' milk protein-containing products from the diet. Pediatric dietetic advice is advisable since milk and milk products continue to contribute significant amounts of energy and other nutrients to normal children's diets, even after the start of mixed feeding. Difficulties in meeting nutritional needs on milk-free weaning diets can lead to undernutrition. Soya-based infant formulas can be helpful but infants with CMPI may also develop soya protein intolerance. Hydrolyzed cows' milk protein formulas are more suitable for treatment of CMPI but are rather unpalatable (to mothers anyway), not available in supermarkets in the UK, and costly.

Tolerance to cows' milk protein usually develops as children move into the second or third year of life.

Eczema

The extent to which food intolerance is relevant to the development of infantile eczema remains controversial. Some infants with atopic eczema show significant improvement in their skin problem when all milk products are withdrawn from the diet. Others only improve when put on very restricted lists of foods. Studies of infants with familial high risk of atopic eczema suggest that eczema may be prevented in some infants by exclusive breast-feeding for the first 6 months of life. Moreover, exclusively breast-fed infants who do develop eczema may have become sensitized to foreign proteins transferred through the breast milk.

Other Food Allergens

Other food allergies are quite common in infancy, especially in those with an atopic family history. Common precipitants are egg protein, citrus fruits, nuts (not advised for young children anyway because of the risks of inhalation), and the food colorants tartrazine and quinoline yellow. Diarrhea, vomiting, rashes, wheezing and – rarely – behavioral disturbances may occur. (Most behavioral problems are disciplinary rather than allergic.) The pattern of response in each child is usually repeated on subsequent contact with the allergen but there is great variation in the pattern of individual responses.

Colic

Around 3 months of age healthy infants often develop bouts of fractiousness and inconsolable crying, usually in the early evening. Their abdomens become tight and distended, probably because of the air swallowed whilst crying. Infants tend to flex their legs when crying and this may be interpreted as abdominal pain. 'Three-month colic' is an ill-defined problem with a wide range of symptomatology. In the long term, colic resolves without specific treatment. It may be a behavioral rather than a medical problem. Nevertheless, it causes great distress to the child and parents. Removal of cows' milk formula and substitution with nonallergenic formula or soya protein formula has sometimes been associated with improvement. However it is difficult to know if this has anything to do with resolution of symptoms in a benign self-limiting condition.

Cot Death: Sudden Infant Death Syndrome

Sudden unexpected infant death (SUID) affects about 1 in 500 infants in the UK. The condition is of mixed etiology, since detailed history and autopsy reveal cause of death or evidence of illness in many of the infants. There remains a group of SUID infants for whom detailed investigation shows no adequate explanation for death. These are the cases of true 'sudden infant death syndrome' (SIDS). In the past, anaphylactic shock from acute CMPI was sometimes cited as possible etiology for SIDS since SUID is more common in formula- than in breast-fed infants. Some infants have postmortem evidence of milk/formula in the respiratory tract, perhaps as a terminal event. However, true SIDS is probably not more common in formula-fed

than breast-fed infants. It now seems likely that a major component of death in SIDS relates to impaired cardiorespiratory arousal. Putting infants to sleep supine, rather than prone or on their sides, has reduced SIDS by about 35% in many countries.

Another nutritional explanation proffered for some forms of SUID is undiagnosed inborn errors of metabolism involving inhibition of breakdown of long-chain fatty acids. Children with inborn errors of this kind are unable to metabolize fats to cope with the stress of fasting and die of hypoglycemia. Postmortem examination reveals acute fatty degeneration of the liver. In such very rare cases, SUID may be familial since inborn errors of metabolism involving fatty acid breakdwon are inherited, usually by autosomal recessive genes.

Teething Problems

Teeth are erupting more or less continuously between 6 and 30 months. Teething children may show excessive salivation, gingival swelling, and general irritability. These symptoms may exacerbate existing illness but there is no evidence that teething causes fever or diarrhea. Rubbing the gums with cool cloths or giving infants firm objects to bite may reduce teething discomfort.

Most children develop their first teeth around 6 months of age but some do not develop teeth until around 2 years. Late tooth erupters usually cope well with chewing and should be encouraged to progress in the weaning process in the normal way.

Nursing Bottle Syndrome: Rampant Caries in Infancy

Nursing bottle syndrome is the rampant carious destruction of the upper incisors in young children. Although associated with offering bottles of juice/milk or pacifiers sweetened with sugary solutions to infants when they are ready to sleep, rampant caries in this age group probably also reflects underlying enamel hypoplasia in the primary teeth which is secondary to prematurity or to maternal nutritional deficiencies in pregnancy.

Constant bathing of upper incisors with sugary fluids, together with reduced salivary secretion and reduced mouth movements at night, encourages the development of plaque. *Streptococcus mutans*, which survives well at low pH, collects under plaque and adheres to tooth enamel. Enamel is eroded, allowing opportunity for further tooth infection by other bacteria. Excessive vomiting, by creating an acid environment in the mouth, may contribute to the risk. Teeth in the front of the upper jaw are reduced to carious discolored stumps. Children may become faddy eaters due to the discomfort of chewing meat and biting vegetables and fruit.

Fluoridation of water supplies with one part per million of fluoride protects against dental caries. If water is not fluoridated, children can be supplemented with fluoride 1.25 mg day^{-1} in infancy and 1.5 mg day^{-1} between 1 and 3 years. Regular, at least daily, tooth brushing should be taught from the first appearance of teeth. Adults should supervise loading children's toothbrushes with small pea-sized lumps of toothpaste since small children may eat toothpaste rather than spit it out after cleaning their teeth. As much as 1.66 mg of fluoride could be consumed by small children brushing their teeth inexpertly twice a day with fluoridated toothpaste.

All food, and particularly sweetened drinks, should be discouraged after tooth brushing at night.

INFECTION, FEVER, AND NUTRITION

C J Field, University of Alberta, Edmonton, Alberta, Canada

Background

Infection is a broad term that encompasses a number of pathological situations initiated by invasion of infectious organisms. An effort to reduce the number of infectious incidences is a primary focus for those who work in public health but also for those who work in the clinical setting. Infections are responsible for worsening the nutritional status of patients, doubling the length of hospital stay, increasing the number of medical and surgical procedures required, delaying the provision of adjuvant therapies, and significantly reducing patients' quality of life. This article will briefly review the immune response/role in infection and fever, the importance of nutrition to the immune system, and the role of nutrition and specific nutrients on the response to fever and infection.

The Immune Response to Infection

The immune system (cells and molecules responsible for immunity) is defined as part of the host's defense against destructive forces from outside the body (i.e., bacteria, viruses, and parasites) and those from within, such as malignant and autoreactive cells. Appropriate interactions between the different cells of the immune system are necessary to eliminate infectious organisms (Table 1). The purpose is to disadvantage and destroy invading organisms, while protecting healthy tissue from the damaging influences of the compounds produced during the response. Cytokines and other compounds play a central role orchestrating the immune response to infectious organisms. However, the proinflammatory cytokines and other molecules produced during the inflammatory response also pose a danger to the host. The host response (cytokines and acute phase response) designed to fight infection is partially responsible for a serious and life-threatening metabolic condition called sepsis. Sepsis is characterized by an unregulated host inflammatory response and the presence of bacteria (though primary invasion or secondary to other infections) or their products in the bloodstream.

The Innate Immune System and Infection

The innate immune system comprises defenses that are present early in life that function without depending on previous exposure to a particular pathogen, thereby providing the first line of defense that protects the host during the 4–5 days it takes for lymphocytes in the acquired immune system to become activated. The major components of the innate immunity are illustrated in Figure 1. The resistance to bacterial invasions is thought to depend primarily on nonT-cell branches of immunity such as physical barriers (skin and mucous membranes),

Table 1 Immune responses to some common infectious agents

Infection type	*Examples*	*Immune response*
Viruses	HIV, influenza, rhinovirus	• Humoral immune system blocks initial infection and recruits other immune cells • Cell-mediated response is most effective at destroying cells once infected with virus
Parasites	*Trichinella*, Helminths	• Low immune response, as there is no of the infectious agent inside the host's cells • May be some humoral and inflammatory response from B-cells and macrophages/neutrophils near the invasion site
Protozoa	Malaria	• Bloodborne protozoa are destroyed by B-cell antibodies • Once cells are infected, cells are destroyed by cell-mediated functions
Intracellular bacteria	*Listeria monocytogenes, Mycobacterium tuberculosis*	• Cell-mediated, delayed-type hypersensitivity response important in destroying intracellular bacteria • Stimulates a type-2 helper T-cell response (pattern of cytokines)
Extracellular bacteria	*Streptococcus pneumoniae*	• Humoral immune system (located in lymphoid tissues throughout the body) secretes antibodies
Sepsis (systemic inflammatory response system)	Endotoxin, lipopolysaccharides	• Caused by a dysregulated inflammatory response to an infectious agent

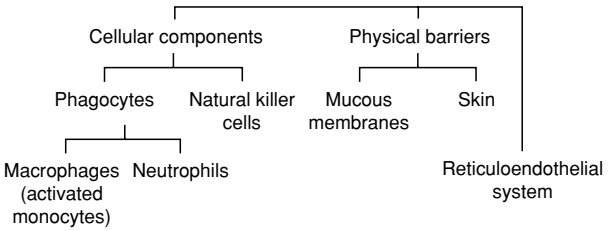

Figure 1 Defenses of the innate immune system.

neutrophils, macrophages, complement, and acute phase proteins. If infectious organisms penetrate this barrier, the innate immune system responds immediately by activating the acquired immune system. If the pathogens are bloodborne, the reticuloendothelial system becomes involved.

The Acquired Immune System and Infection

The acquired (or adaptive) immune response develops over one's lifetime in response to environmental challenges (pathogens/antigens). The cells that comprise the acquired immune defense are illustrated in Figure 2. T- and B-lymphocytes (cells) are the primary cells of this arm of immune system. The T-cell population is divided into two basic subsets CD4 (helper/inducer) and CD8 (cytotoxic/suppressor) cells. T-cells play multiple roles functions including providing help to B-cells, stimulating the inflammatory response, maintaining antigen-specific memory and producing cytokines. Once activated, some T-cells can directly destroy cells (via cytotoxic killing) infected with intracellular pathogens. B-cells produce and secrete antibodies for the elimination of extracellular pathogens and parasites. B-cells can also serve as antigen-presenting cells and activate T-cells.

The Mucosal Associated Lymphoid Tissue

Mucosal tissues (contain components of both the innate and acquired immune system) are strategically located in areas where external pathogens enter the body. Immune cells that reside in mucosal tissues protect against the entry of infectious agents. The immune responses arising in these regions must be very selective so as to avoid mucosal damage that would impair functions such as gas exchange (lungs). The gastrointestinal system serves as a primary reservoir for bacteria that have the potential, if not properly controlled, to induce life-threatening infections. A vast immune system exists in the gastrointestinal tract with immune cells located in intraepithelial and lamina propria regions of the gut and in specialized lymph tissues, Peyer's patches, lining the large and small intestine. The main defense in the gut comes from the large number of activated B-cells present in the lamina propria region that secrete IgA.

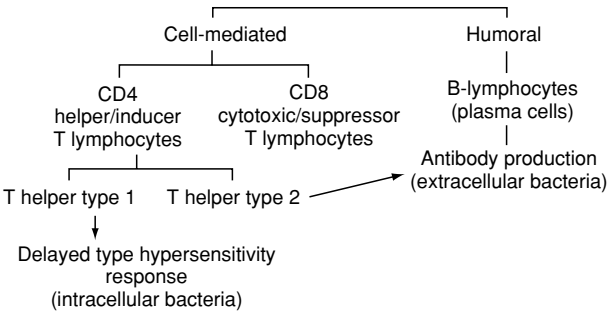

Figure 2 Defenses of the acquired immune system.

Mediators of the Immune System

The response of immune cells to infectious agents is mediated by a number of compounds. Cytokines are glycoproteins that are secreted by immune and other cell types and are a means of communication between cells of the immune system and with other cells in the body. The localized concentration of various cytokines will determine what immune cells are activated. T-helper cells type 1 cells (Th1 CD4+ cells) produce interleukin (IL)-2 and interferon-γ (IFN-γ), which generally promote a cell-mediated inflammatory response. Th2-type CD4+ cells produce IL-4, IL-5, IL-10, and IL-13, which support a humoral antibody response. It has been hypothesized that the balance of these cytokines offers a mechanism by which the immune system can respond appropriately to a specific type of infection.

Other important mediators of immune function include epinephrine, glucagon, and cortisol, which are released in response to stress and infection. These hormones have been shown to have immunosuppressive effects on immune cells. Lipid-derived factors such as eicosanoids, leukotrienes, and platelet-activating factor, made by a variety of cell types in response to cytokines and other signals, also modulate immune function. When tissue is injured during infection, the complement cascade is activated, and fibronectin, vasoactive amines, and chemoattractants are released. The complement cascade is important in mediating inflammation and promoting phagocytosis of microorganisms. Nitric oxide is a potent immunobiological compound produced by macrophages and neutrophils to combat intracellular pathogens (i.e., parasitic fungi, protozoa, helminths, and mycobacteria) and viruses.

Fever

Fever is a host response that is characterized by an elevation of core body temperature. The most

frequent cause of fever in acutely ill patients is infection (by bacteria, viruses, and/or their toxins). In most cases, fever is initiated by the production of cytokines (IL-1, IL-6, tumor necrosis factor (TNF)-α) from macrophages and neutrophils. In general, it is believed that proinflammatory cytokines stimulate the production of arachidonic acid metabolites (PGE_2 and thromboxane A_2), which affect the temperature-regulating areas in the brain (hypothalamus, medulla). Subsequently, the brain signals mechanisms that generate heat and reduce heat loss, thus increasing core body temperature.

It is widely accepted that fever has three distinct phases. The first is known as the chill phase where the individual experiences shivering and feeling cold. The second phase is a plateau phase when the thermostatic set point and body temperature are at the same level. This is followed by a third phase known as 'defervescence' when the fever 'breaks,' resulting in flushing and sweating. This increase in body temperature is important as it increases the speed at which neutrophils move and secrete antibacterial substances, increases B-cell and T-cell replication, and results in a higher production of IFN-γ (antiviral and antibacterial properties). High fever, however, is clearly maladaptive to the host resulting in loss of appetite, increased sleepiness, muscle aches, and hypermetabolism. Resting energy expenditure rises by as much as 10–15% for each degree Celsius increase in body temperature.

Interaction Between Nutrition, Infection and the Immune System

In children and adults with marginal or poor nutritional status, episodes of infectious diseases are more severe and result in more complications. Almost any nutrient deficiency, if sufficiently severe, will impair resistance to infection. The impact of infection on nutritional status depends on the previous nutritional health of the individual, the nature and duration of the infection, and the diet consumed during the recovery period. Thus, infections themselves promote malnutrition (appetite loss and anorexia, malabsorption, and elevated metabolism of energy, and other nutrients), creating a complex cycle of immunosuppression and worsened nutritional status. Worsened nutritional status will then further suppress immunity and predispose the individual to opportunistic infections (Figure 3).

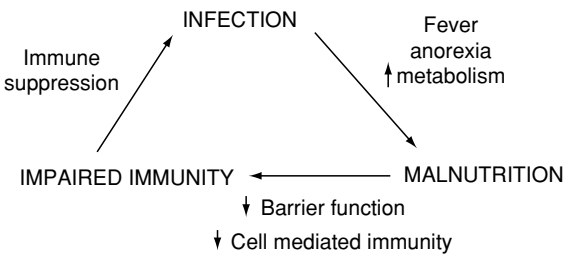

Figure 3 Relationship between malnutrition, immunity, and infection.

The interaction between nutrition and infection is complex. The physiological mechanisms responsible for metabolic changes during infection are not completely understood, although cytokines are clearly involved. Some degree of appetite loss (anorexia) is present during most infections. In some cases, this anorexia is due to nausea and vomiting; in others, gastrointestinal lesions. Additionally, the presence of a fever can result in appetite loss (anorexia) resulting in a 10–40% decrease in dietary intake, not only of protein and energy but also of most nutrients. Anorexia will precipitate clinical nutrient deficiencies of any nutrient in which body stores are limited. The extent of the depletion of nutrient status will subsequently increase the risk of damage to the host's tissues from the inflammatory response. To sustain a hypermetabolic rate (i.e., in fever), there is an acute mobilization of endogenous energy stores (glucose and fat). However, during infections, there is also an impaired ability to use these substrates. If body stores are used to provide for the metabolic needs of infection and fever, weight loss occurs. In fact, this sort of observation led to the introduction of the lay-term 'consumption' to describe tuberculosis, the classic chronic wasting infectious disease. The high prevalence of infections among children living in poor areas of developing countries results in impaired linear growth. In addition, the acute phase response (e.g., proinflamatory cytokine release) to fever directly affects bone remodeling that is required for long bone growth.

Nutrition and the Immune System

The past 25 years have resulted in an explosion of scientific literature defining the role of specific nutrients on immunity. Most host defenses are breached in protein-energy malnutrition, particularly cell-mediated immunity. It is now generally accepted that nutrition is an important determinant of the immune response. It appears that almost every known nutrient deficiency can affect disease resistance if it is sufficiently severe, and this may also be true for many nutrients consumed in excess. Nutritional state and specific nutrients may impact on the immune system directly (e.g., triggering immune cell activation, or altering immune cell interactions) or

indirectly (e.g., changing substrate for DNA synthesis, altering energy metabolism, changing physiological integrity of cells, altering the synthesis and release of cytokines/hormones, or changing the sensitivity of target tissues to various mediators). These changes have widespread effects on lipid, carbohydrate, and protein metabolism.

Knowledge of the importance of nutrition to the functioning of the immune system has led to several practical applications. These include the use of immunological tests: as prognostic indexes in surgical patients, for assessing nutritional status, and for measuring the efficacy and adequacy of nutritional therapy. However, our knowledge of the effects of nutrition on immune function now extends beyond clinical nutrient deficiency, and there is a growing body of literature demonstrating the immune benefits of increasing the intake of specific foods and nutrients.

Nutritional Management of Infectious Disease

Many interventions are possible to reduce the effect of infection on morbidity and mortality. Prevention of disease through sanitation, vector control, promotion of breast-feeding, and vaccination is crucial. Appropriate treatment of infections (e.g., antibiotics) as well as supportive nutritional therapy during and after recovery is also important. However, once the stress response has been activated, and inflammatory mediators released, it is unlikely that nutritional intervention alone can stop this process. It was not until 1980 that the first prospective randomized clinical trial was reported that clearly demonstrated that nutritional intervention could improve patient survival and reduce infectious incidences. Maintaining nutritional status is an essential component of the management of infectious illness. Recent advances in our understanding of the role of specific nutrients in modulating immunity and inflammation have stimulated the development of diets and supplements aimed at improving recovery from trauma and critical illness.

Even when efforts are made to maintain intake and nutritional status during illness, the anorexia associated with infections, even those as mild as those produced with immunization, is a major obstacle. As measured by the occurrence of infectious complications, most clinical studies find that the enteral (oral) route of providing nutrition is superior to the parenteral (intervenous) route. Reasons for this phenomenon are not clear, but it appears that enteral nutrition supports the gut barrier and gut-associated lymphoid tissue. However, when nutrient intake via the enteral route is not possible, total parenteral nutrition (TPN) has become a life-saving therapy to meet the nutritional needs of patients.

In the management of sepsis, the most severe complication of infectious disease, the effects of the resulting hypermetabolism can be at least partly thwarted through delivery of enteral nutrients. The introduction of hyperalimentation, together with a diet high in protein content, has been shown to improve survival by decreasing the number of septic episodes. General considerations for the nutritional management of infection are listed in Table 2 and the need for specific nutrients are discussed below.

Energy

During starvation, there is a specific adaptive response that is designed to preserve lean body mass. However, during the stress response, hormones, cytokines, and inflammatory mediators heavily influence the way in which energy substrates are metabolized. Energy substrates are mobilized to support inflammation, repair of tissues, and maintenance of immune function, usually at the expense of lean body tissues. Lean tissue is broken down to its constituent amino acids, which provide precursors for the synthesis of glucose in the liver (gluconeogenesis).

Resting energy consumption during sepsis is reported to increase as much as 30–40%. Thus, providing additional energy to meet the increased needs during infection and fever is an essential part of nutritional management. The energy needs of adult patients are usually based on estimations of energy

Table 2 General considerations for the nutritional management of infection

- Attempts should be made to prevent chronic or multiple bouts of even mild infections. The cumulative effects of repeated infections result in a greater net energy deficit than one infectious episode
- Encourage breast-feeding, as it is a useful and cost-efficient dietary intervention to prevent infections diseases in small children
- Begin feeding early in acute infection, as it has been shown to have a significant, positive effect on the course of the disease
- Efforts should be made to continue provision of nutrition during mild or moderate episodes of common infections, including diarrhea
- Repletion of nutrients lost during the acute phase of infection will require high intakes of most nutrients for extended periods of time. Above-normal nutrient requirements continue after normalization of the clinical manifestations of infection
- After an infectious episode, the energy density of habitual diets should be assessed, to determine if they can sustain recovery growth after common illnesses. Enrichment or supplementation may be required. Patients with chronic infections and a poor appetite may require supplemental feeding of high-energy formulas, either orally or by tube

expenditure by the Harris–Benedict equation, with the addition of energy losses or increased requirements due to the infection. The metabolic needs of any other underlying disease and the effects of drugs used to treat infection should also be considered in estimating energy requirements. In children, dietary intake during infection and recovery must be sufficient to sustain rates of growth that may be several times higher than in healthy children of the same age (catch-up growth). Most studies have found little correlation between dietary protein intake at adequate ranges and rate of weight gain, while there is a clear association between energy intake and nitrogen accretion.

Protein

Acute infection has a negative impact on nitrogen balance. It has been estimated that approximately 45 g of protein is required daily during a severe infection just to support the increased synthetic demand by immune cells and related tissues. Amino acids from skeletal muscle, skin and possibly bone are released to provide substrate for the synthesis of cells and proteins associated with the response to infection. This biosynthetic response by the host is choreographed by the cytokines, which both stimulate catabolism of protein stores and reduce the availability of amino acids for other processes in the body. The specific effect of infection on muscle protein loss varies depending on the causative agent and the initial nutritional status of the host. In the well-nourished host, mild infection is associated with an increased protein turnover. However, in a more chronic and prolonged infection, the modest rise in protein synthesis, is overcome by the marked increase in the rate of protein breakdown. Additionally, chronic diarrhea, intestinal parasitism, and protein-losing enteropathy can result in additional protein losses.

Most often, the supply of amino acids from the diet does match the increased demand during an infection, and this results in depletion of body stores. The inhibitory effects of infection upon growth, pregnancy, and lactation are well recognized. During infection-induced weight loss, there are reductions in the plasma concentrations of sulfur amino acids, glycine, serine, and taurine. These amino acids are found in high concentrations in many compounds associated with immune and inflammatory responses, most notably cytokines, glutathione, metallothionein, and acute-phase proteins. Early provision of sufficient calories and protein has proven beneficial and is now a common feeding protocol in critically ill patients. However, it has been reported that, apparently, adequate nutritional support in the presence of a severe inflammatory stimulus only attenuates the gluconeogenic process and the breakdown of lean tissue continues.

Fat

Hypertriglyceridemia, resulting from accelerated fat mobilization from stores, decreased clearance, increased synthesis, and/or release from the liver, is characteristic of septic patients. Additionally, studies have shown fatty acids to undergo inefficient cycling between organs, which may also contribute to the elevated metabolic rate. Thus, the energy that, under normal circumstances, can be obtained from a concentrated energy source such as fat is reduced. At present, there are limited clinical data to support that providing additional calories in the form of fat will be beneficial during infections.

Metabolic pathways for *de novo* synthesis of fatty acids may be impaired during stress states, and supplementation of certain fatty acids in the diet may be required. The dietary requirements for specific fatty acids during infection are not known, and this issue is heavily debated. Studies have demonstrated that feeding specific fatty acids can impact on oxidation, metabolism, and the inflammatory response. At present, however, the extent to which fatty acid metabolism, particularly that of the essential fatty acids, is altered during infection and cancer and the ability to improve patient outcome with supplementation of fatty acids in the diet are not known.

Extensive studies carried out, mostly with animal models, feeding different amounts and types of fats have shown that fatty acid content of the diet affects most immune functions. In general, fats rich in *n*-3 polyunsaturated or monounsaturated fatty acids suppress inflammation, and fats rich in *n*-6 polyunsaturated fatty acids exert the opposite effect. The ability of inflammatory cells, such as macrophages, to produce cytokines may also be influenced in a similar manner by feeding different fatty acids. Adding *n*-3 fatty acids to the diet have been shown to suppress the thermic (fever) response to experimental infection. There are a number of levels at which fats may modify host defense and cytokine biology. Most relate to the ability of fats to change the fatty acid composition of membrane phospholipids. Subsequently, changes in membrane lipid composition will change cell signaling, gene expression, and the synthesis and release of inflammatory mediators, which will modify the intensity of the inflammatory response.

Vitamins

Vitamins and minerals play widespread and complex roles in the response to fever and infection. Some of these micronutrients are incorporated into substances

that are released during the response to infection, others are components of antioxidant defense, while others support the response by the host.

Vitamin A The role of vitamin A deficiency in vulnerability to infection was recognized early in the twentieth century. The impact of vitamin A deficiency on increasing the susceptibility to, and severity of, infections is related to its essential functions in metabolism, glycoprotein synthesis, cellular differentiation, and immune function. Vitamin A deficiency is associated with impaired T-cell, B-cell, and neutrophil function and decreased epithelial defense against bacterial invasion. Lower serum levels of both carotene (provitamin A) and vitamin A have been reported during various infections, including hookworm, acute respiratory infections, gastroenteritis, and measles. Intestinal infections reduce the absorption of vitamin A from the diet and can precipitate the clinical appearance of xerophthalmia and keratomalacia in those who have a marginal vitamin A status.

The efficacy of vitamin A supplementation during infections has been examined in randomized, double-blind, placebo-controlled trials of malnourished children in various regions of the developing world. Supplementation with this vitamin is reported to improve the response to measles vaccines, maintain the health and barrier function of the intestine, lower the incidence of respiratory-tract infections, and reduce mortality associated with diarrhea and measles. The World Health Organization currently recommends that vitamin A be given to all individuals who develop measles in developing countries, whether or not they have symptoms of vitamin A deficiency. There are also clinical data suggesting that vitamin A deficiency in HIV-1-infected individuals contributes to increased mortality, disease progression, and a higher rate of maternal–infant disease transfer.

Excessive intakes of vitamin A are potentially toxic in humans. Although there has been little work on the relationship to infection in humans, chronic megadosing with vitamin A increases the susceptibility to infectious organisms, suppressed hematopoiesis, T-cell proliferation, and antigen-specific antibody production in animals.

B vitamins A clinical deficiency of thiamin (beriberi) or niacin (pellagra) is associated with an increased risk of infections. The B vitamins are involved in energy and protein metabolism and are needed for cell division and the formation of both red and white blood cells. Although there are no specific requirements for these nutrients determined during infection, the increase in metabolic rate and immune activity that occurs during an infection would likely increase their requirement above that of a healthy individual.

Vitamin C The essentiality of vitamin C (ascorbic acid) to protection from infections is most clearly illustrated during its clinical deficiency disease (scurvy), where immunosuppression and infections almost always occur. Poor vitamin C status results in a loss of integrity of epithelia and impaired bactericidal capacity of neutrophils. Vitamin C is highly concentrated in leukocytes and is rapidly utilized during infection (e.g., to prevent oxidative damage). Reductions in vitamin C levels in plasma have been reported during even mild infections such as the common cold and after immunization against smallpox and measles. A reduced concentration of this vitamin in leukocytes is associated with reduced immune function.

The immune system is a major producer of reactive oxygen radicals and is particularly sensitive to oxidative stress. The actions of vitamin C as a reducing agent and oxygen-radical quencher are well established. If these oxidants are not rapidly neutralized, they can inhibit chemotaxis, phagocytosis, and other antimicrobial activities of immune cells. There has been a long-standing debate concerning the possible function of high doses of vitamin C in 'boosting' immunity to combat infections. Supplementation of this vitamin was recently reported to reduce the incidence of respiratory infections in ultramarathon runners. The results of animal studies and a few human studies have suggested that the function of T-cells and neutrophils and antiviral resistance are increased with large intakes of vitamin C. Since the early interest and advocacy by Linus Pauling, subsequent studies on megadosing with vitamin C have not unequivocally shown that vitamin C can prevent and/or treat upper respiratory-tract infections. Some experts suggest that positive effects of vitamin C supplementation, in early efficacy studies, were complicated by the use of a mixture of antioxidant nutrients, not controlling for physical stress or studying subjects with low overall nutritional intakes.

Unlike many other dietary antioxidants, even when consumed at very high levels ($5000\,mg\,day^{-1}$), vitamin C appears to be safe. However, one might still remain cautious, as some *in vitro* experiments demonstrate that very high levels of vitamin C suppress the T-cell and neutrophil response to infectious agents.

Vitamin E Vitamin E-deficient rats demonstrate an enhanced inflammatory response to endotoxins and addition of the vitamin to their diet suppressed this effect. Vitamin E supplementation has been shown to increase T-cell response, reduce the production of

some inflammatory/stress cytokines, and improve the ability of macrophages to destroy bacteria. Although the data are still limited, there is evidence that vitamin E may play roles beyond basic nutrition function to aid in host defense to infection.

Minerals

Dramatic changes in mineral distribution occur at the outset of infections, with particularly striking shifts of iron and zinc to intracellular compartments. Because iron and zinc are essential for growth and replication of microorganisms, it is possible that the rapid decrease in circulating iron and zinc during infections would limit the supply of these essential minerals for the invading pathogens. The importance of this nutrient as a host strategy to deprive the invading pathogens of the essential divalent cationic factors they need to thrive is controversial, as these nutrients are also essential to the host.

Iron Experimental and clinical data suggest that there is an increased risk of infection in the presence of iron-deficient anemia, although a small number of reports indicate otherwise. Experimental studies in laboratory animals uniformly report reversible deleterious effects of iron deficiency on most measures of functional immunity. It is well documented that iron regulates the function of T-cells, and in most studies (*in vivo* and *in vitro*), a deficiency results in impaired cell-mediated immunity. Humoral immunity may be less affected by iron deficiency than cellular immunity. Iron is a component of the cytotoxic enzymes that are used by neutrophils, macrophages, and natural killer cells. It has been proposed that the immunosurveillance role of macrophages may be mediated in part by modulation of the iron status in cells. This sequestration of iron into macrophages has been proposed to be beneficial during the early acute stages of infectious disease, as it would limit the availability to microorganisms (particularly intracellular microorganisms).

The relationship between iron repletion and infection is somewhat controversial. The major dilemma focuses around the studies demonstrating a positive relationship between iron repletion/supplementation and increased morbidity from infections. Administration of parenteral iron during an infection has been demonstrated to heightened susceptibility to infection. These clinical observations have been supported by studies *in vitro*, in which the rate of microbial growth diminished when iron was removed from culture media. Although animal studies have shown that excess iron promotes the growth of some microorganisms, there is no compelling clinical evidence (except perhaps for tuberculosis, malaria, and brucellosis) that this occurs in adult humans receiving oral iron supplementation. In a recent review, it was concluded that there is little evidence that oral iron supplementation or provision of iron fortified foods to iron deficient individuals inhibits immune function or increases the susceptibility to most infectious agents (with the possible exceptions of malaria-related disease, HIV, and tuberculosis). Thus, the relationship between iron and infection may depend on the ability of the infectious organism to acquire iron and the state of iron nutriture of the host. In conclusion, both iron deficiency and iron excess exert adverse effects on immune responses and alter the metabolism and growth of the pathogens. The balance of these various effects ultimately will determine clinical outcome.

Zinc Zinc is a constituent of key enzymes involved in cell replication (DNA and RNA polymerase). Thus, deficiency will impact on any antimicrobial activity that depends on cellular replication and differentiation. Zinc plays a role in regulating the activation of acute-phase genes (via its ability to bind to RNA finger loop domains known as 'zinc fingers'), such that zinc deficiency impairs translation of genes normally activated during the acute-phase reaction. Another essential role of zinc in the immune response is its binding to certain thymus-derived peptides (thymulin) that appear to function as hormones in the differentiation and maturation of T-cells. In zinc deficiency, the depletion of mature T-cells heightens susceptibility to infection. Thus, clinical zinc deficiency results in thymic involution, lymphoid tissue atrophy, lymphopenida, decreased cell-mediated immunity, and impaired natural killer cell activity. Defects in cell-mediated immunity and increased susceptibility to infections are well described in the human disease acrodermatitis enteropathica, an inherited defect of zinc absorption. Animal studies have confirmed that zinc deficiency impairs cellular immunity, compromises B-cell development and antibody production, inhibits macrophage function, decreases natural killer activity, and increases the mortality to various infectious organisms.

Plasma zinc decreases during infection, even in the zinc-sufficient individual. The hypozincemia of infection is, like iron, part of the acute-phase response mediated by cytokines, which induce the synthesis of the intracellular zinc-binding proteins liver, thymus, and bone marrow. The physiological role of this acute transfer of zinc from the extracellular to the intracellular compartment is not clear but is hypothesized to be an attempt to limit viral and bacterial DNA transcription and RNA translation.

The impairment in immune response associated with zinc deficiency is readily reversed by supplementation.

A number of experimental trials have illustrated the efficacy of zinc supplementation to improve immune function during recovery from infections. For example, zinc supplementation was reported to reduce the duration and severity of cold symptoms. Community-based prospective zinc supplementation of poorly nourished infants and children, and therapeutic trials in acutely ill children, suggest a decrease in diarrhea duration, pneumonia, growth-stunting, acute lower respiratory infections, dysentery altered intestinal permeability and improved food intake, and a more rapid improvement in patients.

Other minerals The diarrhea associated with gastrointestinal infections reduces the absorption and increases the endogenous loss of many of the other trace minerals, notably copper. It is recommended that treatment regimens for diarrhea should include supplementation with copper and other minerals in addition to zinc. Recently, it was found that elderly residents in long-term care facilities taking a micronutrient supplement containing zinc and selenium had up to four times fewer infections than those taking a placebo. In addition to zinc and iron, other trace elements are present in several acute-phase proteins and enzymes associated with antioxidant defense. These proteins include caeruloplasmin (copper), superoxide dismutases (manganese, copper, and zinc), and glutathione peroxidase (selenium). Deficiencies in these micronutrients alter the ability of immune cells to respond to inflammatory agents.

Immunonutrients

An immunonutrient is loosely defined as a nutrient that provides specific benefits to the immune system. It is hypothesized that, under certain physiological conditions (e.g., infection), the demand for the nutrient may exceed the ability of the body to synthesize it. There is growing evidence, from both animal and human studies of infectious diseases, that immunity might be improved by providing immunomodulatory nutrients (e.g., arginine, glutamine, docosahexaneoic acid, eicosapentanoic acid, gamma linolenic acid, zinc, and/or nucleotides). Based on these studies, there are now commercially available enteral and parenteral solutions that contain mixtures of immunomodulatory nutrients. Complete enteral diets containing combinations of immunonutrients (arginine, glutamine, nucleotides, ω-3 fatty acids), when given postoperatively to surgical patients, have been reported to reduce hospital stay, medical treatment costs and the incidence of wound complications and infections. The promising experimental evidence of the metabolic and immune effects of these nutrients offers therapeutic potential for the future, and ultimately might help prevent and reduce the mortality and morbidity associated with infections. Owing to the inclusion of multiply immune-enhancing nutrients in experimental studies, it is difficult, at present, to isolate the specific nutrient or combinations responsible for improvement. Furthermore, one nutrient may work synergistically with others to produce an effect over and above what would be observed with a single nutrient alone. At present, more studies are necessary to find the dosage and duration of the feeding to obtain the desired clinical outcome.

Conclusions

Infectious diseases are on the increase world-wide and are a major cause of morbidity and mortality and contribute to malnutrition. Today, protein energy malnutrition is accepted as a major cause of immunodeficiency world-wide. Infections occur frequently in both the healthy population and with more severe consequences, in individuals who are immunosuppressed through malnutrition. Thus, nutrition plays an important role in the prevention and treatment of infections. There are many levels at which nutrient intake can modify the intensity and characteristics of the response of animals and humans to inflammatory stimuli. Recently, it was demonstrated, that for an RNA virus, the host diet influenced the genetic make-up of the pathogen and thereby alter its virulence. New knowledge on the interaction between nutrition and the host immune function and perhaps also the infectious agent will permit the development of designer feeding formulas/regimens with selective ingredients to optimize immunity to reduce the risk of infection and promote the recovery from infections and fever.

INFLAMMATORY BOWEL DISEASE

A Bousvaros, Children's Hospital Boston, Boston, MA, USA

Background

Inflammatory bowel disease (IBD) is characterized by chronic relapsing intestinal inflammation without an infectious or dietary cause. The term idiopathic IBD is traditionally limited to the illnesses Crohn's disease (CD) and ulcerative colitis (UC), which will be the focus of this chapter. However, there are many other conditions (chronic granulomatous disease, BehÓet's disease, graft- vs. host-disease, HIV) which may cause immune-mediated gastrointestinal inflammation.

CD and UC are two separate illnesses that may share some common genetic background, because a family history of either disease increases an individual's risk of developing both diseases. CD is characterized by a transmural granulomatous intestinal inflammation, which may occur anywhere in the intestinal tract from the mouth to the anus; extraintestinal granulomas in the lymph nodes, skin, and genitalia may also be seen. The most common disease locations include the terminal ileum, cecum, entire colon, and perianal regions. Intestinal strictures, fistulae, and abscess are common in CD but not in UC. Up to 30% of individuals with CD may have microscopic gastroduodenal inflammation. In contrast, ulcerative colitis is characterized by mucosal inflammation limited to the large intestine. UC extends from the rectum proximally. Three major phenotypes of UC have been described: proctitis (limited to the rectum), left-sided disease (distal to the splenic flexure), and pancolitis (extending past the splenic flexure). Pharmacotherapy of both CD and UC includes the use of aminoslicylates, corticosteroids, 6-mercaptopurine, and other immunosuppressive agents. Nutrition may be used as primary therapy in CD but is only palliative in UC.

The precise etiology of these two diseases is unknown. However, it is hypothesized that an underlying genetic mutation involving regulation of the immune system predisposes an individual to the development of CD or UC. When that individual is exposed to a dietary or infectious antigenic trigger for the disease, excessive and aberrant intestinal inflammation results. In support of this hypothesis, mutations in an immunomodulator gene (NOD2) have been identified in a subset of individuals with CD.

Nutritional Complications in IBD

Before determining the extent of evaluation and therapy in a patient with inflammatory bowel disease, the clinician must ask several questions. First, does the patient have CD or UC? Nutritional complications are far more common in patients with CD, though anemia is common in both. Second, where is the location of the disease? A patient with CD and ileal disease is more likely to develop steatorrhea and vitamin B_{12} deficiency than a patient with disease limited to the colon. Third, what is the patient's age? Children and teenagers with chronic malnutrition from Crohn's disease are more likely to present with slowed growth and short stature, whereas adults present with weight loss. Finally, how active is the patient's disease? A patient with IBD and multiple relapses is at greater risk for nutritional complications than a patient who has been in remission for

Table 1 Nutritional complications of inflammatory bowel disease

Global
Inappropriate caloric restriction – anorexia
Weight loss
Growth failure (in children)
Steatorrhea (in Crohn's disease)
Protein-losing enteropathy
Cholestasis (in primary sclerosing cholangitis)
Osteopenia/low bone density
Common micronutrient deficiencies
Iron-deficiency anemia
Hypoalbuminemia
Vitamin B_{12} deficiency (in ileal Crohn's disease)
Folate deficiency (especially in patients taking sulfasalazine)
Hypovitaminosis (vitamins A, D, and E)
Zinc and selenium deficiencies

years. Nutritional complications of IBD are summarized in (Table 1).

Caloric Deficiency and Growth Failure

Acute severe exacerbations of CD and UC may cause a sudden cessation of food intake, with weight loss and dehydration. More commonly, however, low-grade disease activity causes subtle changes in appetite and growth, especially in CD. Adults with CD have a significantly lower percent body fat (as determined by bioelectrical impedance) compared with patients with UC and controls. In children, growth failure (decreased height velocity leading to short stature) results primarily from inadequate caloric intake. Approximately 50% of children with CD and 10% of children with UC demonstrate decreased height velocity in childhood and adolescence, with accompanying pubertal delay. Growth failure may precede intestinal symptoms of CD in childhood. The etiology of the decreased intake is multifactorial, and may include gastritis and esophagitis, cytokine-mediated anorexia, fear of eating secondary to intestinal inflammation, and decreased taste sensation secondary to micronutient deficiencies (e.g., zinc deficiency). Chronic corticosteroid usage, whether with prednisone or newer agents such as budesonide, may also impair linear growth. While levels of growth hormone and IGF-1 may be low in children, the levels rise with nutritional restitution.

Patients with CD of the small bowel may experience fat malabsorption and steatorrhea, because terminal ileal inflammation leads to decreased enterohepatic circulation of bile acids. Steatorrhea is less common and less severe than in patients with pancreatic insufficiency.

In an anthropometric study of 24 children with moderately active CD, requiring hospitalization, researchers identified a depletion of lean body mass and expansion of the extracellular water compartment. The mean resting energy expenditure (REE), as estimated by indirect calorimetry, was 1250 kcal per day, which was significantly higher than patients with anorexia nervosa and similar degrees of malnutrition. The authors hypothesized that malnourished patients with CD may have a 'lack of REE adaptation' mediated by tumor necrosis factor and interleukin-6.

Osteoporosis

Patients with IBD, especially those treated with long-term corticosteroids, are at increased risk for pathologic fractures, including vertebral compression fractures. The bone mineral density (BMD) of the lumbar spine, as assessed by quantitative computed tomography and dual energy X-ray absorptiometry, demonstrates that approximately 30% of patients with IBD have a BMD *Z*-score of less than -1, compared with approximately 15% of age-matched controls. Patients with CD are at a higher risk of osteopenia than UC patients. Reports suggest that up to 70% of children may have a low BMD, but these reports must be interpreted cautiously because of the lack of well-established pediatric standards. The etiologies for osteopenia in IBD are multifactorial and include hypovitaminosis D, decreased calcium intake, calcium malabsorption from steatorrhea, corticosteroid effects, and cytokine-medicated bone resorption. In addition, primary sclerosing cholangitis, an immune-mediated disease causing bile duct strictures and cholestasis, occurs in 1–4% of IBD patients and may result in additional impairment of vitamin D and calcium absorption.

Anemia and Iron Deficiency

Anemia in IBD is multifactorial and may reflect iron deficiency, folate or vitamin B_{12} deficiency, gastrointestinal blood loss, impaired utilization of iron, or myelosuppression caused by medications (e.g., sulfasalazine, 6-mercaptopurine). The most common cause of anemia in IBD is iron deficiency secondary to impaired iron absorption and intermittent GI bleeding. Laboratory features include microcytosis, serum iron levels $< 30\,\mu g\,dl^{-1}$ and ferritin levels $< 12\,ng\,ml^{-1}$. Iron indices may be misleading, because the chronic inflammation may cause a decrease in the total iron binding capacity and an elevation of serum ferritin.

Micronutrient Deficiencies

While a laboratory studies of micronutrient deficiencies are commonly reported in patients with CD and UC, clinical manifestations of such deficiencies are fortunately quite rare and largely limited to case

reports. Vitamin B_{12} deficiency complicating Crohn's ileitis or ileal resection is the most clinically important vitamin deficiency. In patients with extensive small bowel CD, vitamin A deficiency causing impaired dark adaptation and night blindness may occur. Zinc deficiency causing dermatitis has also been reported. Studies of IBD patients both with active disease and in remission have demonstrated reduced plasma levels of vitamins A, C, D, and E, as well as selenium, magnesium, and zinc. The risk of micronutrient deficiency may be increased with greater disease activity. Folic acid deficiency may occur in individuals taking sulfasalazine. In addition, some of the newer immunomodulatory agents used to treat severe UC or CD (e.g., cyclosporine or tacrolimus) may cause hypocalcemia or hypomagnesemia.

Other Nutritional Complications

CD patients with ileitis or ileal resection may develop hyperoxaluria and renal stones. Increased gut oxalate absorption occurs because the luminal bile acid deficiency results in steatorrhea, and the increased intraluminal fat binds calcium, so there is no free calcium to bind oxalate. High levels of homocysteine have been reported in CD patients from countries where there is no supplementation of grains with folate.

Nutritional Therapy

Nutritional Therapy of the Acute IBD Patient

Hospitalized patients with IBD are typically severely ill. A patient with a severe exacerbation of ulcerative colitis may be passing 15–20 bowel movements per day and have severe abdominal cramping. Eating and drinking may exacerbate the pain, so patients tend not to eat. Thus, while there is no evidence that use of parenteral nutrition helps heal the colitis, bowel rest and parenteral nutrition will help forestall weight loss and may decrease pain. Thus, nutritional support of these patients is a useful adjunct to medical therapy (intravenous corticosteroids and/or cyclosporine). If no response to medical therapy occurs within approximately 14 days, the patient should be considered for colectomy.

Hospitalized patients with CD present with small bowel or colonic mucosal inflammation, abdominal abscess, or small bowel stricture. While ill patients commonly require treatment with corticosteroids, antibiotics, and (in the case of abscess and stricture) surgery, enteral feeding and/or parenteral nutrition is once again a useful adjunct. Hospitalized CD patients who are less ill, whose disease is primarily limited to the small bowel, whose principal symptoms are weight loss and diarrhea, and who do not have stricture or abscess may be candidates for parenternal nutrition as primary therapy (see below).

Enteral Nutrition as Primary Therapy for CD

Multiple randomized controlled trials demonstrate that in patients with active CD, nutritional therapy may induce a remission. Such therapy involves cessation of eating food and exclusive intake of elemental and/or polymeric formula by mouth, nasogastric tube, or gastrostomy. The typical elemental formula has a density of $1\,kcal\,ml^{-1}$, and provides 15% of calories as free amino acids, 25% as medium-chain triglyceride, canola or soybean oil, and 63% maltodextrin or starch. Polymeric formula has a density of $1–1.5\,kcal\,ml^{-1}$, contains similar fat and carbohydrates, but has sodium and calcium caseinate instead of free amino acids.

While the exact mechanism by which formulas induce remission in CD is unknown, postulated mechanisms include decreased dietary antigenic load and modification of the intestinal bacterial flora. In a metaanalysis of eight studies conducted prior to 1995, the remission rate ranged from 50–80% after 4 weeks of therapy. However, it was concluded that corticosteroids were more effective than enteral nutrition at bringing about remission. Trials comparing elemental with polymeric formula as a primary therapy have not demonstrated any clear benefit of one over the other. It is therefore reasonable to use a polymeric formula first, given its lower cost and greater palatability. While liquid diets have the advantage of bringing about remission without exposing patients to corticosteroid side-effects, the disease may relapse within 1–2 months once patients return to a regular diet. In addition, the passage of the nasogastric tube may be uncomfortable for children, and children who go to school with an indwelling nasogastric tube may be stigmatized socially. Enteral nutrition as a primary therapy is commonly utilized in Europe, but less so in the USA.

Enteral Therapy for Growth Failure in Children

Since growth failure and short stature in children and adolescents with CD are principally caused by decreased caloric intake, nocturnal supplementation with formulas increases the height velocity and improves growth. The advantage of nocturnal supplementation is that a child can eat normally during the day, and the nasogastric tube can be removed before a child goes to school. In a typical adolescent or adult, 1000–1500 calories of an elemental or polymeric formula are delivered overnight at a rate of $100–150\,ml\,h^{-1}$. In a controlled study of children aged 8–15 years, nocturnal nastogastric infusion of elemental

formula for 1 out of every 4 months for 1 year resulted in a mean weight gain of 6.9 kg and a height gain of 7.0 cm. In addition, it has been suggested that children who respond initially to 4 weeks of exclusive enteral feeding have a higher probability of staying in remission if they continue with nocturnal supplementation after they resume eating.

Home Parenteral Nutrition

While total parenteral nutrition was a commonly utilized therapy for CD patients in the 1970s and 1980s, home parenteral nutrition is infrequently utilized now. Improvements in medical therapy with the introduction of immunosuppressive agents (azathioprine, 6-mercaptopurine, methotrexate, infliximab) have decreased the number of patients with chronically active disease. In addition, surgeons have become more cautious about resecting bowel in patients with CD, so there are fewer patients with short bowel syndrome. Lastly, it is now realized that enteral nutrition is as effective as parenteral nutrition in bringing about remission in most patients with CD. Home parenteral nutrition may have a limited role in the rare patient with CD refractory to other therapies, intestinal stricture, fistulae, or abscess awaiting surgery. Given that many of these patients are commonly maintained on immunosuppressive drugs, the risk of bacterial or fungal sepsis is significant with prolonged PN.

Nutritional Therapy of Nonmalnourished Outpatients

Most adults and children with CD and UC feel well, are not interested in nasogastric tube feeding, and are either of normal weight or minimally underweight. While clinically asymptomatic, they remain at risk for nutritional complications of IBD and desire dietary counseling. There is no specific diet universally recommended for patients with CD and UC. Low-residue, low-fiber diets may be palliative for patients with narrowed regions of bowel (i.e., CD patients with inflammatory or fibrotic strictures). While there are anecdotal reports of elimination diets (e.g., milk-free, low-carbohydrate) maintaining remission in some patients, there is not enough evidence in the literature to encourage patients to attempt these diets. Studies of fish oil capsules suggest some efficacy in the treatment of ileocolonic CD and mild ulcerative colitis. The efficacy of fish oil may be due to the polyunsaturated fatty acids, which may decrease the production of leukotriene B4 and inflammatory mediator seen in UC.

Given the many studies documenting micronutrient and antioxidant deficiencies, patients should be counseled to take a daily multivitamin. Most such vitamins contain 400 μg of folic acid, but in patients receiving sulfasalazine, 1 mg of folate per day is recommended. Given the risk of osteopenia, patients should be counseled to take 1200–1500 mg of total daily calcium, either through their diet or as supplements. Studies of complementary medicine use in IBD suggest that 20–40% of CD and UC patients routinely utilize herbs and/or megavitamins and fail to tell their physician. Thus, the physician should specifically inquire about such use and inform the patient of the potential toxicities of megavitamin therapy. Patients with chronic ileitis and/or ileal resections should be monitored for vitamin B_{12} deficiency and supplemented with oral or intramuscular vitamin B_{12}.

Prevention of IBD

Both CD and UC have strong genetic components. It is estimated that a child born to a parent with CD or UC has a 5% chance of developing IBD over their lifetime. However, the fact that IBD varies so dramatically by region suggests that environmental factors may also confer risk. Environmental factors already identified include smoking and oral contraceptive use, both of which increase the risk of CD. Since the potential exists that food antigens may be a trigger for the onset of IBD, investigators have tried to identify modifiable dietary factors that may increase risk. Unfortunately, because of the low incidence of CD and UC, prospective cohort studies of risk factors are nearly impossible. Case-control studies suggest that patients with UC have higher intakes of sucrose and fat, and a reduced intake of fructose, fruit, and vitamin C. Given the limitations of these studies, no formal recommendation for a preventative diet can be made at this time.

INSECT PESTS

Contents

Insects and Related Pests

R Davis, Pest Management Consultants and Associates, Savannah, GA, USA

Background

All animals, including our insect pests and their relatives, are here on earth as a part of the balance needed to maintain the health of the biosphere. This need is often questioned, particularly when we so often find insects and mites infesting our food, feed, seed, and fiber. It sometimes seems that these pests can invade and infest almost any commodity under any storage situation despite our most conscientious efforts to exclude them.

The fossil evidence supports the success of these animals which are recorded as having remained relatively unchanged for at least the last 400 million years. We can point to several characteristics, common to all insects, which contribute to this success. Such attributes as the various types of metamorphosis, ability to fly, a high reproductive potential, the ability to survive for long periods of time without food and water, and tolerance to adverse low temperatures all have survival value. Many insects can and will slow their development as a result of population pressure, lack of food, or adverse temperature. There is now evidence of different life-cycle forms within strains of at least two species of flour beetles (*Tribolium* spp.) that may be of value for the establishing of new infestations. These two forms are ones with six larval instars – the invaders – and one with seven

larval instars – the colonizers. Such a division is of great survival value to a species.

Insects are the most successful animal class. Their great variation in food and other environment requirements is of great survival value. Additionally they have enormous dispersal abilities by wing, wind, and piggybacking on higher animals such as birds, bats, and flightless animals, including humans, and this has led to wide distribution for many species. Today, with the assistance of worldwide commerces, insects have now colonized every continent except Antarctica. Many species which now find human food, feed, seed, and fiber as their food and environment are cosmopolitan.

Classification

In order to explain the success of these groups of pests of humans, it is essential to learn something of their classification and their developmental biology. An appreciation is needed of these insect and mite pests in their proper place among all the other animals of the world. In an effort to arrange the world's animals in an orderly manner, humans have developed a hierarchical classification system of seven primary groupings. Each of these groups may have supra- or sublevels, and in some instances additional primary groups are added to accommodate animal groupings that have a large number of species. For our purposes, simply recognizing the seven classification groups presented in Table 1 will suffice for this discussion.

The individuals in the animal kingdom are distinguished from those in the plant kingdom by their ability to move from place to place and their ability to make food from inorganic materials. While there are some exceptions to these characteristics for the animal kingdom, they will not affect our discussion of the phylum Arthropoda. It is in this phylum that we find our insect and mite pests along with their close relatives. Arthropoda is the animal kingdom's largest phylum, in terms of both number of species and the number of individuals. Six distinct classes of animals are readily recognized in the phylum Arthropoda.

Table 1 Classification of the animal kingdom

Classification	*Examples*	
	Insects	*Mankind*
Kingdom	Animalia	Animalia
Phylum	Arthropoda	Chordata
Class	Insecta (Hexapoda)	Mammalia
Order	Coleoptera	Primata
Family	Tenebrionidae	Hominidae
Genus	*Tribolium*	*Homo*
Species	*confusum*	*sapiens*

Several other classes have been placed in this class from time to time by various specialists, but again the placement of these questionable classes will not affect our discussion.

The major characteristics of the phylum Arthropoda are as follows: (1) the body is segmented; (2) the appendages are paired and segmented; (3) the body possesses an exoskeleton; and (4) the body is bilaterally symmetrical.

By using these four characteristics for the phylum we can develop a simple key that will distinguish for us the main classes of Arthropoda and show us something of their relationships.

1a. Aquatic species (2 go to couplet)
1b. Aerial species, but some may be limited to very moist environments (3 go to couplet)
2a. Marine species without antennae. This class is represented by a single species: *Xiphosura polyphemus*, the horseshoe crab: class Merostomata
2b. Both marine and fresh-water species, possessing two pairs of antennae and at least five pairs of legs, e.g. crayfish, lobsters and shrimps: class Crustacea (in part)
3a. Possess two pair of antennae and live in moist environments, e.g., sowbugs, pillbugs (order Isopoda) and shrimp fleas (order Amphipoda): class Crustacea (in part)
3b. Does not possess two pairs of antennae (4 go to couplet)
4a. Possess no antennae, four pair of legs as adults, and have only two apparent body regions (cephalothorax and abdomen), e.g., spiders, scorpions, ticks, and mites (order Acarina): class Arachnida
4b. Possess one pair of antennae (5 go to couplet)
5a. Possess more than three pairs of legs and no wings (6 go to couplet)
5b. Possess three pairs of legs and usually wings in the adult stage, e.g., beetles, moths, cockroaches, and flies: class Insecta
6a. Possess two pairs of legs on the same body segment, e.g., millipedes: class Diplopoda
6b. Possess one pair of legs on each body segment, e.g., centipedes: class Chilopoda

In the protection of agricultural commodities (food, feed, seed, and fiber) we are primarily interested in the mites, class Arachnida, order Acarina, and the insects, class Insecta, primarily the orders Lepidoptera (moths) and Coleoptera (beetles).

The classes Insecta and Arachnida are very large animal groupings from the standpoint of both numbers and species. While the total number of animals species worldwide is often debated, it can really be stated that the arthropods, principally the insects and mites, represent over 90% of the known

and described species. There are various estimates of this number, but it is safe to say that the known and described species would easily exceed one million. Fortunately, the number of species infesting our stored subsistence and fiber is quite limited. A US Department of Agriculture publication provides an illustrated key listing 650 species of insects and mites known to infest food in the USA. As most insects attacking stored subsistence have traveled with their food around the world, they are considered as cosmopolitan in distribution. A publication of the American Peanut Research and Education Society lists 120 species collected in the south-eastern USA on stored-in-shell peanuts, an excellent host for many insects attacking stored food. However, they only elected to discuss 21 of these species as major pests. Many of the others collected were parasites and predators on the pests, or insects that attack peanuts which are out of condition, e.g., possessed a high moisture content, were moldy, or had an excessive amount of debris mixed with the peanuts.

Mite species attacking stored commodities would likewise be quite limited. Only 16 mite genera have been listed as possessing species attacking stored commodities. Here again most other species found in stored commodities are predators of insects and mites infesting the commodity. These naturally occurring parasites and predators, e.g., members of the mite genus *Pyemotes* (family Pyemotidae), which prey on insects infesting the commodity, are often as serious a problem as the phytophagous species. Members of this family will often attack humans and cause a dermatitis known as 'grocer's itch.' These mites and insects are food contaminates and will be considered as filth by sanitarians and food inspectors. However, it must be realized that the management of phytophagous insects and mites will in turn control these insects and mite contaminates. (*See* **Parasites**: Occurrence and Detection.)

When infestations of birds, rodents, or bats exist within or close to storage facilities, there may occur in and on the commodities, and its packaging, insects and mite parasites, as well as predators of these higher animals. Some of these parasites and predators may also attack humans, and their occurrence will always be considered to be evidence of unsanitary storage conditions.

It is probably safe to say that for most stored subsistence we will find a limited number of major pests among those found infesting the commodity. There will be a slight variation in the species complex for each commodity and for that part of the world where the storage takes place. However, this latter variation will usually be quite small and perhaps go unnoticed because most of these pests are cosmopolitan, resulting from world trade in commodities.

For the convenience of humans, the insects and mites attacking stored commodities have been grouped in nonscientific ways by those responsible for handling the commodities and those responsible for controlling these pests. These groupings are artificial and primarily designed to assist warehouse-workers, pest control operators, sanitarians, and farmers in discussions of their observations. In the protection of stored whole grain, one often speaks of internal feeders, external feeders, scavengers, and secondary and tertiary feeders. If the commodity is a packaged product the terms become penetrators and invaders. The terms long-lived and short-lived will, on occasion, be used in relation to adults. Other terms heard will be grain beetles, flour beetles, grain moths, flour moths, mealworms, warehouse beetles, fabric pests, hide beetles, and many others, depending upon their environment and/or their food habits. Most of these terms are self-explanatory. Several are not and will be defined below and followed by examples.

Pests of Stored Plant Products (Seeds)

Internal Feeders

These insect larvae feed entirely within the seed. Examples of internal feeders include the rice, granary, and maize weevils, *Sitophilus* spp., the Angoumois grain moth, *Sitotroga cerealella* (Olivier), and all the bean and pea weevils.

External Feeders

All stages of these insects feed outside the seed. Examples of external feeders include the lesser grain borer, *Rhyzopertha dominica* (F.) the khapra beetle *Trogoderma granarium* Evert, and the cigarette beetle, *Lasioderma serricorne* (F.)

Scavengers

These insects feed on seeds only after the seed coat is broken. Examples of scavengers include the flour beetles, *Tribolium* spp., flat grain beetles, *Cryptolestes* spp., and grain beetles, *Oryzaephilus* spp.

Secondary Feeders

These insects feed only on products that are deteriorated, damp, and moldy. Examples of secondary feeders include *Tenebrio* and *Alphitobius* spp., mites *Acarus siro* L. and *Tyrophagus* spp., and psocids, *Liposcellis* spp.

Penetrators

These insects have the ability to penetrate many of the types and combinations of paper, films, and foils used

in packaging. Examples of penetrators include the lesser grain borer, cigarette beetle, and many of the moth larvae.

Invaders

These insects usually depend upon openings in the packages resulting from the manufacturing process, or openings made by penetrating insects. Examples of invaders include the flour beetles and the grain beetles.

Pests of Animal Products

Some insects and mites need or prefer a diet higher in protein than they can secure by feeding exclusively on plant-derived foods. These pests feed on dried meats, hair, feathers, dried fish, and on processed animal products such as woolen cloth, dried milk and eggs, fishmeal, cheese, and leather. These pests can be grouped according to the foods eaten. The following are some of the more common and important groupings.

Fabric Pests

Fabric pests feed on keratinous materials such as wool cloth, mohair, and hair, and include such species as the clothes moths, *Tinea* and *Tineola* spp., and the carpet beetles, *Attagenus* and *Anthrenus* spp.

Pests of Hides and Skins

These pests will feed on green hides and skins, and can cause considerable damage and defects. Pests of hides and skins include several species of the genera *Dermestus* and *Trogoderma* spp., the ham beetle, *Necrobia rufipes* (DeGeer), the spider beetles, *Ptinus* spp., flesh flies *Sarcophaga* spp., carpet beetles of the genera *Attagenus* and Anthrenus spp., and the cheese skipper, *Piophila casei* (L.).

Pests of Processed Animal Products

These insects can be represented by almost any of the above species as well as many of the species that commonly feed on processed plant products. Many animal feeds are mixtures of both animal- and plant-derived products.

Pests of Root Crops

In the part of the world where root crops are commonly stored dry, they are attacked by many of the boring beetles that are known to attack dried grain and harvested wood, e.g., the lesser grain borer.

Pests of Perishables

The most common pests of perishables such as fresh fruits, particularly those fruits of tropical and subtropical origins, are the fruit flies of the insect family Trypetidae, e.g., the Mediterranean fruit fly.

Pests of Dried Fruits and Nuts

These commodities have many insect pests, many of which come in from the field at harvest time. They include pests that feed on the commodity and also on the fungus and molds that grow on and in the commodity. Major pests include several moth species, e.g., the almond moth, *Cadra cautella* (Walker), beetle species of the genera *Tribolium* spp., *Oryzaephilus* spp., and *Carpophilus* spp.

Mite Pests

The phytophagous mites attacking and infesting stored commodities must be classified as scavengers. In some instances they have been recorded as attacking sound kernels of grain and consuming the germ. This is questionable, but most probably the grain possessed a high moisture content, and fungi has infested the germ and the kernel. Like insects, mites contaminate much more commodity than they consume – with their feces, odors, cast skins, and dead bodies. As with the insects, scavengers and secondary feeders, contamination by mites suggests that the commodity is out of condition.

Unfavorable temperatures and relative humidities will result in significant deterioration of the commodity for further spread of insect, mite, and fungi infestations.

Developmental Biology

It is important that we understand the biology and life cycles of these pests of our food and fiber. All insect and mite pests develop from eggs. Most young hatch from the egg after the female lays it, but a few are born alive from eggs that hatch inside the mother. Following the hatching, these pests develop in a stepwise fashion by stages. Each stage is limited in size by the space provided inside the exoskeleton. As the pest develops it lays down a new exoskeleton beneath the current one. At specific times, determined by hormonal action, the old exoskeleton splits down the back of the pest and the next stage emerges and expands to its new size limitation. The process of shedding an old exoskeleton and emerging with a new exoskeleton is called moulting. Usually an insect will have four to eight moults but some insects, e.g., members of the family Dermestidiae, can have more than 20 moults. The period of time between moults is called an instar.

During growth, insects change not only in size but also in form. In some instances the only change will be maturity and development of the sexual organs

while in other species the changes will be quite startling. This process of change accompanying growth is called metamorphosis. There are four distinct types of metamorphosis in insects: ametamorphosis, gradual metamorphosis, incomplete metamorphosis, and complete metamorphosis.

In ametamorphosis there is very little change in form as the insect grows, and the only visual changes will be size and sexual maturity. An example of an insect possessing this type of metamorphosis is the silverfish.

In gradual metamorphosis the insect develops from egg to nymph to adult. The nymphs resemble the adult except that they are smaller, not winged or sexually mature. An example of an insect with this type of metamorphosis is the grasshopper.

Incomplete metamorphosis involves much greater body changes than those in gradual metamorphosis. The young have a completely different body structure and habitat from the adults. The young are aquatic and called naiads. The adults are terrestrial and often winged. An example of an insect with this type of metamorphosis is the dragonfly.

In insects with complete metamorphosis we find four distinct life stages: egg, larva, pupa, and adult. The larva is worm-like in appearance, but its activity varies from a rapidly moving individual or free-living larva to legless grubs found inside seeds. The pupal stage, which is a resting stage between the larva and adult, is really a very active time. It is at this time that the larval body is broken down and the adult body constructed. The last stage, the adult, which is often very different from the larva and pupa, has as its main function dispersal, mating, and extending or finding new habitat.

Members of the class Arachnida also possess a form of metamorphosis, but changes are not so extensive as those in insects. In the Acarina (mite) there are usually four life stages: egg, larva, nymph, and adult. The larva has only six legs and there are three nymphal stages. The nymphs appear to resemble the adults, but are not sexually mature.

Some species in both the insects and mites have or can develop forms, during the larval and nymphal stages respectively, that are resistant or tolerant to adverse environmental conditions. These resistant or tolerant stages are referred to as a condition of diapause in insects and as a hypopus in a mite.

Most of the insect pests of food, feed, seed, and fiber have complete metamorphosis. This type of development allows for the larva and adult to have separate ecological niches on the same food or separate habitats for all their life activities. This developmental method has great survival value. The various life stages within the species development usually do not cause any population pressure on each other.

The study of insects and mites and their relationship to the welfare of humans has been both a valued and an interesting pursuit of science. Elucidating their behavior, physiology, and genetics has led and will continue to lead to newer and safer ways to control these animals with a penchant for our food and fiber.

Problems Caused by Insects and Mites

R Davis, Pest Management Consultants and Associates, Savannah, GA, USA

Background

In 1978, contributors to the US National Academy of Sciences report, *Postharvest Food Losses in Developing Countries*, pointed out that to quantify food losses to insects and other postharvest pests was virtually impossible. They set 10% as an average minimum overall loss for cereals and legumes and 20% as the minimum for perishables and fish. Because diets in developing countries contain little, if any, dried or

smoked red meat or poultry, no loss figures were considered.

In 1975, worldwide losses due to insects and rodents were estimated by the Food and Agriculture Organization (FAO) of the United Nations as about 20%. These figures ranged from about 10% in developed countries to 30% in African and Asian countries. However, in the literature, authoritative sources often refer to losses of 50% in grain, with much of the remainder so contaminated or damaged as to be nearly worthless. Whether we will ever be able to quantify the losses correctly may not be as important as we believe. In any of the underdeveloped or developing countries of the world there are instances where pests have ruined entire storages; there is clearly a need for correction.

The effort to secure adequate loss data to estimate worldwide losses requires a study of the continuum from the farm to the consumer. This has proved to be a major logistics problem in even the most developed countries. In addition, social and cultural factors will also limit the methods of preparation and utilization. Politics will affect the storage, distribution, and availability. It requires a concerted effort on the part of all levels of government and the consuming public to insure an adequate supply of wholesome and nutritious food and quality fiber.

The seriousness of the postharvest losses has been recognized by the United Nations. In 1975, the FAO organized a conference on postharvest food losses. This conference stressed the losses in the tropical regions and established a goal of reducing postharvest food losses by 50% by 1985. To achieve this goal it was necessary to develop methods of loss assessment. Neither goal has been reached as yet, but many improvements have been made in protecting harvested foods during their movement from the farm to the ultimate consumer.

Sites of Possible Food Losses

Losses may occur at any point during the interim between the harvest and gathering up to the point of consumption. For the convenience of this discussion this continuum will be broken into the following intervals:

1. Harvest – the separation of, or collection of, the part of the plant to be utilized by humans or the slaughter of animals.
2. Initial processing – the separation of, or extraction of, edible from nonedible, e.g., peeling of fruits and vegetables, removing corn (maize) from the cob, and other activities associated with cleaning, drying, and grading, or cleaning and cutting-up of animal carcasses.
3. Preservation – the prevention of loss and spoilage, e.g., providing proper storage conditions and facilities, drying to inhibit fungus growth, and the use of pesticides to protect against insect attack.
4. Storage – the management of the storage facility, e.g., protecting food from damage by moisture, temperature, and pests through the use of aeration, pesticides, refrigeration, controlled atmospheres, etc.
5. Transportation – the use of all kinds of vehicles and containers to move foods from point of production to the point of final consumption.
6. Processing – the conversion of edible forms of plant and animal products into another form which is more acceptable or more convenient to the consumer, e.g., reducing the fat content in meats, packaging and canning fruits and vegetables, and quick-freezing raw and partially prepared individual foods or even complete meals.

Industries at Special Risk

The loss of a food for any reason is significant to those who suffered the loss. However, when losses are very large and involve significantly large areas, such as regions and countries, the economics and logistics of supplying these areas with replacement food stocks become a major problem which usually results in suffering and starvation. In the underdeveloped countries and, to a somewhat lesser extent, in the developing countries, the most important industry is farming.

The farmers must store sufficient food to feed themselves and their families for about a year, and produce enough surplus first, to sell in order to secure needed staples and second, to meet their seeding needs for the next cropping season. To some extent farmers have to backstop themselves against catastrophic losses by joining in cooperative storages at the village or other local levels. In many countries the national governments have established programs of food storage administered by departments or ministries of food, agriculture, or supply. However, such programs are dependent upon food production within the country, or the availability of currency or credit that will allow for importation in the event of harvest shortfalls.

It is well documented that many pests attacking stored products, particularly the grains and oilseeds, first attack these seeds in the field. Similarly, it is also known that many transportation vehicles and containers often harbor pests left from previous uses of these vehicles and containers. While these insects and mites are, without question, the source of many subsequent infestations that arise in storage and processing facilities, they are rarely, if ever, adequately

controlled. Proper insect-resistant packaging and intransit and static fumigation of ships, barges, railcars, and containers are examples of procedures that have helped to minimize the effect of residual insects and mites in such vehicles. (*See* **Cereals**: Handling of Grain for Storage; **Fumigants**.)

In the continuum of food moving from the farm to the ultimate consumer, there are two primary areas where the industries involved in the interim can be at special or high risk. These two areas are storage and processing. While it is recognized that some firms may well be involved in both storage and processing, the two areas will be discussed separately.

Storage Industries

It is in the industries that provide and maintain storage facilities that those rather large losses due to pests occur. In these facilities raw or partially processed products are stored in bulk, providing a large, readily available food supply for any pest that can gain entry. In the case of insect and mite pests the process of exclusion is often very difficult, or expensive, or both. Fortunately, these pests are poikilothermic (cold-blooded) and cannot adjust their body temperatures from that of the environment. Therefore proper regulation of the temperature and the moisture content of the commodity can be used to prevent any incipient infestations from getting out of hand and causing large amounts of damage. (*See* **Storage Stability**: Parameters Affecting Storage Stability.)

The problems of providing proper storage and educating those responsible for managing such storage have occupied an important place on the agenda of international organizations such as the FAO, the International Atomic Energy Agency (IAEA) and the World Bank, as well as international consortiums such as the Group for Assistance on Systems Relating to Grain After Harvest (GASGA). Placing emphasis on well-managed storage is, of course, a proper approach; logistics, transportation, and processing are rather unimportant if there is nothing to move, distribute, or process. Storage is also the point at which significant losses in both quantity and quality can occur in developing countries, unless trained and experienced personnel are responsible and alert to such potential problems.

Processing Industries

In the industries preparing and modifying foods for increased acceptance and convenience, we rarely see major losses in quantity of food products. However, losses in quality will occur unless those responsible for the actual processing are not constantly alert. The loss in quality will usually come about through an inspection or regulatory procedure, and will usually be in the form of adulteration and contamination. Most developing countries have regulations, supported by an inspection procedure that will establish the quality of food produced as a result of processing. Industry, to protect itself, develops good manufacturing practices that, if followed, meet their country's regulations for clean, safe food.

Therefore it is essential for the maintenance of a safe food industry that correct identifications of insects and their related pests are readily available. Such identifications must include all life stages – eggs, larvae, pupae, and adults – found in both raw and processed food. In fact, this need for rapid and accurate identifications extends to fragments of insects found in processed foods.

In the USA, this regulation of foods is found in the Food and Drug Act (FDA). Regarding insects, mites, and other pests, this law says that a food is adulterated if it has been prepared, packed, or held under conditions whereby it may have become contaminated. The food inspected does not have to contain pests. The FDA inspector noting excessive evidence of insects will try to find the infested product, but such a finding is not required for regulatory action. (*See* **Legislation**: Contaminants and Adulterants.)

Processing industries may also confront another regulatory process in many countries, that of plant and animal quarantine. These laws are not promulgated to protect humans and their animals from adulterated foods but rather to prevent the importation of pests that will affect the nation's agriculture. However, these laws may impact upon the availability of a product scheduled to be processed.

Problems and Control of Beetles and Weevils

Beetles and weevils are most often thought of as pests of grains and legume seeds. This is apparently due to the large quantities of these seeds stored and our heavy dependence upon them. However, they are also major pests of roots and tubers, dried fruits and nuts, and dried meats and other animal products. In Table 1 is a listing of the major beetle and weevil pests of these stored products.

The control of beetles and weevils has traditionally been to maintain a low and uniform temperature and moisture content throughout. Most insect and mite pests have quite specific optimum temperatures for activity and reproduction, and a lower level with regard to moisture content of the product for survival. This optimum temperature is between 21 and 35 °C, with minimum moisture content of 10–10.5%.

Table 1 Beetle and weevil pests of stored products

Pests of grain and legume seeds and their processed products	
Khapra beetle (*Trogoderma granarium*)	Siamese grain weevil (*Lophocateres pusillus*)
Larger grain borer (*Prostephenus truncatus*)	Rusty grain beetle (*Cryptolestes ferrugineus*)
Lesser grain borer (*Rhizopertha dominica*)	Foreign grain beetle (*Ahasverus advena*)
Cigarette beetle (*Lasioderma serricorne*)	Longheaded flour beetle (*Latheticus oryzae*)
Sawtoothed grain beetle (*Oryzaephilus surinamensis*)	Broadhorned flour beetle (*Gnathocerus cornutus*)
Merchant grain beetle (*Oryzaephilus mecator*)	Drugstore beetle (*Stegobium paniceum*)
Confused flour beetle (*Tribolium confusum*)	Bean weevil (*Acanthoscelides obtectus*)
Red flour beetle (*Tribolium castaneum*)	Cowpea weevils (*Callosobruchus* spp.)
Granary weevil (*Sitophilus granarius*)	Pea and bean weevils (*Bruchus* spp.)
Rice weevil (*S. oryzae*)	Groundnut beetle (*Caryedon serratus*)
Maize weevil (*S. zeamais*)	Coffee bean weevil (*Araeceres fasciculatus*)
Pests of roots and tubers	
Powder-post beetles (*Lyctus* spp.)	Sweet potato weevils (*Cyclas* spp.)
False powder-post beetles (*Bostrichid* beetles)	Yam beetles (*Prionoryctes* spp.)
Siamese grain beetle (*Lophocateres pusillus*)	Broadnosed grain weevil (*Caulophilus oryzae*)
Flat grain beetles (*Cryptolestes* spp.)	
Pests of dried fruit and nuts	
Cigarette beetle (*Lasioderma serricorne*)	Red flour beetle (*Tribolium castaneum*)
Sap beetles (*Carpophilus* spp.)	Nut weevils (*Curculio* spp.)
Sawtoothed grain beetles (*Oryzaephilus surinamensis*)	
Pests of dried meats and other animal products	
Hide beetles (*Dermestes* spp.)	Carpet beetles (*Anthrenus* spp.)
Carpet beetles (*Attagenus* spp.)	Ham and copra beetle (*Necrobia* spp.)

At temperatures below 13–15 °C reproduction is severely limited in most species, and at lower temperatures it is prohibited altogether.

In conjunction with managing the storage environment there have been two approaches – preventive and corrective – to the effective use of chemical pesticides. The preventive approach has involved the use of grain and oilseed protectants, residual pesticides sprayed or dusted directly on to the seeds, or into raw foods that have a legal tolerance for the pesticides. Residuals will be applied most often into the storage in the form of crack and crevice, spot or general sprays or dusts, to prevent crawling pests from reaching the product. Often a program of periodic applications of insecticide fogs or aerosols is used to supplement these residual pesticide applications. These fogs and aerosols are contact pesticides and provide little, if any, residual, but provide excellent control of exposed crawling and flying pests. (*See* **Pesticides and Herbicides**: Residue Determination.)

The corrective approach involves the use of fumigants, particularly when an infestation gets out of hand, or when there is a need for a quick kill to facilitate a sale or meet a quarantine requirement. When a food requires this treatment, it is generally the result of the preventive program being ineffective as a result of some breakdown in the pest management program.

There are several fumigants available throughout the world, but many are now being phased out or banned because of their adverse effect on humans or the environment. Two fumigants, methyl bromide and phosphine, are still readily available and used throughout most of the world for the protection of foods. Phosphine or hydrogen phosphide gas, a product of atmospheric moisture reacting with a metal phosphide to release the gas PH_3, is the easiest to use, readily available and leaves little, if any, residue. It does require 3–5 days' confinement, with the product under ideal temperature conditions of 15–35 °C, and longer if the gas is to penetrate to depths of 10–20 m without the assistance of a recirculation system. Methyl bromide is still the fumigant of choice when fumigations must be effected within 24 h or less. It is also the fumigant of choice by most quarantine agencies. However, methyl bromide has been determined to be an ozone depleter and therefore is considered to be detrimental to the earth's protective ozone layer (in an international treaty referred to as the Montreal Protocol). Currently methyl bromide is being phased out of production and use and most probably will not be available as a fumigant in developed nations after the year 2005 and developing nations after the year 2015.

The major problem in effecting satisfactory control is the difficulty of detecting infestations of the weevils and borers. Shortly after an infestation is established, more than 95% of the population – larvae and pupae – is hidden within the seeds. This results in a large amount of damage for the small number of adults that may be visible. It is therefore important to maintain an effective surveillance and inspection program if populations of these insect pests are to be managed and damage is to be minimized.

Problems and Control of Moths

As with the beetles, moth pests of stored products are also primarily pests of grains and legumes. However,

Table 2 Moth pests of stored products

Moth pests of grain and legume seeds and their processed products	
Almond moth (*Cadra cautella*)	Meal moth (*Pyralis farinalis*)
Indianmeal moth (*Plodia interpunctella*)	Rice moth (*Corcyra cephalonica*)
Angoumois grain moth (*Sitotroga cerealella*)	Mediterranean flour moth (*Ephestia kuehniella*)
Tobacco moth (*Ephestia elutella*)	Pink bollworm (*Pectinophora gossypiella*)
Moth pests of roots and tubers	
Potato tuber moth (*Phathorimaea operculella*)	Gray pyralid (*Pyralis manihotalis*)
Moth pests of dried fruits and nuts	
Almond moth (*Cadra cautella*)	Hickory shuckworm (*Lespeyresia caryana*)
Dried fruit moth (*Ephestia calidella*)	Naval orangeworm (*Paramyelois transitella*)
Raisin moth (*Ephestia figulilella*)	Indianmeal moth (*Plodia interpunctella*)
Moth pests of dried meats and other animal products	
Gray pyralid (*Pyralis manihotalis*)	White-shouldered house moth (*Endrosis sarcitrella*)
Case-bearing clothes moth (*Tinea pellionella*)	Brown house moth (*Hofmannophila pseudospretella*)
Common clothes moth (*Tineola bisselliella*)	

they are major pests of dried fruits and animal products. In Table 2 is a listing of the major moth pests by commodity groupings. (*See* **Legumes**: Legumes in the Diet.)

The control of moths in storage situations is effected in much the same way as the control of beetles and weevils. Their presence is readily recognized by the presence of flying adults. The larvae of the moths, the caterpillars, do not penetrate deeply into the stored product and usually are found feeding close to the surface. The larvae trail out a dragline of silk as they move about. In very heavy infestations these silk lines can coalesce and form a cover over the surface like a tarpaulin and even affect the penetration of fumigant gases. However, when any amount of silk occurs it is the result of a neglected or mismanaged situation. One pest, the Angoumois grain moth, has a behavior somewhat similar to that of weevils. It often infests the grain in the field, and the larvae mine inside the seed, making it difficult to assess the population. The adults of the moths do not feed; the larvae cause all the damage.

Today the monitoring for infestation of moths is made much easier by the use of pheromones and traps. However, their acceptance by warehouse staff has been slow because of the low dollar value per unit of raw commodity stored. There also remain some questions as to how to space these traps in a warehouse and exactly what the catch means. It is only a matter of time before these questions are answered, at least for our major commodity groups.

Problems and Control of Mites

Mites are not primary pests of most foods, except possibly for crops such as mushrooms and cheeses, and similar products associated with fungi and fermentation. There are relatively few mites of importance to foods, but those that do attack often cause very serious problems and great loss of product. In Table 3 is a list of some of the major mite pests occurring in foods. (*See* **Spoilage**: Yeasts in Spoilage.)

When mite infestation occurs, it is usually the result of unfavorable storage conditions. Mite populations flourish in cool, moist environments which are also conducive to the growth of fungi and yeasts. Under these conditions, the mites feed on both the fungi and yeast and on the substrata that have been prepared by these fungi and yeasts. The fungi and yeast break down the seed coat on the grain and the legumes, and moisten or otherwise prepare the food for the mite to feed on.

The control of mites is largely one of correcting the environmental conditions so that it is unfavorable for the mites. The use of residual pesticides is usually ineffective because the fungi, yeasts, and moisture degrade the pesticides. Residues on adjacent surfaces, e.g., walls and floors, are quite ineffective, as the mites are small; they move slowly and rarely, if ever, encounter these surfaces. The use of fumigants is effective, but they may not always be legally used on the food product involved. Some success has been achieved by use of high temperatures, above 38 °C, but some foods may not accept such high temperatures.

Past, Present, and Future of Insect Pest Control

Pest control methodology can be found in the ancient writings of biblical times. Grain was stored in sealed

Table 3 Mite pests of stored products

jars, providing a lethal atmosphere devoid of oxygen and high in carbon dioxide, or grain was treated with abrasive minerals or diatomaceous earth or fumigated by sulfur dioxide produced by burning sulfur. During the last century dependence has also been on the arsenicals and botanicals and several fumigant gases. Since World War II, we have been heavily dependent upon chemicals, e.g., chloronated hydocarbons, organophosphates, carbamates, and pyrethroids. We have now learnt that the effects of these chemicals on the environment and their efficacy for insect control have been counterproductive to our goals for a quality of life.

During the last 30–40 years our research efforts have been ever-increasing in the search to protect our food, feed, seed, and fiber by better detection and damage assessment and the implementation of programmes of integrated pest control. Integrated pest control is described as including an integration of pest control tactics that emphasize the prevention and avoidance of pest problems and meet economic, public health, and environmental goals.

The following list describes some pest control tactics of the present and future for possible use in integrated pest control:

1. Modified atmospheres – the use of reduced oxygen concentration by the addition of carbon dioxide, nitrogen, or combustion gases.
2. Gamma-radiation – the use of ionizing electromagnetic energy, which causes cell and tissue damage.
3. Accelerated electrons – the use of high-speed electrons, which upon impact destroy cells and tissues.
4. Hermetic storage – the sealing of a food in a container so that natural respiration of the food and any pests present will reduce the oxygen content to a level that will not sustain life.
5. Parasites and predators – the addition of insect parasites and predators to raw commodities to control the pest feeding on the food.
6. Insect pathogens – the use of bacteria, viruses, and fungi that naturally attack the pests of foods but are not harmful to humans or animals.
7. Temperature – the use of high or low temperatures, including infrared and microwave radiations.
8. Genetic engineering – the insertion of a gene that produces a material that is toxic to the insect pests but not to other animals.
9. The safe and responsible use of chemical insecticides and acaricides in combination with other pest control tactics. (*See* **Chill Foods:** Effect of Modified-atmosphere Packaging on Food Quality; **Irradiation of Foods:** Basic Principles.)

INSTRUMENTATION AND PROCESS CONTROL

R G Moreira, Texas A&M University, TX, USA

Introduction

Process control involves the regulation of variables in a process. It is the combination of raw materials and equipment that produces a desirable final product through changes in their energy and physicochemical properties. These processes can be continuous or batch.

In the food-processing industry, automatic control is one of the key elements that affect productivity, quality, safety, and competitiveness. Automation has become an integral part of modern food manufacturing today. It is essential, for example, in controlling pressure, temperature, viscosity, humidity, and flow rate as well as product quality attributes such as color, texture, bulk density, moisture, and oil contents.

In the past, food-processing systems used only crude control of flow rates, ampere meters to estimate the power drawn by drive motors, and thermocouples and visual observation at the process discharge to maintain product specifications. Nowadays, new applications require precise control over the input variables to achieve a consistent product within narrow specification limits and to maximize throughput. Food process operations today are monitored and controlled by computer systems, using accurate information of input and output variables and advanced control algorithms.

Description of Control Systems

The Control System

A control system is considered to be any system that exists for the purpose of regulating and controlling a process output. Consider, for example, the air-conditioning system used to keep fruits and vegetables fresh in a warehouse. The air-conditioning unit (consisting of a condenser and a compressor) is a system that produces cold air as a result of the flow of refrigerant. This process is assembled with subsystems such as valves and valve actuators that regulate the temperature of the warehouse by controlling the cold air output from the air-conditioning unit. Other subsystems, such as thermostats, which act as sensors, measure the room temperature.

Simply stated, a control system provides an output or response for a given input or stimulus, as shown in Figure 1. The input–output relationship represents the cause-and-effect relationship of the process.

The Input and Output

The input represents a desired response: a factor (variable) that is used to modify the system behavior. It is also called manipulated variable, i.e., a dependent variable of the process used to cause a change in the process.

The output is the actual response – a factor (variable) that is caused by a system and is used as a measure of performance for the given system. It is also called controlled variable, i.e., an independent variable of a process, and can be defined as the parameters of the process that indicate product quality or the operating condition of the process.

The input–output relationship represents a processing of the input signal to provide an output signal variable, often with power amplification.

Open-Loop and Closed-Loop Systems

An open-loop control system (Figure 2a) utilizes a controller (or control actuator) to obtain the desired response (also called reference input or setpoint). The input is sometimes called the reference (or target). An example of such a system is a bread machine, where mixing, raising, and kneading operate on a time basis. The bread machine does not measure the output that is the final product – the bread quality (color, volume, doneness).

Open-loop control systems are used when the relationship between the input and output is known and when internal or external disturbances are not present in the process. Disturbances such as machine wear and ambient humidity can affect the final product quality and the system cannot correct for these disturbances.

Therefore, open-loop systems do not correct for disturbances and are simply commanded by the input. A toaster is another typical example of an open-loop system. In this case, the controlled variable (output) is the color of the toast. The machine

Figure 1 Simplified description of a process to be controlled.

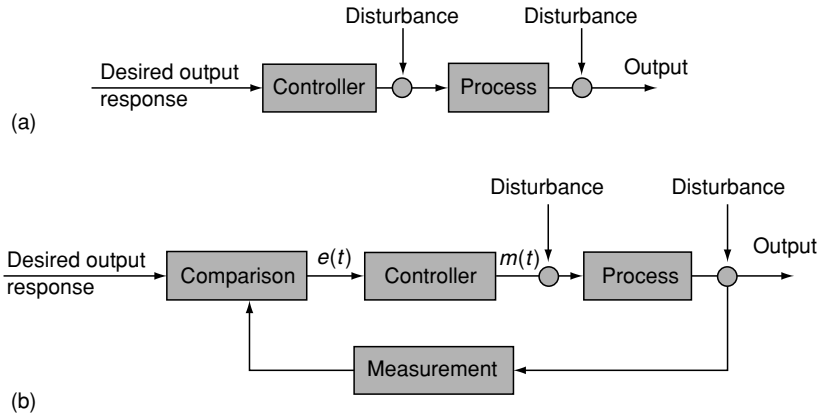

Figure 2 (a) Open-loop control system; (b) closed-loop control system.

operates by applying heat to turn the toast darker. The toaster does not measure the color of the toast. It does not correct for the fact that the toast is rye, white, or sourdough, nor if the toast comes in different thicknesses.

Sensitivity to disturbance and the system's inability to correct for disturbances are the main disadvantage of the open-loop system. Closed-loop control systems may be used to overcome the drawbacks of open-loop systems. A closed-loop control system uses an additional measure of the actual output to compare the actual output with the desired output response. The measure of the output is called the feedback signal. A simple closed-loop feedback control system is shown in Figure 2b.

A feedback control system uses a function of the prescribed relationship between the output and the reference input to control the process. At the comparison box (Figure 2b), the difference between the output of the process under control (which arrives via the feedback path) and the reference input is amplified and used to control the process so the difference is continuously reduced. This difference is referred as the input error ($e(t)$ in Figure 2b).

The comparison box generally consists of an input transducer that converts the input signal to a form used by the controller. At the measurement box, an output transducer (sensor) is used to measure the output response and also to convert this response signal to the form used by the controller. For example, if the controller uses electrical signals to operate the valve of a temperature control system, the input position and the output temperature are converted to electrical signals. Potentiometers are used to convert input position to voltage. A thermistor, a device that changes its electrical resistance with temperature, is used to convert output temperature to voltage.

The closed-loop system compensates for disturbances by measuring the output response, feeding the measurement back through a feedback path, and comparing that response to the input at the comparison box (Figure 2b). If there is any difference between the two responses ($e(t) \neq 0$), the system drives the process to make a correction. If there is no difference ($e(t) = 0$), the system does not drive the process, since the process response is already the desired response. Closed-loop systems are also called feedback control systems.

To illustrate the concept of feedback control, Figure 3a shows a simplified manual control of a baking process. On the outlet side of the oven, there is an indicator (colorimeter) to provide the operator with information on the actual value of the biscuit outlet color (controlled variable). The operator wants to keep the biscuit final color close to the desired value. If the operator watches the colorimeter and finds that the color value is higher (the biscuit is darker) than the desired response, he/she will increase the conveyor speed, i.e., the auger r.p.m. It is considered in this example that the oven temperature and air flow rate are maintained constant for simplicity. The desired response, of course, is in the operator's mind and the operator makes all of the control decisions. It is quite possible that the color becomes lighter so the operator will have to repeat the operation in the opposite direction until the desired value is reached and kept constant during the operation.

If the operator is replaced by an automatic controller, as shown in Figure 3b, the system becomes an automatic feedback control system. The actual outlet biscuit color (the process output), measured by the colorimeter, is compared to the desired response and an acting error signal generated. The output color is converted to the same units of the desired response by

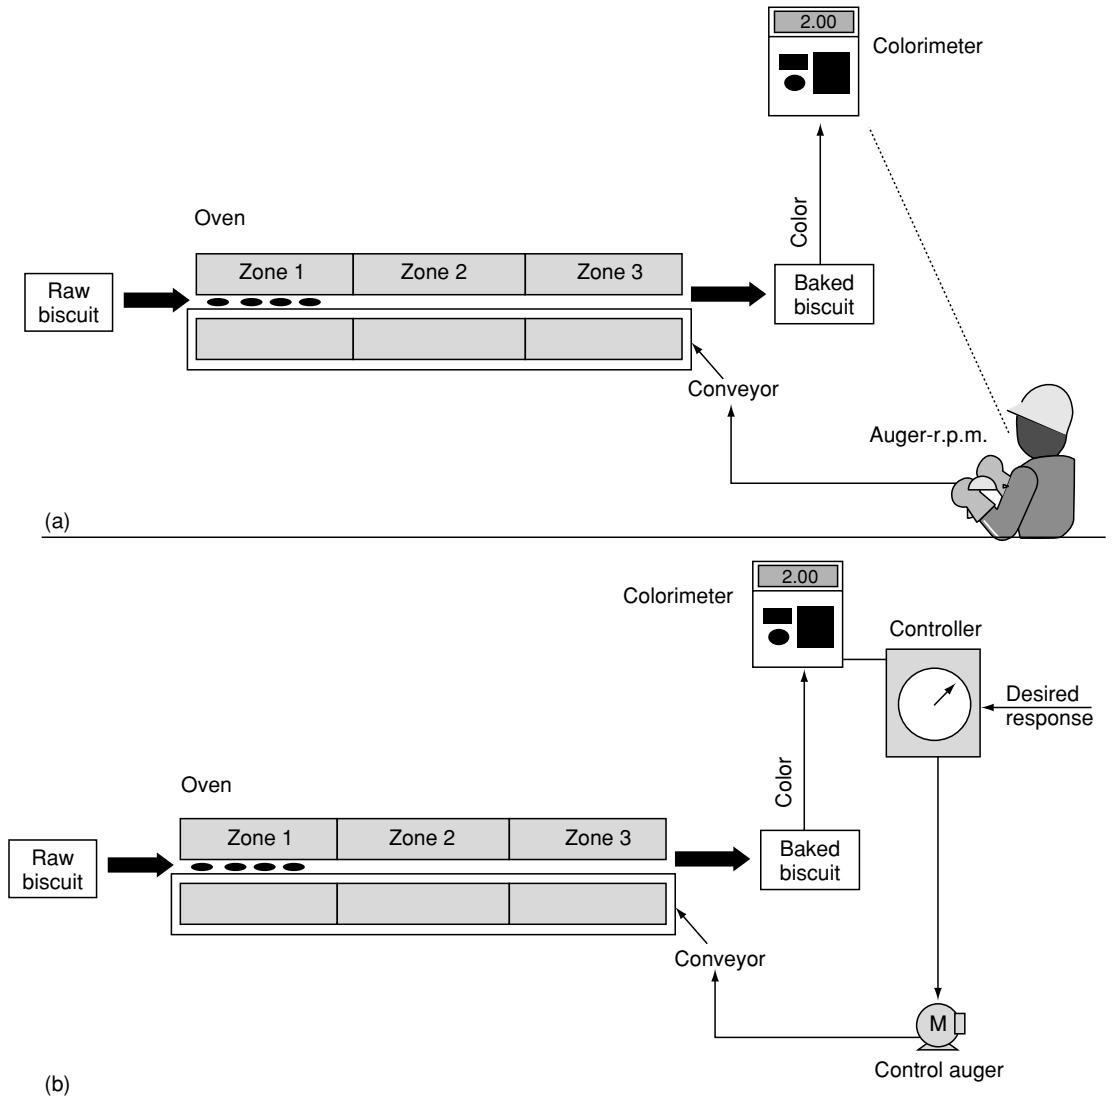

Figure 3 Manual and automatic control of a baking process.

a transducer. Based on the acting error value, the controller calculates the changes that need to be made in the auger r.p.m. to reduce and then eliminate that error.

Both manual and automatic controls operate likewise. In this case, the operator's eyes correspond to the acting error device, the brain corresponds to the automatic controller, and the operator's muscle represents the actuator.

Advantages of closed-loop systems as compared to open-loop systems include greater accuracy and less sensitivity to noise and disturbances. The transient response and the steady-state error can be controlled easily and with great flexibility in closed-loop systems. On the other hand, closed-loop systems are more complex and expensive than open-loop systems.

Computer-Controlled Systems

Since the 1970s, process controls have evolved from pneumatic analog technology through electronic analog technology to microprocessor-based controls.

Nowadays, many systems use a digital computer as the controller. The use of a computer in the control-system loop allows for the control and compensation of many loops by the same computer through time sharing. In addition, any adjustment of the controller parameters can be made by changes in software rather than hardware.

One important aspect of computer-controlled systems is its real-time computing application. It allows initialization of data acquisition operations and other tasks as control output calculations, supervision, scheduling, and so on. Real time means

that an operation is to be completed within a specified time constraint.

The Control Problem

The control problem can be stated as follows: determine the one value of the manipulated variable (input) that establishes a balance among all the influences (loads/disturbances) on the controlled variable (output) and keeps this variable constant at the desired value.

The steps required to design a control system are: process description, process and signal modeling, design method, and control algorithm. Once the controlled, manipulated, and load variables have been identified, the next step is to describe mathematically the process and signals (disturbances, reference variables, initial values). The design methods for linear control systems can be classified into parameter optimized control systems and structure optimized control systems. Once the design method has been selected, designing principles are applied to determine the control parameters.

Closed-Control System Analysis and Design

From the control point of view, a system is composed of controlled variables, manipulated variables (process input), and disturbances. In a control scenario, the number of manipulated (independent) variables must be at least as large as the number of controlled (dependent) variables. The controlled variables should measure product quality directly or strongly affect it. The manipulated variables should have a large effect on the controlled variables (large gain), should rapidly affect the controlled variables (minimum delay, small time constant), and should affect the controlled variables directly rather than indirectly.

Control systems are dynamic systems. That is, the response of a control system to an input is generally transient before reaching a steady-state response. Consider, for example, the baking process (Figure 3b) where a new biscuit is baked to a darker color by changing the conveyor speed. When the desired response (color of the biscuit) is changed to a higher level (darker), the biscuit entering the oven will leave the oven with a speed and color accuracy designed for product quality. Figure 4 shows the input and output for the baking system. The change in the desired color value is the input and is represented by a step command. Due to the limited power available and to keep the products already in the oven from breaking apart, it is not advised to have the oven

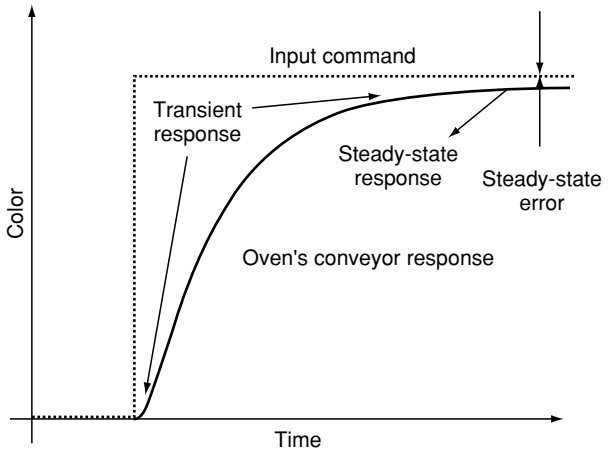

Figure 4 Oven input and output.

mimicking the suddenness of the input. The input represents what the output must be after the conveyor speed has changed; the conveyor follows the change described by the curved region in Figure 4; this is termed the oven's conveyor response. This part of the response is called the transient response.

After the transient response, the process approaches its steady-state response, i.e., approximates the desired response. For the baking process example, this response occurs when the biscuit reaches the outlet side of the oven. The accuracy of the biscuit's final color is a second factor that could make the output different from the input. This difference is called steady-state error. Steady-state errors exist when the control systems are defective.

Transient Response

In the baking process presented above, if the transient response were too slow, the process would be inefficient (low throughput), whereas an excessively rapid response would not be sufficient to bake the product to the desired color. If the conveyor speed oscillated around the desired response, the product color would be different from one biscuit to the another, resulting in poor quality. Therefore, transient response is very important in the design and analysis of control systems.

Steady-State Response

Another important objective in the analysis and design of control systems is that the system has a 'good' steady-state error performance. The steady-state response resembles the input and is usually what remains after the transients have decayed to zero. In the baking process, this response is the conveyor speed modified to a speed that produced the desired biscuit final color.

Stability

System stability under all system operating conditions is another control system specification. A system is unstable when its natural response (the way the system dissipates/acquires energy independently of the input) is much greater than the forced response (dependent upon the input) making the system uncontrollable. This condition could lead to self-destruction of the physical device if limit stops are not provided as part of the design. Therefore, control systems must be designed to be stable, i.e., their natural response must decay to zero or oscillate as time approaches to infinity.

Process Control

The objective of a process control system is to maintain a variable in the process at its setpoint (desired response). A process control system may be either open-loop or closed-loop, but closed-loop systems are more common. The process control industry has developed controllers that are standard and flexible for closed-loop systems.

Examples of common features shared by many process controllers include: (1) the values of the setpoint, process, and output variables are shown in either analog or digital format; (2) the operator is allowed to adjust the setpoint and switch between automatic and manual control; (3) when manual control is selected, the operator is allowed to adjust the controller output to vary the manipulated variable in an open-loop control mode; (4) the operator is allowed to adjust the control model settings to 'tune the controller' for optimum response; and (5) to provide for remote setting of the setpoint by an external signal. Many additional features are provided by microcontrollers (microprocessor-based digital controllers).

A control system (feedback or feedforward) performs essentially three operations: (1) measurement; (2) manipulation; and (3) signal transmission. Measurement is an integral part of a control system. To control a variable, its values need to be measured and converted to suitable signals. Manipulation consists of use of the control action to manipulate some variable in the process in a way that will tend to reduce the error. Signal transmission refers to signal communications between controllers and instruments.

Measuring Transmitter

A measuring transmitter (sensor) senses the value of a controlled variable and converts it into a usable signal. Example of sensors include temperature transmitter, flow transmitter, pressure transmitter, etc. Consider, for example, a temperature transmitter. The primary element of this sensor could be a thermocouple, a resistance element, a thermistor, or a filled thermal element. The signal transducer receives the output of the primary element and produces an electric current signal. In the case of a thermocouple, for example, it converts temperature into a millivolt signal, and the thermocouple transducer converts the millivolt signal into an electric current.

Manipulating Element

A controller has two interfaces with the process it controls: the input interface to the controller, and the output interface from the controller. The input side is handled by sensors and signal conditioners. Various types of manipulating elements handle the output side.

A manipulating element uses the controller output to regulate the manipulated variable and usually consists of two parts: actuator and final controlling element. An actuator translates the controller output into an action on the final control element, and the final controlling element changes the value of the manipulated variable. Manipulating elements include valves, dampers, fans, pumps, heating elements, and electric motors.

The pneumatic control valve is the most common final control element used to manipulate the flow rate of a fluid. Figure 5 illustrates a typical pneumatic control valve. The input to the valve is air pressure that acts on the diaphragm, compressing the spring, thus pulling the stem out and finally opening the valve. The actuator of a pneumatic valve can be

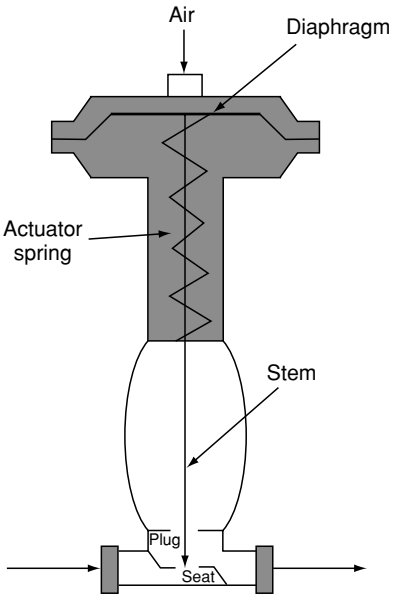

Figure 5 Pneumatic control valve.

described as direct actuator (if the actuator spring is located below the diaphragm) or reverse actuator (when the spring is above the diaphragm). The valve position is the displacement plug from the fully seated position. The valve action is in the direction in which the valve plug moves as the air pressure increases. If the valve closes as the pressure increases, an air-to-close valve results. If the increased air pressure opens the valve, it becomes an air-to-open valve.

Signal Transmission

Most signals can be described as analog, digital, or pulse. Analog signals typically vary smoothly and continuously over time; digital signals are present at discrete points in time. In most control applications, analog signals range continuously over a specified current or voltage range, such as 4–20 mA DC or 0–5 V DC. Digital signals are essentially on/off (the pump is on or off), while analog signals represent continuously variable entities such as temperatures, pressures, or flow rates. Computer-based control systems understand only discrete on/off information, therefore conversion of analog signals to digital representations is necessary.

Transduction is the process of changing energy from one form into another. Hence, a transducer is a device that converts physical energy into an electrical voltage or current signal for transmission. There are many different forms of analog electrical transducers. Examples of transducers include thermocouples and resistance temperature detectors (RTDs) for measuring temperature via voltage and resistance measurement, respectively. Transmission channels may be wires or coaxial cables. For noise-resistant transmission over significant distances, the raw transducer signal is often converted to a 4–20 mA signal by a two-wire, loop-powered transmitter.

Industrial networks that transmit data using digital signals are often an integral part of a process control solution. Signals from digital instruments and controllers are transmitted in digital format (on–off pulses) using, for example, a number of parallel wires. New instrumentation systems use a single data highway to transmit digital signals to a series of instruments and controllers. These data highways are usually coaxial cables linked in serial or daisy-chain (serial with complete loop). A microcomputer built in the instrument and controller communicate periodically over the highway by sending to or requesting from information between different devices installed in the system.

Examples of data highway are wide area network (WAN) and local area network (LAN). Networks are communication channels that connect large numbers of stations to one or more central stations. WANs are used to connect process systems separated by considerable distance (branch offices in different cities). LAN is a data highway used to connect local process units with central operator displays and high-level computers. LANs are used to connect process systems located within a radius of about 1.5 km.

Nearly all digital network descriptions start with the open systems interface (OSI) model. The OSI model is based on several functional levels. The lower levels are responsible for transmitting messages between nodes on the same cable and from one cable to another. The upper levels handle data formatting and access security. A number of LANs are based on the OSI model, such as the manufacturing automation protocol (MAP) and the Ethernet.

The MAP is a multilevel communication network whose objective is to link together all the computers, controllers, equipment, devices, and offices in an entire factory. The Ethernet is able to handle error detection and address the source of destination.

Control Modes

The operations performed by a feedback control system include measurement, decision, and manipulation. A closed-loop control system is shown in Figure 2b. Measurement and manipulation have been described above. Decision consists of calculating the error (desired value minus measured value) and using the error to form a control action.

The control modes convert the error into a control action (controller output) that will reduce the error. The most common control modes are the proportional mode (P), the integral mode (I), and the derivative mode (D).

The simplest of the three modes is the proportional mode. As the name indicates, the proportional mode produces a control action that is proportional to error. If the error is small, the control mode will produce a small action. If the error is large, the control action will be large. To accomplish the proportional mode, the error is multiplied by a gain constant, K_p. In a proportional control, the controller output is algebraically proportional to the error input signal to the controller as:

$$m(t) = K_p e(t) \tag{1}$$

where m(t) is the controller output, $e(t)$ is the error input signal, and K_p is the controller gain. Eqn (1) is called the control algorithm.

The integral mode produces a control action that continues to increase its corrective effect as long as the error persists. The integral mode increases slowly when the error is small, and corrects more rapidly if the error is large. Integral control action is based on

the principle that the controller output *m(t)* is proportional to both the size and the duration of the actuating error signal *e(t)*:

$$\frac{dm(t)}{dt} = K_i e(t) \tag{2}$$

or:

$$m(t) = K_i \int_0^t e(t)dt \tag{3}$$

where K_i is an adjustable constant.

The derivative mode produces a control action that is proportional to the rate at which the error is changing. If the error is increasing rapidly, the derivative mode will prevent the error becoming larger by producing a correction action proportional to how fast the error is changing. Derivative action (also called rate control action) is based solely on the rate of change of the error signal. An ideal derivative action can be described as:

$$m(t) = K_d \frac{de(t)}{dt} \tag{4}$$

where K_d is an adjustable constant.

These three control modes can be used alone (with the exception of the derivative mode) or combined. The common control mode combinations are: P, PI, PD, and PID. The proportional plus integral (PI) control mode is used on processes with large load changes when the proportional mode alone is not capable of reducing the offset. The proportional plus derivative (PD) control mode is used on processes with sudden load changes. The proportional plus integral plus derivative (PID) control mode is used on processes with sudden, large load changes.

Figure 6 shows the typical response behavior of a controlled process after a step change in the setpoint occurs. The output variable is shown as a deviation from the new setpoint change. If no feedback control is implemented, the process slowly reaches the new steady state. Proportional control speeds up the process and reduces the offset. Adding integral action (PI) eliminates the offset but causes the loop to oscillate. The addition of derivative control (PID) made the response faster and less oscillatory.

Advanced Control

The PID controller has been around for more than 50 years and is still today the most widely used industrial controller. It is simple, easy to understand, and does not require a precise process model to start up or maintain. The PID works well if the process system is simple. However, if the process dynamics change, it needs to be retuned, and it has trouble controlling complex systems, i.e., processes that are nonlinear, time-variant, coupled, and have parameter or structure uncertainties.

Several advanced control strategies exist that can provide improved process control over PIDs. Some of these methods include cascade control, robust control, adaptive control, model predictive control, and intelligent control. With the advance of computer control, many of these techniques have been successfully applied in the food industry.

Cascade control involves two controllers, with the output controller providing the setpoint of the

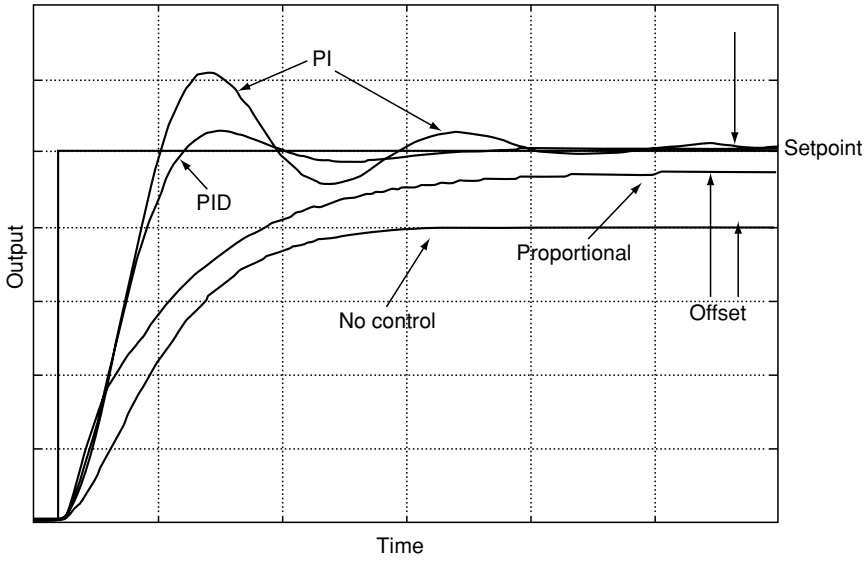

Figure 6 Step response of a feedback control system. PID, proportional plus derivative; PI, proportional plus integral.

secondary controller. The design of controllers or control algorithms described up to now assumed that only the control variable determines the process input. This results in single control loops. By connecting additional measurable variables to the single loop (i.e., disturbances or auxiliary variables) it is possible to obtain improved control behavior. These additions to the single loop lead to interconnected control systems.

Robust control is a controller design method that focuses on the reliability (robustness) of the control algorithm. Robust control methods are suited to processes that have large uncertainty ranges and small stability margins.

Adaptive control is defined as an intelligent feedback control system that adjusts its characteristics to changes in the environment so as to operate in an optimal manner. In process control applications, the PID self-tuning scheme is widely implemented in commercial products.

Model predictive control (MPC) is one of the few advanced control techniques used successfully in industrial control applications. The essence of MPC is based on three key elements: (1) predictive model; (2) optimization in range of a temporal window; and (3) feedback correction. These steps are carried on continuously by computer programs online.

Intelligent methods in control are becoming part of mainstream control approaches. They integrate concepts and methods from areas such as control, identification, estimation, communication theory, and artificial intelligence. Intelligent control paradigms can endow control systems with functionality that traditional methods could hardly make available. They can also improve the analysis, design, operation, and maintenance characteristics of control systems. Examples of this type of control strategy include fuzzy logic and neural network.

Fuzzy logic and neural network aim at mimicking the operation of the human brain to some extent. A control law described by fuzzy rules is more understandable by a human operator who knows the process but who is not an expert control engineer. It facilitates the integration of heuristic knowledge about the system and theoretical control laws from mathematical models, that are always an idealization of the process.

Neural networks go further by aiming at building models of the way a human being thinks and reaches conclusions. In general, neural networks are useful for representing and approximating nonlinear relationships. They are applicable for multivariable systems and require less restrictive assumptions on the process than conventional modeling and control techniques.

INTERMEDIATE-MOISTURE FOODS

J Sych, Université Laval, Québec, Canada

Introduction

Lowering of water activity (a_w) to a level where most microorganisms cannot grow is one of the oldest methods of food preservation and forms the basis for intermediate-moisture foods (IMF). This article will review the nature and uses of IMF by presenting the principles behind formulation, some typical examples on the market, factors limiting stability, and possible future developments of IMF.

Principles Behind Formulation of IMF

IMF have a_w reduced to approximately 0.65 to 0.90 (i.e., moisture content of 15–40%), are plastic enough to be consumed without rehydration, and are stable without refrigeration. Other preservative factors act in association with a_w to insure the shelf-life of IMF.

a_w is the amount of water available for deteriorative processes in a food product and is defined as the ratio of water vapor pressure of the product (p) to the saturation pressure of water (p_o) at the same temperature: $a_w = p/p_o$. At low a_w in food, at or below the monolayer value, water is strongly bound to specific sites and unavailable as a solvent for reaction. In the a_w range of IMF, the growth of microorganisms is largely restricted, compared with high-moisture foods, but certain reactions, such as Maillard and oxidation, can still proceed, due to the increased solvent and mobilization properties of water above the monolayer. A reduction of a_w is achieved by chemical means (addition of humectants) and/or physical dehydration (evaporation, drying, ultrafiltration, etc.). (*See* **Water Activity**: Principles and Measurement; Effect on Food Stability.)

Processing Technology for IMF

Traditional IMF are processed by the withdrawal of water, by adsorption or desorption, and/or by the addition of conventional humectants, such as salt (sodium chloride) and sugar (sucrose). Although some traditional IMF, such as dried fruits, are simply dried to the desired a_w, most IMF are prepared by a combination of drying with added humectants. Bakery products are prepared by adding water and other ingredients to low-a_w cereals, followed by various processing and heating procedures to yield a_w in the range of IMF. (*See* **Sucrose**: Properties and Determination.)

Novel IMF are often processed by using humectants, such as glycerol, propylene glycol, and sorbitol, for a_w adjustment. Combinations of several humectants, each at lower concentrations, are often used to reduce off-flavor problems. Novel IMF may be prepared by:

1. Moist infusion (desorption): solid food pieces are equilibrated in a solution of lower a_w, often with heating. Drying may be used to reduce further a_w (e.g., intermediate-moisture fruits)
2. Dry infusion (adsorption): solid food pieces are dehydrated and then infused by soaking in a solution containing humectants (e.g., bite-sized cubes of meat for space or military rations)
3. Blending: food components are weighed, blended, cooked, and extruded using various processing techniques (e.g., fermented meats)

IMF processed by adsorption normally have slower microbial growth and lipid oxidation due to a lower moisture content than IMF prepared by desorption with identical a_w. This is because of sorption hysteresis – the phenomenon in foods whereby the moisture content of a food is lower during equilibration by adsorption than by desorption. In spite of these hysteresis effects and the waste of residual infusion solutions, the desorption method is generally used more, due to its advantages of lower cost, enzyme inactivation, and better retention of flavor and structural integrity. With this method, it is possible to reduce food weight by 50% by the simultaneous countercurrent diffusion of water out of the food and solute into the food.

In the production of novel IMF, pasteurization and blanching are commonly used to reduce initial levels of microorganisms and to inactivate enzymes. Antimycotics, such as sorbic and benzoic acid and their salts; methyl and propyl paraben; or calcium propionate, assist in the control of mold and yeast growth. Other chemical additives may also be incorporated to slow down physical and chemical deterioration during storage. (*See* **Pasteurization**: Principles; **Spoilage**: Chemical and Enzymatic Spoilage; Molds in Spoilage; Yeasts in Spoilage.)

Effects of a_w on Microorganisms

Minimum a_w for growth and toxin production of some microorganisms capable of growing in IMF

are shown in **Table 1**. Generally, bacteria are less tolerant of decreased a_w than are yeasts, and yeasts are less tolerant than molds (Figure 1). At $a_w < 0.95$, the growth of most Gram-negative bacteria, as well as spore-forming bacteria, such as *Bacillus* and *Clostridium* spp., is inhibited. Gram-positive bacteria, such as *Lactobacillus* and *Micrococcus* spp., tolerate lower a_w and act as competitive microflora in fermented intermediate-moisture (IM) meat. Among the foodborne pathogens, *Staphylococcus aureus* has the lowest minimum a_w for growth (**Table 1**). Yeasts and molds, referred to as xerophiles, are capable of growth in high concentrations of solute, or at $a_w \leq 0.85$. The control of bacterial growth in IMF eliminates competition, which enhances mold and yeast growth. (*See* ***Bacillus***: Occurrence; ***Clostridium***: Occurrence of *Clostridium perfringens*; **Spoilage**: Bacterial Spoilage; ***Staphylococcus***: Properties and Occurrence.)

Table 1 Some microorganisms of concern in intermediate-moisture foods[a]

Microorganism	*Toxin produced*	*Limiting* a_w	
		Growth	*Toxin*
Bacteria			
Staphylococcus aureus	Enterotoxin A, B, C	0.86	0.87–0.97
Halophilic bacteria		0.75	
Yeasts			
Saccharomyces rouxii		0.62–0.81	
Debaryomyces hansenii		0.83–0.88	
Molds			
Aspergillus flavus	Aflatoxin	0.78–0.80	0.83–0.87
A. chevalieri	Xanthocillin X	0.65	
A. ochraceus	Ochratoxin	0.77–0.83	0.83–0.87
	Penicillic acid	0.81	0.88
Penicillium viridicatum	Ochratoxin	0.83	0.83–0.86

[a] a_w range of 0.65–0.90.

Reduced a_w in foods affects the growth of bacteria, yeasts, and molds by increasing the lag phase, decreasing the rate of growth in the logarithmic phase, as well as decreasing the maximum level of development. Sodium chloride is the most effective humectant on a mole-to-mole basis for reducing a_w, followed by glycerol, sorbitol, and sucrose. However, at the same a_w, microbial growth varies with the nature of the a_w-controlling humectant. For relatively salt-sensitive bacteria, sodium chloride exerts a greater inhibitory effect than polyhydric alcohols, such as glycerol, with sugars in between. In contrast, for relatively salt-tolerant bacteria, such as *S. aureus*, glycerol has a greater inhibitory effect than sodium chloride. Many yeasts and molds are more inhibited by sodium chloride than by sucrose, glycerol, or glucose, at the same a_w. The inhibitory effects of sucrose and sodium chloride are attributed to their ability to lower a_w, whereas polyhydric alcohols have less of an effect on a_w, but appear to cause damage to enzymes, and may have antimycotic activity.

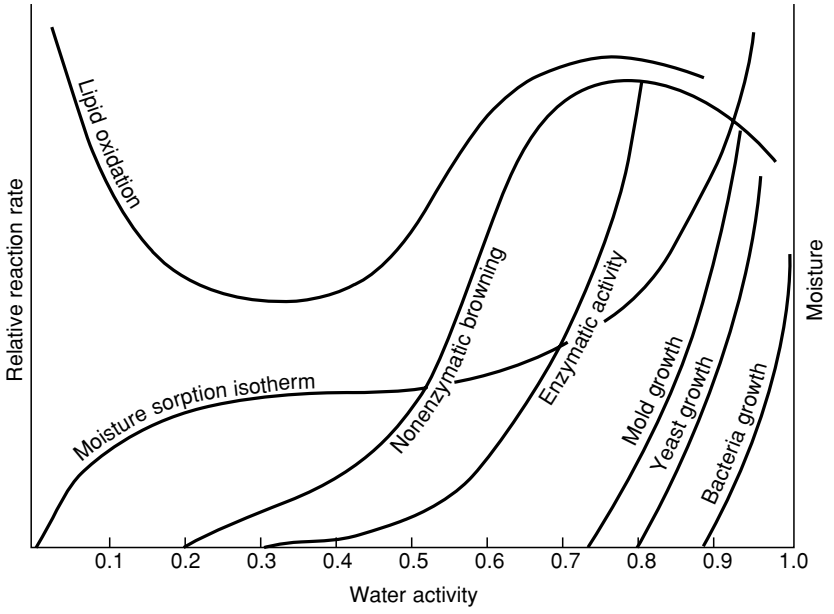

Figure 1 Relative reaction rate as a function of water activity for foods. From Taoukis PS, Labuza TP, Saguy S (1997) Kinetics of food deterioration and shelf-life prediction. In: Valentas KJ, Rotstein E, Singh RP (eds) *Handbook of Food Engineering Practice*, p. 381. New York: CRC Press, with permission.

For several genera of molds, higher a_w is required for spore formation than for germination of spores. The time required for spore germination of microorganisms increases with reduced a_w. Germination of spores of some microorganisms occurs at a_w values below that required for growth, which suggests that decreases in spore numbers can occur during storage of some IMF. The type of solute also affects the minimum a_w for spore germination.

The heat resistance of some bacteria and spores increases under stress, such as reduced a_w; this effect is solute-specific and may be associated with the synthesis of protective proteins. For heat-sensitive strains of *Salmonella*, the increase in heat resistance can be significant, particularly at high levels of small-molecular-weight solutes. Such increases in heat resistance must be taken into account in IMF production, since heat treatments are often applied after incorporating humectants.

The minimum a_w for toxin production of microorganisms is always higher or equal to that for growth (**Table 1**). Mycotoxin-producing molds present the greatest risk since many of their metabolites (e.g., aflatoxins) cause toxic effects in humans. Mold growth and toxin production on IMF surfaces can lead to penetration of toxins inside the product. In addition, data on a_w limits for mycotoxin production in IMF are limited.

Other Preservative Factors of IMF

Generally, water requirements of microorganisms for growth and toxin production increase as environmental factors are changed from their optimum. IMF are most often stabilized by reductions in a_w in combination with other preservative factors, also referred to as hurdles. Current views hold that the presence of hurdles may interfere with the homeostasis or internal equilibrium of microorganisms and thus inhibit their growth. A greater understanding of these principles has led to benefits of improved product quality and microbial safety; reduced additive levels; and reduced refrigeration. Certain combinations of hurdles can also result in additive or synergistic effects allowing for a reduction of individual factors. The most important hurdles used in varying intensities to stabilize IMF are: available water (a_w), heat processing, acidification, redox potential, modified atmospheres, preservatives, and competitive microflora. **Table 2** shows the a_w of some IMF as well as the other factors contributing to microbial stability.

The combined effect of pH and reduced a_w is used in many foods to inhibit the growth of foodborne pathogens (**Table 2**), as in IM meats where a pH of less than 5 or a_w of less than 0.85 is recommended to inhibit *S. aureus*. The removal of oxygen during packaging, i.e., low redox potential, inhibits obligate aerobes (molds and some bacteria), and increases the sensitivity of other microorganisms, including yeasts, to a_w decreases. This is used to delay rancidity and mold growth in novel IMF, such as German mini-salami with a_w between 0.82 and 0.85. Protective packaging is also an important hurdle used to maintain the stabilizing effects of redox potential and modified atmospheres.

Table 2 Water activity (a_w) and other preservative factors of some intermediate-moisture foods

Product	a_w	*Preservative factors*
Traditional IMF		
Jams	0.82–0.90	a_w, pH, F, Eh, pr[a]
Dried fruits	0.60–0.75	a_w, pH, F[a], pr
Baked products	0.60–0.90	a_w, F, pr
Meats	0.65–0.85	a_w, pH, Eh, pr, cf
Novel IMF		
Pet food	0.80–0.85	a_w, F, pr
Ready-to-eat meat cubes	0.66–0.80	a_w, F, pH[a], pr
Fruit pastes	≤ 0.70	a_w, pH, F, pr
Liquid tea concentrate	0.75–0.85	a_w, pH
Fruit-filled cereal bars	≤ 0.85	a_w, F, pH, pr
Liquid whole eggs	≤ 0.88	a_w

[a]Possible preservative factor.
F, heat processing; pH, acidification; Eh, redox potential; pr, preservatives; cf, competitive microflora.

Many IMF contain added or natural chemical preservatives to control the growth of molds and yeasts. Legislation on the types of additives and their permitted levels varies among countries. Although frequently used, benzoic and sorbic acid require the undissociated form ($pH \leq 4.5$) for optimum antimicrobial activity, which is often organoleptically unacceptable in IMF. Another problem is the high tolerance of some molds and yeasts to maximum permissible levels of preservatives. Furthermore, interactions between antimicrobials and a_w may exist; for example, *Saccharomyces rouxii* was found to have greater resistance to sorbate at reduced a_w. The increasing interest in natural preservatives has oriented much research towards the identification of natural substances, such as those in garlic which improve the stability of many traditional IM meats. Edible coatings containing antimicrobials or antioxidants can be applied to IMF to obtain specific functional effects on food surfaces. For example, an edible paste of ground garlic and other spices is used to control surface mold growth during storage of Turkish pastirma, a fermented IM meat.

Microstructure is also an important factor which affects microbial growth, survival, and death in comminuted and blended IMF, such as fermented sausages. The accumulation of natural flora as well as

starter cultures in small cavities has significant implications on the entire fermentation and on the inactivation of pathogens, which are often located in distant areas of the food matrix. An even distribution of bacteria in the sausage is important for optimizing the shelf-life of fermented sausages, obtained by adequately mixing the sausage ingredients and using liquid starter cultures.

Some Typical Examples on the Market

Pet foods have been on the market since the 1960s; they are processed by blending and pasteurizing meat byproducts, cereals, and other ingredients including humectants (sucrose and propylene glycol), followed by extrusion cooking techniques to form a variety of products. Their shelf-life stability of more than 12 months is based on reduced water activity ($a_w \leq 0.85$), heat processing, and addition of antimycotics, most commonly potassium sorbate. Other ingredients, such as sodium caseinate and starch, are sometimes added for specific textural characteristics.

There are many different traditional IM meats. One example is salami, which is a fermented sausage originating from Europe. Its shelf-life stability depends on a specific sequence of the stabilizing factors preservatives, redox potential, competitive microflora, acidification, and a_w. Early in sausage ripening, nitrite added with curing salts inhibits the growth of many bacteria, such as *Salmonella* spp. Nitrite levels eventually decrease, but other bacteria continue to multiply and cause a reduction in redox potential. This inhibits the growth of aerobic organisms, while favoring lactic acid bacteria, which produce acid and reduce the pH of sausages. In long-ripened fermented sausages, a_w (≤ 0.90) becomes the main stabilizing factor, as numbers of lactic acid bacteria decrease with storage time, resulting in slight increases in acidification and redox potential. Other fermented IM meats are French saucisson, and Turkish pastirma.

Beef jerky or jerked beef (North America), lup cheong (China), biltong (South Africa), and carne de sol (South America) are examples of nonfermented IM meats which are produced in different regions of the world. Various combinations of factors contribute to product stability, such as a_w reduction by addition of salt and sugar, mild heat treatments, vacuum packaging, and preservatives. A variety of other ingredients, such as vinegar, pepper, coriander, and garlic, are used for flavor and shelf-life improvements in IM meats.

IM fruit pastes and purées, intended for use in candy, cookies, icecream, etc., have been developed by treating various fruits (apricots, peaches, papayas, etc.) with sulfur dioxide, dehydrating to $a_w \leq 0.70$ and employing extrusion techniques. Meal replacement bars (a_w of approximately 0.60) are IMF which contain a variety of ingredients such as milk protein, soya protein, fat, flour, starch, sucrose, salt, propylene glycol, and preservatives. Multitextured shelf-stable products have been introduced as well, including moist puddings in éclair-type shells; ready-to-eat breakfast cereals containing dried fruits; snack bars with fruit fillings; and cookies with crunchy exteriors and soft-moist interiors. Components of multitextured foods initially have different a_w and equilibrate to a common a_w during storage.

Factors Limiting IMF Stability

The significant effects of a_w on chemical reactions have important implications for the preservation of IMF. The shelf-life of IMF can be limited by nonenzymatic browning reactions, particularly the Maillard reaction which is a condensation reaction between the carbonyl group of a reducing compound, mainly sugar, and a free-amino group. The reaction can greatly affect food color due to the formation of brown pigments during processing and storage. It is also associated with toughening of texture, decreases in protein quality, and slight increases in a_w. Inversely, certain Maillard reaction products have bactericidal effects which contribute to product stability. (*See* **Browning**: Nonenzymatic; **Storage Stability**: Parameters Affecting Storage Stability.)

Generally, as for most deteriorative reactions, browning reaction rates increase exponentially with increasing a_w above the food monolayer due to an increased mobility of reactants (Figure 1). Maximum browning rates occur at approximately 0.65–0.75, which is in the IMF a_w range, and then the reaction decreases as a result of reactant dilution and product inhibition.

Variations in browning rate maxima are due to differences in the physical and chemical structure of IMF. Liquid humectants, such as glycerol or propylene glycol, reduce browning in IMF by shifting a_w maximas from approximately 0.7 to 0.4–0.5. These humectants appear to act as aqueous solvents, allowing greater reactant mobility at lower moisture contents. Maillard reaction rates also decrease with decreasing pH and the addition of sulfur dioxide or sulfites, which are used in IMF as browning inhibitors.

Free radical autoxidation of unsaturated lipids, and other compounds, is another important shelf-life problem of IMF. In the IMF a_w range, lipid oxidation rates generally increase with increasing water content (Figure 1) due to greater mobility of reactants, dissolution of precipitated catalysts, and swelling of solid

matrices, resulting in the exposure of new surfaces for reaction. Hydroperoxides, formed during lipid oxidation, decompose into secondary oxidation products, many of which result in rancidity in IMF. In IM meats, hydroperoxides and their products can react with proteins and reduce their solubility. Carbonyl-reducing compounds formed during oxidation reactions can act as reactants in the Maillard reaction.

Lipid oxidation in IMF is controlled by elaborate packaging technology, using vacuum, modified or controlled atmospheres to reduce oxygen contents; and using oxygen-impermeable and opaque films to reduce exposure to oxygen and light. In addition, IMF often contain lipid-soluble antioxidants (e.g., butylated hydroxyanisole, BHA), which combine with free radicals, or metal chelating agents, such as citric acid. Sulfur dioxide treatments are used to reduce losses of carotene and ascorbic acid in dried fruits. (*See* **Antioxidants**: Synthetic Antioxidants; **Chill Foods**: Effect of Modified-atmosphere Packaging on Food Quality; **Chilled Storage**: Packaging Under Vacuum; **Controlled-atmosphere Storage**: Applications for Bulk Storage of Foodstuffs.)

The major microbiological spoilage problem, limiting the shelf-life of many IMF, is xerophilic mold growth with the associated risk of mycotoxin production. Mold strains of *Aspergillus* and *Penicillium* occur widely in the environment and cause storage problems in many IMF (**Table 1**). Xerophilic yeasts do not produce toxins, but may cause fermentation and spoilage of some IMF.

Temperature fluctuations in the commercial production and distribution of IMF can cause condensation and increases in a_w on product surfaces, which are detrimental to product stability. This occurs when products are transferred between environments of different temperatures or are packaged while warm. In addition, temperature differentials, which lead to moisture migration within products, may occur in lighted, refrigerated display shelves. These effects have been associated with increased sporulation and mycotoxin production of molds, such as *Aspergillus flavus* and *A. parasiticus* at storage temperatures between 25 and 40 °C.

Progress and Future Developments

Some of the obstacles preventing large-scale developments of novel IMF are poor palatability due to the relatively high levels of humectants required to lower a_w, as well as consumer health concerns and legal difficulties associated with the use of antimicrobials. There is also a growing trend in industrialized countries towards minimally processed foods, which require refrigeration.

However, certain developing countries are interested in simple and inexpensive conservation processes based on combined factors, which give stable products without refrigeration. A better understanding of the underlying principles of hurdles in traditional IMF recently led to the development of high-moisture fruit products (HMFP) in Latin America. Similar to most IMF, high-moisture fruits are stabilized by several hurdles, including heat treatments, pH reduction, and the addition of antimicrobials; however, the predominance of the a_w hurdle for preservation is reduced. These innovative products are tropical fruits, whether whole, pieces, or purée; with a_w above 0.92; and stable without refrigeration. The developed processes are energy-efficient and allow a better utilization of tropical fruits. Other similar, higher-moisture products may attract further research and consumer interest, due to their reduced levels of humectants and improved organoleptic quality compared with IMF or fully dried products.

Certainly the enhanced knowledge of hurdle technology, allowing more effective combinations of preservative factors, will be used to improve the quality and safety of existing IMF and preserved foods in general. Of great benefit to this research area and to product design are the increased possibilities for predicting effects of combined factors by computer technology. As for other processed foods, well-defined guidelines of good manufacturing practice and Hazard Analysis Critical Control Point (HACCP) principles must be a priority in the production of IMF and other hurdle-stabilized products to insure food quality.

Another possible area of development is the use of edible coatings containing antimycotics or antioxidants to enhance microbial or oxidative stability, and reduce the overall concentration of additives in IMF. Food films, often based on a high-molecular-mass compound, such as starch, cellulose, proteins, waxes, or fats, reduce the diffusion of preservatives from food surfaces into food bulk. This can lead to improved surface microbial stability allowing for product formulations with slightly higher a_w, lower levels of humectants and improved palatability. Developments in barrier films, which reduce moisture transfer between components of different a_w, will also find applications in heterogeneous IMF.

In addition, research and development will continue to focus on naturally occurring food preservatives. For example, bacteriocins and other antimicrobial substances produced by a variety of lactic acid bacteria may find applications in IMF. Natural antioxidants from plant sources, such as rosemary (*Rosmarinus*), are also being actively

investigated for potential applications in food preservation. There is much research interest in encapsulation and controlled-release systems for increasing the effectiveness and range of application of many natural preservatives.

Finally, there will probably be more developments of IMF for industrial use, as for example concentrated food preparations (e.g., soup, sauce, or meal concentrates) that can be rehydrated, and directly used in fast foods, restaurants, and other food service industries. Certainly, novel IMF bakery products with a variety of characteristics, such as moist texture and long shelf-life, will continue to appear on the market.

INTERNATIONAL UNION OF FOOD SCIENCE AND TECHNOLOGY

K A Buckle, The University of New South Wales, Sydney, Australia
J S Meech, Oakville, Ontario, Canada

WHAT IS IUFoST?

The International Union of Food Science and Technology (IUFoST) is the sole global, country-member organization that represents more than 200 000 food scientists and food technologists. It is a voluntary, nonprofit association that links the world's food scientists and food technologists through international cooperation and exchange of scientific and technical information. IUFoST is a full member of the International Council for Scientific Unions (ICSU), now the International Council for Science. It works closely with several United Nations agencies, such as the Food and Agriculture Organization, World Health Organization, Codex Alimentarius Commission and International Atomic Energy Agency, as well as other international organizations, to transfer technical knowledge and strategies for basic and applied research to the developing world.

IUFoST sponsors international and regional congresses, conferences, symposia, and workshops held in member countries, and promotes a safe, secure, and wholesome food supply for the world's increasing population.

Origin

The profession of food science and technology is generally agreed to have emerged in the USA in the early decades of the twentieth century. The subsequent formation of the (US) Institute of Food Technologists (IFT) in 1939 and its successful development and expansion led to the emergence of similar associations in many countries during the following 20 years. In 1960, the UK government and several British scientific societies hosted a conference in London in commemoration of the centenary of the UK Food and Drugs Act (1860) and the 150th

anniversary of the publication in 1810 of Nicolas Appert's book (*L'art de conserver, pendant plusieurs années, toutes les substances animales et végétales*) on the heat preservation of foods in sealed containers. In the preceding week, Professor John Hawthorn, then at the Glasgow Royal College of Science and Technology (later to become University of Strathclyde), convened a symposium on recent advances in food science, and discussions between several eminent UK and US food scientists raised the concept of an international food society. The first outcome of discussions on the formation of an international organization was the First International Congress of Food Science and Technology held in London in 1962 and organized by the Food Group of the Society of Chemical Industry.

The President of the Congress, Lord Rank, stated in his Presidential address: 'If the potentialities of... food science and technology are to... culminate in the peoples of the world receiving a sufficiency of food that is... appealing and nutritionally adequate, then there must be international collaboration.' Following the Congress, an *ad hoc* International Committee of Food Science and Technology (ICFoST) was formed with eminent scientists from several countries, to promote and foster international cooperation in food science and technology. A Second International Congress of Food Science and Technology was held in Warsaw, Poland, in 1966. By the time the Third International Congress of Food Science and Technology (*Science of Survival: SOS/70*) was held in Washington, DC, USA in 1970, ICFoST had developed a constitution and working arrangements for an International Union. Professor George Stewart of the University of California at Davis, USA, one of the pioneering scientists associated with the preparations of the previous decade, was the Founding IUFoST President.

Membership

IUFoST was inaugurated on 14 August 1970 with 20 nations as the founding membership (Table 1). The present membership is 64 (Table 2). Membership is open to all countries, and consists of one representative body, termed an 'adhering body,' from each country. The term 'country' is understood to be a defined geographical area, or areas, that has an independent science budget. Only one adhering body can represent each such area. Adhering bodies can be a national food science and/or food technology group, society, or institute composed of food scientists and/or food technologists and/or other professionals engaged in food science and/or technology; an academy of sciences, national research council, or similar organization of scientists; an intersociety committee or similar group representing two or more societies composed of food scientists, and/or food engineers, and/or food technologists; or a national committee representing food scientists, food engineers, and food technologists working in the field of food science and technology.

Czech Republic	Kuwait	Portugal	USA
Denmark	Lesotho	Qatar	Vietnam
Egypt	Lithuania	Russia	Zambia
Finland	Macedonia	Saudi Arabia	Zimbabwe

Institutions may be admitted as Institutional Associate Members, and commodity associations and commercial enterprises as Corporate Associate Members.

In addition to member country adhering bodies, four Regional Groupings of adhering bodies have been formed within IUFoST, each with an IUFoST-approved constitution:

- European Federation of Food Science and Technology (EFFoST, formed in 1982);
- Federation of Institutes of Food Science and Technology in ASEAN (FIFSTA, formed in 1988);
- Eastern, Central and South African Associations of Food Science and Technology (ECSAAFoST, formed in 1991);
- La Asociación Latinoamericana y del Caribe de Ciencia y Tecnologia de Alimentos (ALACCTA, the Latin American and Caribbean Association of Food Science and Technology, formed in 1986).

Table 3 Member countries of IUFoST Regional Groupings

Regional grouping	*Member countries*
EFFoST	Austria, Belgium, Bulgaria, Czech Republic, Denmark, Finland, France, Germany, Greece, Hungary, Ireland, Italy, Lithuania, Netherlands, Norway, Poland, Portugal, Spain, Switzerland, UK
FIFSTA	Indonesia, Malaysia, Philippines, Singapore, Thailand, Vietnam
ECSAAFoST	Angola, Botswana, Kenya, Lesotho, Malawi, Mozambique, Namibia, South Africa, Swaziland, Tanzania, Uganda, Zambia, Zimbabwe
ALACCTA	Argentina, Brazil, Chile, Costa Rica, Mexico, Trinidad and Tobago

ASEAN, Association of South-East Asian Nations; EFFoST, European Association of Food Science and Technology; FIFSTA, Federation of Institutes of Food Science and Technology in ASEAN; ECSAAFoST, East, Central and South African Associations of Food Science and Technology; ALACCTA, La Asociación Latinoamericana y del Caribe de Ciencia y Tecnologia de Alimentos (Latin American and Caribbean Association of Food Science and Technology).

Member countries of these groupings are shown in Table 3.

Purposes and Objectives

Vision

The vision of IUFoST is: 'To be recognized as the international agency that most effectively supports food professionals and other food sector constituencies, meeting their needs and aspirations by continuous refinement of a range of services, delivered according to the specific needs of regions, countries and of those we serve.'

Mission

The mission of IUFoST is: 'To be the leading international agency in developing and facilitating co-operative arrangements that bring sought-after services to food professionals and other food sector constituencies in different countries, thereby equipping them to maximize the benefits of food science and technology.'

Objectives

The primary purposes or objectives of IUFoST are to encourage and foster:

- international cooperation and exchange of knowledge and ideas among food scientists and technologists;
- further development of and support for food research;
- progress in the fields of theoretical and applied food science for improvements in the processing, manufacturing, preservation and distribution of food;
- the education and training of food scientists and technologists; and
- development of both individual professionalism and professional organization among food scientists and technologists.

Specific objectives aim:

- to encourage world-wide exchange of ideas and experience in the scientific disciplines and technological fields mentioned above, and specifically by sponsoring international congresses and other such regional and/or world-wide conferences and symposia as may usefully serve this purpose;
- to establish commissions and/or other functioning bodies, as may be required, to deal with scientific and technical problems in these fields on an international scale, and to provide other means of effective international cooperation;
- to maintain, on a world-wide basis, cooperation and coordination of effort with other international scientific and technological bodies with common or similar interests; and
- to engage, as appropriate, in the publication of journals, newsletters, proceedings of congresses, symposia and conferences, and reviews of achievements in food science and technology.

In dealing with external constituencies, IUFoST is:

- committed to upholding the highest professional standards of scientists working in food science and technology;
- committed to nonaligned/global leadership in food science and technology;
- committed to a safe, wholesome, and accessible food supply;
- ethically unquestionable, unbiased, balanced, independent, and honest;
- a positive force for desirable change, forward-looking, and professional;
- sensitive to, and inclusive of, cultural differences;
- financially independent of food industry lobby groups; and
- authoritative/learned in both scientific and industrial food issues.

In dealing with external agencies, groups, and individuals, IUFoST recognizes that it has important relationships with, and responsibilities to, a number of diverse organizations and groups: adhering bodies of IUFoST; regional groupings within IUFoST; international agencies (such as FAO, WHO, Codex, IAEA); community and consumer organizations; food professionals; students; international scientific

organizations such as ICSU; government agencies; industry organizations and groups; opinion formers; associate members; and countries and areas with an insecure food supply.

Structure and Operation

Structure

The principal structures within IUFoST are the General Assembly, Governing Council, Management Committee, Scientific Council, and International Academy of Food Science and Technology (IAFoST). Advisory and other committees are also constituted (Table 4). The Officers of IUFoST are the President, the President-elect, the Scientific Council Chair, and the Secretary-General, who also serves as Treasurer and is an employee selected by the Management Committee (Table 5). The Past President serves as an *ex officio* member for the two years following tenure as President. No more than two officers may be citizens of the same nation.

General Assembly Members of the General Assembly consist of delegates with voting rights representing each adhering body (one for each country) on the basis of its annual financial contribution. The number of delegates and ordinary votes (range 1–7) is determined on the basis of the annual fee payable.

The General Assembly meets biennially (previously every four years until 1999) in conjunction with each World Congress of Food Science and Technology. It has final authority with respect to all matters of official policy for and action by IUFoST. It is responsible for setting policy and broad strategy; electing officers (except the Secretary-General) and the Governing Council for a two-year term; approving the fee schedule for adhering bodies; appointing the Audit, Constitution and Nominations Committees; electing the Scientific Council from candidates nominated by

Table 4 Composition of IUFoST governing structures

General Assembly	Governing Council and 1–7 Delegates of adhering bodies (one for each country) allocated on the basis of a country's financial contribution
Governing Council	President, President-elect, Chair of Scientific Council, Secretary-General, Immediate Past President (*ex officio* and nonvoting)
Management Committee	President, President-elect, Chair of Scientific Council, Immediate Past President (*ex officio* and nonvoting), Secretary-General (*ex officio* and nonvoting), Chair of Audit Committee (*ex officio* and nonvoting)
Scientific Council	Chair, Chair-elect, Past Chair, two Scientific Councillors, President (*ex officio* and nonvoting), Secretary-General (*ex officio* and nonvoting)
International Academy of Food Science and Technology	Elected group of independent distinguished food scientists and technologists (Fellows) from whom IUFoST may draw nonaligned advice on scientific matters
Audit Committee	Five members, each from a different country and not holding an elected position
Nominations Advisory Committee	President-elect (Chair) and four members, each from a different country and not holding an elected position
Constitution Advisory Committee	Five members, each from a different country and not holding an elected position

Table 5 Officers of IUFoST 1970–2003

Years	*President*	*Secretary-General*	*Treasurer*

1999–2003	W.E.L. Spiess (Germany)	J.S. Meech (Canada)	D.R. Lineback (USA)

[a]Deceased 1999.

IAFoST; maintaining and approving changes to the Constitution and By-laws; and ratifying decisions of the Governing Council. It considers proposals involving international co-operative scientific programs and activities, and approves methods to finance IUFoST activities and reports of expenditures.

Governing Council The Governing Council (previously the Executive Committee) meets annually to set specific objectives and operational strategies for IUFoST. It has general oversight of the activities of the Officers and Management Committee, adopts budgets upon the recommendation of the Management Committee, sets fees for adhering bodies, appoints external auditors, selects the time and place of international congresses and other such meetings sponsored by IUFoST, appoints advisory committees, and ratifies ongoing actions of the Scientific Council and Management Committee. It often meets in conjunction with symposia organized by adhering bodies or regional groupings.

Management Committee The Management Committee implements strategies to achieve the objectives set by the Governing Council, including exercising general supervision of the activities of the Secretary-General, approving or modifying membership of working groups and committees, preparing annual reports and expenditures, and approving country or individual member applications. It meets at least every three months.

Scientific Council The Scientific Council is independent of the Governing Council and Management Committee. It is responsible for maintaining the scientific standard and integrity of all IUFoST activities, including publicly released scientific statements and the award of prizes. It recommends membership of working groups and scientific commissions to carry out specific tasks, and supervises the scientific output of such groups. It meets at least annually.

International Academy of Food Science and Technology The General Assembly, at its 7th meeting in Budapest in 1995, accepted the recommendation of the (then) Executive Committee to form IAFoST. The Academy, which was formed in 1997, is a learned society composed of elected members (Fellows) from all parts of the world. Fellows are usually, but not necessarily, affiliated with adhering bodies of IUFoST. The Academy statutes provide that the President, Secretary-General, and all past Presidents and Secretaries-General are automatically Fellows. The first meeting of the Academy was held at the 10th World Congress of Food Science and Technology held in Sydney in October 1999. The Academy members (Fellows) represent no organization and serve as independent persons to provide a pool of scientific expertise in food science and technology from which IUFoST may draw advice. Nominated candidates are elected in advance of each General Assembly, requiring an approving vote by two-thirds of the voting Fellows. The Academy nominates to the General Assembly candidates for the Scientific Council, provides scientific advice to the President and Scientific Council, and provides scientific advice to the President and Scientific Council, and proposes membership of working groups to the Scientific Council.

Audit Committee The Audit Committee establishes appropriate accounting control procedures, recommends external auditors, and ensures their independence. The Chair presents the annual audit of the IUFoST's financial affairs to the Governing Council.

Nominations Advisory Committee The Nominations Advisory Committee ensures that there are nominated candidates of sufficient merit for all positions to be filled, and that the candidates collectively meet the criteria for regional representation.

Constitution Advisory Committee The Constitution Advisory Committee formulates and presents to the Governing Council and thence to the General Assembly changes to the Constitution and By-laws for the more effective fulfillment of IUFoST's policies and the conduct of its business. It also provides advice to the General Assembly on the suitability of proposed changes to the Constitution, as proposed by adhering bodies.

Operation

The *Constitution* of the IUFoST was completely revised and accepted by the General Assembly in October 1999 at the 10th World Congress in Sydney. The Governing Council replaced the Executive Committee, and a Management Committee was established to execute IUFoST business between Governing Council meetings.

The General Assembly also adopted a *Strategic Plan* to reposition the organization, so that it can operate in a financially viable manner, while at the same time adapting and growing to meet the challenges of the years ahead.

An *Operational Plan* describes the accomplishments and challenges of IUFoST, and outlines procedures taken by IUFoST to develop a management system of *service delivery centers* (SDCs), each with measurable objectives and a budget to achieve these.

With the review of the Strategic Plan in 1999, the Governing Council established six SDCs identified by IUFoST delegates at the 8th General Assembly in October 1999. The SDCs are:

- SDC1: Continuing Professional Development (conferences, workshops);
- SDC2: Information Services (journals, technical publications, internet services);
- SDC3: Advice and Expert Opinion (consulting, expert advice, international databases);
- SDC4: Food Science and Technology Development (new technologies applications, regulatory technical standards, scientific needs);
- SDC5: Development of Professionalism (international standards on professional skills, strategy development, relation to other unions, position papers, status reports); and
- SDC6: Marketing and Support Services (promotion of collaboration/interaction between researchers in different IUFoST countries).

Activities

IUFoST conducts a wide range of activities in order to achieve its objectives of fostering international cooperation and exchange of knowledge and ideas between food scientists and technologists throughout the world. These are conducted in conjunction with the adhering bodies and their regional groupings, or with a range of other local, national, or international organizations.

Congresses

Until 1999, World Congresses of Food Science and Technology were conducted approximately every 4 years in conjunction with the adhering body of the host country (Table 6). From 2001, they have been held biennially, commencing with Congress 11 in Seoul, South Korea.

Table 6 World Congresses of Food Science and Technology

Congress No.	*Year*	*Location*
1	1962	London, UK
2	1966	Warsaw, Poland
3	1970	Washington, DC, USA
4	1974	Madrid, Spain
5	1978	Kyoto, Japan
6	1983[a]	Dublin, Ireland
7	1987	Singapore
8	1991	Toronto, Canada
9	1995	Budapest, Hungary
10	1999	Sydney, Australia
11	2001	Seoul, South Korea
12	2003	Chicago, USA
13	2006	Nantes, France

[a]Congress dates were adjusted to avoid clashes with International Union of Nutritional Sciences Congresses.

Regional Meetings

IUFoST has been associated with over 200 conferences, symposia, seminars, workshops, training programs, and short courses since its inception in 1970, covering diverse topics in areas such as food science, food technology, food engineering, food microbiology, human nutrition, national and international food law, food toxicology, product development, and food security. Proceedings of many of these activities have been published.

Declarations on Food Security

IUFoST has long recognized the role of food science and technology in improving food security in the developing world, especially in Africa and Eastern Europe. The *Victoria Falls Declaration*, supporting the plight of consumers in the developing world, especially subSaharan Africa, was approved by delegates at ICSAFoST '94, the first international food conference held in Zimbabwe in September 1994. The declaration was based on the original declaration from the FAO/WHO International Conference on Nutrition held in Rome in December 1992, which was endorsed by 159 states and the European Economic Community (EEC). Following the 9th World Congress of Food Science and Technology in Budapest, Hungary in July–August 1995, the *Budapest Declaration*, based on the FAO/WHO and Victoria Falls declarations, was approved by delegates to the IUFoST General Assembly. It states:

1. We, the delegates to the 7th General Assembly of the International Union of Food Science and Technology (IUFoST), in reference to the Joint FAO/WHO International Conference on Nutrition (Rome, 1992) and its World Declaration on Nutrition, declare our determination to work for the *elimination of hunger and reduction of all forms of malnutrition* throughout the world. *We recognize that access to nutritionally adequate and safe food is the right of each individual*. We also declare our commitment to work with all other organizations *to ensure sustained nutritional well-being for all people in a peaceful, just and environmentally safe world*. In this endeavor, we recognize the central role of food science and technology in ensuring the year-round availability of the quantity and variety of safe and wholesome foods necessary to meet the nutritional needs of the world's growing population.
2. *Despite appreciable worldwide improvements in life expectancy, adult literacy and nutritional*

status, we all view with the deepest concern the unacceptable fact that about 800 million people in developing countries – twenty percent of their combined population – still do not have access to enough food to meet the basic daily needs for nutritional well-being. We are especially concerned *by the high prevalence and increasing numbers of malnourished children under five years of age in parts of Africa, Asia and Latin America and the Caribbean as well as other parts of the world. Moreover, 2000 million people, mostly women and children, are deficient in one or more micronutrients; babies continue to be born mentally retarded as a result of iodine deficiency; children go blind and die of vitamin A deficiency; and enormous numbers of women and children are adversely affected by iron deficiency. Hundreds of millions of people*, particularly young children, pregnant women, the immunocompromised and the elderly, *also suffer from communicable and non-communicable diseases caused by contaminated food and drinking water. At the same time, chronic non-communicable diseases related to unbalanced dietary intakes often lead to premature deaths*. Taken together, these diseases result in enormous health care costs as well as important losses due to reduced economic productivity. We recognize that the contributions of food science and technology are essential in solving many of these problems, especially those related to inappropriate dietary intakes, food hazards and micronutrient deficiencies.

3. *We recognize* that *poverty* and limited access to *education, which are* commonly *the effects of underdevelopment*, are often major *causes of hunger and undernutrition. There are poor people in most societies who do not have adequate access to food, safe water and sanitation, health services and education, which are the basic requirements for nutritional well-being*. To overcome these problems, there is an urgent need to strengthen the food science and technology base to support food and agriculture sectors, especially in low-income, food-deficit countries, in order to expand and diversify food supplies, create income-earning opportunities and generate local resources for development.
4. *Slow progress in solving nutrition problems in many countries reflects the lack of human and financial resources, institutional capacity and policy commitment needed to assess the nature, magnitude and causes of nutrition problems and to implement concerted programs to overcome them. Basic and applied scientific research, as well as food and nutrition surveillance systems, are needed to more clearly identify the factors that contribute to the problems of malnutrition and the ways and means of eliminating these problems, particularly for women, children and aged persons*. We recognize that food science and technology inputs together with modern biotechnology are essential in many basic and applied scientific research programs. We further recognize our responsibility to promote public understanding of issues involving food science and technology, so that public support and acceptance allow the timely introduction of beneficial applications of present and emerging new technologies.
5. *The right of women and adolescent girls to adequate nutrition is crucial. Their health and education must be improved. Women should be given the opportunity to participate in the decision-making process and to have increased access to and control of resources*. We recognize that, in many parts of the world, women have a particularly important role to play in food production, handling and preparation.
6. *We acknowledge the importance of further liberalization and expansion of world trade, which would increase foreign exchange earnings and employment in developing countries*. We recognize the important role of food science and technology in the establishment of standards, guidelines and other recommendations of the Codex Alimentarius Commission, including their acceptance by national food authorities.
7. We recognize aspects of food science and technology as integral components, both in the preparation of National Plans of Action for Nutrition and in the formulation of economic development plans and identify the following areas as being especially significant:
   - promotion of the safety and quality of all foods;
   - reduction of pre- and postharvest food losses;
   - adaptation and improvement of traditional foods and processes;
   - beneficial application of biotechnology and other new technologies;
   - development and dissemination of improved knowledge of food composition;
   - promotion of domestic and international food trade;
   - development of food materials with improved functionality;
   - more efficient and environmentally sustainable food production and processes; and
   - education in nutrition, food science, and technology at all levels.

8. We support the *active cooperation among governments, multilateral, bilateral and non-governmental organizations, academic bodies, the private sector, communities and individuals to eliminate progressively the causes that lead to the scandal of hunger and all forms of malnutrition in the midst of abundance*. We, the adhering bodies of IUFoST, representing professional food scientists and technologists from 58 nations throughout the world, are fully committed to cooperate and collaborate with all parties in achieving these objectives.
9. We recognize that efforts to ensure safe and adequate diets for the people of the world can only succeed when social, cultural, political, economic and educational components of the problem are also addressed. We further recognize that, in addition to adequate resources to assure household food security, consumers must have an adequate knowledge of the basics of food safety and nutrition to protect their health and to promote their nutritional well-being.
10. *With a clear appreciation for the intrinsic value of human life* and in recognition of the right of all individuals to safe and nutritionally adequate food, we adopt this Declaration and affirm our commitment as food scientists and technologists *to protect and promote the nutritional well-being for all*.

*Note: Words in italics are included in the FAO/WHO Declaration.

Publications

The IUFoST newsletter was first published in 1970. It became *Newsline* with the 25th edition in March 1993 when it was first published as part of *Lebensmittel-Wissenschaft & Technologie (LWT, Food Science and Technology)*, a scientific journal owned by the Swiss Society of Food Science and Technology and published by Academic Press. *Newsline* is now published three times per year and is available on the IUFoST website (http://www.iufost.org). The Elsevier journal *Trends in Food Science and Technology* is also an official journal of IUFoST and EFFoST.

In September 2000, IUFoST and its US adhering body, the IFT, jointly launched the online electronic magazine *The World of Food Science*, directed at food scientists and food technologists at all levels in the international arena. Its mission is:

> To inform the world community of food scientists, technologists, food regulators, governmental advisors, reporters and others interested in the promotion of a safe and sufficient food supply through timely news of events, business activities such as acquisitions, new products and new markets, regulatory measures, government policies, scientific and technological advances, and regional business reports and developments. The magazine has a commitment to be a premier vehicle for information about food science and technology, to encourage interaction of food scientists in the international community and to promote the fields of food science and technology.

An international Editorial Advisory Board contains members representing both IUFoST and IFT, together with a senior staff officer of both organizations.

Relationship to other Organizations

ICSU

IUFoST was admitted as a Scientific Associate member of the International Council of Scientific Unions (ICSU) in 1981. During a hard-fought campaign for recognition of food science, which was led by Dr Ted Hood as President in the early 1990s, the direct support of 12 International Unions and 12 National Academies of Science was eventually achieved. IUFoST was subsequently elected to full membership during the 25th General Assembly of ICSU held in Washington, DC in 1996.

FAO/WHO/United Nations

IUFoST has close relationships with both the FAO and WHO and has a standing invitation to contribute to food-related programs and to make recommendations on FAO and WHO policies and activities. It contributes to activities of the Codex Alimentarius Commission, United Nations University and other UN agencies such as the Organization for Economic Cooperation and Development (OECD).

IUNS

IUFoST is collaborating with IUNS to compile a dictionary or directory of professional terminology in food science/technology for nonEnglish speaking experts.

IODINE

Contents

Properties and Determination

M R L'Abbé, Nutrition Research Division, Health Canada, Ottawa, Ontario, Canada

Background

Iodine is a blueish-black solid of the halogen family of elements which readily sublimes to the deep violet I_2 vapor. The iodine concentration of human foods is usually low and extremely variable. Foods naturally high in iodine include seaweeds and marine fish. In addition, iodine can be added to foods from sources such as fertilizers, animal feed supplements, iodine-containing sanitizers and disinfectants or through the use of iodine-containing food additives and food colorants. Iodine is also added in many countries to foods such as table salt for iodine fortification for the prevention of iodine deficiency disorders (IDD) or goitre. As iodine is volatile and can be easily oxidized or reduced, care must be taken to prevent volatility losses during analysis. The analyst must also be aware of the chemical form and oxidation state of iodine under various conditions to avoid losses.

Physical and Chemical Properties

Iodine (I), atomic number 53, atomic weight 126.91, is a nonmetallic element of the halogen family (group VIIA) after fluorine (F), chlorine (Cl), and bromine (Br) in the periodic table. Of these, iodine is the heaviest and least electronegative. Solid iodine is a bluish-black crystalline solid with a metallic luster in the form of shiny flakes which can be readily crushed into a fine powder. Iodine crystallizes in an orthorhombic structure and is arranged in a unit cell of eight atoms arranged as a symmetrical bipyramid.

Solid iodine readily sublimes, as evidenced by its pressure below melting point (Table 1). The vapor is made up of diatomic iodine molecules (I_2) which dissociate readily at elevated temperatures. Iodine vapor is characterized by its familiar violet color. The specific gravity of I_2 vapor is approximately nine times that of air. Solid iodine is only slightly soluble in water and no hydrates form on dissolution, although it readily dissolves in many organic solvents. The color of iodine in solution varies with the solvent; aliphatic hydrocarbons and carbon tetrachloride give violet solutions, aromatic hydrocarbons give pink or brownish pink solutions, and alcohols, water, ethers, and some amines give brown colors.

The only stable isotope of iodine has a mass of 127. There are 22 other isotopes having masses between 117 and 139, with 14 of these yielding significant radiation. The electron configuration of the iodine atom is $4d^{10}5s^25p^5$. The chemistry of iodine is rather complex as it can exist in a number of valence states, with its principal oxidation states being -1, $+1$, $+3$, $+5$, and $+7$ and an oxide IO_2, with an oxidation state of $+4$. All these forms are thermodynamically stable except the $+4$ state. Iodine dissolves without reaction in concentrated sulfuric acid and with concentrated nitric acid it reacts to form iodine pentoxide; in acidic solution it has mild oxidizing properties. Iodine readily forms covalent iodides of metals such as aluminum, tin, titanium, and many organic substances, but not with S, Se, and the noble gases, and reacts only indirectly with C, N, O, and some noble metals such as Pt. Iodine as a vapor or solid reacts

[b]Color varies with solvent; see text for details.

readily with Mg, Ca, Al, Zn, Sn, Ni, and Fe, forming the corresponding iodides. The metal iodides and polyiodides are bases, whereas the iodine halides are acids.

Sources of Iodine

Iodine is one of the rarest nonmetallic elements on earth. Although not abundant, iodine is distributed widely in rocks, soils, waters, plants, animal tissues, and foodstuffs. Of these, only a few substances characteristically contain large quantities of iodine – these being seaweeds, sponges, and corals, underground waters from deep wells, and the vast natural deposits of sodium nitrate found in northern Chile which contain high amounts of iodine. Sea water contains the largest total amount of iodine, mostly in the form of iodide and iodates. Iodine is readily volatilized by the action of sunlight and heat. Sunlight oxidizes iodide to iodine and about 400 000 tons iodine of escape from the oceans into the air each year. Atmospheric iodine is then deposited on land and vegetation. Many soils are low in iodine, particularly crystalline soils exposed to glaciation and leaching, and soils lacking humus cannot retain iodine. Heavy rains also promote iodine-deficient soils, as does frequent flooding of low-lying coastal regions. Areas of low iodine and consequently a higher prevalence of iodine-deficiency goiter have been located on every continent throughout the world.

Iodine has a wide range of chemical and related industrial uses, some of which can make it into the food supply. In 1996, approximately 39% of iodine production was used for sanitation, pharmaceuticals 24%, heat stabilizers 13%, catalysts 9%, animal feed 7%, and other uses 8%.

Water and Soil

Sea water is high in iodine and contains approximately 50 $\mu g\,l^{-1}$, mainly as iodide salts, although the level in oceans can vary widely (Table 2). The level of iodine in drinking water is much lower than that of sea water and usually reflects the iodine content of the rocks and soils in the region, although water from deep wells can provide significant amounts of iodine. Iodine in soil is in the form of iodide ions which are readily oxidized by sunlight to volatile elemental iodine, which is then released into the atmosphere, thereby reducing soil levels in many areas. Locally grown plants and crops and meat and milk products usually reflect the iodine content of soils and hence, foods from large parts of the world are iodine-deficient unless fortified with iodine or iodine is added to animal feeds or added during food processing.

Dietary Sources

Foods The iodine concentration of human foods is extremely variable. These variations are due to a number of factors, including differences in the iodine content and availability of iodine in the soil and water, as described above. In addition, iodine is added inadvertently to foods from sources such as fertilizers, animal feed supplements, iodine-containing sanitizers and disinfectants, or through the use of iodine-containing food additives and food colorants. Iodine is also added in many countries to foods such as table salt for iodine fortification for the prevention of iodine-deficiency disorders (IDD) or goiter.

Although the concentration of iodine in foodstuffs is extremely variable, oilseed protein supplements (soybean, cottonseed, linseed, and peanut) typically contain 0.11–0.20 p.p.m. iodine, whereas cereal grains range from 0.04 to 0.10 p.p.m. iodine. Milk, milk products, eggs, and meat usually contain more iodine than plant foods, although actual levels may reflect iodine provided to the animals either naturally, or through feed supplements, veterinary uses, or during food processing.

The food sources containing the most iodine tend to be marine products, although in recent dietary surveys in some countries, dairy products and bakery products were found to provide significant amounts of iodine (Table 3). Ocean fish are especially rich in iodine and may contain 300–3000 p.p.b. iodine compared to 20–40 p.p.b. for freshwater fish. No plants are known to preferentially, concentrate iodine although seaweeds are particularly rich sources

Table 2 Typical iodine levels in goitrogenous and nongoitrogenous regions

	Area	
	Goiter-free areas	*Endemic goiter area*[a]
Drinking water ($\mu g\,l^{-1}$)	5–15[b] (4000–16 000)[c]	0.1–2
Sea water ($\mu g\,l^{-1}$)	50	
Air ($\mu g\,m^{-3}$)	0.7	0.02
Soil ($\mu g\,kg^{-1}$)	300[d]	< 100
Dietary intakes ($\mu g\,day^{-1}$)	100–150[e]	< 25
Milk ($\mu g\,kg^{-1}$)	50–1000	< 25
Bread ($\mu g\,kg^{-1}$)	15	< 5
Animal tissues ($\mu g\,kg^{-1}$)	100–400	< 50

[a]Areas of moderate to severe iodine-deficiency disorder (IDD) according to the World Health Organization (1996) classification for prevalence (severity) of IDD; median urinary iodine levels ($\mu g\,l^{-1}$) as mild (50–99), moderate (20–49), or severe (<20).
[b]In some areas, levels as high as 40–100 $\mu g\,l^{-1}$ have been reported.
[c]Final concentration in water after using iodine preparations for water disinfection when used at recommended levels; recommended for short-term use only.
[d]Highest concentrations found in Chilean nitrate deposits (0.5–2 g kg^{-1}).
[e]Intakes should be higher (200–300 $\mu g\,day^{-1}$) in the presence of large amounts of goitrogens.

(50–4500 $\mu g\,g^{-1}$) due to the ocean environment in which they grow. In Canada, milk and dairy products contributed the greatest amounts to intake (239 μg day^{-1}), followed by cereals (84 μg day^{-1}) and meat, eggs, and fish (28 μg day^{-1}).

As noted above, the iodine content of foodstuffs is often modified by food-processing technology and manufacturing practices. Iodine and its compounds are used in a variety of food-related applications, including nutrient fortification (e.g., iodized salt), food additives (e.g., dough conditioners, maturing agents, and food colorants), agricultural chemicals (e.g., herbicides and fungicides), animal feed supplements, and veterinary drugs (e.g., ethylenediamine dihydroiodide, EDDI, which is 80% iodine and is used to treat and/or prevent foot rot in cattle), and sanitizers (e.g., iodophores) (Table 4).

Iodine-containing supplements in the feed of dairy cattle, iodine-containing veterinary pharmaceuticals, teat-dips and udder washes, as well as iodophores used as sanitizing agents in dairy-processing establishments can contribute to high iodine levels in dairy products in countries where such practices are prevalent. Milk from dairy cows where no iodophor sanitizers or iodine-containing veterinary pharmaceuticals are used usually contains less than 50 $\mu g\,l^{-1}$ compared to 200–800 $\mu g\,l^{-1}$ or higher measured in some recent surveys where these practices are common. Iodine concentrations in milk are usually higher in winter than summer, likely reflecting the greater use of supplements and formulated feedstuffs compared to pasture feeding. Very high levels of iodine in milk have been observed with the feeding of relatively high amounts of EDDI (which is 80% I). For example, the

Table 3 Comparison of iodine intakes in various countries by food group (μg day^{-1})[a,b,c]

Food group	*Canada*[d]	*UK*[e]	*China*[f]
Milk and dairy products	239	91	1
Meat, fish, poultry, eggs	28	38	21
Breads, grains, cereal products	84	4	66
Fruits and fruit products	1	3	1
Vegetables, including potatoes	2	13	38
Fats and oils	2	1	NR[g]
Nuts and legumes	<1	0	5
Sugars and condiments	14	12	<1
Beverages	Included above	17	5
Estimated total intake[c] (μg per person per day)	371	180	166

[a]Values are for foods as consumed.
[b]Comparisons by food groups are only approximate as the compositions of the various food groups are not exactly the same in different countries.
[c]Does not include iodine from iodized salt, iodized oil, iodine supplements, or from drinking water.

[e]Calculated from Ministry of Agriculture, Fisheries and Food (2000) Food Standards Agency UK–1997 *Total Diet Study–Fluorine, Bromine and Iodine. Food Surveillance in Formation Sheet, 127*. London: MAFF.
[f]Average from five regions, from Hou X, Chai C, Qian Q, Lin G, Zhang Y and Wang K (1997). The study of iodine in Chinese total diets. *Science of the Total Environment* 193: 161–167.
[g]NR, not reported.

Table 4 Some examples of other sources of iodine contributing to food iodine content or to iodine intakes

Use	*Example (s)*
Therapeutic drugs	Preparations to treat thyroid disorders, radiopharmaceuticals and contrast media, topical antiseptics (povidone-iodine solutions and ointments, betadine – an organically bound iodine), potassium iodide used as an expectorant in cough and cold medications
Fortification	Iodized salt, iodized oil
Food additives	
Dough conditioners	Potassium iodate (KIO_4) in bread and bakery products
Food colorants/dyes	Erythrosine (red dye #3; 2,4,5,7-tetraiodofluorescein)
Agricultural chemical residues	4′-hydroxy-3′5′-diiodobenzoic acid (herbicide)
Veterinary drug residues	Ethylenediamine dihydroiodide (EDDI)
Animal feed supplements	Provided as salt licks, or added as part of animal feed supplement. Dietary requirements for livestock range from 0.14 (swine) to 0.5 (beef and dairy cattle) mg kg^{-1}
Sanitizers	Iodophores used in milking equipment, dairies, food processing, and restaurant grills
Water purification	Effective at 0.5–1 p.p.m. (although water purification with iodine can often contribute 1000–2000 $\mu g\,l\,day^{-1}$)

iodine concentration in milk of cows fed 40 mg EDDI was 361 $\mu g\,l^{-1}$, compared to 1559 $\mu g\,l^{-1}$ in milk from cows given 162 mg EDDI. In Scandinavian countries (except Iceland), cows' milk is a good source of iodine because cattle fodder is iodinated by law.

Iodine fortification and supplements Another potential large contributor to iodine intakes is iodized table salt, although iodized salt is not universally available, nor is fortification mandatory in many countries. According to the World Health Organization in 1994, about 1600 million people were at risk of IDDs because they live in iodine-deficient environments. Of these, 656 million had goiter and 43 million had some degree of mental defect, including 11.3 million overt cretins. Endemic goiter is the most visible sign of iodine deficiency, but impairment of nervous system development and function is the most serious consequence of iodine deficiency. Iodine deficiency is still the world's greatest single cause of preventable brain damage and mental retardation.

In order to combat IDD, iodized table salt has been used in many countries since the 1920s and can contribute significant amounts of iodine to daily intakes. A variety of other vehicles have also been used for iodine supplementation of populations whose dietary intakes of iodine are low. For example, injection with iodized oil has been used in Papua New Guinea and was found to be particularly effective for treatment of goiter in remote mountain villages. In some countries teas, rice, or oils have been fortified with iodine, although problems have been encountered with non-uniform intakes, stability, or bioavailability of some of these forms. Before the advent of iodine fortification, prevalence rates of endemic goiter in many parts of the world were high and still remain so in areas without universal salt fortification or iodine supplement programs.

Iodized salt In Canada, iodide is added at the rate of 76 $\mu g\ I\,g^{-1}$ table salt while, for example, in Norway iodide is added at 5, France 15, Finland 25, Sweden 50, USA 100, and in China at 12–30 $\mu g\ I\,g^{-1}$ salt. In Iceland salt is not iodized because iodine intakes are already sufficiently high (300–350 $\mu g\,day^{-1}$) due to the high consumption of salt-water fish. Intakes of table salt also vary greatly in population surveys. In Canada, some individuals use virtually no table salt, compared to many others who consume more than 2 $g\,day^{-1}$. This contrasts greatly with countries such as China where the consumption of table salt averages 10–30 g per person per day.

Goitrogenic substances Goitrogenic substances are substances that have antithyroid activity and interfere with thyroid hormone production or utilization. The most important goitrogens are thiocyanates, which can compete with iodine for uptake into the thyroid gland, especially when iodine intakes are low. Many goitrogenic substances or their precursors are present in plants of the *Brassica* spp. (the crucifer or mustard) family and at least 10 other dicotyledonous plant families. *Brassica* species such as cabbage, broccoli, cauliflower, rutabaga, mustard, Brussels sprouts, and turnip contain glucosinolates (previously called thioglucosides) which are hydrolyzed to form isothiocyanates, nitriles, and thiocyanates. About 100 different kinds of glucosinolates are known to exist in the plant kingdom, but only about 10 are present in *Brassica*; high levels are also found in a number of seed meals, e.g., some rapeseed and soybean meals. The first toxic effects of isothiocyanates and other hydrolytic products from glucosinolates are goiter and a general inhibition of iodine uptake by the thyroid.

Goiter and IDDs have also been attributed to cassava consumption in many parts of the underdeveloped world. Cassava is a widely grown root crop which accumulates cyanogenic glucosides, linamarin, amygdalin, and lotaustralin. Linamarin accounts for more than 80% of the cassava cyanogenic glucosides and cyanide intoxication can occur when poorly processed cassava meal is eaten.

In some parts of the world, water has been shown as the cause of endemic goiter irrespective of its iodine content, particularly water from shallow wells. Such water is often grossly polluted and/or contains high levels of nitrate or humic substances (and some of their degradation products) which have also been shown to be goitrogenic by blocking thyroidal iodination.

Iodine Determination

Iodine analysis presents some of the most challenging of analytical situations. Iodine is volatile and can be easily oxidized or reduced. Thus, with iodine, care must be taken to prevent volatile losses and the analyst must be aware of the chemical form and oxidation state of iodine under various conditions. Conditions which are usually used to prepare samples and dissolve the ash during the analysis of other trace elements of nutritional concern may not be appropriate for iodine, so that iodine values are usually not available in many multielement food surveys. When iodine data are needed, a separate sample preparation phase specifically designed for iodine is usually employed. In addition, the content of iodine in diets and biological samples is often very low (normally well below $< 1.0\,\mu g\,g^{-1}$; usually in the $ng\,g^{-1}$ range), making accurate determination of iodine a difficult task.

Sampling and Sample Preparation

The complex nature of food samples compared to biological matrices necessitates extra care in preparing food composites representative of different geographic regions, seasons, food preparation (fresh, canned, frozen), manufacturers, and lots. Care must also be taken in thoroughly mixing, blending, and homogenizing a representative sample. It is important to transport and analyze samples as quickly as possible. Homogenized food and biological samples may be stored in a refrigerator for a short time (1 or 2 days prior to analysis). If samples are to be stored for longer periods, samples should be appropriately packaged and frozen at low temperatures (usually $-20\,^{\circ}C$ to $-80\,^{\circ}C$) to minimize iodine loss or sample degradation. As for all trace element analyses, appropriate storage containers should be used, although iodine contamination during preparation is less of a concern than for many other trace elements.

Analytical Quality Control and Reference Standards

Prior to implementation of any analytical method, method verification should form the first essential step in the analysis of food or biological samples. In its simplest form, method verification may consist of low-level standard additions to representative food samples along with the analysis of a certified standard reference material of similar composition and analyte levels as the sample of interest. Unfortunately, until recently, many of the reference standards did not have certified values for iodine, which severely limited the choice of reference standards with similar matrix properties and encompassing the range of iodine seen in diet and biological samples. In recent years, however, certified iodine values have been added for many more reference materials (Table 5).

For implementation of new or previously untried methods, more extensive preliminary testing is required, including a range of recovery testing, analysis of a variety of reference standards, and comparison of results with other established methods. Adoption of new analytical techniques usually involves more rigorous and involved analytical accuracy procedures such as interlaboratory verification.

Choice of standards Volatilization losses are minimized by maintaining iodine in an alkaline mixture or in $2\,mol\,l^{-1}$ H_2SO_4. Iodic acid standards are more stable than other forms of iodine such as sodium or potassium iodide or iodate. Iodine solutions are unstable in light and should be stored away from extended exposure to white light. If sodium or potassium iodide standards are used, stock solutions should be prepared, stored at room temperature, protected from white light, and discarded after 30 days. We have found that iodic acid stock solutions are be stable up to 5 years when protected from light. Diluted working standard solutions are normally prepared fresh each week.

Analytical Techniques for Determination of Iodine

There is a limited choice of methods for the determination of iodine in biological samples or food samples, with the exception of certain seaweeds or thyroid tissue which contain high concentrations of iodine. The most common methods are based on catalytic reactions, ion-selective electrodes, or neutron

Table 5 National Institute of Standards and Technology (NIST) reference standards suitable for analysis of iodine in food samples and agricultural commodities

NIST identification	*Sample*	*Certified value for I*[a] *(mg kg*$^{-1}$*)*
SRM 1566a	Oyster tissue	4.46 ± 0.42
SRM 1549	Nonfat milk powder	3.38 ± 0.02
RM 8435	Whole milk powder	2.3 ± 0.4
RM 8415	Whole egg powder	1.97 ± 0.46
SRM 1846	Infant formula (milk-based)	1.11 ± 0.17

[b]Reference material discontinued; replacement indicated by same SRM number followed by next letter designation, but replacement SRM is not yet certified for iodine.

activation analysis. A few others such as spot tests are useful in a limited number of situations.

The method used in the analysis of samples should be as sensitive as possible relative to the levels of analyte in the samples under investigation. Prior to the implementation of any iodine analysis, it is essential that the analytical method under consideration be shown to be adequate for the range of food or biological samples to be analyzed. The limit of detection is usually defined as the minimum concentration of analyte that can be qualitatively detected, but not quantitatively determined, under a predefined set of conditions. Limit of quantification, on the other hand, is the minimum concentration which can be determined quantitatively with acceptable accuracy and consistency. Quantities measured between the two are usually referred to as 'trace.' Unfortunately, in large surveys of food samples when multielement analyses are performed, limits of quantification for iodine are often not sufficiently sensitive to determine accurately iodine levels in a wide range of food samples. For example, in the 1995 US total diet study, the limit of quantification for iodine was 0.002 mg 100 g^{-1} (20 ng g^{-1}), so that a large number of samples had reported iodine values of zero. Food iodine values are not currently available on the US Department of Agriculture nutrient database.

Sample Preparation

The two methods commonly used to destroy organic matrix prior to iodine analysis are based on dry alkaline combustion or wet acid digestion. The former are usually done in open vessels, but can be done in a closed-vessel microwave digestion apparatus. In general, both methods are time-consuming, but necessary prior to most analytical techniques. There are a number of possible sources of iodine loss during the sample decomposition phase, including evolution of gaseous I_2, absorption or adsorption on to surfaces, or precipitation of undissolved material.

Dry ashing typically involves treating samples with 2.5 × volume 2 mol l^{-1} KOH in ethanol, drying, gradual heating in a combustion oven to 600 °C for 2 h, cooling, dissolution (often ultrasonic dissolution is necessary), followed by slurry filtration or centrifugation prior to analysis of the filtrate. Details can be found in the Association of Official Analytical Chemists method 935.14.

For wet acid digestion, samples are digested in borosilicate tubes in aluminum heating blocks or in Kjeldahl flasks on Kjeldahl digestion racks with a mixture of acids. Approximately 0.5–2 g of sample is added to the flasks and an equal volume of water if the sample is dry. Ten milliliters concentrated HNO_3 is added, followed by 20 ml $HClO_4$ and 5.0 ml H_2SO_4. Samples are covered and left overnight at room temperature. Digestion is performed slowly for the first 30 min with a cold finger inserted into the top of the flask to prevent volatile losses of iodine with the volatile nitrogen oxides. Thus the iodine is refluxed back into the flask and oxidized by the large excess of perchloric acid to nonvolatile iodates. If insufficient perchloric acid is used, elemental iodine will be lost. Once the evolution of nitrogen oxides subsides, the remaining nitric acid is distilled off and the temperature rises. Any lipid material will then be converted to CO_2 and the rest of the perchloric acid distilled off, resulting in a solution of pale straw color. At this point dense sulfuric acid vapor will begin to form and it is imperative that digestion ceases. Samples are cooled and diluted to 100 ml with water (final concentration 2 mol l^{-1} H_2SO_4). Iodic acid (HIO_3) standards (1 ml each of 10, 50, 100, 250, 500, and 1000 p.p.b) and blanks are digested and then analyzed with each batch of samples. Aliquots of the digestate solution are then analyzed for iodine using the iodine-catalyzed reduction of Ce^{4+} by As^{3+}. A microplate modification of this colorimetric method is described in the following section.

Determination of Iodine

Chemical or catalytic methods The spectrophotometric determination of iodine is based on the catalytic effect of iodide on the redox reaction between the yellow ceric (IV) and arsenic (III) which yields the colorless cerium (III) and arsenic (V), first reported by Sandell and Koltoff in 1934. This is a two-step reaction, where the rate of reaction is measured by the determination of the loss of the yellow ceric (Ce^{+4}) ions at 410 nm. Of the two steps, reaction (1) is generally regarded as slow compared to the rapid reaction (2). The net reaction (3) proceeds with extreme slowness in dilute sulfuric acid at room temperature, but is greatly increased in the presence of I^-.

$$2\,Ce^{+4} + 2\,I^- \rightarrow 2\,Ce^{+3} + I_2 \qquad (1)$$

$$As^{+3} + I_2 \rightarrow As^{+5} + 2\,I^- \qquad (2)$$

$$\text{Net} \quad 2\,Ce^{+4} + As^{+3} \rightarrow 2\,Ce^{+3} + As^{+5} \qquad (3)$$

A couple of points are important to remember when using this reaction. The catalytic coefficient of iodide is a function not only of iodide concentration, but also of the Ce^{+4}/As^{+3} concentration ratio, the chloride concentration, and the sulfuric acid concentration. The reaction is linear with respect to iodide when there is a large ratio of As III to Ce IV. Chloride can increase the velocity at low concentrations and also inhibit the catalysis by iodide at high sodium chloride concentrations, leading to large fluctuations in

background rates which interfere with iodine determination of food samples with widely differing salt contents. This interference is overcome by using a large excess of NaCl in the reaction mixture, typically 10%, although this results in a slight loss of sensitivity.

The iodine-catalyzed reduction of Ce^{4+} by As^{3+} colorimetric method has been semiautomated using a Technicon autoanalyzer, which is no longer available. More recent modifications have adapted the colorimetric assay to 96-well microplate assay systems. In the assay, 300 μl Ce^{4+} (0.015 mol l^{-1} $(NH_4)_4Ce(SO_4)_4 \times 2H_2O$ in 2 mol l^{-1} H_2SO_4), 300 μl As^{3+} (0.015 mol l^{-1} As_2O_3 in 2 mol l^{-1} H_2SO_4), 300 μl NaOH (10% NaOH) are added to each well. One hundred microliters of sample or standard are added to each microplate well at timed intervals. The plates are mixed, centrifuged at 110 **g** for 40 s (IEC Centra MP4R, Fisher Scientific, Nepean, ON) and incubated for 35 min at 37 °C. The color change of samples, which is directly proportional to the concentration of iodine in the sample, is measured at 410 nm using a microplate spectrophotometer and compared to the color change from the standard curve prepared from the ashed standard solutions. Standard curves used for food samples typically range from 10 to 1000 ng ml^{-1}.

Alternative colorimetric procedures based on the destruction of the intensely colored orange iron thiocyanate complex by nitrite in the presence of iodide have also been employed and have the same range of iodide sensitivity as the iodide catalyzed ceric/arsenic reaction.

The acid digestion followed by semiautomated colorimetric determination of iodine has several advantages for the analysis of large numbers of food samples. There are few losses of iodine; typical recoveries of iodine added to a variety of food composites are > 95%, and similar recoveries are found for National Institute of Standards and Technology (NIST) reference materials within the range of the standard curve. An analyst can typically digest 36 samples per day for 3 or 4 days per week followed by colorimetric determination of all sample digestates on a single day. The disadvantages are that one must take appropriate safety precautions when working with concentrated acids, a perchloric acid fume hood is required, and the digestion must be monitored continuously by the analyst.

Iodide electrodes Iodine in water, milk samples, and other liquids in which the only source of iodine is iodide (I^-) can be determined using an ion-specific electrode. In short, the protein in milk is removed by acid precipitation, samples are filtered, and iodine in the filtrate is determined by an iodide-specific electrode using the standard addition procedure. Nickel nitrate is added to reduce interferences to the iodide response. Ion-specific electrodes, however, are only suitable for liquid samples, although samples do not have to be digested prior to analysis. Because the gels get coated quickly when analyzing samples such as milk and infant formula, the electrodes must be carefully cleaned and conditioned often to ensure accurate results. Full details for the determination of iodide in ready-to-feed milk-based infant formula using an ion-selective electrode have been described in the Association of Official Analytical Chemists method 992.24.

Spot tests Several rapid spot test kits have been developed for the semiquantitative or qualitative estimation of iodide in iodized table salt. In this procedure the presence of iodine in salt is determined with a standard starch solution, provided in a ready-to-use formulation. In the standard test procedure, one drop of test solution is added to a spoon of salt. The change in color of the salt sample ranges from white to light blue to dark violet depending on the iodine content of the salt (usually classified as nil, 7, 15, or 30 p.p.m.) when compared to the standard color chart provided with the kit. These kits are useful in field situations because results are available immediately, particularly in underdeveloped countries where analytical lab facilities are not readily available. Errors are usually associated with the subjective nature of the color grading of the reaction.

Neutron activation analysis (NAA) When high sensitivity and freedom from reagent blanks are desired, neutron activation analysis (NAA) is often the method of choice. In general, NAA is the best confirmation technique for trace element analysis as it is independent of potential chemical interferences from the sample matrix, although its widespread use in food analysis is often limited due to high cost and limited sample throughout capacity. NAA measures radioactive iodine via gamma-ray spectroscopy after a period of irradiation. Various forms of NAA have been used, including: (1) radiochemical NAA; (2) epithermal NAA, which permits nondestructive analysis of samples; and (3) more recent modifications such as preirradiation combustion (PC-NAA), which permits extraction of the iodine from the sample matrix without using strong chemical reagents, followed by NAA.

For diet samples, conventional NAA of iodine is critically interfered with by the strong radioactivities of ^{24}Na, ^{38}Cl, and ^{42}K. In order to improve the detection limits of iodine, epithermal NAA using boron nitride as a shield material has been used.

In a further refinement using PC-NAA, iodine is first volatilized from the sample matrix by

combustion and adsorbed on charcoal after a series of combustion steps. The segment of quartz containing the charcoal is sealed under vacuum and NAA performed on the material. Detection limit is typically 50 ng and recovery using iodine-125 as a tracer is usually 80–100%. Stable iodine is determined following a 60-s irradiation to produce iodine-128. After irradiation, samples and standards are counted using a gamma-ray detector and sample concentration determined by comparing the peak heights of iodine-128 in the standards and samples. Due to the high equipment expense and low throughput (typically an analyst can only analyze two samples per day), this method is not useful for routine applications, although it may be useful for verification of results.

Inductively coupled plasma–mass spectrometry (ICP-MS) ICP-MS has also been used for iodine analysis. Samples are extracted with tetramethyl ammonium hydroxide (TMAH) at 90 °C prior to analysis by ICP-MS using metal compounds such as tellurium as an internal standard. Although recoveries are usually very good, ICP-MS, like NAA, is expensive and too time-consuming for large-scale food surveys.

Physiology

J A T Pennington, Division of Nutrition Research Coordination, National Institutes of Health, Bethesda, MD, USA

Absorption, Bioavailability, Transport, and Storage of Iodine

Iodine in foods is primarily in the inorganic iodide (I^-) form, which is readily absorbed form the stomach and upper small intestine. Other forms of iodine in foods are reduced to iodide before or after absorption. Absorbed iodine is rapidly cleared from the blood plasma by the thyroid gland, kidney, salivary glands, gastric mucosa, and lactating mammary glands. Iodine intake in excess of body need is excreted primarily through the urine.

The total amount of iodine in the body is about 10–50 mg for an adult, and most of this is concentrated in the thyroid gland. Thyroid-stimulating hormone (TSH), from the anterior lobe of the pituitary gland, stimulates the active transport of inorganic iodide from the blood into the thyroid gland. Within the thyroid cells, iodide is oxidized to iodine and combined with tyrosine to form the thyroid hormones, thyroxine (T_4) and triiodothyronine (T_3). The formation of thyroid hormones is also stimulated by TSH. Thyroid hormones are stored in the thyroid gland bound to the glycoprotein, thyroglobulin.

Proteolytic enzymes release the thyroid hormones from thyroglobulin so that the hormones may diffuse into the blood. In the blood, thyroxine is found primarily bound to globulin and albumin. The secretion of thyroid hormones into the blood is regulated by TSH through a biofeedback system. When dietary iodine is adequate, thyroid hormone is produced in normal amounts at a low level of TSH; if dietary iodine is limited, TSH secretion is increased, which promotes iodine uptake by the thyroid. The thyroid gland stores enough thyroid hormone to last several months in the event that dietary iodine is not available. (*See* **Hormones**: Thyroid Hormones.)

Functions of Iodine in the Body

Iodine is a structural constituent of the two thyroid hormones thyroxine (T_4) and triiodothyronine (T_3). The chemical names of T_4 and T_3 are, respectively, 3,5,3′,5′ tetraiodothyronine and 3,5,3′ triiodothyronine. T_4 and T_3 are iodinated molecules of the essential amino acid tyrosine. Iodine accounts for about 65% of the weight of T_4 and 49% of the weight of T_3. The thyroid secretes T_4 and small amounts of T_3. The

principal role of these hormones is to regulate cellular metabolism. The hormones are also required for normal growth and bone maturation in children. In infants, adequate supplies of thyroid hormone are necessary for the development of the central nervous system in the first 1–2 years of life. (*See* **Children**: Nutritional Requirements; **Infants**: Nutritional Requirements.)

Thyroid hormones accelerate cellular reactions in nearly all cells of the body, resulting in increased oxygen consumption and an increase in basal metabolic rate. The effects of the hormones are partially the result of increases in enzyme activity, as many enzymes are reported to be affected by T_4. Within body cells, thyroid hormones increase glycogen synthesis, gastrointestinal uptake of glucose and galactose, uptake of glucose by adipocytes, lipolysis, oxidation of free fatty acids, and protein synthesis. Thyroid hormones decrease serum cholesterol by increasing the removal of low-density lipoprotein from the blood.

Iodine Requirements

Approximately 60–100 μg of iodine per day is needed to produce an adequate supply of thyroid hormones. The Recommended Dietary Allowances (RDAs) for iodine in the USA are 40–50 μg per day for infants, 70–120 μg per day for children 1–10 years of age, and 150 μg per day for adolescents and adults. The USA RDAs are 175 μg per day during pregnancy and 200 μg per day during lactation. Similar recommendations for iodine intake are found in other countries. Reported average daily intakes of iodine in the USA, Australia, New Zealand, Canada, and European countries generally meet or exceed these recommendations.

Iodized salt is a convenient and effective means of meeting recommended intakes of iodine and preventing iodine deficiency in countries where the usual intake of iodine from food sources is low. In many countries, the level of iodine in salt ranges from 0.002 to 0.005%; in the USA, it is 0.01%, or approximately 416 μg of iodine per teaspoon of salt. Thus, one teaspoon of iodized salt provides 277% of the adult RDA.

Dietary Sources of Iodine

The inherent or natural iodine content of foods is variable, depending upon the iodine content of soil and water (for plant-based foods) and the iodine content of feed (for animal-based foods). The highest natural source of iodine is likely to be some species of seaweed.

Milk and products containing milk may be high in iodine due to the presence of indirect (i.e., unintentional) food additives. The iodine in milk is derived from ethylenediamine dihyroiodide (EDDI), a dietary iodine supplement added to dairy cattle feed and from iodophor solutions used as sanitizing agents on dairy cattle and dairy equipment. The use and extent of use of EDDI and iodophor solutions by the dairy industry cause great variation in the iodine content of milk. Seasonal and regional variations in the iodine content of milk may reflect different feeding and supplementation practices. During the summer or in warmer climates, dairy cattle may be pasture-fed. During the winter or in colder climates, dairy cattle may be given feed with EDDI supplementation. Feeding during spring and autumn or in moderate climates may reflect mixtures of pasture feeding and indoor feed supplementation.

Other foods high in iodine are those with iodine-containing food additives such as iodate dough conditioners, the red food dye erythrosine, and iodized salt. Iodate dough conditioners may be used in breads and other grain products. Erythrosine (tetraiodofluorescein) is 58% iodine (w/w) and may be present in some red-colored candies, pastries, and breakfast cereals. Although the concentrations of iodine in foods with erythrosine are quite high, the iodine from this source is only about 2–5% bioavailable. Regulations regarding the mandatory or voluntary iodization of salt and the level of iodization vary among countries. In the USA, for example, both iodized and noniodized salt are available in the marketplace, and the salt used by food manufacturers and by restaurants is usually noniodized. In other countries, the iodization of salt is mandated by government regulations.

Iodine is also available in dietary supplements as single supplements, in multiple mineral pills, and in multiple vitamin–mineral pills. The level of iodine in dietary supplements varies but is often 100% or more of the RDA. Iodine may also be present in other nutritional supplements and botanicals, especially if they include dried extracts of seaweed, plants, or fish.

Iodine Intakes

Iodine intake varies widely among population groups. Intakes may be less than 50 μg per day in iodine-deficient areas, over 400 μg per day in areas with iodized salt, and 1–5 mg per day or more in coastal areas of Japan where seaweed is commonly consumed. The main sources of dietary iodine for adults in the 1982–1991 US Total Diet Studies (TDS) were grain products (32% of iodine intake); milk and cheese (18%); animal flesh, especially fish

(13%); and desserts made with milk (10%). These results for the US TDS were based on a yearly analysis of 234 core foods for iodine content. Iodine intakes from the 1982–1991 US TDS ranged from 170 μg per day for infants to 386 μg per day for 25–30-year-old men. Average intakes for the more recent (1990–1991) TDS, were somewhat lower, ranging from 117 μg per day for infants to 317 μg per day for 14–16-year-old males, and there seems to have been a declining trend in iodine intake from 1982 to 1991. Nonetheless, these more recent iodine intakes are well above the RDAs without including iodine from discretionary salt (that added during cooking or at the table). Thus, the TDS estimates of iodine intake would be underestimated for individuals using iodized salt. The use of a half a teaspoon of iodized salt per day (iodized at the US level of 76 μg of iodine per gram of salt) would add an additional 208 μg of iodine.

Iodine Deficiency

Dietary iodine deficiency leads to a decrease in plasma T_4 and an increase in TSH. Under the influence of TSH, the thyroid becomes overactive, leading to hypertrophy and hyperplasia of the gland. This is known as 'endemic goiter.' Most individuals with goiter are euthyroid (i.e., have normal thyroid levels). Goiters range in size for modest enlargements to those that are several times the normal size and are frequently nodular in appearance. Large goiters may cause obstruction of the trachea and esophagus, and interfere with breathing and speaking. Prolonged deficiency of iodine, resulting in decreased levels of thyroid hormones, causes hypothyroidism or myxedema. The characteristics of this disease include decreased metabolic rate, fatigue, cold intolerance, weight gain, puffy face, dry skin, hoarse voice, edema, easy bruising, drooping upper eyelids, mental apathy, and problems with coordination. These symptoms are reversible with iodine therapy. Iodine deficiency during fetal development, infancy, or early childhood may result in cretinism, a condition that is not reversible and is characterized by retarded growth, mental retardation, deafness, and neurological problems.

In a few geographical areas, the development of endemic goiter as a result of iodine deficiency may be exacerbated by the ingestion of naturally occurring compounds in foods, known as 'goitrogens.' Goitrogens act by impairing iodine uptake by the thyroid or impairing the incorporation of iodine into tyrosine. Foods that contain goitrogenic substances include cassava, sweet potatoes, millet, and vegetables of the genus *Brassica* such as cabbage, broccoli, and turnips. The goitrogenic effect of these foods is not usually apparent if the diet is adequate in iodine. (*See* **Goitrogens and Antithyroid Compounds**.)

The FAO/WHO estimates that more than 20% of the world's population lives in geographic areas that are iodine-deficient. Iodine deficiency affects about 685 million people in Asia and the Pacific, 150 million in Africa, almost 55 million in the Americans, 33 million in North Africa and the Near East, and 82 million in Europe. Goiter from iodine deficiency affects about 200 million people world-wide. Prevalence rates for goiter of 5–20% are considered mild; in some communities, in Africa, Asia, and Latin America, more than 60% of the people have goiter. Children and women are more vulnerable to iodine deficiency than other population subgroups. About 26 million people have some degree of brain damage and mental retardation, and six million are affected by cretinism because of iodine deficiency.

Iodine Toxicity

Some individuals can tolerate very high levels of iodine with no apparent side-effects, and iodine intakes of up to 1 mg per day are probably safe for the majority of the population but may cause adverse effects in some individuals. Those who are most likely to respond adversely to iodine are those who have lived in areas of endemic goiter or who for other reasons have a habitually low intake of iodine, those with other thyroid disorders, and those who are sensitive to iodine.

Exposure to excessive iodine has occurred through foods, water supplies, drugs, dietary supplements, topical medication, and/or iodinated contrast media (used for X-rays). In the past, iodine-containing drugs (most commonly potassium iodide solutions) have been prescribed as expectorants for respiratory disease such as asthma, bronchitis, cystic fibrosis, and chronic pulmonary obstruction. Such drugs have also been prescribed for goiter, hyperthyroidism, rheumatism, and syphilis. Amiodarone, an iodine-containing drug, was prescribed for cardiac problems. The medical literature reveals that excessive exposure to iodine has resulted in thyroiditis, goiter, hypothyroidism, hyperthyroidism, sensitivity reactions, or acute responses for some individuals. Maternal iodine exposure during pregnancy has resulted in goiter, respiratory problems, enlarged hearts, and death of infants.

Iodine-induced hyperthyroidism may occur in some people receiving iodine supplementation. This condition is referred to as Jod–Basedow disease. These individuals may have underlying Graves' disease (hyperthyroidism) and react adversely when

given adequate supplies of iodine. Another explanation for the hyperthyroidism is that thyroid nodules of iodine deficiency become autonomous of normal control and produce excess thyroid hormone when iodine becomes available. High levels of iodine appear to interfere with the synthesis of thyroid hormones. This is referred to as the Wolff–Chaikoff effect. The block is usually temporary, but it persists in some subjects and leads to development of goiters.

Individuals who are sensitive to iodine may react to even small quantities of this element with fever, salivary gland enlargement, ioderma, visual problems, and/or other symptoms. Ioderma (dermatoses) resulting from iodine sensitivity vary from acne-type eruptions, rashes and urticaria, to eruptions described as bullous vesicular, purpuric hemorrhagic, pustular, or tuberous fungating. Deaths from these more severe forms of ioderma have been reported. Acute responses to the ingestion or injection of large doses of an iodine-containing solution have included cardiovascular collapse, convulsions, asthma attacks, and death.

Assessment of Iodine Status

Assessment of iodine status for an individual may be done by a physician checking for the presence of goiter, by measuring serum T_4 and TSH, by measuring urinary iodine, and by checking for other signs and symptoms of iodine deficiency or excess (e.g., level of fatigue, blood pressure, heart rate). Urinary iodine alone is not sufficient for determining the iodine status of an individual because it is a 'short-term' measure of iodine status reflecting the previous day's iodine intake, which may not be consistent with long-term measures of iodine intake. Individuals should also be asked about their usual diet, use of iodized salt, and use of dietary supplements that might contain iodine. Dietary assessment may be inaccurate due to the difficulty of obtaining precise information about iodine used as indirect or direct food additives (e.g., in milk, salt, bread) and in supplements.

Assessment of the iodine status of population groups requires methods that are both rapid and inexpensive. The methods used include the rate of palpable and/or visible goiter, urinary iodine excretion, and blood T_4 and TSH. In countries where assessment of iodine status is especially important for public iodine supplementation programs, iodine status may be measured by assessing the level of TSH in neonatal blood. Even though urinary iodine is a short-term measure of iodine status, it gives a useful indication of the distribution of iodine intakes for a population. Urinary iodine levels of $<20\,\mu g\,l^{-1}$ are considered to reflect severe deficiency, $20–49\,\mu g\,l^{-1}$ are moderate deficiency, and $50–99\,\mu g\,l^{-1}$ are mild deficiency. Urinary iodine levels between 100 and $200\,\mu g\,l^{-1}$ are considered satisfactory.

Iodine-deficiency Disorders

E N Pearce and S L Lee, Boston Medical Center, Boston, MA, USA

Introduction

Iodine is a chemical element found in trace amounts in the human body (15–20 mg). Iodine is stored almost entirely within the thyroid gland. The amount of iodine found in extrathyroidal tissues is minute and, therefore, it is considered a 'trace element' or a 'micronutrient.' The only function for iodine in human physiology is in the synthesis of thyroid hormones. Severe iodine deficiency will result in impairment of thyroid hormone synthesis that is necessary for normal childhood growth and adult metabolic function. Population effects of severe iodine deficiency include endemic goiter (enlarged thyroid gland), cretinism, decreased fertility rate, increased infant mortality, and mental retardation. The term iodine deficiency disorders (IDD) refers to the full clinical spectrum of disease caused by iodine deficiency.

Iodine Deficiency

Worldwide, there are large geographic areas with soil deficient in iodine. Human iodine intake is derived approximately 90% from food and 10% from water. The iodine content of foods and water generally reflects the iodine content of the local soil in which the food is grown. Current calculations by the International Council for Control of Iodine Deficiency Disorders (ICCIDD) have suggested that 29% of the world's population, or approximately 1.6 billion people, live in areas of iodine deficiency and are at risk for IDD. Those people at highest risk for IDD are located primarily in mountainous regions such as the Himalayas, the European Alps, the Andes, and the mountains of China. Iodine in the soil at these locations has been washed away by millions of years of glaciation and flooding. Iodine deficiency also occurs in lowland regions which are far from the oceans, such as central Africa and eastern Europe. Human iodine intake is obtained only through the diet. Crops grown in iodine-deficient areas will have decreased iodine concentrations. Animals in these areas will also be deficient, which may lead to decreased yields of meat, milk, and wool. In all these areas, those who consume only locally produced foods are at risk for IDD.

The dietary iodine requirement for normal thyroid physiology in adults is 100–150 $\mu g\,day^{-1}$. Two similar sets of recent recommendations from the US National Academy of Sciences, UNICEF (United Nations Childrens Fund), ICCIDD, and the World Health Organization (WHO) for different populations are shown in Tables 1 and 2.

In areas where iodine is not added to food products meant for humans or domesticated animals the primary sources of dietary iodine are saltwater fish and seaweed, because of the high iodine concentration in the oceans. Trace amounts are also found in grains and vegetables.

In countries such as the USA and the UK, iodine deficiency has been eliminated by means of 'silent prophylaxis.' Iodine has been voluntarily supplemented in table salt ($\sim 70\,g\,kg^{-1}$). After initial success in the 1920s to 1960s, areas that became iodine-sufficient after voluntary dietary supplementation have had a measurable decrease in iodine intake. Data collected for the first US National Health and Nutrition Examination Survey (NHANES I), conducted from 1971 to 1974, showed that the average urinary iodine concentration was 293.3 $\mu g\,g^{-1}$ creatinine, reflecting adequate dietary iodine intake. By the time of NHANES III in 1988–94, however, the average urinary iodine had fallen to 124.6 $\mu g\,g^{-1}$ creatinine. In particular, between the two surveys, the risk for insufficient dietary iodine intake of women of child-bearing age (15–44 years) increased 3.8 times.

It is not clear why iodine intake has fallen again in these areas but the etiology is likely multifactorial. This decrease in dietary iodine may be a result of reduced intake of eggs and salt, decreased iodate conditioners in bread, decreased use of iodized salt in manufactured foods, and poor education about the use of iodized salt. Currently in the USA only 50% of the salt sold in supermarkets is iodized. Noniodized salt contains little or no iodine. Another major source of dietary iodine in industrialized countries is egg yolks, because of iodine supplementation of chicken feed. Dairy products and meats have variable amounts of iodine, as some dairy cows and cattle are fed extremely high levels of iodine in supplements to maintain fertility and prevent hoof root. Levels of iodine in cows' milk reflect the animal's iodine oral intake. It has been often erroneously concluded that iodine in milk is from the iodophors used in the dairy industry to cleanse cows' teats. Small published studies suggest that, when properly used and rinsed off the cows' teats, very little iodine is transferred from iodophors into milk. Starting in the 1940s, iodate had been used as a bread stabilizer by

the commercial baking industry; this practice was abandoned in the USA in the 1960s but has reappeared in some breads in the US. One particular type of red dye, erythrocine (US Food, Drug and Cosmetic (FD&C) no.3), contains large amounts of iodine. This dye was commonly used until the 1960s in candy and breakfast cereals in the USA and is still found in some medications. In most other countries, iodination of salt, bread, or drinking water is mandated by law, and is performed under government supervision.

Prevalence

More than 13% of the world's population has some form of IDD. In 1990, at least 1.572 billion people worldwide were at risk for IDD. These included 710 million people in Asia, 60 million in Latin America, 227 million in Africa, and 20–30 million in Europe. Of these, 655 million were known to have goiter, and 11.2 million had cretinism. IDD is known to affect 50 million children: 100 000 cretins are born each year. The ICCIDD maintains a database of iodine nutrition in different countries (CIDDS database) available at the website: http://www.med.virginia.edu/~jtd/iccidd.

Pathophysiology of IDD

Dietary iodine is readily taken up through the gut in the form of iodide. From the circulation, it is concentrated in the thyroid gland by means of an energy-dependent sodium-iodate symporter. In the follicle cells of the thyroid gland, four atoms of iodine are incorporated into each molecule of L-thyroxine (L-T_4) and three atoms into each molecule of triiodothyronine (T_3). These hormones are essential for neuronal development, sexual development, and growth, as well as for regulating metabolic rate, body heat, and energy.

When dietary iodine intake is inadequate, the serum T_4 level initially falls, and a number of physiological processes occur to restore adequate thyroid hormone production. The pituitary gland detects low T_4 levels and releases more thyroid-stimulating hormone (TSH). TSH stimulates the growth, iodine uptake, and metabolic activity of thyroid follicular cells. TSH stimulates the thyroid to increase iodine uptake, thyroid hormone synthesis, and thyroid hormone secretion into the circulation. Increased TSH and the reduction of iodine stores within the thyroid result in an increased ratio of T_3 to T_4 production. T_3 is 20–100 times biologically more potent than T_4, and requires fewer atoms of iodine, so this tends to conserve iodine stores and maintain normal thyroid function. In addition, thyroid hormones are deiodinated in the liver and the iodine is released back into the circulation for reuptake and reuse by the thyroid gland. Under these circumstances of an efficient reutilization process, approximately 100–150 μg of iodine daily is passively lost in the urine, with additional small losses from biliary secretion into the gut, and must be replaced by dietary intake.

Enlargement of the thyroid gland is a normal adaptive reaction to low iodine intake. Iodine deficiency is the most frequent cause of endemic goiter, which is defined as a goiter prevalence of > 10% in a population. Thyroid gland volume measured by the sensitive and accurate method of ultrasonography shows that at any age the glands of an iodine-sufficient population are smaller than an iodine-deficient population. Iodine-deficiency goiter is initially diffuse with homogeneous hyperplasia. With time, the hyperplasia becomes nonuniform and interspersed by areas of regression or degeneration and fibrosis, resulting in nodular changes. Some nodules may become autonomous and secrete excess thyroid hormone regardless of the TSH level. Autonomous thyroid nodules in areas of iodine deficiency frequently contain TSH receptor-activating mutations that keep the TSH receptor in the activated or 'on' state, regardless of TSH ligand binding. With time (years to decades), growth and accumulation of the autonomous nodules may result in mild thyrotoxicosis. When a goiter is associated with hyperthyroidism, it is called a toxic multinodular goiter. In addition, autonomous nodules in goiters of euthyroid patients subsequently exposed to normal or high iodine levels may also lead to thyrotoxicosis. Depending on the exposure time and severity of the iodine deficiency, goiters may enlarge sufficiently to cause tracheal and esophageal narrowing and obstruction. Generally, treatment with iodine supplementation or T_4 therapy will not decrease the size of large nodular goiters in adults but will shrink small diffuse goiters of young children with iodine deficiency.

If iodine deficiency is extremely severe, thyroid hormone production will fall, and patients will become hypothyroid. Adults will have the usual signs and symptoms of hypothyroidism with goiter. Hypothyroidism in the fetus, neonates, and in young children prevents central nervous system maturation, especially neuronal myelination, leading to permanent mental retardation. In the most severe form, the constellation of mental retardation and growth abnormalities is called cretinism.

The severity of iodine deficiency in a population can be estimated by several measurements that can be obtained in the field, as shown in Table 3.

Table 3 Measures of iodine deficiency disorder severity in populations

	None	*Mild*	*Moderate*	*Severe*
Urinary iodine, median ($\mu g\,dl^{-1}$)	> 100	50–99	20–49	< 20
Goiter prevalence	< 5%	5–20%	20–30%	> 30%
Neonatal thyroid-stimulating hormone > 5 mIU ml^{-1} whole blood	< 3%	3–20%	20–40%	> 40%
Cretinism	0	0	+	+++

Adapted from WHO-UNICEF-ICCIDD (1993).

Dietary iodine intake is not the sole determinant of goiter development. Even in areas of severe iodine deficiency, there can be substantial variations in the incidence of goiter. One reason for this is the presence of goitrogens in the diet. The clinical disorders of iodine deficiency are magnified in the presence of dietary goitrogens. Goitrogens are substances that decrease the bioavailability of iodine or interfere within the thyroid hormone biosynthethic pathway. The presence of these substances was first established through animal experiments in the 1920s. Thiocyanates inhibit the thyroid gland's iodine-concentrating mechanism. Vegetables of the genus *Brassica*, which include cabbage, Brussels sprouts, broccoli, cauliflower, turnips, rape and rapeseed, and horseradish, all contain thioglucosides which are converted to thiocyanate after ingestion. Foods that contain cyanogenic glucosides release cyanide when digested; this is detoxified in the body to become thiocyanate. These goitrogenic foods include many major dietary staples of the developing world, such as cassava, maize, sweet potatoes, pearl millet, and lima beans. Finally, flavonoids (polyphenols), organic compounds found in many food plants, including millet species, also have antithyroid activity that inhibit thyroid hormone synthesis. Additionally, the clinical disorders of iodine deficiency tend to be more profound in geographic areas with coexisting selenium and vitamin A deficiencies, or protein-calorie malnutrition. Generally, the foods listed here by themselves do not contain sufficient goitrogens to be clinically important for thyroid physiology until the intake constitutes a major portion of the diet or is combined with iodine or other dietary deficiencies.

Clinical Manifestations

Affected patients come from geographic regions where IDD is endemic. The first sign of iodine deficiency is diffuse thyroid enlargement, which becomes nodular or multinodular with time. If a goiter is large enough, individuals may complain of compressive symptoms such as hoarseness, shortness of breath, or dysphagia. Goiters can be assessed by palpation and can be graded from 0 to 2, as shown in Table 4.

Table 4 Clinical grades of thyroid enlargement

Grade 0	No visible or palpable goiter
Grade 1	Enlarged thyroid that is palpable but not visible when the neck is in the neutral position
Grade 2	Enlarged thyroid swelling that is palpable and visible when the neck is in a neutral position

Reproduced from Delange FM and Utiger RD (eds) (2000) In: *Werner & Inbgar's The Thyroid*, 8th edn. Philadelphia: Williams & Wilkins, with permission.

Thyroid size, determined by ultrasound, has recently been shown to reflect the iodine sufficiency of a population. Unlike size estimates determined by palpation alone, ultrasound measurements are reproducibly accurate to within 10%. When goiter appears in >5% of a regional population, iodine deficiency should be considered (Table 3).

Iodine requirements increase during pregnancy, in part because of fetal requirements but also because of the mother's increase in total body volume. This increased iodine requirement will increase maternal goiter size in areas of mild, moderate, or severe iodine deficiency. Even in areas of borderline iodine intake, up to 10% of women may develop goiter during pregnancy. This pregnancy-related increase in thyroid volume has been carefully documented by ultrasound scans and may not be fully reversible after pregnancy, so goiter may increase in size in the mother after each pregnancy.

Patients with hypothyroidism due to severe iodine deficiency may experience fatigue, weight gain, cold intolerance, dry skin, constipation, or depression. Signs on physical exam may include dry skin, periorbital edema, and delayed relaxation phase of the deep tendon reflexes. Neonates and young infants are much more severely affected by iodine deficiency than are adults, and are more likely to become overtly hypothyroid.

Children are profoundly affected by iodine deficiency. In addition to the risk of goiter formation, neurological development and linear growth are critically dependent on prenatal and postnatal iodine intake and thyroid hormone sufficiency. Significant neuronal maturation and myelination

Table 5 Neurologic and myxedematous cretinism

Neurologic cretinism	Mental retardation, abnormal gait, and deaf-mutism, but not goiter or hypothroidism
Myxedematous cretinism	Mental retardation, short stature, goiter, and hypothyroidism

occur postnatally. Cretinism is the most extreme manifestation of IDD. It is rare, but is still seen in regions of severe iodine deficiency in southern and eastern Europe, Asia, Africa, and Latin America. Despite efforts by many international health organizations, including the WHO, 100 000 cretins are born each year. Cretinism can be divided into neurologic and myxedematous subtypes, although these subtypes have considerable clinical overlap, as shown in Table 5. Neurologic cretinism is more common and is thought to be caused by maternal hypothyroidism secondary to iodine deficiency during pregnancy (especially between gestational weeks 12 and 30). Myxedematous cretinism is found primarily in Nepal, western China, and Zaire. It is considered a result of iodine deficiency and hypothyroidism in the fetus during late pregnancy or in the neonatal period. Both conditions can be prevented by adequate maternal and childhood iodine intake.

Although overt cretinism is rare, populations in which severe iodine deficiency is prevalent are at risk for lower IQ and mental retardation, sometimes known as IDD developmental retardation. In fact, iodine deficiency is the leading cause of preventable mental retardation worldwide. This decrease in mental acuity in afflicted communities, combined with decreased agricultural yields of meat, milk, and wool from iodine-deficient animals, can have a devastating impact on local economies.

Severely iodine-deficient women are more likely to experience infertility, and pregnancy in this group is more likely to result in miscarriage or congenital anomalies. Children born to these women are more likely to have low birth weights, and to suffer infant mortality. Recent studies in the USA suggest that infants born to mothers with untreated hypothyroidism have a small reduction in intelligence as measured by standardized tests.

Finally, it is unclear whether iodine deficiency increases the incidence of thyroid cancer. There are clearer data that iodine intake affects the histiological subtypes of thyroid cancers. In areas where iodine deficiency is endemic there is a higher proportion of more aggressive thyroid cancers (follicular and anaplastic thyroid carcinoma) and an increased thyroid cancer mortality rate. Iodine prophylaxis has been demonstrated to reduce the proportion of follicular thyroid carcinomas and increase the proportion of the less aggressive form of thyroid cancer, papillary thyroid carcinoma.

Laboratory Data

The kidneys excrete approximately 90% of ingested iodine. The best diagnostic test for IDD, therefore, is a 24-h urine iodine collection. Based on this, IDD can be classified as mild (3.5–5 $\mu g\,l\,dl^{-1}$), moderate (2.0–3.5 $\mu g\,l\,dl^{-1}$), or severe (< 2.0 $\mu g\,l\,dl^{-1}$). If a 24-h urine collection is not practical, a random urine iodine-to-creatinine ratio can be substituted. In this case, 50–100 $\mu g\,l\,g^{-1}$ creatinine is consistent with mild iodine deficiency, 20–49 $\mu g\,l\,g^{-1}$ creatinine with moderate deficiency, and < 20 $\mu g\,l\,g^{-1}$ creatinine with severe deficiency.

Population studies have shown that neonates with IDD will have elevated TSH levels at birth but normal levels when evaluated weeks later. The extent of their transient hypothyroidism correlates with the severity of the iodine deficiency (Table 2). Blood from the umbilical cord or from a heelstick can be saved on filter paper and sent to a laboratory for screening within the first few days of life. Neonatal TSH screening is used widely in Europe, Japan, and North America. In areas of adequate iodine intake, about one in 4000 infants will be hypothyroid. In iodine-deficient areas, by contrast, hypothyroidism may be present in up to 10% of newborns. Early treatment of these hypothyroid infants with exogenous thyroid hormone can reduce the risk for developmental delays and mental retardation. Unfortunately, neonatal TSH screening is difficult and expensive and is not done in much of the developing nonindustrialized world.

Thyroid function studies are usually within the normal range in the presence of mild iodine insufficiency. In euthyroid patients with iodine deficiency, however, serum TSH levels may be normal to increased, T_3 levels normal or slightly elevated, and T_4 levels normal or decreased. Only in very extreme iodine deficiency does hypothyroidism develop; in this setting serum TSH will be elevated and both T_3 and T_4 decreased.

Twenty-four-hour radioactive iodine uptake is used in developed countries to help distinguish between different types of thyroid disease. Uptakes will be substantially increased in the presence of IDD due to increased TSH stimulation and reduction in the nonisotopic iodine pool. Therefore, thyroid uptake values in iodine-sufficient areas such as the USA are significantly lower than in areas with iodine deficiency such as western Europe.

Thyroid size as determined by ultrasound reflects the iodine sufficiency of a population. When goiter appears in > 5% of a regional population, iodine deficiency

should be considered (Table 3). Ultrasound scans of a goiter can be used to document size, volume, and normal size of individual nodules within the gland.

Medical Treatment

Prophylactic iodine replacement therapy will prevent IDD, including goiter, hypothyroidism, and cretinism, and is indicated for the entire population within an area of iodine deficiency. Once IDD has been established, long-term dietary iodine replacement may decrease the size of small diffuse goiters of short duration in infants, young children, and pregnant women. The supplementation of iodine will not reverse cretinism or reduce the size of large nodular endemic goiters.

Otherwise, patients do not routinely require specific therapy unless goiter is large enough to cause compressive or obstructive symptoms (for example, tracheal obstruction, thoracic inlet occlusion, or hoarseness). Radioactive iodine (I-131) has been used, primarily in Europe, to decrease thyroid volume of euthyroid goiters by up to 40–60%. Exogenous (L-T_4) can also be used to decrease goiter size, but is generally not effective in adults and older children. Supplemental L-T_4, when added to T_3 and T_4 secretion by the autonomous nodules in the endemic goiter, may cause thyrotoxicosis. Long-term L-T_4 therapy that results in the suppression of TSH to below-normal levels may have deleterious effects on cardiac and bone health and, therefore, is no longer routinely given to patients with goiter.

Surgical treatment by thyroidectomy may be indicated for compressive symptoms of a large goiter.

Prevention

At a population level, IDD can be prevented by the iodination of food products or the water supply. Optimal supplements should provide physiologic iodine levels, must be able to reach all of the affected population, and must be affordable. Different approaches have been required in different areas of the world.

Iodized salt was first instituted in the USA and Switzerland in the 1920s. In practice, the iodination of salt has proved to be the best method of iodine supplementation. Everyone needs salt, it is consumed at the same rate throughout the year, and there is little variation in patterns of salt use with differences in socioeconomic status. Salt can be used in animal feeds as well as in table salt for human consumption. Additionally, in most areas salt comes from a limited number of production centers. The technology involved in salt iodination is relatively straightforward. The iodine does not affect the appearance or the taste of the salt. Either iodide or iodate can be used; the iodate is more stable in tropical climates. Salt iodination programs cost US$0.05 per person annually. Iodine dose recommendations for each region are based on the average salt intake of the local population, local iodine requirements, and average losses of iodine during salt transportation and storage. Despite the relative simplicity of this approach, salt iodination can take years to reach the most severely affected areas of an iodine-deficient region.

An alternative to salt iodination in some developing countries has been the periodic use of iodized oil supplements. This is frequently used as an interim measure while iodized salt programs are being implemented, and is especially used for women of child-bearing age and for children. The iodized oil can be given as an intramuscular injection of 0.5 ml (240 000 μg iodine) during the first year of life or 1.0 ml (480 000 μg iodine) thereafter. A single dose is effective for 3–5 years. However, the injections require individual contact with a skilled caregiver. There is also a risk of disease transmission if sterile syringes and needles are not readily available. Therefore, oral iodized oil administration has been gaining favor instead. One oral administration can be effective for up to a year, although it does not provide the constant levels attained by injection. The usual oral dose is 0.1–0.25 ml (about 380 000 μg iodine).

Iodized bread has been used with some success in several countries, including the Netherlands, Tasmania, Russia, and Australia. Iodination of other substances such as tea and sugar has also been tried, though these substances tend to be consumed in variable quantities. An alternative approach is the iodination of drinking water. Relatively constant daily amounts of iodine can be added to either household or school water supplies. However, this is generally more expensive than large-scale iodized salt programs and requires a significant amount of monitoring and oversight. In some remote areas of China, where other approaches were not feasible, the iodination of irrigation and well water was highly effective over several years. This intervention was shown to decrease infant mortality by about 50%. This approach was extremely cost-effective, improving not only human health but livestock production.

Education of government officials and of affected populations is a critical component of any iodine supplementation program. It is important for the public to understand the importance of using iodized salt, especially in countries such as the USA and the UK, where iodination of salt is not mandated by law (only 50% of salt sold in US supermarkets and 2.5% of salt sold in the UK is iodized).

Complications of Iodine Treatment

The primary complication of iodine prophylaxis for IDD is the development of hyperthyroidism. This is known as the Jod–Basedow phenomenon, or iodine-induced hyperthyroidism (IIH). The presentation of hyperthyroidism may be subtle. Typical symptoms include anxiety, heat intolerance, palpitations, weight loss, increased appetite, tremor, and menstrual disturbances. IIH is caused by the hyperfunctioning areas of autonomy that tend to develop in long-standing iodine-deficient goiters. It tends to be observed in patients over age 45 during the early phase of IDD prevention programs. It has been seen in almost all iodine supplementation programs worldwide. Well-documented IIH epidemics occurred in the USA from 1924 to 1928, in Tasmania in the 1960s, and, more recently, in Zaire and Zimbabwe. The outbreaks in Zaire and Zimbabwe were thought to be due to iodine overload secondary to insufficient monitoring of salt iodination programs. IIH occurs, however, even with physiologic iodine supplementation levels (100–200 $\mu g\,day^{-1}$). IIH is usually benign and easily treatable, but in rare cases severe cardiovascular complications can lead to fatalities. For this reason, iodized oil administration is not recommended for adults over age 45. In general, doses of up to 1100 μg of iodine per day are considered safe for adults.

Eliminating IDD: Worldwide Progress

At the United Nations World Summit for Children in 1990, a plan was adopted for the elimination of IDD by the year 2000. Although substantial progress has been made toward this goal, it has not been achieved. According to WHO data, the proportion of the world population at risk for IDD dropped from 28.9% in 1994 to 13.7% in 1997. The proportion of the population in developing countries regularly consuming iodized salt increased from only 5% in 1990 to 60% in 1994. Currently 68% of the 5 billion people residing in countries with iodine deficiency have access to iodized salt. Rates of goiter, cretinism, and mental retardation are decreasing worldwide. However, programs must be continually monitored, and must be sustainable.

IRON

Contents

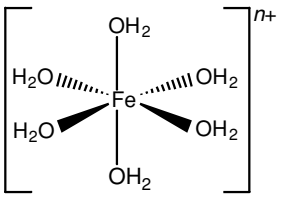
Properties and Determination

J R Chipperfield, University of Hull, Hull, UK

Physical and Chemical Properties

The element iron (Latin *ferrum*), atomic number 26, relative atomic mass 55.85, has an electronic configuration [Ar] $3d^6\,4s^2$. Iron normally occurs in one of three oxidation states iron(0) (metallic iron), iron(II) and iron(III). Iron(II) and iron(III) compounds were formerly called 'ferrous' and 'ferric' respectively. Iron oxides are high-melting-point solids. Iron(II) oxide (FeO), is black, whereas iron(III) oxide (Fe_2O_3) is orange-red. Both iron(II) and iron(III) form many ionic salts, such as halides ($FeCl_2$ and $FeCl_3$), sulfates ($FeSO_4$ and $Fe_2(SO_4)_3$), and nitrates ($Fe(NO_3)_2$ and $Fe(NO_3)_3$). Iron(II) sulfate, iron(II) gluconate, and iron(II) fumarate are used medicinally for oral iron supplementation. In acidic solution these salts dissolve to give the aquated cations $[Fe(H_2O)_6]^{2+}$, and $[Fe(H_2O)_6]^{3+}$ (Figure 1). These octahedral aquated ions are also found in solid hydrated salts such as hydrated iron(II) sulfate ($FeSO_4.7H_2O$), and hydrated iron(III) sulfate, $(Fe_2(SO_4)_3.9H_2O)$. As pH increases, insoluble hydroxides $Fe(OH)_2$ and $Fe(OH)_3$ precipitate, the latter being so insoluble that, at pH 7, the equilibrium concentration of iron(III) in solution is only 10^{-9} mol dm^{-3}. Solutions of iron(III) salts are strongly acidic due to hydrolysis of the $[Fe(H_2O)_6]^{3+}$ cation (eqn 1).

$$[Fe(H_2O)_6]^{3+} + H_2O \rightleftharpoons [Fe(H_2O)_5(OH)]^{2+} + H_3O^+ \qquad (1)$$

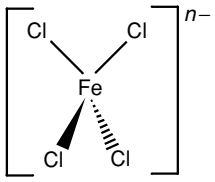


n = 2[iron(II)] or 3[iron(III)]

Figure 1

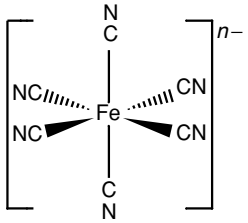
The pK_a of $[Fe(H_2O)_6]^{3+}$ is around 2, similar to that of phosphoric acid, and therefore solutions of iron(III) salts are as acidic as a solution of phosphoric acid of the same molarity.

Both iron(II) and iron(III) form complexes with many ligands. Simple monodentate ligands such as Cl^- and CN^- give complex ions such as tetrahedral $[FeCl_4]^{2-}$ and $[FeCl_4]^-$ (Figure 2) and octahedral $[Fe(CN)_6]^{4-}$ and $[Fe(CN)_6]^{3-}$ (Figure 3). Chelating ligands such as phen (1,10-phenanthroline), (Figure 4), and dipy (2,2′-dipyridyl), (Figure 5), give the chelated complex ions $[Fe(phen)_3]^{2+}$, $[Fe(phen)_3]^{3+}$, $[Fe(dipy)_3]^{2+}$, and $[Fe(dipy)_3]^{3+}$ (Figure 6).



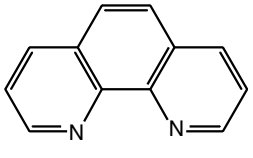
n = 2[iron(II)] or 1[iron(III)]

Figure 2



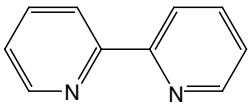
n = 4 [iron(II)] or 3[(iron(III)]

Figure 3



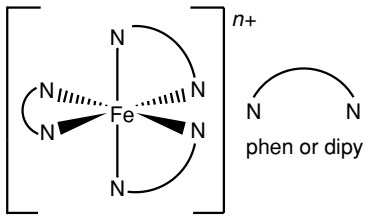
1,10-phenanthroline (phen)

Figure 4



2,2'-dipyridyl (dipy)

Figure 5



n = 2[iron(II) or 3[iron(III)]

Figure 6

In the absence of ligands, aerial oxygen will readily oxidize solutions of iron(II) compounds to iron(III). When ligands are present they most commonly (e.g., CN^-, F^-) stabilize iron(III) more than iron(II), or more rarely (e.g., phen) stabilize iron(II) relative to iron(III) such that aerial oxidation of iron(II) to iron(III) is prevented. Iron(II) has the electron configuration [Ar] $3d^6$, and in octahedral complexes the six 3d electrons may be found in two configurations – high-spin, with four unpaired electrons, or low-spin, with no unpaired electrons. The presence of unpaired electrons imparts paramagnetism to high-spin iron(II) compounds. Iron(III) is similarly found in a high-spin (five unpaired electrons) or low-spin (one unpaired electron) configuration. The nature of the ligands determines whether complexes are high- or low-spin.

In Pearson's terminology of 'hard' and 'soft' acids and bases, iron(III) is a 'hard' acid and forms its most stable complexes and compounds with 'hard' ligands (i.e., those containing oxygen or nitrogen donor atoms). Iron(II) is 'softer' than iron(III) and, as well as bonding to both oxygen and nitrogen donor atoms, is also found bonded to 'soft' ligands such as sulfur donor ligands.

In life processes, iron(II) complexes are needed which are not irreversibly oxidized to iron(III) by aerial oxidation.

Occurrence and Speciation in Foods and in the Environment

Foods

Iron is found in foods derived from both animals and plants. Table 1 shows typical concentrations of iron found in a variety of common foods. The iron may be present either as heme-based compounds or as non-heme compounds.

Heme compounds In mammals the two main iron-containing compounds are the heme proteins hemoglobin and myoglobin, which are used to transport oxygen. Heme proteins consist of an iron–porphyrin unit (Figure 7) and a protein unit. The porphyrin unit coordinates to the iron in a plane. In myoglobin and hemoglobin the fifth coordination position of the iron is occupied by a nitrogen atom (from a histidine residue) which is linked to the protein chain, and the sixth position is occupied by a water or oxygen molecule. This is shown diagrammatically in Figure 8. Other heme proteins are the cytochromes in which, as part of redox reactions, the iron atoms shuttle between iron(II) and iron(III). They have a similar porphyrin–iron core to that shown above, but both the fifth and sixth coordination positions of the iron are linked to the protein chain (Figure 9).

Although most familiar in animals, photosynthesis in plants involves similar heme proteins.

Nonheme proteins Nonheme proteins in animals and plants are used to store and transport iron. The most abundant in mammals is ferritin. This consists of an iron-containing core surrounded by a protein sheath (Figure 10). The core may contain up to 4500 iron atoms (as iron(III)), and has a structure somewhat similar to the hydrated iron(III) oxide ferrihydrite $5Fe_2O_3.9H_2O$. The surrounding protein sheath consists of 24 similar subunits. Another iron transport protein, transferrin, is a glycoprotein containing a single polypeptide chain folded into two lobes. Each protein can strongly bond two iron(III) ions and each iron(III) ion has a carbonate or bicarbonate anion associated with it. The iron(III) atoms are octahedrally coordinated.

A variety of microorganisms produce and release siderophores. These are powerful chelating agents which bond to iron atoms through oxygen atoms, and yield neutral molecules which can pass through cell walls. One particular example is ferrichrome (Figure 11) which is a cyclic hexapeptide containing three hydroxamate groups.

Iron–sulfur proteins These are widely distributed and encompass rubredoxins, ferredoxins, and high-potential iron proteins (HIPIPs). Rubredoxins (Figure 12) contain a single iron atom bonded through four tetrahedrally arranged sulfur atoms to the rest of the protein. Ferredoxins can have two iron atoms (Figure 13), or four iron atoms (Figure 14). In each case there are sulfur atoms bridging between the

iron atoms, while the iron atoms are linked to the rest of the protein via the sulfur atoms of cysteines. In each of these three types of iron–sulfur protein each iron atom is tetrahedrally surrounded by four sulfur atoms. Compounds containing more than one iron atom show complex redox behavior as each iron atom can be either iron(II) or iron(III).

Environment

Terrestrial The earth's core is composed of metallic iron, and iron compounds form 1.5% of the lithosphere, making iron the eighth most abundant element. The most common iron mineral is hematite (Fe_2O_3), with magnetite (Fe_3O_4), siderite ($FeCO_3$), limonite (FeO(OH)) and iron pyrites (Fool's gold, FeS_2) also widely distributed. At neutral pH, aerial oxygen readily oxidizes iron(II) in solution to iron(III). To be stable, iron(II) compounds must, like iron pyrites, be insoluble.

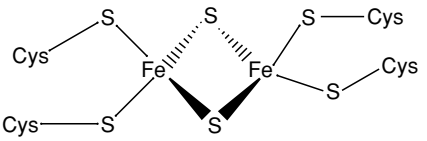

Figure 13

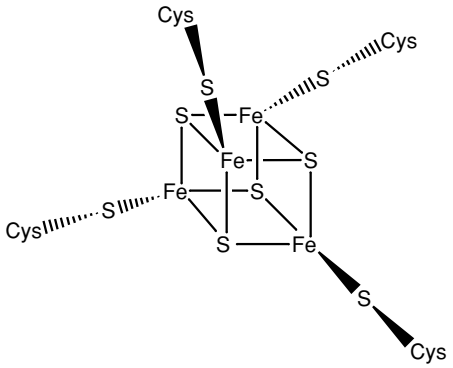

Figure 14

Aquatic Sea water contains low concentrations of iron (0.002–0.02 ppm) complexed by chloride ions. Fresh water, with pH around 7, can contain suspensions of hydrated iron(III) oxide, or iron complexed to organic material.

Losses/Gains during Food Processing (Including Changes in Speciation)

Iron compounds in foods are not appreciably volatile so iron cannot be lost by vaporization during normal processing. As iron compounds occur naturally associated with proteins, the iron compounds found in foods are generally changed on heating, so that the tertiary structure of the protein is destroyed. This will cause the iron compound to lose its functionality. Thus, after heating, myoglobin will no longer reversibly bind oxygen – the iron(II) is irreversibly oxidized to iron(III). Normal cooking will not break the peptide links in the protein, or free iron from its coordination shell.

In principle, foods cooked or processed in iron or steel vessels could potentially pick up significant amounts of iron. However, as commercial processing is now largely carried out in equipment constructed of stainless steel, this is not a major problem. The most likely situation where significant iron pick-up may occur is with acidic foods or those containing high levels of chloride ions. In domestic situations where cast iron pots are used, iron uptake may be appreciable, in relation to the amounts naturally present.

The levels of iron resulting from contamination are unlikely to be significant from a toxicological (or even nutritional) point of view. However, they may lead to metallic taints in some foods and they may accelerate formation of rancidity by acting as a catalyst of lipid oxidation.

Iron Fortification of Foods

Iron compounds used for fortification of foods are varied. These additives are still widely referred to by their older (ferrous/ferric) names. Iron(II) (ferrous) sulfate is the cheapest iron source, and iron introduced this way is well absorbed. Iron absorption depends on the nature of the food. Sources of ascorbic acid enhance iron absorption from additives, while tea inhibits absorption. Choice of fortificant is a balance between using iron in a form which is well absorbed, while not causing unacceptable color or taste changes in the food. Many countries add iron compounds to flour and cereals to counteract iron-deficiency anemia. Flour is fortified to iron levels of between 16.5 ppm (UK) and 44 ppm (US).

Dependent on the liquidity of the product, one can use soluble compounds with good iron bioavailability (iron(II) (ferrous) sulfate, iron(II) (ferrous) gluconate, iron(II) (ferrous) lactate, iron(III) (ferric) saccharate, iron(III) (ferric) ammonium citrate, soluble iron(III) (ferric) pyrophosphate). Care has to be taken to avoid unpleasant taste, undesirable coloring and catalysis of fat oxidation. Less soluble iron sources (iron(II) (ferrous) fumarate, iron(II) (ferrous) succinate, iron(III) (ferric) pyrophosphate, elemental iron, sodium iron(III) pyrophosphate, iron(III) (ferric) orthophosphate) may be better with more solid foods.

Analysis: Isolation and Extraction

It is relatively easy to analyze food samples for their iron content. The method of analysis depends on the nature both of the samples, and of the detection technique selected. It is usual to remove the organic part of foods from the inorganic constituents before analysis. This can be done by wet digestion or dry ashing methods.

Wet digestion

Many wet analytical techniques require the iron to be present as uncomplexed iron(II) or iron(III) ions in the analyte with absence of organic residues. A universal method to achieve this is to heat the sample with a digestion mixture containing concentrated nitric, perchloric and sulfuric acids in a Kjeldahl flask for some hours. All organic matter is oxidized

to water and carbon dioxide, while metal ions are left behind as uncomplexed ions (the anions from these acids are poor ligands). While not necessary for oxidation, the presence of sulfuric acid insures that samples do not dry out to an explosive perchlorate. After digestion, the sample is diluted appropriately.

Dry Ashing

The simplest way to remove organic matter from a sample prior to analysis is by aerial oxidation at red heat in a silica, porcelain, or platinum crucible. Samples (1–10 g) are normally dried carefully at 100–110 °C before heating in a muffle furnace. All iron is oxidized to Fe_2O_3, and organic matter present is oxidized to carbon dioxide and water vapor. At high temperatures, iron porphyrin compounds and others may volatilize before oxidation and iron may be lost, so ashing temperatures must be kept as low as possible – temperatures of 500–550 °C are generally used. Dry ashing methods must be tested for iron recovery before routine use. After ashing, the cooled ash is dissolved in dilute hydrochloric acid.

Analysis: Spectroscopic and Electrochemical Methods

The simplest way to assay the iron content of the solutions resulting from ashing is to reduce all iron to iron(II) using metallic zinc, and then to titrate the iron(II) with potassium permanganate.

Spectroscopic Methods

Instrumental methods, mainly spectroscopic, are now widely used.

UV/Visible Absorbance Both iron(II) and iron(III) form colored complexes, which can be used to assay iron. Samples from ashing normally contain iron as iron(III). Addition of thiocyanate produces a blood-red color of $[Fe(H_2O)_5SCN]^{2+}$, which can be spectrophotometrically measured at 480 nm. Normally samples are reduced to iron(II) with a reductant such as ascorbic acid, or hydroxylamine hydrochloride, the complexing ligands 1,10-phenanthroline (phen) or 2,2′-dipyridyl (dipy) added, and absorbances of the colored complex ions $[Fe(phen)_3]^{2+}$ or $[Fe(dipy)_3]^{2+}$ measured at 505–510 nm.

Atomic Absorbance Spectrophotometry Atomic absorption spectrophotometry (AAS) has been widely used to assay for iron. Solutions containing iron(II) or iron(III) are introduced as an aerosol into the flame where atomization takes place. The method has a detection limit of 0.003 ppm, and is easily automated for the analysis of many samples. Interference from other metals in the sample is minimal. Normally only a single element, e.g. iron, can be analyzed for at a time on each sample.

Inductively Coupled Plasma Optical Emission Spectrophotometry (ICPOES) Solutions containing iron(II) or iron(III) are introduced into a plasma as an aerosol, and the emissions from atomic transitions specific to iron are measured in a suitable spectrophotometer. This technique has a similar sensitivity to AAS, but is more convenient for multielement assays. As atomic transitions are detected, the technique is sometimes referred to as Inductively Coupled Plasma Atomic Emission Spectrophotometry (ICPAES).

Spark Emission Spectroscopy This works in a similar way to ICPOES. The liquid sample is placed so that sparks are formed between the solution and an inert electrode. In the sparks, iron atoms are excited to high energy levels, and emissions at wavelengths specific to iron are measured.

Electrochemical Methods

Spectroscopic methods are now widely used for iron analysis. Electrochemical methods, though effective, are of secondary importance. Iron-containing solutions may be reduced to convert all iron to iron(II) which can be titrated with ceric sulfate, and the endpoint detected potentiometrically. Low concentrations of iron may be determined by polarography, but advanced polarographic techniques such as differential pulse polarography generally give better results.

Physiology

S R Lynch, Eastern Virginia Medical School, Norfolk, Virginia, VA, USA

Introduction

Iron plays a central role in metabolic processes involving oxygen transport and storage as well as oxidative metabolism and cellular growth. The fact that it readily serves as an electron donor or acceptor accounts both for its critical metabolic role and its potential toxicity. Iron-containing compounds function as carriers for oxygen and electrons and as catalysts for oxidation and hydroxylation reactions. Ionic iron can also participate in reactions that produce toxic free radicals. Free radicals may in turn damage cellular constituents. It is therefore not surprising that body iron content is controlled within narrow limits, and that the metal itself is transported and stored as a component of specific iron-binding proteins rather than as the free cation.

This article reviews the functional role of iron in the body, the physiological processes responsible for the control of internal exchange and balance, and the consequences of iron deficiency and excess. Some aspects of the physiology of iron that are specifically related to iron-deficiency anemia are discussed later. (*See* **Anemia (Anaemia)**: Iron deficiency Anemia.)

Body Iron Distribution

The normal human body contains 3–4 g of iron (40–50 mg per kg of body weight; **Table 1**), 75% (approximately 36 mg kg^{-1}) of which is present in metabolically active compounds. The remainder is contained in a storage pool (approximately 10 mg kg^{-1} in men and 5 mg kg^{-1} in menstruating women) which is readily available if metabolically active iron is depleted for any reason.

Table 1 Distribution of iron in adult human beings

	Men: total body content		Women[a]: total body content	
	mg	mg kg^{-1}	mg	mg kg^{-1}
Functional				
Hemoglobin	2300	31	1700	28

Nonheme enzymes	100	1	76	1
Storage				
Ferritin	540	7	200	3
Hemosiderin	235	3	100	2

[a]Age range 18–44 years.

Functional Iron Compartment

Heme Proteins

Most of the functional iron in the body is present in the form of heme proteins, i.e., proteins with an iron protoporphyrin IX prosthetic group.

Hemoglobin, which is made up of four globin chains, each with an attached heme group, transports oxygen to the tissues. It is quantitatively the most important heme protein and contains 80% of all functional iron.

Myoglobin is found in the sarcoplasm of muscles. It has a structure similar to hemoglobin but contains only one globin chain attached to a single heme group and accounts for a further 10% of functional iron. Myoglobin acts as an oxygen store, insuring an adequate oxygen supply during muscle contraction. (*See* **Exercise**: Muscle.)

Despite its vital metabolic role, all other tissue iron represents only a small fraction of total body iron. The cytochromes are a group of heme-containing electron transport enzymes that are essential for the oxidative metabolism necessary to generate adenosine triphosphate (ATP) as well as for the oxidative degradation of drugs and endogenous substrates. Catalase and peroxidase are involved in the reduction of endogenously generated hydrogen peroxide.

Nonheme Tissue Iron

In mitochondria, nonheme compounds account for more iron than do those containing heme. This group of enzymes includes the metalloflavoproteins, the iron sulfur proteins, and ribonucleotide reductase. In addition, iron is necessary in a loosely bound form for the activity of other enzymes, such as those responsible for the hydroxylation of proline and lysine in protocollagen, during the synthesis of collagen. (*See* **Coenzymes**.)

All functional iron compounds are constantly being degraded and replaced by newly synthesized material.

Internal iron exchange therefore plays a crucial role in preserving normal iron-dependent metabolic processes.

Iron Transport and Storage

Iron entering the plasma is rapidly bound to the specific iron transport protein, transferrin. The iron-free protein apotransferrin is a single-chain glycoprotein (mol wt 79 570) with two nonidentical iron-binding sites that have a high affinity for ferric iron under physiological conditions (effective stability constant, $10^{24}\,\mathrm{mol\,l^{-1}}$). Plasma apotransferrin is synthesized predominantly in the liver. It exists in the plasma in the iron-free form or as monoferric or diferric transferrin since iron loading at each binding site is a random process.

Iron delivery from plasma transferrin to the tissues is mediated by a specific transferrin receptor which is a transmembrane glycoprotein dimer composed of two identical subunits (each with mol wt 94 000) linked by a disulfide bond. Transferrin receptors are expressed on the surfaces of all cells in proportion to their iron requirements. Large numbers are present in tissues with high requirements, e.g., developing red blood cells and placenta.

At the pH of plasma and extravascular fluid bathing cell surfaces, receptors have very little affinity for apotransferrin and the highest affinity for diferric transferrin ($2–7\times10^{-9}\,\mathrm{mol\,l^{-1}}$). Once bound, the transferrin–transferrin receptor complex, together with its attached iron, is internalized by the cell in a clathrin-coated pit that closes to form an endosome. The endosome then fuses with an acidic vesicle ($\mathrm{pH} < 5.5$). The fall in pH results in release of iron from the transferrin. The iron is transferred across the endosomal membrane into the cell. Natural resistance-associated macrophage protein 2 (Nramp 2, now also called divalent metal transporter 1, DMT-1) has recently been identified as the putative transmembrane iron transport protein that transfers iron out of the endosome. The rat isoform of Nramp 2 is a divalent cation transporter (DCT-1) with a broad substrate range that includes ferrous iron. The transferrin receptor remains intact. Its affinity for apotransferrin increases, becoming equal to that for diferric transferrin, because of the lower pH. The complex is transported back to the cell surface, where the apotransferrin is released back into the circulating plasma.

Any iron entering a cell that is not immediately used for the synthesis of metabolically active compounds is stored in the form of ferritin. Apoferritin is a hollow, spherical protein shell composed of 24 subunits that may be of two types, differing slightly in molecular weight – L (mol wt 19 700) and H (mol wt 21 100). Each complete apoferritin molecule can store as many as 4500 iron atoms within its central core as ferric hydroxyphosphate. Iron enters and leaves the intact protein through channels in the shell.

Catabolism of cellular ferritin may result in the formation of a second type of iron storage protein, hemosiderin, which is water-insoluble. It has both a higher iron content and a slower turnover than ferritin.

The acquisition and storage of iron by cells is regulated by the translational control of the synthesis of transferrin receptors and of apoferritin. Two iron-regulatory proteins (IRP-1 and IRP-2) that both sense and adjust cellular iron supply have been identified. They are cytoplasmic RNA-binding proteins that modulate the expression of messenger RNA (mRNA) for transferrin receptor and apoferritin by binding to iron-responsive elements (IREs) on the 3′ and 5′ untranslated regions of the mRNAs for transferrin receptors and the H- and L-chains of ferritin respectively. Low cellular iron levels favor increased binding of the IRPs to the IREs, repressing the synthesis of ferritin, but stabilizing transferrin receptor mRNA against cellular ribonucleases, thereby increasing transferrin receptor expression and cellular iron uptake. High cellular iron leads to decreased IRP binding with a decrease in iron uptake and increased ferritin synthesis and iron storage.

The two IRPs are functionally similar, but are regulated in different ways. In iron-replete cells IRP-1 has been identified as cytosolic aconitase, an iron-sulfur protein that mediates the enzymatic interconversion of citrate to isocitrate in the tricarbocylic acid cycle. Low cellular iron results in reversible conversion of enzymatically active aconitase to a form with high RNA-binding affinity and no enzymatic activity. Transferrin receptor synthesis is enhanced, apoferritin formation is suppressed, and functional iron homeostasis is restored. IRP-2 is functionally similar to IRP-1, but lacks aconitase activity. Unlike IRP-1, the binding of IRP-2 to the IREs is regulated by degradation of the protein when cells are iron-replete.

The above description characterizes iron transport and storage in most cells of the human body. However, erythroid cells have very high iron requirements and appear to possess mechanisms for regulating iron uptake at a transcriptional level that can override posttranscriptional control. Iron transport and storage by the macrophages of the spleen, bone marrow, and liver are also different. These are cells primarily involved in processing hemoglobin derived from senescent red blood cells. At the end of their life span, erythrocytes are phagocytosed by macrophages,

predominantly in the spleen. The heme is separated from the globin and rapidly catabolized by the enzyme, heme oxygenase. Iron is released and either returned to the plasma within a few hours or incorporated into the storage compartment of the cell with a more gradual return to the plasma (half-life about 7 days). Normally, two-thirds of the iron is released immediately, but this fraction may be either increased when demands are high or reduced when less iron is required.

Internal Iron Exchange

The development of radioiron tracers made it possible to quantify the processes involved in the internal iron exchange described above. Since 80% of the body's functional iron is in the hemoglobin of the circulating red blood cells, measurements of internal iron exchange are dominated by the requirements of this compartment (Figure 1). Complete exchange of the iron in the circulating red blood cell compartment occurs every 4 months. This involves rapid transfer of iron by plasma transferrin. Only 3–4 mg iron is found in the plasma at any one time, but 35 mg is transported through this compartment each day. Most of it comes from hemoglobin catabolism in macrophages. Two-thirds (24 mg day^{-1}) is delivered to erythroid precursors in the bone marrow for the synthesis of new hemoglobin. While there is some iron loss owing to ineffective red cell production or the removal of iron not used for hemoglobin synthesis from red cell precursors, most of the iron (70%) is returned to the circulation as hemoglobin in erythrocytes. Erythrocytes have a life span of about 120 days. The senescent cells are catabolized in the macrophages of the liver, spleen, and bone marrow, completing the cycle.

Most of the iron lost during red cell production and the iron derived from senescent red cells is processed by macrophages. Thus a quantity of iron equivalent to about 1% of the functional hemoglobin iron in the circulating red cell compartment (22 mg iron) enters the macrophages each day with a corresponding quantity being released to the plasma.

A smaller but quantitatively significant daily exchange occurs between the plasma iron and storage iron in hepatocytes. The rate of exchange and direction of net flow is dependent on serum iron concentration and transferrin saturation. A high serum iron concentration favors the accumulation of iron in the liver.

Finally, a minor fraction of the daily iron turnover (about 3 mg day^{-1}) is transferred between the plasma and the extravascular transferrin compartment and approximately two-thirds of this (2 mg day^{-1}) exchanges with the tissues, supplying iron to heme and nonheme iron-dependent enzymes.

Iron Absorption and Excretion

The total body iron content of healthy human beings is held within narrow limits. This is primarily a consequence of the fact that most of the iron is located in tightly regulated functional compartments. Iron stores usually account for only 15–30% of total body iron. The size of the storage compartment may vary 25-fold without any apparent physiological impairment.

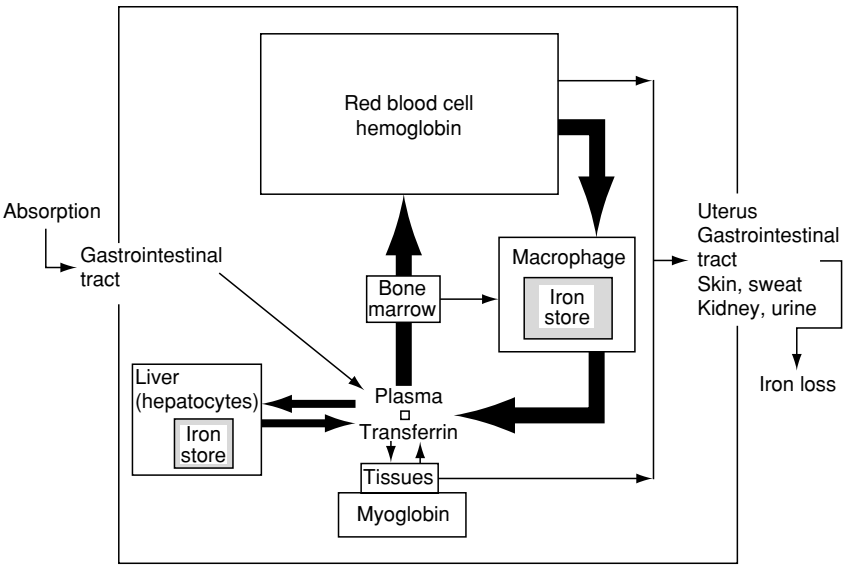

Figure 1 Body iron exchange.

Iron Loss

In contrast to the dynamic transfer of iron between body compartments, exchange with the external environment is minimal. No adjustable excretory mechanism exists, but a small obligatory loss occurs with the physiological turnover of skin epithelium and the cells of the gastrointestinal and urinary tracts (Figure 1). Low concentrations of iron are also present in sweat, bile, and urine. In addition, the feces contain small quantities of blood. Finally, menstruation accounts for a significant proportion of the iron lost by women of child-bearing age.

In normal men the loss of iron from the body is about 1 mg day^{-1}. This is balanced by an equivalent absorption. Complete iron exchange with the environment in a normal man would therefore be expected to take about 10 years. In women menstrual losses account for an extra 0.5 mg day^{-1}. The higher iron loss is matched by a higher rate of absorption.

Iron Absorption

Typical western diets contain approximately 1.5 mg iron MJ^{-1}. From the point of view of absorption, food iron may be considered to exist in one of three forms. Ten percent or less is present as heme derived chiefly from hemoglobin and myoglobin in meat. Heme iron is readily absorbed and little affected by dietary factors. This small fraction may supply a third of the iron requirements of individuals eating a mixed meat-containing diet. The remainder of the iron (90% or more in western diets and often virtually 100% in the diets of developing countries) must be solubilized for absorption. If solubilized, nonheme iron derived from all dietary sources enters a common pool in the lumen of the upper small intestine before absorption. A variable proportion of nonheme iron is insoluble and unavailable for absorption. This iron is generally regarded as contaminant iron. Much of it enters food products during storage or processing, particularly in developing countries. (*See* **Meat: Nutritional Value.**)

Absorption of soluble nonheme iron from the common pool is quite variable. It is governed both by the body's requirement and the balance between enhancing and inhibiting ligands in the diet that either promote uptake by mucosal cells (increase bioavailability) or render the iron in the pool unavailable for absorption. Enhancing factors include ascorbic acid, other organic acids, and meat and fish tissue. Low gastric luminal pH resulting from hydrochloric acid secretion by the stomach or from the ingestion of acidic foods also promotes nonheme iron absorption. The most powerful inhibitors are found in vegetable foods and include phytates, polyphenols, and vegetable proteins. (*See* **Bioavailability of Nutrients.**)

Absorption of both heme and nonheme iron is maximal in the duodenum, partly because the luminal conditions (particularly lower pH) favor solubilization and absorption of nonheme iron, but also because cells in his region show the greatest ability to respond to changes in body iron needs.

Absorption may be considered to occur in three phases: first, uptake across the mucosal cell brush border; second, a phase that involves either rapid transfer of iron through the mucosal cells or its retention in the cellular ferritin store; and third, transfer from the mucosal cell to plasma transferrin. Most of the iron retained in the cell is lost when the cell exfoliates. The absorption of both heme and nonheme iron is regulated by the size of the body iron stores.

Heme iron enters the mucosal cell through a pathway different from that for nonheme iron. It is taken up as the intact heme moiety. Once within the cell, iron is released from heme by the enzyme, heme oxygenase. It joins an absorption pathway common to both heme and nonheme iron.

Percentage absorption from the small heme pool varies about twofold. The primary adaptation to changes in iron requirements occurs in the adjustment of absorption from the larger nonheme pool. Percentage absorption is inversely correlated with the size of the body iron stores and may vary as much as 20-fold. Regulation occurs both during mucosal iron uptake by the enterocyte and during release of iron from the cell to circulating transferrin. Mucosal uptake is the rate-limiting step.

Despite years of research, the precise molecular mechanisms involved in the uptake of elemental iron into mucosal cells and its transfer to the plasma remain a subject of controversy. However, it was recently discovered that two isoforms of Nramp 2 (DMT-1) are expressed at the brush borders of the apical poles of enterocytes in the duodenum, the site of maximal iron absorption. Dietary iron starvation leads to a marked upregulation of Nramp 2 isoform 1 in proximal duodenal enterocytes. Cells in the rest of the small intestine are not affected. Nramp 2 mRNA has an IRE in its 3′ untranslated region.

It has been postulated that the iron status of duodenal enterocytes is determined by their iron uptake from the circulation during development in the duodenal crypts. They only become functional iron-absorbing cells 48 h later when they reach the duodenal villous tips. According to the theory the cells are programmed to regulate iron absorption during this period of time by an IRP–IRE mechanism. In the face of iron deficiency, enterocytes acquire less iron from the plasma during their early development.

DMT-1 is upregulated and apoferritin synthesis limited. The cells absorb and transfer dietary iron through the basolateral membrane to circulating plasma transferrin efficiently. If the individual is iron-sufficient, the enterocytes acquire more iron during early development. They will express less DMT-1, take up less iron from the duodenal lumen, and store some of the absorbed iron intracellularly as ferritin. Very little of the iron stored as ferritin reenters the absorptive pathway at a later stage. Most of it is lost when the cell exfoliates.

Iron Deficiency

In western countries iron deficiency occurs most often when there is a relatively sudden increase in iron requirements or iron losses, e.g., during pregnancy or in association with pathological blood loss.

The physiological importance of both the storage iron compartment and the capacity for the rapid transfer of iron through the plasma in preventing overt functional iron deficiency is illustrated by the effect of blood loss. In response to significant anemia caused by bleeding, individuals with an iron store of 1000 mg can mobilize 40 mg day^{-1}, allowing rapid restoration of the functional deficit. On the other hand, an individual who lacks storage iron and depends on absorption from an average diet for the additional iron will increase delivery to the bone marrow by only 2–4 mg day^{-1}. Red cell production increases by a small margin. Thus, loss of iron from the major functional compartments is rapidly corrected when stores are adequate, but very slowly replaced by absorption, even when dietary iron bioavailability is relatively high. If meal iron bioavailability is low, positive balance may not be achieved, leading to chronic iron-deficiency anemia. Low bioavailability diets also lead to iron deficiency when requirements are increased by rapid growth or menstruation.

Negative iron balance leads to a reduction in the iron content of all functional compartments. Anemia caused by reduced hemoglobin synthesis is the most easily documented. Nevertheless, the availability of iron to support metabolic systems in the tissues is reduced concurrently. The physiological consequences of iron deficiency therefore result both from impaired oxygen delivery and functional abnormalities in the tissues. However it is noteworthy that clinically significant tissue iron deficiency does not appear to occur in the absence of anemia.

Effects of Iron Deficiency

The clinical manifestations of moderate to severe anemia are well known and include pallor, fatigue, weakness, dizziness, and reduced maximal work capacity. The consequences of anemia *per se* and the adverse effects of iron-deficiency anemia on the outcome of pregnancy are dealt with in the section on iron-deficiency anemia. (*See* **Anemia (Anaemia)**: Iron-deficiency Anemia.)

Several additional consequences are thought to result primarily from the associated tissue iron deficiency. From the epidemiological point of view, the most important are developmental delay and cognitive impairment in childhood and impaired work performance at all ages.

Mental and Motor Development

Iron-deficiency anemia is associated with impaired mental development and physical coordination in children under the age of 2 years, difficulty with visual discrimination tests, and the ability to maintain selective attention in preschool children and poor school achievement in later childhood. Short-term memory and emotional health may also be affected. These functional abnormalities are thought to be the result of the effects of iron deficiency on brain neurotransmitters, but their biochemical basis is poorly understood. In older children they appear to be reversible by successful iron supplementation.

Skeletal Muscle Dysfunction

Significant limitation of the ability to perform endurance physical activity has emerged as an important consequence of chronic iron deficiency. Animal studies conducted by Finch and coworkers demonstrated that iron-deficient rats show marked impairment of running ability which is unrelated to hemoglobin level. It results from impaired oxidative metabolism in iron-depleted muscles. Field studies from many developing countries suggest that a similar disability reduces an iron-deficient individual's ability to carry out prolonged physical work.

Immunity and Infection

Several laboratory tests of immune function are abnormal in patients with iron-deficiency anemia. Lymphocyte proliferation in response to the mitogens, phytohemagglutinin, and concanavalin A is reduced, demonstrating defective T-cell immunity. Intracellular bacterial killing by polymorphonuclear leukocytes is impaired. The clinical importance of these laboratory observations is uncertain, although some studies have suggested that the administration of iron to iron-deficient children may reduce the prevalence of enteritis and influenza-like illnesses. Iron deficiency also appears to be a predisposing factor in chronic mucocutaneous candidiasis.

Miscellaneous Liabilities

Angular stomatitis, glossitis, postcricoid webbing of the esophagus associated with painful dysphagia (Patterson–Kelly or Plummer–Vinson syndrome), atrophic gastritis, and koilonychia (spoon-shaped finger nails) have all been attributed to tissue iron deficiency. These clinical findings appear to be less common in recent years and a marked geographic variation in prevalence has frequently been noted, suggesting that factors other than iron deficiency may play an important role.

An intriguing sensory disturbance encountered in both children and adults who are iron-deficient is the perversion of taste leading to the consumption of nonfood items (pica) or compulsive ice eating (pagophagia). The specificity of pagophagia as a symptom of iron deficiency has been confirmed by the study of patients in whom iron deficiency was induced by phlebotomy alone, making the contribution of confounding nutritional and social factors unlikely. It is corrected by iron repletion.

Iron deficiency may also lead to impaired thermogenesis as well as abnormalities in thyroid metabolism and catecholamine turnover. Finally, lead absorption may be enhanced, increasing the risk of lead toxicity, particularly in children.

Iron Toxicity

Acute Iron Toxicity

The ingestion of large quantities of elemental iron can cause acute iron poisoning. This occurs most often in young children who may eat iron tablets as 'candy.' The pathological consequences include a severe necrotizing gastroenteritis as well as disseminated intravascular coagulation, liver and cardiac injury. Death may ensue if the dose is large or treatment is not instituted immediately.

Chronic Iron Toxicity

More important from the nutritional point of view is the gradual accumulation that occurs when the quantity of iron entering the body exceeds requirements by even a small margin. The body has no means of increasing iron excretion significantly, making a positive iron balance inevitable if regulation of absorption is impaired, or if the diet contains a quantity of available iron that overwhelms the absorptive control mechanisms. Excess iron can also be introduced through the parenteral route (blood transfusion, parenteral iron administration).

Impaired regulation of absorption Hereditary hemochromatosis is the commonest cause of iron overload resulting from the impaired regulation of iron absorption, and the commonest form of iron overload in the USA, western Europe, and Australia. It is an autosomal recessive disorder with a gene frequency reported to be as high as 1 in 10 in people of northern European descent. One in 300 are homozygous and at risk for developing severe iron overload with its associated pathological consequences. A single G-to-A mutation resulting in a cysteine-to-tyrosine substitution (C282Y) in the HFE gene has recently been shown to be responsible for the majority of cases of human leukocyte antigen (HLA)-linked hereditary hemochromatosis. The HFE gene is located on the short arm of chromosome 6 and is tightly linked to the HLA locus. It has been identified in between 60% and 100% of patients depending on whether their ethnic origin was southern or northern Europe. A second mutation, H63D, has been linked to an additional 1–10% of cases, especially when present with C282Y in the compound heterozygous form. The mechanisms by which mutations in the HFE gene lead to tissue iron overload have not yet been established.

HFE-associated hemochromatosis is characterized by a rate of iron absorption that is inappropriately high for the size of body iron stores. Downregulation of nonheme iron absorption in the face of rising storage iron is impaired and heme iron absorption virtually unregulated. Equally important to the pathogenesis of the condition is the presence of an abnormally high serum iron and transferrin saturation associated with disordered iron distribution within the body, favoring iron accumulation in the parenchymal cells of organs such as the liver, heart, and pancreas. Comparatively less iron is located in the normal macrophage iron store.

Although the defective control of absorption is an inborn error of metabolism manifest from birth, the prevalence of the clinical syndrome is highest in men over the age of 40 years. Excess iron is accumulated slowly because maximal absorption from the average western diet is only 3–5 mg day^{-1}. Once the total body iron load has increased to 15 g or more (a process which takes 15–20 years), organ damage becomes evident.

The exact mechanism by which the iron injures tissues has not been established, but lipid peroxidation in membranes and subcellular organelles, as well as iron-induced lysosomal disruption, are probably involved. The clinical consequences include increased skin pigmentation, cirrhosis of the liver associated with an increased risk of developing liver cancer, congestive cardiac failure and cardiac arrhythmias, diabetes mellitus, and hypogonadism owing both to end organ and pituitary dysfunction. In addition,

patients with hemochromatosis often suffer from an arthropathy characterized by chondrocalcinosis and a predilection for involvement of the second and third metacarpophalangeal joints of the hand.

If HFE-associated hemochromatosis is identified before significant iron overload has occurred, all of the clinical findings may be averted by iron removal. Therapeutic phlebotomy is usually employed. Unchecked progressive iron overload is associated with severe irreversible morbidity and a significantly shortened life span.

Excessive iron absorption from a normal diet may also occur in association with certain iron-loading anemias, chronic liver disease, and porphyria cutanea tarda.

Dietary iron overload is a form of chronic iron toxicity unique to the indigenous population of several countries in southern Africa (subSaharan iron overload). Traditional acidic fermented beverages brewed in containers made from iron become contaminated with iron at concentrations of 15–40 mg l^{-1}. The beer has a low alcohol content and the large volumes consumed may supply 50–100 mg of available dietary iron per day. Total body iron burdens comparable to those encountered in hereditary hemochromatosis are encountered. Organ damage with progression to cirrhosis and the development of diabetes mellitus occur. However in the earlier stages cellular iron distribution tends to be different from that seen in HFE-associated hereditary hemochromatosis with greater accumulation in the macrophages of the spleen, liver, bone marrow, and muscle. Two other clinical conditions are commonly associated with the presence of excess iron – ascorbic acid deficiency and osteoporosis. Ascorbic acid deficiency results from accelerated catabolism in patients with severe iron overload, often in association with a low dietary intake. The factors responsible for the osteoporosis remain poorly understood.

SubSaharan dietary iron overload was originally believed to be solely a consequence of excessive iron consumption. Recent investigations have challenged this belief. Family studies suggest that iron loading occurs only when iron intake is excessive and a putative non-HLA-linked iron-loading gene is present.

Biosynthesis and Significance of Heme (Haem)

J J Klawe, The Ludwik-Rydygier Medical University, Bydgoszcz, Poland

Iron – Biological Significance

Iron is important for the synthesis of hemoglobin, myoglobin, and as a cofactor of numerous enzymes, including cytochromes, cytochrome oxidase, peroxidase, and catalase.

The total quantity of iron in the human body averages about 4.5 g, 65–70% of which is present in the form of hemoglobin. Several forms of iron 'biological container' are presented in **Table 1**.

The maintenance of iron balance is essential and necessary for health. Iron deficiency causes anemia. Prolonged iron overload causes an accumulation of hemosiderin in the tissues, clinically manifested as hemosiderosis, and its severe form with damage of tissues – hemochromatosis.

Table 1 Forms of iron 'biological containers'

Biological iron storage	*% of total iron quantity*
Hemoglobin	70
Myoglobin	3–4
Various heme enzymes controlling intracellular oxidation	1
Transferrin in the blood plasma	0.1
Ferritin or hemosiderin	15
Other forms	10–15

Iron – Absorption, Transport, and Loss

Iron is readily absorbed in the state Fe^{2+}, but most dietary iron is in the ferric form Fe^{3+}. The gastric secretions dissolve the iron and permit it to form soluble complexes with ascorbic acids and other substances that aid its reduction to the Fe^{2+} form. In humans iron-deficiency anemia is a relatively frequent complication of partial gastrectomy. Heme is also absorbed because of its solubility. Fe^{2+} contained in heme is released into mucosal cells.

Iron is absorbed from the upper part of the small intestine, because duodenum and adjacent jejunum contain most mucosal cells suitable for iron absorption. Various dietary factors influence iron absorption, for example, phytic acid from cereals, which forms iron-insoluble compounds in the intestine, as do phosphates and oxalates.

Nonheme iron binds to mucin. Cell adhesion molecule integrin transfers the iron to mobilferrin. Mobilferrin carries iron into the cell and binds more iron in iron-deficiency states. The mucosal cells contain iron-binding protein, or apoferritin. Some iron is utilized by mitochondria, and the remainder is partitioned between apoferritin in the mucosal cells and transferrin. Transferrin is a protein that carries iron in the blood. Specific cell-surface receptors deliver the transferrin with its bound iron to endosomes. Here the low pH induces the separation of transferrin and the iron. Excess iron in the blood is deposited in all cells of the body, especially in liver cells. Apoferritin is also found in many other tissues, where, together with iron, it forms ferritin. Apoferritin is a globular protein. Iron forms a micelle of ferric hydroxyphosphate. In ferritin 24 subunits of protein surround each micelle. The ferritin micelle can contain 4500 atoms of iron. It is the iron storage form in tissues. Molecules of ferritin may aggregate in lysosomal membranes as deposits, containing up to 50% iron. These deposits are called hemosiderin.

Iron is also transported across the placenta from mother to fetus. Maternal iron plasma concentration is usually lower than fetal concentration. However, the binding capacity of maternal plasma for iron is much higher, even though iron is actively transported into the fetal compartment. A daily transport of about 1.8 μmol is necessary to meet total fetal requirements.

In adult humans, the amount of iron lost from the body is relatively small. It is unregulated, and total body stores of iron are regulated by changes in the rate at which iron is absorbed. Men lose about 0.6 mg day^{-1}, whereas women have a variable, larger loss because of the additional iron lost in blood shed during menstruation.

Biosynthesis and Significance of Heme

Evolution of higher organisms has been accompanied by the development of oxygen transport protein. In humans this protein – hemoglobin – is concentrated in specialized cells – erythrocytes. Each erythrocyte contains about 300 million hemoglobin molecules. The organic structure of a protein is unable to direct binding of oxygen. However, certain metals, in their lower oxidation states (for example, Fe^{2+}) have a strong tendency to bind oxygen. Thus, in the evolution of the hemoglobin–myoglobin family of proteins, Fe^{2+} has been utilized in the O_2-binding site.

There are a number of possibilities in which various iron-containing proteins hold iron in the form Fe^{2+}. Hemoglobin and myoglobin are a family of proteins, in which iron is chelated by the tetrapyrrole ring system – protoporphyrin IX. It is one protein in a large class of porphyrins, which are also encountered in chlorophyl, cytochrome proteins, and other natural pigments. The porphyrins are colored. The iron porphyrin in hemoglobin accounts for the red color of blood. The complex of protoporphyrin IX with Fe^{2+} is called heme. Ferrous iron is octahedrally coordinated, which means it should have six ligands or binding groups attached to it. The nitrogen atoms of the porphyrin ring account for only four ligands. Two remaining available coordination sites lie along an axis perpendicular to the plane of the ring. In myoglobin one of these sites is occupied by nitrogen of histidine (part of the protein helix).

When oxygen is bound, the O_2 molecule occupies the vacant side. Hemoglobin has evolved from myoglobin and forms a tetrameric structure. Each of the four chains in hemoglobin has a folded structure similar to that of myoglobin, and each carries a heme. Hemoglobin contains four subunits: two α-chains and two β-chains. Both chains are very similar but are distinguishable in primary structures and folding. Each subunit has primary, secondary, and tertiary structures. Amino acid side chains in hemoglobin provide hydrophobic, salt bridges, and hydrogen bond interactions. These are necessary to stabilize a particular quaternary structure.

Each hemoglobin molecule can bind four oxygen molecules, in four myoglobin-like sites. To simplify, we can consider hemoglobin as having two states of quaternary structure: one characteristic for the deoxy form and the other for the oxygenated form. The oxy form has a higher affinity for O_2. The transition from the deoxy to the oxy conformation involves changes in the interactions between the subunits. A ligand oxygen, binding to its side, tends to pull the Fe^{2+} a very short distance down into the heme and flattens the heme. Consequently, a molecular rearrangement

occurs, and pulling the Fe into the heme produces a much larger shift in the surrounding structure, particularly at the αβ interfaces. Cooperative binding, oxygen transport, and allosteric transition between structurally different high-affinity and low-affinity states mean that hemoglobin behaves in an allosteric way. Several factors, such as carbon dioxide, protons, and other substances, promote these changes. They are called allosteric effectors.

For each polypeptide chain produced by an organism there exists a corresponding gene. The nucleotide sequence in the gene dictates, via the genetic code, the amino acid sequence of the protein. This process is exemplified by the β-globin gene. In the gene for human β hemoglobin, introns (noncoding regions) alternate with exons (regions that are expressed in the polypeptide sequence). From this gene is produced a primary transcript (pre-mRNA), which is spliced to yield the final mRNA. This mRNA is translated into the β-chain, which then adopts its favored three-dimensional structure. Very primitive animals had only a myoglobinlike, single-chain globin for oxygen storage (transport was not necessary; most of these animals were very small). More than 800 million years ago the primitive globin gene was duplicated. The one copy evolved into the gene for an oxygen transport protein and to hemoglobins. The evolutionary line led to mammals carrying both α- and β-globin genes and capable of forming tetrametric hemoglobins. Gene duplication has also occurred in the hemoglobin line, leading to embryonic and fetal forms, and accounting for the special hemoglobin, which is adapted to promote oxygen transfer through the placenta from the mother to the fetus.

Evolution of hemoglobin genes continues. This fact is seen in the existence of several hundred recognized mutant hemoglobins in the human population. Each of these mutant forms exists in only a small part of the total human population. Many give rise to recognized pathologies, while others are referred to as neutral mutations.

IRRADIATION OF FOODS

Contents

Basic Principles

P B Roberts, Institute of Geological and Nuclear Sciences Ltd, Lower Hutt, New Zealand

Introduction

The absorption of energy during irradiation can provide foods with desirable new benefits. Irradiation is therefore analogous to more common processes such as pasteurization or drying that use heat energy. The energy absorbed during irradiation is high-energy, ionizing radiation. (*See* **Drying**: Theory of Air-drying; **Pasteurization**: Principles.)

Irradiation of food must not be confused with the contamination of food by radioactive materials, which themselves emit radiations that may harm a consumer. Such contamination followed nuclear weapon tests and the Chernobyl accident. Food irradiation cannot make food radioactive since the radiation used, though of high energy, is not powerful enough to induce the necessary changes in atomic nuclei. (*See* **Radioactivity in Food**.)

This article discusses the history and current status of food irradiation. The radiation sources and

potential applications are outlined and the general chemical, microbiological, and nutritional effects summarized.

History

Before 1950

Röntgen discovered X-radiation in 1895 and Becquerel observed natural radioactivity in 1896. The radiations produced were soon found to have many biological effects, including the ability to inactivate bacteria. In 1904 Prescott suggested that spoilage bacteria in food could be destroyed by radiation. Patents were obtained in the US and France in 1921 and 1930. However, no practical source of radiation to treat significant food volumes existed until the 1940s when high-energy electron accelerators and nuclear reactors able to produce large quantities of artificial radioactive nuclides became available.

1950–1983

The US Army Quartermaster Corps sponsored the first cooperative effort to develop food irradiation as part of research into light-weight, shelf-stable army rations. By 1966 safety studies on 21 foods were complete and sterilization of bacon and pork, disinfestation of wheat and its products, and inhibition of potato sprouting were uses of radiation approved by the US Food and Drug Administration (FDA). After this, safety studies in the US stalled for 10 years and commercial interest waned.

European interest increased, however, and in 1970 the International Project in the Field of Food Irradiation (IFIP) was initiated. IFIP compiled safety data on many foods to be considered by expert committees that were sponsored by the United Nations organizations responsible for secure, safe food supplies and for the peaceful uses of atomic energy.

In 1980 a joint expert committee on food irradiation stated that 'the irradiation of food up to an overall average absorbed dose of 10 kGy presents no toxicological hazard' and 'introduced no special nutritional or microbiological problems.' This advice prompted the Codex Alimentarius Commission, the body responsible for world food standards, to adopt a worldwide general standard for irradiated food in 1983. The standard sets general conditions for the irradiation of food. It does not imply that irradiation is appropriate for all foods but that irradiation should be regarded and controlled like other physical processes such as canning, dehydration, etc.

Current Status

The Codex standard was issued at a time of increased awareness of food losses in developing countries and a growing aversion to chemical contamination of food via chemical fumigation and preservation in developed countries. By 1999, 41 countries had cleared one or more foods for irradiation. There are over 50 irradiation plants in nearly 30 countries irradiating food, although the volume treated in most is small.

However, the 1980s saw a rise in public suspicion about any technology associated with radiation. Demand for 'natural,' minimally processed foods has increased and official assurances on the wholesomeness of processed foods and additives are increasingly questioned. There has been sufficient public opposition to food irradiation to insure a very cautious attitude to it within the food industry. The annual volume of food irradiated is probably only 500 000 tonnes worldwide. Foods that are irradiated include dried herbs and spices, potatoes, onions, garlic, dried vegetables, tropical fruits, and chicken. Countries that regularly irradiate foods on a commercial basis include the US, The Netherlands, France, Belgium, Japan, South Africa, and China.

The Radiations Used

The changes in food or its contaminating organisms achieved by irradiation processing are caused by chemical reactions induced between the constituent atoms or molecules. These reactions are initiated by radiations that can strip electrons away from atoms or molecules that are left positively charged (ionized). The charged species rapidly split into fragments called free radicals that have a free or unpaired electron. Free radicals react extremely rapidly with each other and nearby molecules as they seek to become more stable by gaining or losing an electron. It is these free radical reactions that trigger the chemical effects leading to the ultimate changes in the food.

There are two principal forms of ionizing radiation: accelerated subatomic particles and high-energy electromagnetic (EM) radiation.

Accelerated Particles

Particles travelling at speeds approaching the speed of light can cause ionization. The only particle used for food irradiation is the electron. An electron accelerator works on similar principles to a television tube (Figure 1). Electrons produced by heating a filament are injected into a vacuum chamber and attracted to a positive terminal. An electron beam is focused and then accelerated within the chamber by the voltage difference experienced by the electrons between the

start and finish of their travel in the chamber, a difference generated electrostatically or by a radio-frequency field. The beam emerges through a thin window at a speed close to that of light. It is swept from side to side by a changing magnetic field while irradiating large targets such as food.

An electron accelerated by a voltage difference of 1×10^6 V acquires an energy of 1 MeV (megaelectron volt). Energies above 1 MeV provide sufficient penetration in food to be useful. An upper limit of 10 MeV is recommended by the Codex general standard to avoid inducing radioactivity in the food.

Electromagnetic Radiation

Figure 2 shows that there is a range of EM radiations, each characterized by different wavelengths or energy and with different uses. Only X- and γ-rays have sufficient energy to cause ionization.

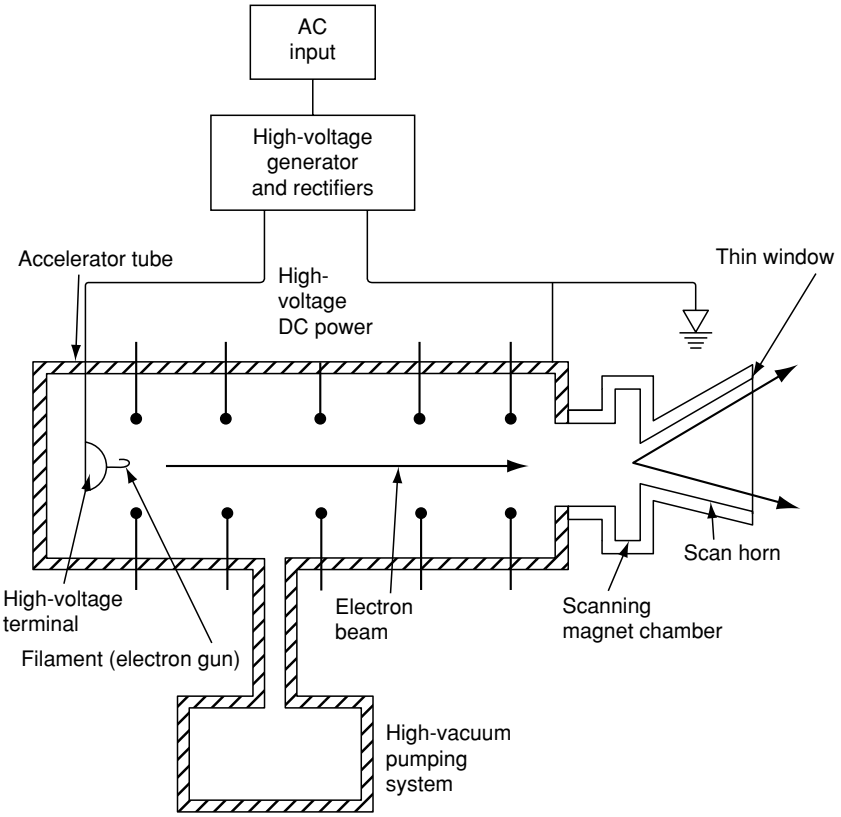

Figure 1 Schematic diagram of an electron accelerator with the voltage difference obtained electrostatically. Reproduced from Irradiation of Foods: Basic Principles. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

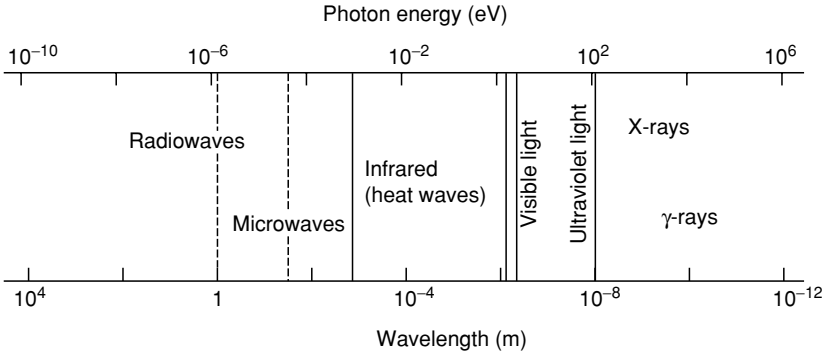

Figure 2 The electromagnetic spectrum. Reproduced from Irradiation of Foods: Basic Principles. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

X-rays are produced when high-speed particles strike a metal target and are rapidly decelerated. To avoid inducing radioactivity in food, X-ray sources must operate below 5 MeV. The efficiency of the conversion of 5 MeV electrons to X-rays is under 10%, making X-ray generators more costly to operate than simple electron machines.

γ-Rays are emitted by many atomic nuclei undergoing radioactive decay. Sources for food irradiation are limited to cobalt-60 and caesium-137, which emit γ-rays with energies around 1 MeV that cannot induce radioactivity.

Cobalt-60 is produced in a nuclear reactor by neutron bombardment of the stable element. It is a highly insoluble, high-melting-point metal. Caesium-137 is one of the fission products produced in the fuel rods of nuclear reactors from which it is chemically separated as a potentially volatile, soluble salt. Cobalt-60 dominates the γ-processing industry because of its more favorable production and environmental features.

Commercial decisions about the type and source of radiation to use are dictated by cost, beam penetration, and the form of the food to be treated. Most irradiation plants use cobalt-60. A few use electron beams and the first plants using X-rays are being constructed.

Dose and General Radiation Effects

Radiation effects in food are caused by the energy that is transferred to the food. The transferred energy is called the absorbed dose (commonly, just dose). Its unit is the gray (Gy) which is the absorption of one joule per kilogram. An older unit is the rad; 1 Gy equals 100 rad.

As the absorbed dose increases, the number of chemical reactions and the severity of the effects caused will increase. Food irradiation usually involves doses of 0.05–30 kGy, depending upon the desired result, although the upper limit recommended by the Codex Alimentarius is 10 kGy.

At low doses chemical reactions can disrupt biochemical and hormonal processes in fresh produce. As the dose increases, cell division is prevented as chemical disruption of DNA becomes severe. In this way microorganisms are inactivated and insects sterilized. At the highest doses used, all the microorganisms are killed and the food is sterilized.

Such effects indicate that extensive chemical changes are induced by irradiation. It may seem surprising that any food can withstand irradiation without being altered to an unacceptable extent. However, radiation deposits energy randomly throughout the food while inactivation of microorganisms, for example, requires that energy be deposited at a few critical points in a vital molecule such as DNA or a chromosome. Such molecules are relatively large targets and present in very few copies. In contrast, significant depletion or alteration of individual food constituents (e.g., amino acids) requires energy to be deposited in a large fraction of molecules that are far smaller and far more numerous than DNA. Frequently, therefore, food irradiation results in a product that is virtually indistinguishable from unprocessed food. However, as with conventional processes, some foods will suffer from undesirable changes in taste, smell, or texture.

Beneficial Uses of Irradiation

The major potential benefits of food irradiation are summarized in **Table 1**. Each benefit requires a minimum dose to be effective. For a particular food the maximum dose is limited by the onset of unacceptable changes in quality. Before a commercial decision is taken to irradiate a food, it is necessary to perform a cost-versus-benefit analysis and to assess the benefit to consumers against any potential loss in sensory qualities.

Table 1 Major technical benefits of food irradiation

Benefit	*Dose range (kGy)*	*Candidate foods*[a]
Inhibit sprouting	0.05–0.15	Potato, onion, garlic
Delay ripening	0.05–0.15	Some tropical fruit
Reduce parasites	0.1–0.3	Pork
Disinfest insects	0.1–1	Grain, rice, some fruit and vegetables
Delay spoilage (ambient)	0.5–5	Strawberry
Delay spoilage (refrigerated)	0.5–10	Meat, poultry, fish
Reduce pathogens	2–10	Meat, poultry, seafood, dried foods
Sterilization	10–30[b]	Spices, herbs, special diets

[a]Not a comprehensive list.
[b]Doses above 10 kGy exceed a Codex recommendation and are permitted only in a few countries for special purposes.

Safety Considerations

When considering whether any processed food is safe and wholesome the chemical, microbiological, and nutritional changes must be evaluated. Several expert international and national committees have considered the safety of irradiated foods. The World Health Organization (WHO) completed its latest reviews in 1994 and 1999. All the reviews reinforce the 1980 joint expert committee finding that, provided good manufacturing practice is followed, the irradiation of any food up to an overall average absorbed dose up to 10 kGy presents no toxicological hazard and no special microbiological or nutritional hazards.

The 1999 WHO report examined the safety of foods irradiated above 10 kGy. It concluded that foods treated above 10 kGy should also be considered safe and nutritionally adequate when produced under established good manufacturing practice.

Chemical Changes

Chemical reactions induced by a 10 kGy dose lead to about 300 mg of products per kilogram of food. Radiation, therefore, produces a large number of compounds but at very low individual concentrations. A few products are species that were not present significantly before irradiation. Some could conceivably be unique to irradiated foods and of unknown toxicity.

Any unique products must be present in extremely low concentrations since modern analytical methods can identify all the radiation products (or very similar compounds) in other processed or unprocessed foods. Several expert committees have considered a huge database of toxicological experiments. Although a small number of experiments initially raised some questions, the committees are satisfied that any doubts were due to inadequate experimental or analytical methods and that any toxicological risk is negligible.

Microbiological Changes

All physical processes have the potential to mutate microorganisms and lead to increased resistance, enhanced pathogenicity, or changed physiological traits important to their identification. If the process does not sterilize the food the surviving organisms will be those most resistant to the process. Subsequent regrowth can lead to microbial populations and risk different to those originally present.

However, irradiation appears little different to other physical processes in its potential for microbiological change. An exception may be its inability to destroy toxins produced by microorganisms that were present before processing, a useful property of heat for some toxins. In practice the risks are small. Following codes of good manufacturing practice developed for other processes and for storage will insure microbiologically safe irradiated foods.

Nutritional Changes

Irradiation up to 10 kGy does not alter significantly the nutritional value of proteins, carbohydrates, minerals, or saturated fats. Oxidation reactions can lead to the loss of essential unsaturated fatty acids. These reactions also induce rancid flavors and some foods with a high unsaturated fat content will not be suitable for irradiation. (*See* **Oxidation of Food Components**.)

In common with heating, freezing, dehydration, and storage, irradiation causes vitamin loss. Vitamin E and thiamin are the most radiation-sensitive, with vitamins A, C, and K also quite sensitive. Losses below 1 kGy are insignificant. Above 1 kGy the losses are comparable to those caused by other physical processes and may reach 10–20% for the more sensitive vitamins. If irradiated foods are to be further processed or cooked, the combined losses must be taken into account. (*See* **Ascorbic Acid**: Properties and Determination; **Retinol**: Properties and Determination; **Tocopherols**: Properties and Determination.)

The overall nutritional consequences of irradiating a particular food will depend upon:

- whether the food is a significant source of particular nutrients
- whether those nutrients are radiation-sensitive
- the dose
- the overall proportion of the food in the diet that is irradiated

Although there may be consumers with particular dietary habits or needs who could be adversely affected, the nutritional consequences of food irradiation will be insignificant for people eating a reasonably balanced diet.

Applications

P B Roberts, Institute of Geological and Nuclear Sciences Ltd, Lower Hutt, New Zealand

Introduction

This article discusses for various foodstuffs the practical benefits of irradiation, including reduction of pathogens, insect disinfestation, extension of shelf-life, and delay of ripening or senescence.

General Principles

Food presented for irradiation should be of good quality and the process must not substitute for good manufacturing practice (GMP) at any stage in the production of food. When food is treated to reduce pathogen or insect numbers, appropriate packaging should be used to prevent recontamination.

The maximum dose recommended by the Codex Alimentarius, 10 kGy, causes a temperature rise of under 2.4 °C, resulting in an unchanged appearance and texture in many temperature-sensitive foods. Oxidative stress does occur and not all foods withstand the doses required to achieve the intended benefits without a loss of quality. The doses suggested here are guides only; the optimum dose varies with conditions and varieties of food. (*See* **Oxidation of Food Components**.)

Combining irradiation with another process may result in an overall improvement in quality. For example, fruit is less susceptible to softening when lower radiation doses are combined with a mild heat treatment, and insect disinfestation is still achieved. Combination treatments are not discussed further.

Major Applications

Applications of food irradiation fall into several major categories.

Improved Food Safety

Foodborne pathogens are a significant and increasing cause of ill health and economic loss. Irradiation has great potential to control pathogen numbers in at-risk foods. For example, it is being considered for use as part of Hazard Analysis Critical Control Point (HACCP) systems for control of pathogens in meat. Irradiation is a 'cold pasteurization' process suitable for solid foods, especially for foods of animal origin and consumed raw. Concern in some countries about the increase in the presence of *Escherichia coli* 0157 H7 in foods has added considerable impetus to the use of irradiation as a decontamination measure.

Improved Food Security

Irradiation can control insect numbers, inhibit sprouting of bulbs and tubers, and delay maturation, decay, and senescence of some fruits and vegetables. Therefore irradiation can help to combat postharvest food losses that may range from 10 to 50% for some crops, depending on climatic conditions and available storage technologies.

Quarantine Security

Most countries require that insect species not found within their borders do not 'hitchhike' on imported foods. The available chemical fumigants are being phased out because of health and environmental concerns. Irradiation is being accepted by plant protection authorities as a technically viable, broad-spectrum alternative to fumigation.

Reduction in Chemical Residues

Irradiation leaves no treatment residues. Consumer demand for foods free of chemical residues is therefore an opportunity for irradiation to supplant chemical fumigation and preservation methods.

Increased Trade

The four applications above provide increasing opportunity for increased international trade in foods.

Irradiation can assist in meeting the hygiene, quarantine, and quality demands of food-importing countries. This is likely to become economically important for developing countries seeking to expand food exports to markets in developed countries.

Raw Plant Products

Fresh Fruits

Insect disinfestation The doses required to guarantee quarantine security are far lower than the Codex-recommended maximum (Table 1) and many fruit suffer no loss of quality (Table 2) or vitamins. Fruit still require proper storage conditions and ozone produced during treatment should be vented to reduce damage to the fruit. (*See* **Insect Pests**: Insects and Related Pests.)

Irradiation up to 1 kGy guarantees that insects cannot reproduce. However, not all insect stages will be rapidly killed. US authorities have a regulation in place on the use of irradiation as a phytosanitary treatment of imported fruits and vegetables.

Extension of shelf-life

Reduction of spoilage Spoilage of fruit is usually caused by fungal or yeast infections. These organisms are inactivated by doses above 1.75 kGy, which approaches the maximum dose tolerated by most fruit. Above the tolerated dose, softening and texture loss occur because of degradation of pectin and cellulose. Spoilage may even be accelerated since infection of the weakened tissue becomes easier or natural antibiotic production is inhibited. (*See* **Spoilage**: Yeasts in Spoilage.)

Sweet cherries and apricots may be protected from fungal rots by a 4 kGy dose without loss of quality but the only fruit generally considered suitable for such treatment is the strawberry. Grey mold rot (*Botrytis cinerara*) in temperate climates and rhizopus rot (*Rhizopus stolonifer*) in subtropical areas can be controlled. Treatment with 2–2.5 kGy and refrigerated storage can increase strawberry shelf-life by a factor of 2–4. (*See* **Apricots; Cherries; Strawberries**.)

Delay in ripening Nonclimacteric fruit are picked ripe and then steadily deteriorate. Climacteric fruit, which are mature but unripe at harvest, undergo an initial decrease in respiration followed by a burst of respiration associated with ethylene production and the start of ripening. (*See* **Ripening of Fruit**.)

Irradiation can suppress ethylene production and the ripening process in preclimacteric fruit. The time between harvest and full ripening is an important marketing consideration and irradiation could induce a useful extension.

Doses above 1 kGy are required to delay ripening of apples and pears and result in fruit of poor quality. In peaches, nectarines, and apricots ripening is accelerated, not delayed. (*See* **Apples; Peaches and Nectarines; Pears**.)

Ripening can be delayed successfully in some subtropical fruits. A delay of a week (30 °C storage) or 10–12 days (20 °C) is observed in bananas after a dose of 0.4 kGy. Higher doses cause softening and discoloration. The fruit should be treated before full maturity – an exception to the general rule. Mangoes in the hard green state are delayed from ripening by about 7 days (25 °C storage) after 0.25–0.75 kGy. Higher doses cause skin darkening. Papayas have a

Table 1 Irradiation treatments to provide quarantine security against insect pests[a]

Insect species	*Stage*	*Minimum dose (kGy)*	*Criterion*
Bactrocera tryoni (Queensland fruit fly)	Eggs/larvae	0.075	Nonemergence of normal adults
Tephritidae	Eggs/larvae	0.15	Nonemergence of normal adults
Cydia pomonella (coding moth)	All	0.25	Nonemergence of normal adults
All other	All	0.3	Sterilization of any adults present, and nonemergence of normal adults from preadult stages

Table 2 The ability of fruits to retain quality after doses up to 1 kGy[a]

Quality retention	*Fruit*
Good	Apple, cherry, date, guava, mango, nectarine, papaya, peach, raspberry, strawberry, tamarillo, tomato
Reasonable	Apricot, banana, cherimoya, fig, grapefruit, lychee, orange, passionfruit, pear, pineapple, plum, tangelo, tangerine
Poor	Avocado, grape, lemon, lime, olive
Unknown	Pomegranate, kiwifruit

[a]Adapted from Kader AA (1986) Potential applications of ionising radiation in post-harvest handling fresh fruits and vegetables. *Food Technology* June: 117–121.

ripening delay of 3 days at ambient temperature induced by 0.5–0.75 kGy. Skin scald results from higher doses. (*See* **Bananas and Plantains; Mangoes; Papayas.**)

Delay of senescence All fruit, even if not susceptible to rots, eventually deteriorate as the carbohydrate polymers responsible for firmness and texture break down. Generally, irradiation accelerates breakdown but senescence is delayed in sweet cherries, apricots (3 kGy, 4 °C storage) and papayas (0.75 kGy, 25 °C storage).

Fresh Vegetables

Inhibition of sprouting in tubers and bulbs The saleable life of potatoes, onions, garlic, etc., is reduced by sprouting. Low doses (0.02–0.2 kGy), allied with cool, dry storage can inhibit sprouting for months. The mechanism is uncertain but the likely causes are interference with nucleic acid and protein synthesis, chromosomal aberrations in meristematic cells, and inhibition of the production of hormones that control dormancy and sprouting. At even lower doses (< 0.01 kGy) sprouting may be stimulated. Irradiation inhibits wound healing in potatoes which are therefore stored 3–4 weeks before processing. (*See* **Onions and Related Crops.**)

Texture and overall appearance are unaffected but other features can be affected adversely depending upon dose, storage conditions, and variety. A small brown discoloration near the stem end may occur in onions. A blue-gray discoloration that occurs on cooking potatoes that have been stored for several months may be increased by irradiation. Many potato varieties display a temporary rise in sugar content after irradiation. Some varieties are unsuitable for processing into French fries or potato chips since the sugar content increases permanently on storage.

Inhibition of greening Greening of potatoes on exposure to air is inhibited by doses that prevent sprouting. There is conflicting evidence on whether the production of the toxic alkaloid solanine which is associated with greening is also prevented. Greening of endive can be reduced by a dose of 2 kGy.

Other effects Undesirable changes during storage of mushrooms include opening and browning of the cap, darkening of the gills, and browning and elongation of the stem. Doses in the range of 0.05–0.5 kGy inhibit these changes with little effect on flavor. (*See* **Mushrooms and Truffles:** Use of Wild Mushrooms.)

Postharvest curvature of asparagus is inhibited by 0.15 kGy. Higher doses produce splitting of the ends and a slimy, darkened appearance. (*See* **Vegetables of Temperate Climates:** Stem and Other Vegetables.)

Cereal Grains

Dry cereals such as barley, wheat, rice, and maize are subject to depredation by insects (e.g., coleoptera, lepidoptera, and mites). Doses of 3–5 kGy are needed to kill the insects within 24 h. However 0.5 kGy reduces their ability to feed and renders them sterile. This is useful as the grains are usually stored for long periods. Grains should be stored cool and dry to avoid mold growth. (*See* **Cereals:** Handling of Grain for Storage.)

Processed Plant Products

Dried Fruits and Vegetables

Low moisture content acts as a sufficient preservative measure in dried produce. The major benefit of irradiation is to disinfest them of insects such as the saw-toothed grain beetle, the fig moth, and the Indian meal moth. Doses up to 1 kGy are required and generally cause no detectable sensory changes. Darkening may occur upon storage in some dried fruits.

An additional benefit of irradiation is that rehydration and swelling properties tend to be improved and cooking times reduced.

Dried Herbs, Spices, and Vegetable Seasonings

These useful food ingredients are usually dried and ground, chopped, or finely divided. They may be sold as such or used as an ingredient of other processed foods. (*See* **Herbs:** Herbs and Their Uses.)

The initial microbial population is often high (over $10^6\,g^{-1}$) and irradiation at the recommended Codex limit of 10 kGy is used as a decontamination measure. Some countries permit treatment at 30 kGy because these ingredients are of minor dietary importance.

The changes in aroma, color, and flavor caused by irradiation are insignificant at 10 kGy and slight at 30 kGy.

Fresh Meats

Red Meats

Inactivation of Trichinella spiralis The infectious cycle of the helminthic parasite *Trichinella spiralis* in pork can be broken by a dose of 0.3 kGy. No special handling procedures are required and meat quality is retained.

Extension of Shelf-life and Pathogen Reduction

Meat is sterile at death but bacterial contamination may occur during slaughter and processing. Adequate

Table 3 Sensitivity to ionizing radiation of some pathogenic bacteria when present in red meat[a]

Genus	D_{10} (kGy)[b]
Campylobacter	0.08–0.16
Escherichia	0.30–0.55
Listeria	0.20–1.10
Salmonella	0.31–1.30
Staphylococcus	0.34
Streptococcus	0.69–1.20
Yersinia	0.04–0.21

[a]Data adapted from Farkas J (1987) Decontamination, including parasite control, of dried, chilled and frozen foods by irradiation. *Acta Alimentaria* 16: 351–384, and as published by the US Council for Agricultural Science and Technology in Task Force Report no. 115, June 1989.
[b]The dose required to reduce viable cell numbers to 10% of the original numbers.

GMP should insure sufficient retail shelf-life, and vacuum packaging technology can extend the shelf-life of lamb and beef by several weeks. (*See* **Meat**: Preservation.)

If a further guarantee of product hygiene is required, irradiation may be used to reduce pathogen numbers. This will coincidentally extend the shelf-life by reducing spoilage organisms. The induction of off-flavors limits the maximum dose applied. Highly trained taste panels can detect flavor changes in some meats at quite low doses but the threshold dose for unacceptable changes in pork is 1.75 kGy. Doses in the range 1–2.5 kGy are acceptable for beef and lamb.

Such doses significantly reduce the population of many pathogens (Table 3). The meat will not be pathogen-free if the initial contamination is substantial or if more resistant pathogens are present. Spoilage is usually caused by Gram-negative bacteria of the family Enterobacteriaceae and genus *Pseudomonas*, which are radiation-sensitive. Irradiation shifts the population to Gram-positive *Lactobacillus* and *Achromobacter* (*Moraxella-Acinetobacter*) sp. with different spoilage characteristics.

Other processes that reduce shelf-life are 'drip,' an unsightly exudate, and oxidation which causes discoloration and flavor changes. Irradiation does not inhibit such processes.

Fresh Poultry

The principles of decontamination and shelf-life extension are similar for poultry and red meats. Poultry have generally been considered the more likely candidate for irradiation since poultry are a major vehicle for the spread of foodborne pathogens. (*See* **Poultry**: Chicken; Ducks and Geese.) However, concerns about *E. coli* 0157 H7 have put more emphasis on red meats.

Doses of 1–2.5 kGy significantly reduce pathogen numbers and double shelf-life. Below 2.5 kGy, sufficient spoilage organisms will survive to insure spoilage occurs prior to the possible, though unlikely, production of botulism toxin. Other safety measures include storage below 4 °C and oxygen-permeable packaging.

Frozen Red Meats and Poultry

Irradiation can provide extra protection against the presence of pathogens. Doses in the range 3–7 kGy are effective, require no special handling, and retain quality.

Processed Meats

Processed meats are often vacuum-packaged to insure a long shelf-life. However, they may be highly spiced and have a high surface/volume ratio if sliced. During long storage these factors favor pathogen growth which can be inhibited by 2.5–3 kGy.

Seafoods

Dried or Salted and Dried Fish

Irradiation at 0.5 kGy disinfects the stored fish of insects (*Dermestes maculatus, Necrobia rufipes* and members of the family Sarcophagidae) but will not inhibit spoilage due to mold growth. Sensory quality is unaffected.

Fresh Fin Fish

Fresh fish has a relatively short shelf-life due to microbial spoilage, enzyme action, and oxidation. Irradiation (1–2.5 kGy) reduces microbial spoilage, and the shelf-life can be extended safely by several days. Other spoilage mechanisms are unaffected and fish still lose quality during storage. Ideally the fish should be irradiated on board the fishing boat; alternatively, the fish should be put on ice before irradiation on shore. (*See* **Fish**: Spoilage of Seafood.)

Both marine and fresh-water fish can be treated successfully. Accelerated rancidity is a greater problem in fish with a high oil content (herring, salmon, tuna), though in some oily fish (mackerel) their strong flavor can mask taste changes. Storage below 4 °C is essential to prevent growth of *Clostridium botulinum* and toxin production. This can also be inhibited by oxygen-permeable wrapping which will, however, not inhibit oxidation. Below 2.5 kGy sufficient other microorganisms such as radiation-resistant *Achromobacter* spp. will survive and cause spoilage before toxin is produced.

Table 4 Other suggested benefits of the irradiation of foodstuffs

Foodstuff	*Proposed benefit*	*Likely dose range (kGy)*
Wheat flour	Increased loaf size from low-sugar formulations	0.5–1
Nuts	Insect control	1
Beans	Oligosaccharide reduction	2–3
Egg powder/dried whole egg	Decontamination	2–6
Frog legs (frozen)	Decontamination	2–7
Grapes	Increased juice yield	4–5
Fruit juices/purees	Stabilization	5–10
Cured meats	Nitrite reduction	7.5–30
Animal feed	Decontamination/sterilization	7–30
Complete meals	Sterilization (for immunosuppressed patients)	30–50

Shellfish

Shellfish are prone to heavy contamination by pathogenic and spoilage bacteria. Frozen shellfish can be decontaminated using 2–5 kGy with little quality loss. Fresh shellfish (peeled/unpeeled) can be treated with 1–2 kGy, doubling shelf-life, but quality decreases at higher doses. Refrigeration below 4 °C is essential. Viral contamination of shellfish cannot be reduced by these dose levels. (*See* **Shellfish:** Contamination and Spoilage of Molluscs and Crustaceans.)

Black spot occurs on shrimps when they are stored. Radiation inhibits its formation provided the shrimp is very fresh when irradiated.

Other Possible Uses of Irradiation

A number of other uses of irradiation have been implemented or proposed (Table 4).

Processing Technology

P B Roberts, Institute of Geological and Nuclear Sciences Ltd, Lower Hutt, New Zealand

Introduction

This chapter describes the facilities required to irradiate food, how to measure the absorbed dose, and the likely processing costs. Suitable packaging and methods to detect irradiated foods are also outlined.

General Description of Irradiation Plants

All irradiation facilities have the following components (**Figure 1**):

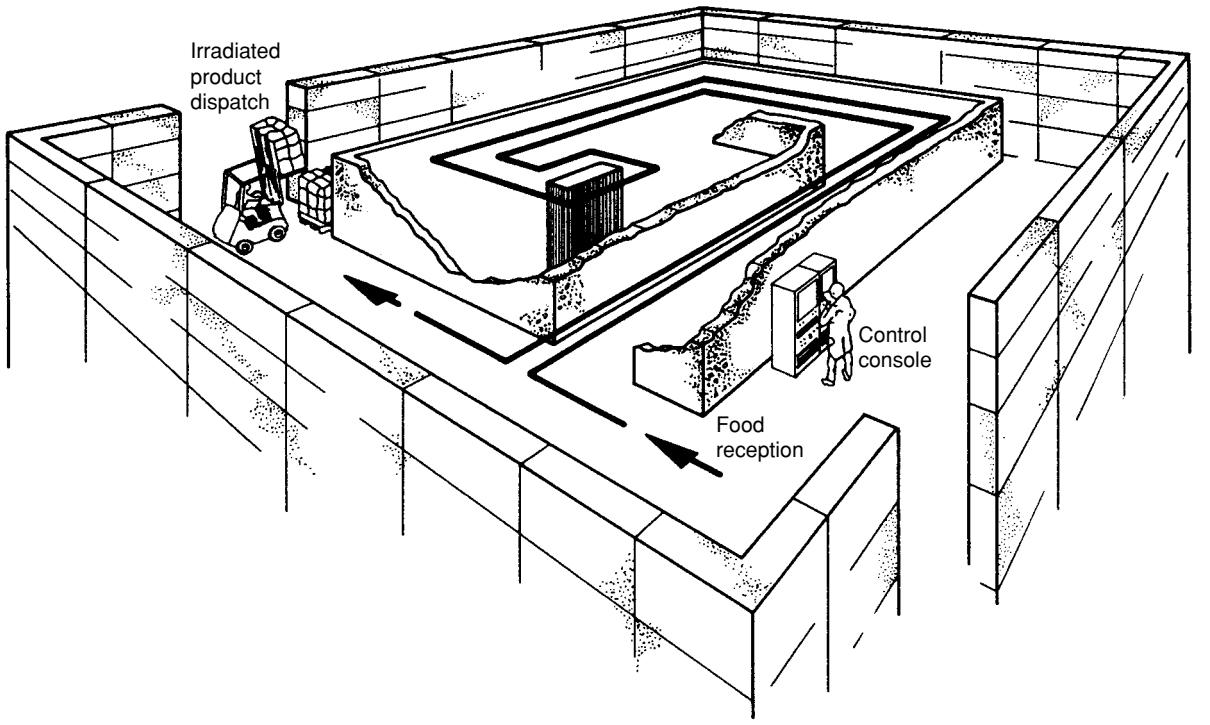

Figure 1 A diagrammatic representation of a cobalt-60 food irradiation plant. The arrows depict the movement of the food through the irradiation chamber and around the central source. Reproduced from Irradiation of Foods: Processing Technology. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

- a source of radiation in an irradiation chamber
- a protective shield
- a conveyor system
- a general area containing a control room or control console and warehouse space

Source

The commonly used sources of radiation are cobalt-60, a radioactive element emitting γ-rays, or an accelerator producing a beam of electrons.

Cobalt-60 is produced by neutron bombardment of stable cobalt in a nuclear reactor. Small nickel-plated slugs of the radioactive metal are loaded into a sealed alloy cylinder typically 10×450 mm and doubly encapsulated in a corrosion-resistant steel pencil. An array of such pencils is built into a rack typically 1–2 m^2. Cobalt-60 decays continuously. The time taken to lose 50% of its initial activity, i.e., its half-life, is 5.26 years. Usually 10% of the cobalt-60 is replenished annually.

There are several types of electron accelerator but all produce a fast-moving stream of electrons in a narrow beam that is rapidly scanned across a 0.2–1.2 m wide 'horn' positioned above the food to be irradiated. Radiation is produced only when the machine is switched on. The source strength can be varied within limits by altering the operating current or voltage.

Shielding

The irradiation chamber is enclosed by a 1.5–2 m thick concrete shield. This incorporates a maze system through which the food is conveyed to the source. The shield and maze reduce direct and reflected radiation levels in the general areas of the facility to safe levels and prevent exposure of the plant staff to radiation. In cobalt-60 plants penetrating γ-rays are emitted continuously in all directions. The radioactive source requires a nonoperating position in which all the radiation can be absorbed, making the chamber safe for staff to enter. This position is at the bottom of a 7 m deep pool of water set into the chamber floor. A hoist moves the source between operating and nonoperating positions.

Electrons (10 MeV) are absorbed within a few centimeters in condensed matter. However, penetrating X-rays are produced when electrons strike objects within the chamber. Therefore, shielding is just as necessary in accelerator facilities as in γ-plants, although its design may be simpler. The accelerator is simply switched off when staff enter the chamber.

Conveyor

Some γ-plants operate in a batch mode. Food is carried into the chamber with the source nonoperational, then irradiated and removed. However, a

conveyor system carrying food continuously past the source is more usual. Conveyor design must insure that the food is irradiated with reasonable uniformity. The speed of the conveyor and, hence, the time spent near the source is a major determinant of the dose received.

A railed system is used to transport large containers (up to $1 \times 1.2 \times 1.8$ m) past cobalt-60 sources in a single- or multiple-pass arrangement. The latter provides more efficient absorption of radiation and more uniform dose distribution.

An electron beam is emitted in one basic direction. This and its limited penetration permit only thin layers of food to be treated under the beam. A simple moving belt acts as the conveyor. Electron beams have been used mainly to treat grains, seeds, and homogenous meat products up to 70 mm thick.

General Area

Controls and servicing equipment are housed outside the shielded area. Areas for receiving incoming food and storing irradiated product are kept separate and contain temperature-controlled rooms if necessary.

Beam Penetration

Figure 2 illustrates the ability of γ-rays and electrons to penetrate food packages. Two-sided irradiation doubles the thickness treatable and reduces the dose variations within the package.

A completely uniform dose throughout a package is not feasible. The ratio of maximum to minimum dose is called the dose uniformity (DU) and should be as close to unity as possible. This is achieved more easily by treating thinner packages, a strategy that wastes radiation energy and reduces the volume treated in a given time. DU values close to unity in bulky packages are achieved more easily with γ-rays than with electrons (Figure 2).

Acceptable DU values differ for different foods and processes. The minimum dose must guarantee the intended effect and the maximum must not be detrimental to the food. Initial plant design must balance the acceptable DU, the throughput required for economic operation, and the range of doses required.

Dosimetry

The energy absorbed by the food (i.e., the dose) is the most important parameter in the treatment process.

Standards and Reference Dosimeters

The dose can be measured absolutely by calorimetry or ionization chamber methods. Calorimetry measures the heat released into water; ionization chambers record the number of ion pairs produced in air. Specialized laboratories have used both methods to provide national standards and reference dosimeters.

However, any effect that varies detectably and reproducibly with dose can be used as a reference dosimeter provided its response can be calibrated against a national standard. The Fricke dosimeter is a particularly well-characterized and common reference dosimeter. It consists of an aqueous solution of ferrous sulfate and sulfuric acid. Free radicals produced during irradiation oxidize ferrous ions to ferric ions, a change detected as an increase in optical absorption. Doses in the range 10–400 Gy can be measured by Fricke dosimetry. A small modification to the solution extends the range to 2 kGy.

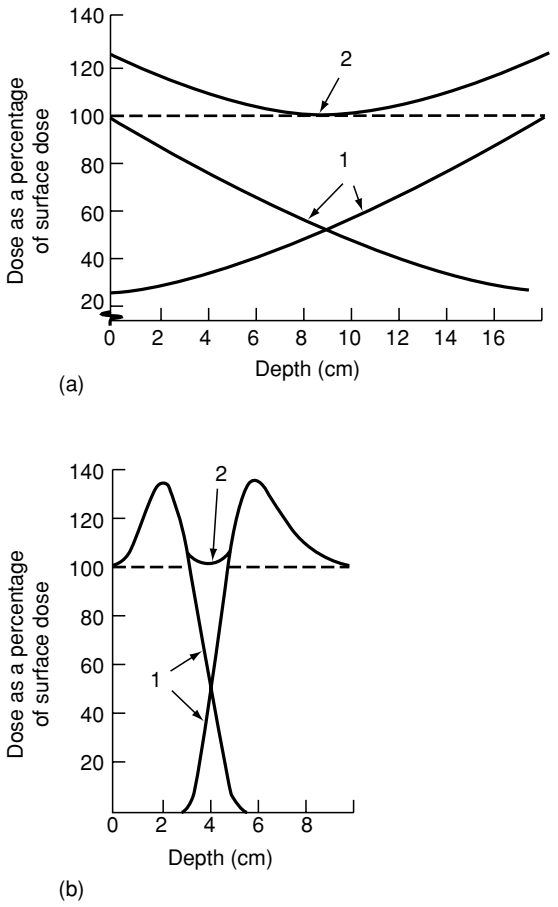

Figure 2 The relationship between dose and depth for unit density packages exposed to (a) cobalt-60 γ-rays or (b) 10 MeV electrons either from one side (1) or two sides (2). Adapted from Cleland MR, Pageau GM (1985) Electron versus gamma rays – alternative sources for irradiation processes. *Food Irradiation Processing. Proceedings of a Symposium*, Washington DC, March, pp. 397–406. Vienna, Austria: International Atomic Energy Agency, with permission.

In-plant Dosimetry

The reference dosimeters are difficult to use routinely in commercial operations. More practical dosimeters comprise plastic materials such as polymethylmethacrylate. Small pellets of the plastic, either clear or colored by dye, can be easily handled and change color over a wide dose range. The color induced gradually fades. Such dosimeters must be calibrated against a reference dosimeter that has itself been calibrated against a national standard.

When any food is presented initially for irradiation, potential dose variations throughout the food must be assessed in trial runs. Plastic dosimeters are placed strategically throughout the food container to map the dose distribution. The positions of maximum and minimum dose (D_{max}, D_{min}) are determined and checked against the prescribed treatment protocol.

During routine operations some packages that contain dosimeters at the points receiving D_{max} and D_{min} are conveyed past the source. Most operators provide a label that is impregnated with a radiation-sensitive dye on the outside of every package. The label changes color upon radiation. It is a simple yes/no indication that the package has been treated rather than a true dosimeter.

Overall Average Absorbed Dose

Technically, the important dose parameters are D_{max} and D_{min} since these will determine the quality and effectiveness of the treatment. However, the Codex General Standard for Irradiated Food refers to an overall average value, D_{av}. This is rigorously defined as:

$$D'_{av} = \frac{1}{M}\int p(x,y,x)d(x,y,z)dV$$

where M is the total mass of product, p is the density at a point defined by the coordinates (x, y, z), d is the absorbed dose at (x, y, z) and dV is the infinitesimal volume element. D_{av} can only be determined in an extensive dose-mapping exercise. However, the simple equation:

$$D_{av} = \frac{D_{max} + D_{min}}{2}$$

is often sufficient.

The Code General Standard for Irradiated Foods recommends a maximum dose in terms of a D_{av} value of 10 kGy. At least 97.5% of the food should receive less than 15 kGy. The dose uniformity should also be optimized. This is usually interpreted as DU values less than 2, but higher values are acceptable for some applications using low doses.

Plant Capacity and Costs

If all the radiation emitted by the source is absorbed in the food then a source of 1 kW can treat 360 kg of food per hour to a dose of 10 kGy. However, radiation is wasted when some of the beam misses or passes completely through the food. Some radiation is absorbed within the source or in the conveyor system. The percentage of radiation actually used, the efficiency factor (E), is usually 20–50%. Simple cobalt plants have relatively low-efficiency factors. Large multiple-pass cobalt plants and electron beam facilities can be designed with an E value approaching 50%.

A useful equation for the production rate of a plant is:

$$T = \frac{3600S}{D}E$$

where T is the throughput (kg h^{-1}), S is the source power (kW), D is the minimum dose (kGy), and E is the efficiency factor.

The source power is given by the cobalt-60 activity (1 kW = 67 kCi or 2.5 PBq) or the accelerator voltage and current (1 kW = 1 MeV × 1 mA).

Plant costs depend on the processing capability (volume and dose) required and, hence, on the source power and warehouse space. Costs can be in the range US$1–6 million. For a typical 1 MCi (37 PBq) cobalt-60 plant the source, the conveyor system, and the building each account for about one-third of the total cost.

Processing costs depend upon whether a high or low dose is required and on the source power. If sufficient volumes of food are available to dedicate the plant to a paticular purpose (e.g., poultry decontamination), then the plant can be designed to maximize efficiency. Most plants treat a variety of foods for different purposes and require greater flexibility at added cost.

In general, processing costs increase in proportion to the dose required and are approximately US$10–100 per tonne over a range of low- to high-dose applications.

Food Handling

Irradiation resembles pasteurization and fumigation in its ability to reduce the bioburden of pathogenic organisms in food. However, such methods must not be used to substitute for good hygiene practices at any stage in the pre- or posttreatment handling of food. Ideally, irradiation should be integrated within a Hazard Analysis Critical Control Point (HACCP) system. Codex has prepared guidelines for the use of HACCP systems.

Overall standards of food handling are discussed in the Codex General Principles of Food Hygiene. Operating standards within an irradiation plant are covered in a Codex Recommended International Code of Practice for the Operation of Irradiation Facilities Used for the Treatment of Food. (*See* **Fumigants; Pasteurization**: Principles.)

Irradiation can penetrate foods prepackaged in plastic or simple insect-proof wrapping. Food such as poultry, fruit, or vegetables can be decontaminated or disinfested in their final package, ready for transport, storage, or display. This eliminates the risk of recontamination until the package is opened by the purchaser.

For some irradiation treatments (e.g., inhibition of sprouting), foods such as potatoes can be treated loose in suitable totes or containers. If foods for which temperature control is an essential part of good storage technique are irradiated, then the plant must have suitable areas set aside to control the temperature. Special care may be needed with seafoods and some meats in which resistant *Clostridium botulinum* spores can survive irradiation. Subsequent growth of the bacterium would produce a fatal toxin, but this is prevented by storage below 4 °C. (*See* ***Clostridium***: Occurrence of *Clostridium botulinum*.)

Irradiation while food is frozen or vacuum-packed inhibits the free radical reactions leading to oxidation rancidity and off-flavors. Treatment while frozen and under vacuum was originally proposed for foods intended for very-high-dose treatments (50–60 kGy) to make them shelf-stable indefinitely at room temperature. The product is an attractive alternative to canned food. Since Codex presently recommends that dose is limited to 10 kGy, the application of food

Table 2 Major methods of detecting irradiated foods

Method	*Basis*	*Suitable foods*	*Status*
Electron spin resonance	Free radicals, paramagnetic centers in rigid matrices (e.g., bone, shell, seeds)	Meat (bone in), shellfish, some fruit	Established
Thermoluminescence[a]	Centers of energy excess or deficit in dry material	Herbs, spices, shellfish	Established
Gas chromatography–mass spectrometry	Radiation products from volatile fatty acids	Meat, lipid-containing foods	Advanced, standardization required
Impedance	Change in electrical properties	Potato	Advanced, wider testing required
Microbiology	Change in microbial population	Most uncooked foods	Well developed, indicative test only, not definitive
DNA alterations	Damage to DNA bases and strand breaks	Most uncooked foods	Experimental

[a]The signal arises mainly from adherent minerals (soil, dust). Mineral separation leads to better discrimination and wider applications. A related method using light rather than heat to release stored energy is very promising but suitable equipment is lacking in most laboratories.

irradiation to produce sterile shelf-stable foods in light plastic packaging has received little attention. However the conclusion of a World Health Organization Study Group in 1999 that foods irradiated to any practical dose above 10 kGy are safe and nutritious may lead to more interest in this application.

Packaging

Packaging must meet standards for the retention of postirradiation stability, strength, and permeability. The risk of low-molecular-weight chemicals in the irradiated packaging (e.g., stabilizers) diffusing into the food must also be negligible.

Table 1 lists the packaging materials approved by the US Food and Drug Administration and by regulatory authorities in Canada, Poland, India, and the UK for concurrent use when food is irradiated.

Labeling and Detection of Irradiated Foods

Irradiation is one of a group of food processes that leave no obvious signs to a purchaser, food inspector, or retailer that a food has been processed. Labeling of irradiated foods is generally considered desirable. In its General Standard for Labelling of Pre-packaged Food, Codex recommends use of the phrase 'irradiated [name of food]' or 'treated by ionizing radiation.' Most countries legislate for this wording or a near equivalent to be used with complete foods that have been irradiated. The words are placed on the food package or are prominently displayed near foods sold in bulk containers.

There is considerable debate about the labeling of irradiated minor ingredients or components of a food. The practicality, cost, and need for such labeling are questioned. National regulations vary in their requirements.

Methods to detect irradiated foods would boost consumer confidence in legislative controls, particularly that labeling information was accurate. Unambiguous detection of an irradiated food proved to be a difficult problem. No single method for all foods seems feasible. However, international collaborative trials have established a number of detection methods. Table 2 summarizes the methods that are established or under further investigation. Germany and the UK have official protocols in place for the use of some methods to enforce labeling requirements. Postprocessing detection is not a suitable way to control actual processing conditions.

Legal and Consumer Aspects

P B Roberts, Institute of Geological and Nuclear Sciences Ltd, Lower Hutt, New Zealand

Background

Governments have a responsibility to ensure the safe use of facilities that involve radiation sources, including those used to process food. An increase in the present limited commercial use of food irradiation will depend on the regulatory environment at national and global level, and on the attitude of the food industry and consumers to the product. This article discusses these issues.

Legislative Principles

Governments control the processing of food by various legislative methods. Some governments approve a particular treatment, whereas others may license a facility. In some countries, a single agent or minister is responsible. In other countries, multiple agencies must approve different aspects of the process and the sale of products.

Although regulatory mechanisms differ, there are a few basic principles that authorities should adopt to ensure the safe irradiation processing of food. These are summarized within a number of international documents, in particular:

- Codex General Standard for Irradiated Foods;
- Codex Recommended International Code of Practice for the Operation of Irradiation Facilities for the Treatment of Food;
- Codex General Standard for the Labelling of Prepackaged Food;
- Codex General Principles of Food Hygiene, and related Codes of Practice for specific commodities;
- Codex Hazard Analysis and Critical Control Point System and Guidelines for its Application.

Radiation Safety

Staff within the plant, as well as the public, must be protected against the radiation emitted by the source. Most countries already have effective controls in place to deal with nonfood uses of irradiation facilities. Authorities refer to international guidelines of the International Atomic Energy Agency for the following:

- permissible exposures of the workforce and public;
- safe handling, transportation and disposal of radioactive material;
- safe operation of high-energy accelerators and sources containing large amounts of radioactivity activity;
- emergency procedures in the event of accidents.

Radioactivity cannot be induced in food unless it is irradiated with radiation above a threshold energy. Therefore, the types and maximum energy of the radiation used to process food are restricted to the following:

- γ-rays emitted by the radionuclides cobalt-60 and cesium-137;
- X-rays generated by machine sources operated at or below 5 MeV;
- electrons generated by machine sources operated at or below 10 MeV. (*See* **Radioactivity in Food**.)

Food Hygiene

The irradiation facility must meet the design, construction, and general operating criteria imposed on all well-regulated food handling plants. Authorities must also take into account the packaging and temperature requirements of the food while in the treatment plant.

Irradiation must not be used to relax current standards of hygiene during any stage in the production, storage, transportation, processing, or sale of foodstuffs. The food presented for irradiation must meet all normal standards of microbiological and general

quality, and must have been produced under conditions of good manufacturing practice for which Codex standards and other guidelines are available. In this way, irradiation will confer further benefit or enhanced safety on high-quality food.

Prior Approval and Quality Control

There is no routine method of checking whether or not food has been irradiated, or of estimating the dose received once the food has left the facility. Therefore, the management and operation of the plant must be adequate at all times to guarantee proper control of the process. This is achieved by requiring prior approval of the irradiation of foodstuffs and of the facility. The approval process considers the following factors:

- staffing (numbers, training, skills, supervision);
- dosimetry methods and standards;
- ability to assess initial, especially microbiological, quality;
- separation of incoming and treated food;
- measures to prevent accidental reirradiation;
- hygienic storage and handling techniques and conditions;
- record-keeping and documentation;
- regular inspection by authorities.

The overall goal of the approval process should be to meet the principles of the *Codex Recommended International Code of Practice for the Operation of Radiation Facilities used for the Treatment of Foods*. (*See* **Quality Assurance and Quality Control**.)

International Trade

Foods are subject to documentary requirements when traded internationally. Importing countries often require assurance that the regulatory environment in which the processors operate is at least as stringent as their own. Minimum information on documentation should be as follows:

- an identification number for the batch of food;
- the treatment given (dose, purpose, place, and date of processing);
- the national regulations under which treatment was approved;
- any special handling requirements such as temperature control.

Laboratory methods are becoming available to prove that foods have been irradiated, although it remains a major problem to estimate absorbed doses once the product has left the irradiation plant. Therefore, it remains necessary for countries to ensure that irradiated foods are properly tracked as they move in trade, and that documentation accompanies each shipment. This will require effective cooperation between countries.

Labeling

A label is the only way by which consumers can be informed about whether a food has been irradiated. There is no obligation to inform consumers about some competing technologies (e.g., chemical sprout inhibition, fumigation). However, commercial use of irradiation has coincided with a growing recognition of the consumer's right to be informed and make a considered choice about which foods to purchase.

A secondary reason for use of labeling is the prevention of fraud (i.e., false claims in regard to whether foods have or have not been irradiated).

The Codex General Standard for Pre-packaged Food recommends the use of terms such as 'irradiated (name of food)' or 'treated with ionizing radiation' for English-speaking countries. In France, the term 'ionization' is favored. If a food is sold in a prepackaged form, the label will be on the package. Foods sold loose will have the information provided close to the food container.

Figure 1 illustrates the international symbol or logo for irradiated foods. It would be a simple visual guide to consumers and the international food trade that a food or ingredient had been irradiated. However, its use as the sole identifier of irradiated foods has not been supported by consumer organisations. A logo may be considered as a voluntary addition to the mandatory text.

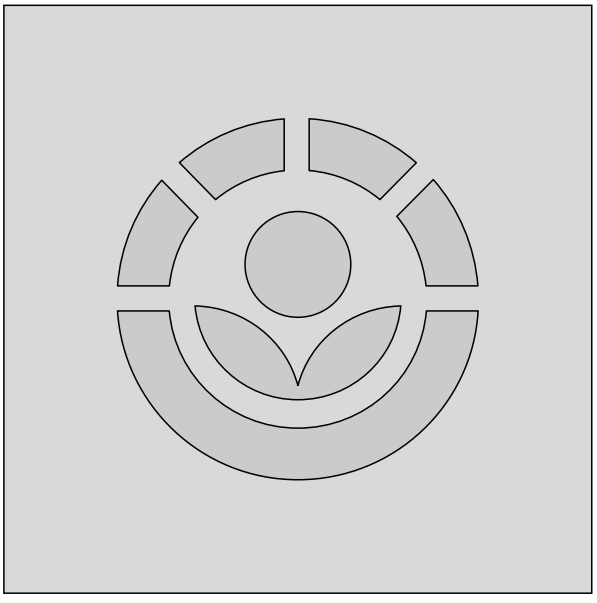

Figure 1 The international logo for irradiated foods.

Role of International Organizations

International organizations such as the Food and Agriculture Organization (FAO), the World Health Organization (WHO), and the International Atomic Energy Agency (IAEA) support the irradiation processing of food as a contribution to safe and secure food supplies. In 1984, these organizations agreed to sponsor the International Consultative Group on Food Irradiation (ICGFI) to act as an international group of experts designated by governments to evaluate and advise on global activities in food irradiation.

A priority for ICGFI is to encourage trade in irradiated foods by working towards regulatory requirements that are as consistent as possible in different countries. The ICGFI has issued a number of documents that advise on the control of food irradiation processing. These include:

- Guidelines for Preparing Regulations for the Control of Food Irradiation Facilities;
- International Inventory of Authorized Food Irradiation Facilities;
- Guidelines for the Authorization of Food Irradiation Generally or by Food Classes;
- Codes of Good Irradiation Practice for individual commodities (amalgamated into a single Code in 2000) and associated monographs of technical data.

The Codex Alimentarius Commission has also issued important documents related to regulating food irradiation, as discussed elsewhere in this series of articles.

International Status of Food Irradiation (1999)

Forty-one countries have informed the Joint Division of the FAO/IAEA that they have listed at least one type of food as cleared for irradiation for one or more purposes. Although the Codex General Standard declares that *any* food can be irradiated up to an overall average dose of 10 kGy, most countries regulate irradiation using the principles of food additives and still require each food or application to be approved on a case-by-case basis.

Some countries have specific regulations on food irradiation, and the list of approved items is part of the regulation. In other countries, the list of approved items has been drawn up by a statutory agency or special committee. There is no specific food irradiation regulation, but an authorization can be given within general food regulations.

A few governments (e.g., Luxembourg, Sweden) have a policy that precludes the irradiation of food or the sale of irradiated food products, though this is not always reflected directly in legislation. Others have a regulation that provides for an overall prohibition on irradiation of foods but with the possibility to seek an exemption for specified foods and purposes (e.g., Australia, New Zealand).

The listing of countries and approved foods appears extensive. However, the existence of an approval does not necessarily mean that there is automatic authorization to proceed with commercial processing. Usually, it is still necessary to make a specific application to process food, to provide justification, and to show that good manufacturing practice will be carried out.

Over 40 different foods or food classes have been approved for irradiation for a variety of purposes, and about 50 irradiation facilities worldwide treat food. However, most of these facilities treat only very small volumes of food.

Two aspects of national regulations, in particular, can vary greatly between countries. One is labeling, especially the labeling of food ingredients. The Codex General Standard on Labeling of Pre-packaged Foods is being interpreted in different ways. Some countries require no labeling of irradiated foodstuffs once the food becomes an ingredient in another food; others require labeling regardless of how small a proportion that an irradiated ingredient constitutes of the complete food; other countries make no reference to labeling.

Another cause of nonuniformity concerns the allowable doses of radiation applied to the food. The Codex Standard allows irradiation of food up to a maximum overall average dose of 10 kGy. This maximum is based on very conservative safety and nutritional considerations. In practice, it is also necessary for processors to limit the dose range applied to foods for technological reasons. These reasons include ensuring that the intended benefit is achieved, for which a minimum dose is necessary, and retaining the quality of the food, for which a maximum below 10 kGy may be necessary. These technological limits, which are basically advisory and the business of the radiation processor, are often included in national regulations in different ways in different countries.

In 1999, the WHO published the findings of a Study Group on the wholesomeness of food irradiated above 10 kGy. It concluded that foods treated above 10 kGy were safe and nutritionally adequate when produced under conditions of good manufacturing practice. Thus, on the grounds of safety, there is no need to legislate a maximum safe dose for irradiation of food. The maximum can be determined by the need to retain the quality and sensory properties of food acceptable to consumers.

During 2000, the Codex Alimentarius Commission will review the implications of the Study Group finding for its General Standard on Irradiated Foods, particularly the recommended maximum dose limit. This may then influence the way in which national regulations deal with dose limits.

Two exceptions to the 10-kGy maximum are already recognized in some countries. Higher doses may be permitted to sterilize minor food ingredients such as herbs and spices or foods for special groups such as hospital patients, astronauts, or the armed forces.

Consumer Issues

Food irradiation has remained a specialized process used for small volumes of food. In developed Western countries, this is mainly because of reluctance on the part of retailers and the food industry to adopt the process. This industry position has arisen from initial doubts or a lack of understanding about the process by consumers. Without widespread acceptance of the process in US and European markets, developing countries have little incentive to invest in irradiation facilities.

Formation of Consumer Opinion

Resistance to irradiated foods was initially based on a misapprehension that the food became radioactive. Among the public and the media, there persists an inability to distinguish between radiation and radioactivity and between eating an irradiated product and being irradiated. Accidents such as Three Mile Island and Chernobyl reinforced these misapprehensions. However, if such confusion were the sole reason for consumer resistance to irradiated foods, it would be relatively easy to counter.

There are a number of general issues related directly or indirectly to food irradiation:

- Interest in natural, unprocessed foods has grown. Associated with this has been a perception of the harmful health consequences of additives and processing. Doubts about the safety of irradiated foods continue to be expressed in spite of expert opinion.
- Consumers' rights to choose and to be informed about their food are widely accepted. The possible additional costs and requirements for accurate and informative labeling reinforce the reluctance of food retailers to stock irradiated foods.
- There remains a general opposition to any new technology that uses radioactive material or radiation.

This mix of issues has ensured that food irradiation has maintained a profile as a controversial process in the media and among consumer activist groups that is hardly warranted by its present importance as a food technology.

Consumer Attitudes

Consumer attitudes vary greatly by country and are dependent on development status, the extent to which irradiated foods are available and media exposure. Surveys of consumer attitudes (e.g., Table 1) have shown that most members of the public are unaware or have little knowledge of food irradiation. When surveyed for an initial reaction, most consumers are either unwilling to purchase irradiated foods or express strong reservations. Individual opposition may decrease when the process is explained more fully. General opposition tends to increase when conflicting pro- and antiirradiation views are publicized.

Consumer opinion has been studied most closely in the USA, where there has also been a substantial public debate on the issue to help inform the consumer. As information has been made available, consumer concern has decreased. In the late 1980s, over 40% of consumers surveyed expressed serious concern about irradiation. By 1996, this had fallen to less than 30%.

Several studies in the USA indicate that up to 20% of consumers oppose the irradiation of foods and are unlikely to change that view. A similar percentage is willing to try irradiated foods on the basis of minimal information. The remainder are open to persuasion in either direction on the basis of the information placed before them.

Some surveys have found that concern about irradiation ranks far lower than other concerns related to food safety (Table 2). Irradiation was classed as a serious concern by 29% of US consumers surveyed, compared with 77 and 66% seriously concerned about bacteria and pesticides, respectively. Nitrites, additives, and other preservatives elicited slightly less concern than irradiation. In the longer term, the fact that

Adapted from *Opinion Research, Trends, Consumer Attitudes and the Supermarket* (1996). Washington, DC: Food Marketing Institute.

irradiation reduces the risk from such high level concerns as bacteria and chemical residues may become more important than fears about irradiation itself.

Another factor shaping public opinion has been increasing opposition among communities to the siting of irradiation plants within their area. This opposition is usually based on exaggerated fears of the transport of radioactive material to the plant or of possible accidents involving environmental contamination.

Market Trials

Between 1984 and 1990, about 40 market trials of 17 irradiated foods were conducted in 13 countries (Table 3). In some trials, food technologies or government officials were available to explain the process and its potential benefits. Sometimes, both irradiated and nonirradiated products were available for comparison.

All of these trials have shown that most people expressed no objection to, or actually preferred, the quality of the irradiated product, and would buy such products again. These results have been borne out when irradiated food goes on retail sale. Irradiated chicken and fruit has been available in small retail outlets in the USA since the mid-1990s. The irradiated food has sold well, and there has been no significant consumer resistance, although some individual consumers may have chosen not to purchase.

The marked difference between attitudes revealed in surveys of general opinion and the experience from market trials or retail sale of irradiated food indicates that food irradiation gains wide acceptance only when irradiated products are available for consumers to sample.

A few trials or surveys have considered the extra cost of irradiated food. Cost is not a major barrier, with many consumers willing to pay extra for obvious improvements in quality. This willingness is dependent on the type of benefit, the cost of food (a basic or luxury item) and the socioeconomic status of the potential purchaser.

Table 3 Examples of market trials of irradiated foods[a]

[a]Data obtained from information held by the International Consultative Group on Food Irradiation, IAEA, Vienna, from which a complete listing may be obtained.

Summary – The Irradiated Food Dichotomy

Many national authorities are convinced of the safety and benefits of irradiated foods and have approved the process for some specific foods. The public have remained inherently suspicious, however, and opposition is generally reinforced by debates involving opponents and proponents of the process over issues such as safety and labeling.

Favorable responses to irradiated products are elicited if consumers are provided with the products to sample and compare, and if information is available simultaneously. However, little irradiated food is actually available. The food trade remains cautious, fearing adverse consumer reaction and the potential questioning of why existing products need to be irradiated.

Few companies wish to be first to market a product that, despite all its technical advantages, continues to

generate controversy. However, as concerns increase about the safety and security of the food supply and about the effects of chemical treatments, the situation may change. Growth in the volumes of irradiated foods available may be slow for some time yet, but eventually, the process should take its place as one of the key treatments available to the food industry.

ISOMALT

K McNutt, Consumer Magazines Digest, Santa Cruz, CA, USA
A Sentko, Sentko Consult GmbH, Bühlertal, Germany

Background

Isomalt is a sugar-free sweetening ingredient. It is a suitable ingredient for candies, cookies, cough drops, and other products that require the volume and texture properties of sugar, as well as sweetness. Because the same amount of isomalt is used in sugar-free products made with isomalt, as would be used if products were sweetened with sugar, isomalt-containing products have the same appearance and texture as those made with sugar.

Isomalt belongs to the category of carbohydrates known chemically as polyols or sugar alcohols. The term 'sugar replacers,' which more descriptively explains their usage, is now used by many food technologists and nutritionists for this group of sweeteners when communicating with people who are not familiar with chemical nomenclature. The consumer benefits of isomalt include:

1. Its energy value is at most 2 kcal g^{-1}, rather than 4 kcal g^{-1}, as for sugars.
2. It does not promote dental caries.
3. It does not significantly increase blood glucose or insulin levels.

Synthesis and Structure

Development of isomalt began when a patent was issued in 1957 for a process in which *Protaminobacter rubrum* transformed sucrose into the reducing disaccharide 6-*O*-α-D-glucopyranosyl-D-fructose, which is chemically named isomaltulose.

Isomalt is produced as shown in Figures 1 and 2. First, sucrose (2-*O*-α-D-glucopyranosyl-β-D-fructofuranosyl) is enzymatically rearranged into an intermediary product, the more stable isomaltulose (6-*O*-α-D-glucopyranosyl-D-fructose), which is a reducing disaccharide. Then, isomaltulose is hydrogenated with hydrogen and a metal catalyst. The result is isomalt, a mixture of the isomers 1-*O*-α-D-glucopyranosyl-D-mannitol dihydrate (1,1-GPM) and 6-*O*-α-D-glucopyranosyl-D-sorbitol (1,6-GPS).

Technical Properties

Isomalt is an odorless, white, crystalline, and low-hygroscopic substance. Isomalt tastes like sugar, but it is less sweet. In a 10% solution, its sweetening power is 50–60% that of sucrose. Although it has less sweetening power, it has a similar sweetness profile.

One of the advantages of using isomalt is that it can be combined with intense sweeteners to achieve various sweetness profiles, thus optimizing sweetness without masking flavor, which is a limitation of some other sweeteners. Furthermore, isomalt blends well with many flavors, including fruity, menthol, and minty. Isomalt's negative heat of solution ($-39.4\,\mathrm{kJ\,kg^{-1}}$) results in a cooling effect lower than all other sugar replacers. Therefore, products such as isomalt-containing chocolates have no unpleasant cooling effect in the mouth.

Standard isomalt has a solubility of 24 g per 100 g of solution at 20 °C, increasing at higher temperatures. Based on its sorption isotherm, an index of raw material hygroscopicity, isomalt is a very stable ingredient. It absorbs virtually no water up to a relative humidity of 85% at 25°C.

Isomalt and its two isomers are very stable to acidic and enzymatic hydrolysis. Since isomalt's disaccharide bond cannot be easily cleaved, it does not provide a substrate for most microorganisms associated with food. As is true for all polyols, isomalt is nonreducing, and therefore does not react with amino or peptide groups. Therefore, no browning reaction occurs during boiling, baking, or extrusion.

Synergistic effects in sweetening power occur when isomalt is combined with other volume-providing sweeteners such as maltitol syrup, xylitol, mannitol, or sorbitol. Because isomalt is less sweet than sugar, it is often used in combination with intense sweeteners such as aspartame or acesulfame-K. Isomalt gives products texture, volume, and mild sweetness. The intense sweetener brings the level of sweetness up to what would occur if sugar were used. Synergistic effects, similar to those occurring with other volume-providing sweeteners, are observed when isomalt is used in combination with intense sweeteners. An additional advantage of such combination usage is that isomalt tends to mask the bitter aftertaste of some intense sweeteners.

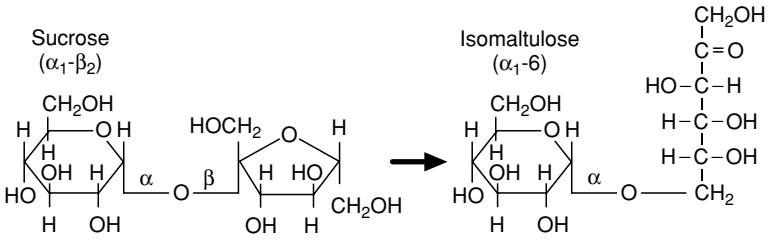

Figure 1 Production of isomaltose by enzymatic transglucosidation.

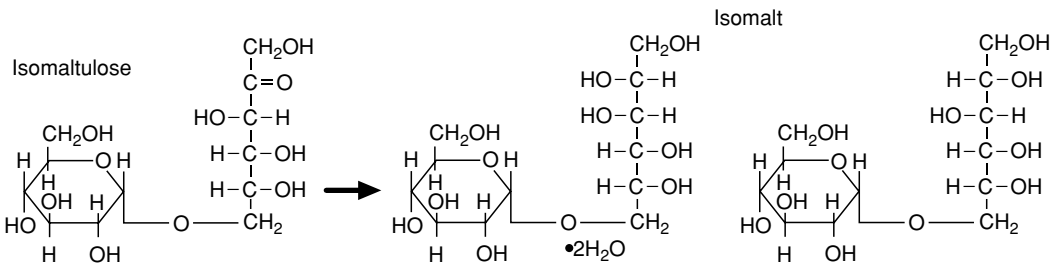

Figure 2 Production of isomalt by hydrogenation.

Consumer Benefits

Isomalt offers benefits that fit health-oriented lifestyles, contemporary weight management guidelines, and the functional foods or nutraceuticals product category.

The current focus of health professionals regarding obesity prevention and weight maintenance is to help people set reasonable weight goals, rather than striving for a defined ideal weight. People are encouraged to develop moderate but regular exercise patterns and to consume a variety of healthful foods. Although no foods should be considered forbidden, the total diet should have a caloric content appropriate for one's energy expenditure. In this context, isomalt expands food-choice options for the growing number of people who are willing to make moderate, but not extreme, lifestyle changes and improvements in their diet. Because of its lower calorie value and other health benefits, isomalt is an ideal ingredient of products for consumers who will adopt healthier eating patterns, as long as foods still taste good and as long as they can still occasionally enjoy desserts, candy, and other sweetened foods.

Another consumer benefit arises from the fact that isomalt is frequently used as an ingredient for many products consumed as snacks or between meals, rather than eaten with other foods. Therefore, it is useful for people who wish to consume sweetened foods without increasing their cariogenic risk or elevating blood glucose and insulin levels.

Isomalt's benefits extend beyond the health arena. Many consumers already factor into their product-choice decisions their concerns about environmental waste. This consumer expectation will, no doubt, become increasingly important as it relates to packaging. Since isomalt absorbs very little water, products made with it tend not to be sticky. Therefore, small items such as candies can be put into a package without each being wrapped separately, an appealing attribute for the growing market of environmentally conscious consumers.

Physiological Properties

The stability of the disaccharide bond between GPM and GPS explains many of the physiological properties of isomalt. From the beginning of the gastrointestinal tract to the end, this enzymatic stability is the key to understanding isomalt's health benefits (see Table 1)

- The reason isomalt does *not promote dental caries* is that oral bacteria cannot readily break its disaccharide bonds and therefore cannot convert it into decay-causing acids.
- Isomalt's *lower caloric value* is mainly due to the fact that intestinal enzymes are not able to hydrolyze its disaccharide bond easily. It is only partially digested and absorbed from the small intestine into the blood, and therefore only partially metabolized.
- The *low-glycemic* benefit of isomalt occurs because of its partial digestion and slow absorption.
- The possible *gastrointestinal* effects of isomalt also result from its incomplete absorption.
- Isomalt's more stable structure also contributes to its usefulness in a *large variety of products*. (*See* Product Applications Section.)

Lower Caloric Value

Based on scientific studies evaluated by the Federation of American Societies for Experimental Biology, an energy value of $2\,\mathrm{kcal\,g^{-1}}$ is used for isomalt for food labeling purposes in the USA. This value is also accepted for food labeling purposes in Canada and other countries where an individual approach to energy values based on scientific evidence is used. The European Union labeling regulation administratively prescribes an average unitary energy value for isomalt and all sugar replacers of $2.4\,\mathrm{kcal\,g^{-1}}$.

Determining the exact amount of food energy that actually becomes available to body cells is more difficult for low-digestibility carbohydrates such as sugar replacers and high-fiber foods than for totally digestible carbohydrates. The energy actually available for body functions depends on:

- the amount of a food digested and absorbed across the intestine wall into the blood;
- how the absorbed products of a food component are metabolized by the body; and
- whether intestinal bacteria use, for their own energy needs, food components that are not digested or absorbed.

Table 1 Isomalt's stable bond explains its health benefits

	because of isomalt's more stable bond . . .		*Therefore, isomalt . . .*
Mouth	Isomalt is not broken down by oral bacteria.	→	*. . . does not cause tooth decay.*
Small intestine	Isomalt is only partially and slowly digested.	→	*. . . provides 50% less kilocalories.*
		→	*. . . does not raise blood glucose and insulin levels.*
Large intestine	Non-absorbed isomalt can pull water into the intestines and can be metabolized by some colonic bacteria.	→	*. . . Eating excessive amounts may cause more gas and looser stools in sensitive people.*

Although isomalt is only partially digested and, therefore, only partially metabolized, the nonabsorbed portion may be used as an energy source for normal colonic bacteria, and some of the end products of this metabolism may be absorbed and converted into biological energy.

Several methods, each with certain advantages and disadvantages, have been utilized to determine the energy value of isomalt. The types of studies include body composition of laboratory animals, indirect calorimetry in human subjects, gastrointestinal absorption research, and studies of the effects on blood glucose, insulin levels, and other metabolic parameters.

Lower Dental Caries Risk

Isomalt is used in many sugar-free products that are frequently consumed between meals such as candies, chewing gum, throat lozenges, and cough drops. This usage increases the importance of its noncariogenic property. A recent review of studies in laboratory animals and humans, using several different techniques to test the cariogenic potential of isomalt, concluded, 'The evidence shows clearly that isomalt has a low acidogenicity and a low cariogenic potential according to criteria established within the dental profession.'

Isomalt does not promote dental caries, because:

- It cannot be fermented by most oral bacteria. Consequently, little or no acid is produced from isomalt metabolism within plaque. The critical pH, 5.7, at which demineralization occurs, is not reached after isomalt ingestion.
- It is not used for polyglucan synthesis, and therefore, it reduces plaque formation.
- Consumption of isomalt-containing products helps remineralize early caries lesions.

Considerable research has been conducted regarding the noncariogenicity of isomalt. The types of studies include *in-vivo* pH studies, *in-vitro* animal studies, and *in-vitro* acid-production studies.

Isomalt solutions alone and a large number of isomalt-containing sugar-free confectionery products have been tested extensively by an *in-vivo* pH telemetry test developed at the University of Zurich. This methodology measures pH changes in interdental plaque and in intraoral fluid after consumption of sugar replacer-containing solutions and sugar replacer-containing food products. The rationale on which it is founded is that the more acidic the environment on the tooth surface, the greater the chance for enamel demineralization and caries formation. Figure 3 shows the details of this procedure.

Imfeld studied the cariogenicity of several confectionery products prepared with isomalt versus similar sucrose-containing products. Isomalt-based chocolate did not cause interdental or intraoral pH levels to drop below 6.0. The sucrose-based chocolate, however, resulted in acid production below the critical level at which tooth decay occurs.

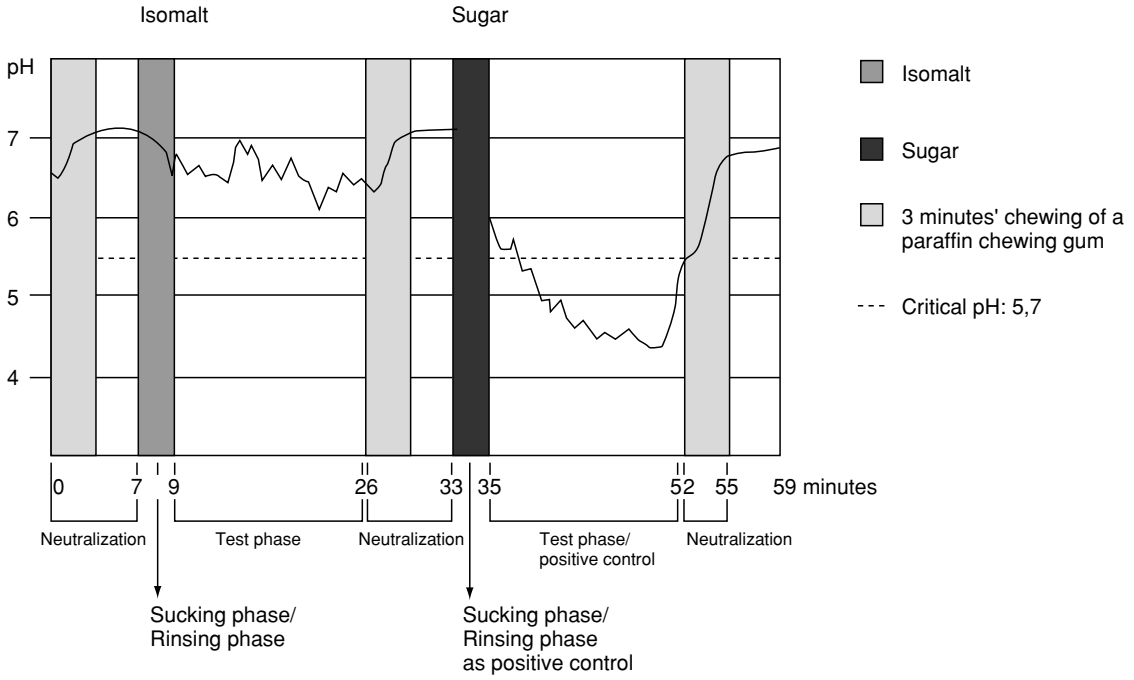

Figure 3 Comparison of oral pH changes after isomalt versus after sucrose using pH telemetry.

Figure 4 The Happy Tooth logo issued by Tooth-Friendly Sweets International.

In 1996, the US Food and Drug Administration (FDA) published a regulation that allows, under specific circumstances, the use of a 'health claim' based on the association between polyols (including isomalt) and the nonpromotion of dental caries. A nonpromotion of dental caries statement is used for food labeling in many other countries. In Switzerland and several other countries, confectionery products that meet criteria similar to those of the US FDA may use the claim 'tooth-friendly.' Manufacturers of products that pass the pH telemetry test may advertise foods as 'safe for teeth' and may print on those products' packaging a logo showing a Happy Tooth, shielded by an umbrella, as shown in Figure 4.

The question of adaptation has been addressed in several studies. The combined results of this research suggest that feeding isomalt to rats does not stimulate the proliferation of those strains that have the ability to ferment isomalt.

Isomalt and other sugar replacers can reverse the initial stages of dental caries, because, owing to their sweet taste, sugar replacers stimulate saliva flow rate and change its composition. Stimulated saliva is an important remineralization agent, because it causes an increase in pH and in salivary calcium concentration, while decreasing inorganic phosphate concentration.

Low Glycemic Response

Isomalt availability has significantly increased the quality and variety of good-tasting, sugar-free products that do not elevate blood glucose and insulin levels. This expansion of low-glycemic response options is especially important for cough drops, throat lozenges, and candies that are usually not consumed at meals, along with foods that contain protein, fat, and complex carbohydrates.

Numerous studies in diabetic and nondiabetic subjects have been conducted on the effect of isomalt alone and of isomalt in comparison with other sweeteners. This research shows that, after ingestion of isomalt, blood glucose and insulin values do not differ significantly from baseline levels.

Two physiological reasons explain isomalt's lower glycemic response. First, isomalt is only partially digested and therefore only absorbed to a limited degree in the small intestine. Second, the portion that *is* absorbed is absorbed slowly, thus resulting in a small increase in blood glucose and insulin levels.

In one study, using nondiabetic subjects who had fasted overnight 43 people were given 50 g of isomalt and seven people were given 100 g. No significant increase in blood glucose was observed during the 2 h after ingestion. In a double-blind cross-over study, 10 healthy young men of normal weight were given comparable amounts of sucrose and isomalt. Blood glucose and insulin showed a marked increase after 30 g of sucrose, whereas after isomalt, these parameters did not change appreciably from the baseline. The differences between isomalt and sucrose responses were highly significant (see Figure 5).

In a randomized cross-over study with 24 Type II diabetics who had fasted for 12 h, subjects were given isomalt or glucose and then blood samples were collected over the next 3 h. In contrast to glucose, after ingestion of isomalt, the blood glucose and insulin curves were not significantly different from those for fasting levels. Petzhold and coworkers confirmed these findings in a comparably designed study. In addition, they found no increase in C-peptides after isomalt, whereas a significant increase occurred after glucose.

In order to evaluate the long-term effects of isomalt, Pometta *et al*. conducted a randomized controlled study with two groups, each composed of 12 Type II diabetics who consumed their usual diet for a period of 3 months. The experimental subjects received 24 g of isomalt daily, offered throughout the day. No significant differences were found between the two groups, either in metabolic parameters (fasting and postprandial blood glucose, hemoglobin A1C, total cholesterol, high-density-lipoprotein cholesterol, triglycerides, phospholipids) or in liver and kidney function tests. In another cross-over study, 60 insulin-dependent children with Type I diabetes were treated for 6 weeks either with a standard diet or with a diet with the daily addition of 20 g of isomalt. This daily dosage level had no effect on insulin requirement, frequency of hypoglycemia, or frequency of glucosuria.

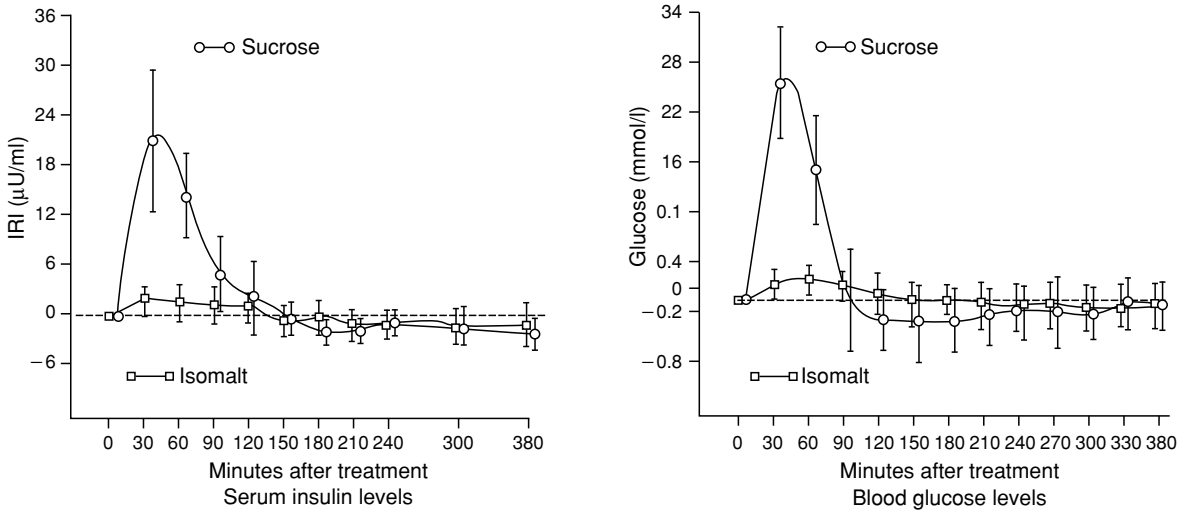

Figure 5 Comparison of serum insulin and blood glucose levels after oral isomalt versus after oral sucrose.

Gastrointestinal Response

Isomalt, as well as all sugar replacers, are low-digestibility carbohydrates, as are high-fiber foods, beans, prunes, cabbage, and dried fruits. Any food that contains a relatively large amount of low-digestibility carbohydrates is, as the term 'low digestibility' indicates, only partially (or not at all) absorbed in the upper part of the gastrointestinal (GI) tract. Nonabsorbed carbohydrates create an osmotic effect, pulling water into the intestine, which may *sometimes* in *some* people result in softer or more watery stools. In the lower part of the GI tract, the nonabsorbed portion of such foods is partially or completely fermented by normal colonic bacteria. During fermentation, some bacteria change low-digestibility carbohydrates into short-chain fatty acids and gases, which can cause flatulence.

Most people can eat fairly large amounts of foods containing low-digestibility carbohydrates without feeling uncomfortable. Others know from experience that, because such foods may cause an unpleasant GI response, they should limit their consumption to smaller portions. Very few, but some, people are so sensitive to low-digestibility carbohydrates that even small amounts cause discomfort.

Setting an absolute level below which an individual can be assured of never having a GI response is impossible, because so many variables affect how each person's body handles low-digestibility carbohydrates. The effect depends on whether the carbohydrate is consumed as a food or a beverage, whether it is eaten as part of a meal or on an empty stomach, and whether the total amount is ingested all at once or spread over the day in small portions. The same person may have no response to a particular food on one day but may be sensitive to it on another day. Usually, the few people who might otherwise be sensitive to a low-digestibility carbohydrate food, adapt after a few days if they start with small portions and gradually increase their total consumption.

A GI study of nonadapted US children given 15, 25, and 35 g, eaten at one sitting, showed no statistically significant difference between isomalt and sucrose. In an adult study, intake up to 48 g, eaten throughout the day over a 12-week period, showed that amounts of isomalt up to that level were well tolerated.

To increase consumer awareness of this physiological aspect of sugar replacers, food legislation in some countries requires a statement on the label of products such as 'Excessive consumption may have a laxative effect.'

Safety Evaluation

The safety of isomalt was evaluated by the Joint Expert Committee on Food Additives (JECFA) of the WHO/FAO. In 1986, JECFA decided that it was not necessary to lay down a numerical acceptable daily intake, and therefore, an acceptable daily intake of 'not specified' was allocated. The most recent Codex Specification for isomalt was published in 1996. A number of national authorities have evaluated isomalt's safety during their approval process, and isomalt is now marketed in more than 80 countries worldwide.

Product Applications

A decade ago, sugar-free products, other than soft drinks and tabletop sweeteners, were consumed almost exclusively by people who avoided sugar

because they had diabetes. People who were not medically required to avoid sugar rarely purchased sugar-free products, because the taste was not sufficiently comparable with those sweetened with sugar. However, the isomalt-containing products available today taste so good that they are marketed to the growing number of people who simply want more healthful diets, as long as they do not have to sacrifice the pleasure of eating.

Isomalt has been used as a product ingredient in Europe and Asia since the early 1980s and in the USA since 1990. It is currently used in more than 80 countries worldwide in a wide range of confectionery, chocolate, baked goods, pharmaceutical, and functional products, including hard candies, lollipops, chewing gum, breath mints, cough drops, throat lozenges, chocolates, fudge, cookies, and wafers.

Several variants of isomalt are available. Standard isomalt ST is offered in different particle sizes, depending on the intended application. Isomalt GS is used in products that require optimum solubility such as coated products; this form also allows low process temperatures. Isomalt LM has a low-moisture content and is designed for premium no-added-sugar chocolate applications using standard processing and standard conching temperatures. Isomalt DC provides good compressibility, flowability, hardness, and stability for direct compressed tablets.

A wide range of deposited, stamped, or filled sugar-free sweets can be produced with isomalt. Existing processing equipment can be used for all applications, and usually, only minor formula and process parameter modifications are needed. The production is similar to that of candies based on sucrose/corn syrup, and only minor changes in parameters and processing are required. In either batch or continuous process production, differences from sucrose/corn syrup that must be taken into consideration include a lower solubility, higher boiling point, lower viscosity of the melt, and higher specific heat capacity.

Because of its low hygroscopicity, isomalt-based hard candies can be packed in flip-top carton boxes without secondary wrapping. When the water content in the finished product is below 2%, hard candies with a very good shelf-life are obtained. Pan-coated products also have a good shelf-life. All types of centers can be panned with isomalt. Depending on the consistency, however, it may be necessary to pregum centers to build up the coating over the smooth surface.

Because isomalt-containing pharmaceutical products, such as cough drops, have a very low moisture absorption, oxidation or hydration of active ingredients is reduced, and shelf-life is extended. Isomalt's minimal hygroscopicity makes it an especially useful ingredient when hydrolysis-proof ingredients are involved. Furthermore, isomalt's lower solubility allows a slower release of active ingredients when a pharmaceutical hard-candy-like product is sucked.

K

KETONE BODIES

C R Barnett and Y A Barnett, University of Ulster at Coleraine, Coleraine, County Londonderry, Northern Ireland

Introduction

The liver is the major organ associated with the processing, production, and export of glucose and fatty acids to support the energy requirements of the other tissues and organs in the body. Under certain physiological and pathophysiological conditions such as fasting and insulin-dependent diabetes mellitus (IDDM) respectively, the liver can produce significant quantities of acetoacetate and D-3-hydroxybutyrate (ketogenesis). These compounds enter the circulation where acetoacetate spontaneously decarboxylates, giving rise to acetone. These three substances are collectively known as ketone bodies (Figure 1).

Formation and Utilization of Ketone Bodies

Glucose is the primary source of respiratory fuel for the body. However, when circulating levels of glucose fall and cannot meet the energy requirements of the tissues, other energy stores are mobilized. Lipid provides the most important energy store within the body and can be mobilized through the action of lipase in the adipose tissues. The released fatty acids are transported to the liver and extrahepatic tissues where they are oxidized in the mitochondria to generate adenosine triphosphate. However, the increased supply of fatty acids to the liver results in an increased abundance of acetyl coenzyme A (CoA). As the concentration of acetyl CoA increases, ketone body production is initiated. The hydroxymethylglutaryl-CoA (HMG-CoA) pathway (Figure 2) is responsible for the production of acetoacetate and D-3-hydroxybutyrate. The initial step is the formation of acetoacetyl CoA from two molecules of acetyl-CoA catalyzed by acetoacetyl-CoA thiolase. The unfavorable equilibrium for this reaction is overcome by the acetoacetyl CoA being bound to the HMG-CoA synthase enzyme. A further molecule of acetyl CoA then reacts to form HMG-CoA which is the precursor for two pathways. HMG-CoA can be reduced through the activity of HMG-CoA reductase to form mevalonic acid, an intermediate in the pathway of steroid biosynthesis, or HMG-CoA can be cleaved by HMG-CoA lyase to form acetoacetate and acetyl CoA. An alternative route for the formation of acetoacetate involves the direct deacetylation of acetoacetyl CoA. However, the concentration of acetoacetyl-CoA in the liver is very low, whereas the Michaelis constant (K_m) of the acetoacetyl CoA deacetylase is high. D-3-hydroxybutyrate is produced from acetoacetate by the action of the enzyme D-3-hydroxybutyrate dehydrogenase (Figure 2), while acetone is produced from the spontaneous decarboxylation of acetoacetate in the blood. The concentrations of acetoacetate and D-3-hydroxybutyrate in the blood are in equilibrium with each other. The equilibrium is dependent on the mitochondrial redox state and can result in plasma ratios of D-3-hydroxybutyrate to acetoacetate concentrations of 1:1 to 10:1.

Many tissues can utilize ketone bodies, with the notable exception of the liver. Conversion of D-3-hydroxybutyrate and acetoacetate back to acetyl CoA involves the enzymes 3-oxoacid-CoA transferase and acetoacetyl CoA thiolase (Figure 3). The equilibrium of the transferase reaction is in favor of acetoacetate but that of the thiolase reaction is towards acetyl CoA. Thus the linking of the two reactions overcomes the unfavorable equilibrium of the transferase reaction. D-3-hydroxybutyrate is metabolized by conversion to acetoacetate catalyzed by D-3-hydroxybutyrate dehydrogenase and then via the reaction pathway outlined previously (Figure 3) to yield acetyl CoA.

Regulation of Ketogenesis

Two hormones are primarily responsible for the regulation of ketogenesis by the liver: glucagon and

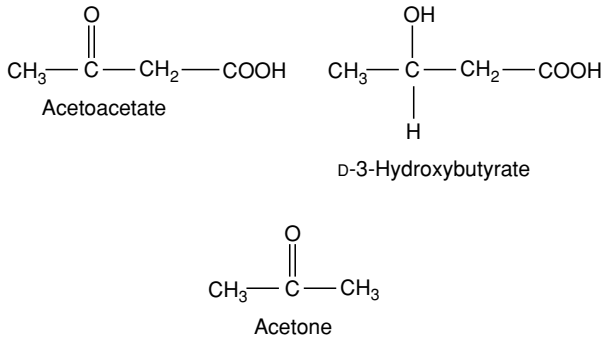

Figure 1 Chemical structures of the ketone bodies. Reproduced from Ketone Bodies, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

insulin. Both hormones are produced by the pancreatic islets of Langerhans which respond to the fluctuations in circulating nutrient concentrations by adjusting the secretion of glucagon (from the pancreatic A cells) or insulin (from the pancreatic B cells) into the circulation. The plasma ratio of these two hormones plays a central role in the regulation of glucose metabolism by the liver and ketogenesis (Figure 4). In the fed state, the ratio of insulin to glucagon is high and glucose is stored as glycogen and oxidized via glycolysis and the tricarboxylic acid cycle, producing a range of biosynthetic intermediates and adenosine triphosphate. The presence of the biosynthetic intermediates, in particular malonyl CoA (used for fatty acid biosynthesis), inhibits the transport of fatty acids into the mitochondria, thereby preventing fatty acid oxidation. As such, ketogenesis is prevented when there is a plentiful supply of plasma glucose for oxidation by the tissues (Figure 4).

During periods of food deprivation the ratio of circulating insulin to glucagon falls, causing activation of glycogenolysis, a reduction in the activity of glycolytic enzymes, and reduced activities of acetyl CoA carboxylase. The decreasing concentration of malonyl CoA results in activation of the

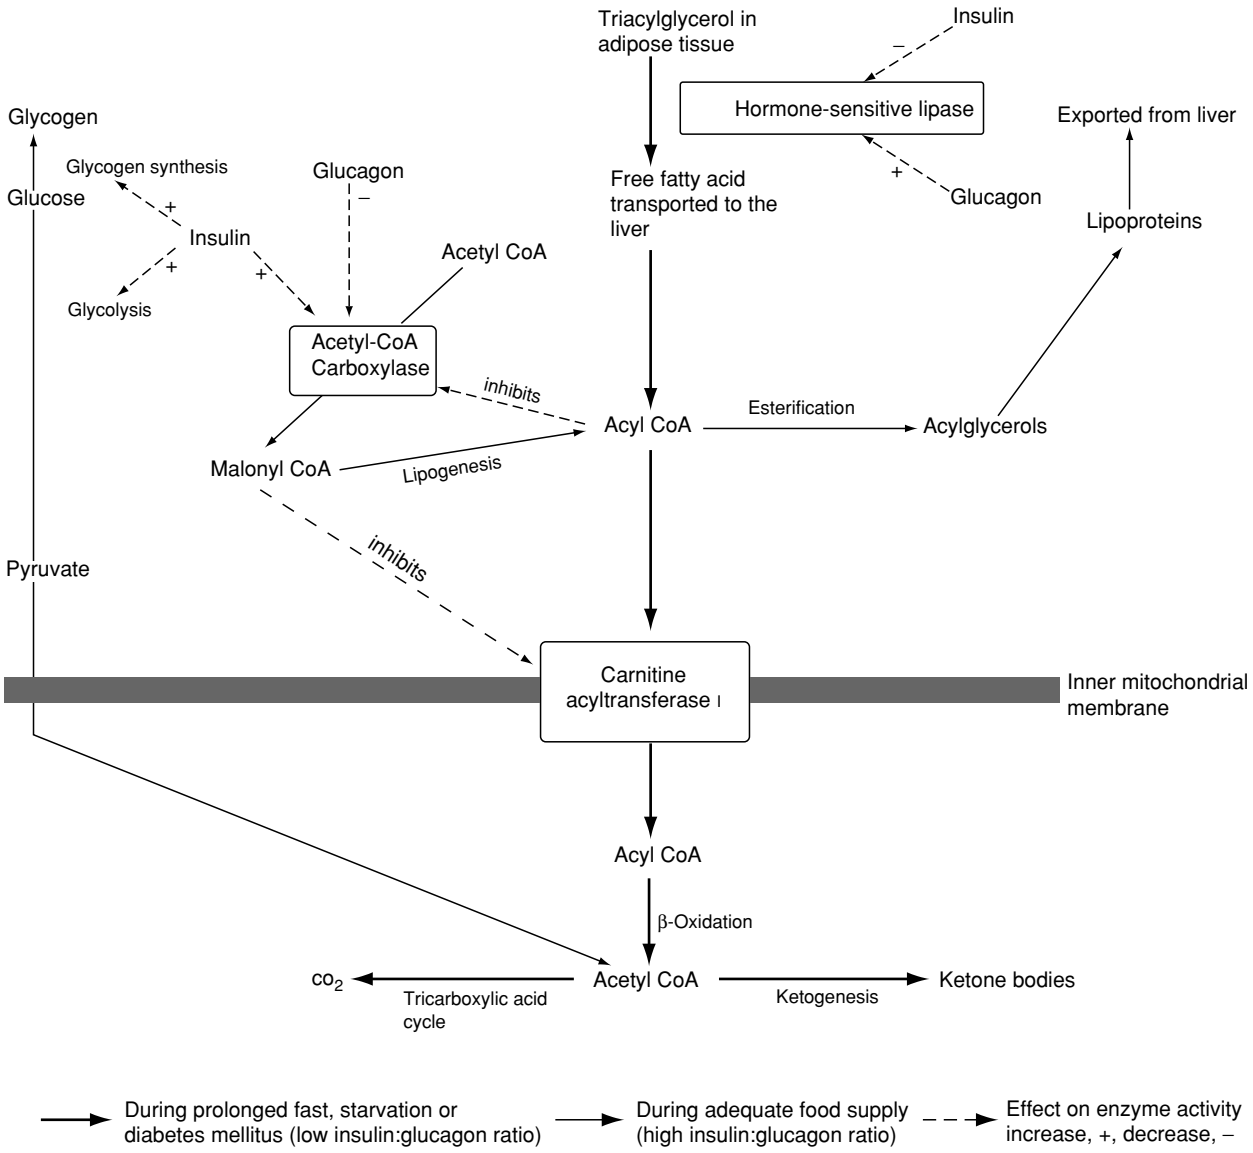

Figure 4 Regulation of ketogenesis in the liver. CoA, coenzyme A. Reproduced from Ketone Bodies, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

mitochondrial transport system, allowing free fatty acids to be transported into the mitochondria for oxidation. As the concentration of acetyl CoA in the mitochondria of the liver rises, ketogenesis is stimulated. In the adipose tissue, glucagon stimulates adenylate cyclase which in turn activates lipases that convert the stored triglyceride into free fatty acids. The increased delivery of these fatty acids to the liver results in increased ketogenesis, the rate of which is primarily governed by the delivery of the fatty acids (Figure 4).

When a fast is terminated, the increased concentrations of nutrients in the plasma cause insulin release from the endocrine pancreas. The rising insulin-to-glucagon ratio causes cessation of adipose tissue lipolysis, and plasma free fatty acid concentrations rapidly fall. Insulin also acts on the tissues, causing a reversion to glucose utilization. In the liver, glucose output is reduced, glycogen stores are repleted, lipogenesis is reinstated, and ketogenesis inhibited.

Physiological Ketosis

A normal balanced diet provides sufficient nutrient content to satisfy the glucose requirements of the brain and other tissues. Under these conditions ketogenesis by the liver is negligible, with plasma ketone

body concentrations generally less than 0.5 mmol l^{-1}. However, the ability of an individual to survive periods of food deprivation normally relies on a complex hormonal and biochemical interaction that insures the appropriate interorgan redirection and utilization of major fuels.

In the early stages of a fast there is a shift in liver metabolism from glucose storage to glucose production, coupled with other metabolic alterations that conserve the glucose released for the maintenance of brain and central nervous system function. Following an overnight fast, most of the glucose produced by the liver is utilized by the tissues with an obligatory requirement for glucose as the major fuel. At this stage, tissues such as skeletal muscle are primarily using nonesterified fatty acids (NEFA) as their major fuel supply. Muscle NEFA oxidation causes a decrease in glucose uptake and subsequent glucose metabolism by muscle cells and glucose transport across the muscle cell membrane is decreased.

Reduction in the plasma glucose concentration as a result of a prolonged fast or food deprivation will result in the production of glucose from noncarbohydrate precursors. Fatty acids are mobilized from the adipose tissue as the fast takes place and gluconeogenic and ketogenic pathways are activated in the liver. The plasma glucose concentration may fall significantly with the concomitant increase in plasma fatty acids and ketone bodies to about five fold and 20-fold, respectively. As more than 99% of plasma fatty acid is complexed with albumin, very little is free to diffuse into the interstitial spaces, limiting their utilization by tissues. However, ketone bodies are soluble in aqueous medium and the concentration in the interstitial fluid will be comparable with that in the plasma (2–3 mmol l^{-1}) during prolonged fasting. As the concentration of glucose in the interstitial fluid under these conditions may be around 4–5 mmol l^{-1}, the ketone bodies are oxidized in preference to glucose and free fatty acids and sparing glucose for use by the brain and central nervous system.

The pancreatic B cells remain responsive to the plasma nutrient concentration and facilitate the maintenance of plasma fatty acid concentrations such that the plasma ketone body concentration does not usually rise to such an extent that ketone bodies are excreted in the urine.

Pathological Ketosis

IDDM is probably the best-known disease associated with life-threatening ketosis if not treated by insulin therapy. IDDM is associated with autoimmune destruction of the pancreatic islets of Langerhans. This results in very low or undetectable levels of circulating insulin in the plasma and is often also associated with increased plasma concentrations of glucagon. As described previously, the alteration of the insulin-to-glucagon ratio has significant effects on the metabolism of the liver and other tissues. The increased relative or absolute levels of glucagon increase the rate of lipolysis in the adipose tissue, resulting in increased circulating levels of free fatty acids. The liver responds to this alteration in the insulin-to-glucagon ratio by increasing glucose synthesis and release. As insulin-stimulated glucose uptake by extrahepatic tissues is decreased, the circulating glucose concentration increases and hyperglycemia occurs. Lipid and glycogen synthesis are inhibited and there is increased oxidation of the free fatty acids being delivered to the liver. In physiological ketosis there is a regulated release of fatty acids from the adipose tissue allowing tight regulation of the plasma ketone body concentrations. However, in IDDM this regulation is nonfunctional due to the autoimmune destruction of the pancreatic B cells. As a result, hyperlipidemia and hyperketonemia occur and, as the concentration of ketone bodies continues to increase above a threshold level of around 7 mmol l^{-1}, the kidneys begin to excrete the excess ketone bodies into the urine.

Metabolic Acidosis

Metabolic acidosis is caused by a decrease in the concentration of bicarbonate ion in the plasma with little or no change in the carbonic acid concentration. The condition is frequently associated with uncontrolled IDDM where it is caused by the presence of high plasma concentrations of ketone bodies. Acetoacetate and 3-hydroxybutyrate are relatively strong acids and dissociate in the plasma, giving rise to H^+ and the corresponding anion. The H^+ ions are effectively buffered by plasma bicarbonate, giving rise to H_2CO_3, which breaks down to yield CO_2 and H_2O. The increase in plasma CO_2 concentration stimulates the respiratory center, producing rapid and deep breathing, thereby excreting the excess CO_2 by way of the lungs. This is an attempt by the body to reestablish the normal CO_2 tension in the blood. As the kidney is the major organ responsible for the maintenance of the acid–base balance, it is also employed to help correct the imbalance caused by the presence of the ketone bodies. The anionic components of the dissociated ketone bodies are filtered in the kidney, each with a cation (principally a sodium ion), thus maintaining electrical neutrality. The renal tubular cells secrete H^+ into the filtrate while reabsorbing one sodium ion and one bicarbonate ion for each H^+ secreted. The energy-dependent H^+ carriers in

the tubular cells are capable of secreting H^+ against a concentration gradient until the urine becomes approximately 800 times more acidic than the plasma (approximately pH 4.5). At this point the concentration gradient becomes too great for the secretory process to continue. For further H^+ secretion to proceed, the majority of the secreted H^+ must be buffered in the tubular fluid. This is achieved in the first instance by phosphate. However, phosphate is present in the urine as a result of dietary excess and the buffering capacity of urinary phosphates is quickly exceeded in severe acidosis. Under these circumstances the tubular cells secrete ammonia (NH_3), which combines with the urinary H^+, giving rise to NH_4. In this way larger amounts of H^+ can be excreted into the urine before the concentration gradient becomes too large for the secretory mechanism to operate. However, when the acid load is very large, as in diabetic acidosis, this occurs and the filtered cations are lost with the ketone bodies. The concomitant electrolyte and water loses lead to dehydration, hypovolemia, hypotension, and subsequent death, if not treated.

Diabetes and Drug Metabolism

Numerous studies have now demonstrated that IDDM in animals and humans is associated with the alteration of drug metabolism by the liver. The cytochrome P450-dependent mixed-function oxidase system is the most important enzyme system involved in the metabolism of plethora of drugs and chemicals. IDDM is associated with alterations in the levels and activities of some of these cytochrome P450 enzymes and ketone bodies have been shown, at least in part, for the alterations observed. Ketone bodies appear selectively to induce some of the cytochrome P450 enzymes, and this has been shown to result in alteration of metabolism of some drugs in humans. Whether these alterations in clinically controlled IDDM individuals over prolonged periods have any significant therapeutic consequences has yet to be determined.

KIWIFRUIT

A R Ferguson and R Stanley, HortResearch, Auckland, New Zealand

Introduction

Kiwifruit are enjoyable to eat. They are also a good source of minerals, of dietary fiber, and they contain a most effective laxative. Their outstanding nutritional quality is their very high content of vitamin C. There is very little, if any, loss of nutritional quality during long-term storage or ripening even if the overall appeal and quality of the fruit deteriorates. In particular, kiwifruit that are still fit to eat are likely to be an excellent source of vitamin C. Their main disadvantage is that they can cause allergic or inflammatory responses in some consumers. Kiwifruit account for perhaps only 1% of the total world production of fresh fruit. Nevertheless they are an important fruit crop. They have rapidly become popular amongst consumers, they are novel and new cultivars are now coming on the market, they are available in a range of colors and flavors, and they can mostly be stored for remarkably long periods under refrigerated and controlled-atmosphere (CA) conditions. (*See* **Allergens**; **Antioxidants**: Natural Antioxidants; **Ascorbic Acid**: Properties and

Determination; **Controlled-atmosphere Storage**: Effects on Fruit and Vegetables; **Dietary Fiber**: Properties and Sources; **Food Intolerance**: Food Allergies; **Fruits of Temperate Climates**: Commercial and Dietary Importance.)

What are Kiwifruit?

Kiwifruit are amongst the most recently domesticated of all fruits. Although the term 'kiwifruit' has traditionally been restricted to cultivars of *Actinidia deliciosa* (A. Chev.) C.F. Liang et A.R. Ferguson, the name is now being extended to include cultivars of the closely related species, *A. chinensis* Planch. Fruit of this latter species have recently appeared on the international market: they are still recognizably kiwifruit, even though they are much less hairy, the fruit shape can be different, the skin may be a different color, and the internal flesh can be yellow instead of green. Fruit of other *Actinidia* species, such as *A. arguta* (Sieb. et Zucc.) Planch. ex Miq. are also being commercialized. Although they are very different in appearance to the usual kiwifruit, being much smaller and with smooth green skins, it is likely that they too will eventually be commonly referred to as kiwifruit. We have therefore included any species within the genus *Actinidia* under the term 'kiwifruit.'

The genus is widespread throughout Asia, with its center of origin in China. Plants of *Actinidia* species were first grown outside Asia during the last decades of the nineteenth century. Commercial orchards of *A. deliciosa* were first established in New Zealand about 1930 and the very first commercial plantings of *A. chinensis* outside China have only been established during the past five years.

World Production

The principal areas of kiwifruit production are located approximately between the latitudes 25° and 45°. Kiwifruit are deciduous, temperate plants and they require a period of winter chilling for adequate budbreak and flowering. They are susceptible to damage from spring and autumn frosts and, depending on the species and cultivar, require a long frost-free growing period of at least 7 or 8 months (about 220 days). They require shelter from strong winds and have a high demand for water: irrigation must be sufficient to supplement natural rainfall to between 800 and 1200 mm of water throughout the growing season.

There are extensive natural resources of kiwifruit in China and appreciable quantities of fruit (perhaps 100 000 tonnes) are collected from the wild each year. China also has the greatest commercial plantings of kiwifruit – about 50 000 ha. Outside China, there are about 70 000 ha planted – approximately 20 000 ha in Italy, 12 000 ha in New Zealand and 8000 ha in Chile. Many of these plantings, particularly in China, are still not mature and yields are therefore increasing. Production in the various countries also varies with climatic conditions each year. In 2001, Italy was producing around 350 000 t of kiwifruit, New Zealand 250 000 t, and China and Chile each about 150 000 t per annum.

The kiwifruit industries of New Zealand, Chile, and Italy are dependent on exports and these industries expanded largely to meet external demand. Thus, 85–90% of the kiwifruit produced in New Zealand are exported each year and Chile and Italy each export about 75% of the fruit they produce. China is quite different and nearly all the kiwifruit it produces are consumed within the country: exports are negligible. However, it is predicted that Chinese exports of kiwifruit may soon be significant in world trade. (*See* **Fruits of Temperate Climates**: Commercial and Dietary Importance.)

Kiwifruit Cultivars

In most countries with commercial kiwifruit plantings, only *A. deliciosa* has been grown, and 'Hayward' is the only fruiting cultivar planted along with its corresponding males. (All *Actinidia* species are dioecious, with both male and female vines required for fruit production.) 'Hayward' has therefore become the standard cultivar of international commerce in kiwifruit, accounting for more than 95% of the kiwifruit traded. This reliance on a single cultivar in most parts of the world is most unusual. Such reliance has advantages in that it facilitates standardization amongst suppliers from different countries. There are, however, also disadvantages in that standardization can lead to greater competition in individual markets and makes branding more difficult. 'Hayward' is such a good cultivar, and responds so well to storage, that it is likely to remain important for many years yet.

Kiwifruit plantings in China are much more diverse – approximately 75% in cultivars of *A. deliciosa* and 25% in *A. chinensis*. The cultivar 'Qinmei' (*A. deliciosa*) accounts for about 40% of the total plantings and is therefore the second most widely planted kiwifruit cultivar in the world after 'Hayward'. Six cultivars of *A. deliciosa* and seven of *A. chinensis*

together make up about 85% of all Chinese kiwifruit plantings.

One cultivar of *A. chinensis*, 'Hort16A', bred in New Zealand from germplasm introduced from China, is now being planted in New Zealand (about 2000 ha in 2001) and in California, Italy, and Japan. It is the first cultivar of *A. chinensis* to have been grown commercially outside China but it is likely that other cultivars, selected in China itself, will soon be grown commercially in other countries.

The Structure of Kiwifruit

The kiwifruit is a berry: that is, it has a large number of seeds embedded in fleshy, edible tissue. The fruit develops after pollination from the lower parts of numerous carpels (usually more than 30) which have fused to form a syncarpous, superior ovary. Each carpel has two rows of 10–20 ovules attached to the central axis. If pollination is adequate, a fruit can thus contain 1000 or more seeds.

Fruit of large-fruited selections of *A. chinensis* and *A. deliciosa* typically weigh on average about 100 g but fruit of many of the other species are much smaller, e.g., those of *A. arguta* average between 10 and 20 g. The exterior surface of the fruit differs according to the species and the cultivar. Fruit of *A. deliciosa* (e.g., 'Hayward') are brown and densely covered with persistent, long, stiff hairs, although these are largely lost during commercial grading and packing. Fruit of *A. chinensis* (e.g., 'Hort16A') are light-brown or greenish and are covered with sparse, much softer hairs, rather like the down of a peach. Fruit of some species, e.g., *A. arguta*, lack obvious hairs and their edible skins are smooth and polished.

Internally, the fruit are very attractive with dark seed in a green to dark-green flesh (*A. deliciosa*) or flesh which ranges from green to lime-green to a clear golden-yellow (*A. chinensis*). In both species there may also be attractive red pigmentation in the inner pericarp. The external appearance and the fruit flesh of some species change color during ripening.

The bulk of the outer pericarp consists of thin-walled parenchyma cells, variable in size. The cells are loosely organized and there can be large intercellular spaces. Nevertheless, fruit are reasonably solid ('Hayward' density, *c.* 1.03 Kg m^{-3}). There are also many mucilage-containing cells with crystals of calcium oxalate. Chloroplasts are generally similar to those found in leaves. In the inner pericarp, the seeds are suspended in a mucilaginous matrix in the locules. Chloroplasts of the inner pericarp are very different in appearance and there are many raphide cells containing calcium oxalate. The central core of the mature fruit is formed of homogeneous, large parenchyma cells, although there is often a hard, woody spike at the stalk end.

Following pollination, there is a phase of rapid growth for the first 8 or 9 weeks, during which the fruit reaches half to two-thirds final volume, then about 3 weeks of much slower growth followed by another period of growth, which is initially rapid but then decreases. During the first stage of fruit growth, there is rapid cell division in the outer and inner pericarp and the central core. Cell division in the pericarp stops after 3–4 weeks and most of the subsequent increase in fruit size is due to cell enlargement as the parenchyma cells of the fruit are 10–15 times the size of those in the ovary wall. Cell division may continue for much longer in the central core, although at a much reduced rate.

The Chemical Composition of Kiwifruit

Only fruit of *A. deliciosa* have been systematically analyzed in any detail and most results are for the cultivar 'Hayward'. There is considerable variation in the published values and those given in Table 1 should be considered only as indicative. Individual fruit from a single vine can vary greatly in composition and many factors such as growing conditions or postharvest treatment can affect some fruit constituents. The ripeness of fruit will obviously also affect the proportions of the various carbohydrates. (*See* **Fruits of Temperate Climates**: Factors Affecting Quality; **Ripening of Fruit**.)

Table 1 Approximate chemical composition of 'Hayward' (*Actinidia deliciosa*) kiwifruit

Proximates	*g 100 g^{-1} fresh weight edible portion*
Total solids	15–20
Protein	1
Lipids	0.5
Carbohydrate	15
Energy	60 kcal
	250 kJ
Minerals	*mg 100 g^{-1} fresh weight*
Calcium	40
Chloride	35
Iron	0.4
Magnesium	25
Phosphorus	30
Potassium	300
Sodium	5
Vitamin C	80 mg 100 g^{-1} fresh weight

Proteins, Lipids, and Amino Acids

Kiwifruit, like most other fruit, contain insignificant amounts of proteins, lipids, and amino acids.

Carbohydrates

Ripe kiwifruit contain almost no starch as it has largely been converted during ripening into soluble sugars, mainly glucose, smaller quantities of fructose, and only minor amounts of sucrose. Carbohydrates in kiwifruit would normally meet only a very small part of the daily requirements. (*See* **Starch**: Structure, Properties, and Determination.)

Minerals

Kiwifruit are typical fruit, being a good source of potassium, with a high potassium-to-sodium ratio. They are also a useful source of magnesium, although a 100-g serving supplies less than 10% of the recommended dietary allowance (RDA) for an adult male. Other minerals are not sufficient to make a significant contribution to the diet. Refer to individual minerals.

Vitamin C

Vitamin C is currently recognized as the single most important nutrient in kiwifruit. 'Hayward' kiwifruit typically contain about 85 mg ascorbate $100\,g^{-1}$ fresh weight of edible portion. The vitamin C content can vary with fruit size, position on the vine, the season, and growing location. Many kiwifruit are eaten after having remained in cool store for long periods and it is therefore a great advantage that comparatively little vitamin C is lost from kiwifruit during storage or ripening. A 'Hayward' kiwifruit stored for 6 months at 0 °C and then ripened will still contain at least 90% of the vitamin C present in the fruit at harvest. Most other selections of *A. chinensis* or *A. deliciosa* likewise show little or no loss of vitamin C during storage over extended periods. It is therefore very likely that when consumers buy or actually eat kiwifruit, the fruit contain about as much vitamin C as they did at harvest. Assuming usual storage conditions and sensible handling, kiwifruit that are acceptable eating are also likely to be an excellent source of vitamin C.

Kiwifruit contain more vitamin C than almost all other fruit: on a fresh-weight basis they typically contain 50% more vitamin C than an orange, five or six times as much as a banana, and 10 times as much as an apple. Only a few readily available fruit, such as blackcurrants, are richer in vitamin C.

Recommended daily requirements (USA) for vitamin C range from 30 mg for a child to 90 mg for a lactating mother. These requirements can easily be met by two medium-sized peeled 'Hayward' kiwifruit. Any new selections of *A. chinensis* and *A. deliciosa* are likely to contain as much or even more, as 'Hayward' contains only relatively modest amounts of vitamin C compared to the rest of the genus *Actinidia*. 'Hort16A', at present the only commercially available fruit of *A. chinensis*, outside of China, usually contains 30–40% more vitamin C than 'Hayward' and many of the commonly grown cultivars in China contain at least twice as much. Even these levels are an order of magnitude less than those in fruit of *A. eriantha* Benth. or *A. latifolia* (Gardn. et Champ.) Merr. which can contain an astonishing 1 or 2% fresh weight of vitamin C. (*See* **Ascorbic Acid**: Properties and Determination; **Dietary Requirements of Adults**.)

Other Vitamins

One kiwifruit could provide 10–20% of the daily requirements for folic acid. Folic acid is readily available in a wide variety of foods and is especially rich in offal and raw leafy vegetables but easily destroyed by cooking. Fresh fruit are therefore a useful source. (*See* **Folic Acid**: Properties and Determination.)

Most foods contain vitamin E but it is seldom found in fruit or vegetables without significant fat content. It is likely, although not yet confirmed, that the vitamin E in kiwifruit is present in the seed and that these seeds will survive passage through the gut, thus making any vitamin E present unavailable. (*See* **Tocopherols**: Properties and Determination.)

The amounts of other vitamins are small in terms of human daily requirements and are similar to those found in many other fruit and vegetables. These vitamins are also available in a wide range of foods.

Pigments

Green-fleshed kiwifruit (e.g., *A. deliciosa* 'Hayward') are amongst the very few fruit that are still green when ripe. This color is due to the presence of chlorophyl and, although many other common fruit are green during the early stages of development, they lose their chlorophyl during subsequent maturation and ripening. The color of green kiwifruit is one of their most appealing characteristics. Chlorophyls, however, have very little direct nutritional value. (*See* **Chlorophyl**.)

Fruit of other kiwifruit cultivars or species may be yellow, orange, or red when ripe, and these colors are due to their content of carotenoids and anthocyanins. Carotenoids could contribute usefully to vitamin A requirements. (*See* **Colorants (Colourants)**: Properties and Determination of Natural Pigments.)

Oxalate

Kiwifruit contain appreciable but not exceptional amounts of oxalate. At least half of this oxalate is

complexed as highly insoluble calcium oxalate, mostly in the form of raphides (needle-like crystals), and this would render much of the calcium present in the fruit unavailable. The levels of oxalate in kiwifruit do not constitute a nutritional problem, assuming normal consumption, as some other common foods, e.g., spinach, contain much higher levels. Eating some processed 'Hayward' kiwifruit products such as nectars, dried slices, or fruit leathers, can cause irritation of the mucous membranes of the mouth. This is due, at least in part, to the mechanical irritation of the membranes by the oxalate raphides. In the fresh fruit, the raphides are embedded in mucilage and therefore do not cause any appreciable irritation. The shape of the raphides varies with *Actinidia* species and this could affect the amount of irritation caused.

Actinidin

Kiwifruit contain large amounts of the highly active proteolytic enzyme actinidin (EC 3.4.22.14) similar to the proteases found in other fruits such as pineapple, figs, or papaya. Actinidin is ideal as a meat tenderizer but can cause problems if fresh fruit are incorporated into gelatine-based jellies (which then do not set) or are mixed with dairy products.

Actinidin, at the levels found in 'Hayward' kiwifruit, does not seem to be a major health hazard for most people, but has been associated with allergic responses to kiwifruit. Actinidin can cause damage to the lips (especially at the corners of the mouth) but only if very large quantities of fruit are eaten. Peeling large numbers of fresh fruit can result in skin loss if hands are not protected. Other *Actinidia* cultivars need to be checked to insure that they do not contain appreciably higher levels of actinidin, capable of causing problems. There is no published evidence on the postulated beneficial role of actinidin in gut health.

Dietary Fiber

Kiwifruit contain about 2–3% dietary fiber due to pectins and other oligosaccharides and polysaccharides that are not broken down and absorbed in the small intestine. A 100-g serving of kiwifruit will therefore supply about 10% of the recommended daily requirement. The relative contributions of the various polysaccharide fractions in kiwifruit to dietary fiber effects such as stool-bulking and laxative action are not yet defined. (*See* **Dietary Fiber**: Properties and Sources.)

Laxatives

Kiwifruit are notorious for being laxative and individuals vary in their response. Consumption of large numbers of fresh fruit could therefore have an excessively vigorous purgative effect and the laxative effect can limit the number of kiwifruit some people are able to eat in any one day. Fresh kiwifruit or dried products are often used to maintain regularity in bowel movement, especially for older and sedentary people such as hospital patients. Although the laxative action is not in doubt, there is as yet no definitive information on the mode of action or the compounds responsible. (*See* **Elderly**: Nutritional Management of Geriatric Patients.)

Allergens

Kiwifruit contain allergens that can cause allergic responses in susceptible consumers. The response can include swelling and itching of the lips and tongue, swelling of the tongue and throat which can make breathing difficult, rashes, stomach pains and vomiting, itchy nose and eyes, or, at worst, anaphylactic shock requiring urgent medical attention. Fortunately, extreme allergic responses to kiwifruit are not frequent. Kiwifruit allergy is often cross-reactive with other common allergies such as to pollens, particularly birch pollen, latex, housedust mites, and some other tropical fruit. Actinidin, the most abundant protein in kiwifruit, has been postulated as a major cause of kiwifruit allergy but it is not known whether kiwifruit are the primary cause of the allergic reactions, or are secondary to exposure to other allergens. (*See* **Food Intolerance**: Food Allergies.)

Possible Medical Uses

Early Chinese pharmacopeia from the Tang Dynasty onwards list a variety of medicinal uses for kiwifruit or extracts from other parts of the plant. Various *Actinidia* species have long been used in traditional Chinese and Japanese medicine but their efficacy has yet to be fully confirmed. The anticancer and antimutagenic potential of the fruit are now being studied. The antioxidant capacity of kiwifruit likewise requires more study.

Myoinositol is a major carbohydrate in some *Actinidia* species and in ripe 'Hayward' fruit comprises about 6–7% of the free sugars. Myoinositol supplementation has been suggested for some medical conditions, but the supplementary amounts proposed would require consumption of 20 or more kiwifruit every day.

Handling, Storage, and Marketing

Actinidia chinensis and *A. deliciosa* flower in mid to late spring and the fruit are ready for harvest nearly 6 months later in late autumn. Harvest maturity is

taken as the stage at which fruit can be harvested from the vine and yet continue to develop to give an acceptable final eating quality which meets consumers' expectations. Fruit that are picked too early often have a poor color and flavor when ripened, a shorter storage life, and a shorter shelf-life when taken out of storage. However, fruit soften as they remain on the vine and if they are picked too late they may be not firm enough for handling, grading, and subsequent storage. Harvest maturity cannot be gaged by the external appearance of the fruit, and if there are no heavy frosts or bird attack, the fruit can hang on the vines until budbreak the following season.

Changes in the chemical composition of the fruit as they mature on the vine are therefore used to determine when fruit may be safely picked. Maturity values are taken on representative samples of fruit from vines of an individual maturity area, an area in which the vines are presumed to be similar through uniformity of age, management, and growing environment. The harvest maturity of 'Hayward' kiwifruit is usually assessed using the soluble solids content of the fruit as determined using a refractometer. As the fruit mature, the soluble solids content increases, largely as a result of the conversion of starch to sugars. In New Zealand, a minimum maturity index of 6.2 Brix is normally used following a standardized measurement procedure: in other countries, a minimum of 6.5 Brix has been set. Dry matter has also been used as an additional harvest index attribute. Other parameters may be more appropriate for different cultivars or different environments. The fruit of 'Hort16A', for example, are promoted in the marketplace for their yellow fruit flesh, but the chlorophyl in the pericarp is lost relatively late in the season and the harvest maturity indices currently recommended therefore include attributes such as soluble solids content (Brix), firmness, and hue angle.

Although kiwifruit are relatively firm when picked, they are still easily damaged if handled roughly. Fruit of 'Hort16A' are particularly prone to damage because their sharp 'beaks' can cause small wounds which allow the entry of fungal rots. Fruit are therefore picked by hand and grading equipment is designed to minimize injury.

Kiwifruit are seldom marketed immediately after harvest and most will be sold only after a period in storage. *Botrytis* stem-end rot was the cause of much of the losses of stored kiwifruit, but curing of the fruit can reduce the severity of rots. Fruit are not therefore cooled immediately after harvest but are left at ambient temperature for several days. Curing presumably allows the picking scar or wound to dry out, making entry of *Botrytis* less likely. Fruit may then be stored in bulk, either in conventional coolstores or in CA stores, or packed immediately into the consumer packs which are then stored until required. Traditionally, fruit were packed into wooden trays containing 3.6 kg of fruit, but a variety of different-sized packs is now common.

The aim in storage is to reduce fruit temperatures and respiration to slow the rate of ripening. This is achieved with kiwifruit by holding them at as low a temperature as possible ($0 \pm 0.5\,^{\circ}C$). Fruit will freeze at about $-1.5\,^{\circ}C$. The fruit may be stored for up to 6 or 7 months so to prevent the shriveling caused by water loss, fruit are held in their packs within plastic film liners and maintained at a relative humidity greater than 95%.

Kiwifruit are very sensitive to ethylene and even low levels of ethylene will promote ripening. It is therefore critical that kiwifruit not be exposed to ethylene from other fruits, e.g., apples, to ethylene from ripening kiwifruit, or ethylene produced in the exhausts of petrol-driven machinery. Cool stores are routinely flushed with fresh air and there is increasing use of ethylene scrubbers to remove any traces of ethylene produced. Although 'Hayward' kiwifruit survive lengthy periods in cool store, their storage life and their quality can be enhanced even further by CA storage and ethylene scrubbers are then essential. (*See* **Controlled-atmosphere Storage: Effects on Fruit and Vegetables**; **Ripening of Fruit**.)

Fruit ripened after a few weeks in storage seem to be of better quality than those ripened immediately after harvest, but during prolonged storage, the processes of ripening occur slowly over a long period: fruit soften and there may be some loss of eating quality. The intensity of the fruit flesh color may diminish and there is a loss of volatile flavor compounds.

Fruit that are newly harvested and stored for only a brief period may reach consumers before they are fully ripe, and an inexperienced customer trying to cope with a rockhard kiwifruit is unlikely to repurchase. About one-fifth of the New Zealand crop is therefore treated with ethylene either on board vessels or at the destination before being distributed to the markets. This insures that consumers are able to buy 'ready-to-eat' fruit. This does, of course, necessitate much more careful stock management.

'Hayward' (green) kiwifruit are now available in many markets throughout the year. For half the year, supplies will come from the big southern hemisphere producers, Chile or New Zealand, and for the other half of the year from northern hemisphere countries such as France, Greece, Italy, or the USA. New Zealand is so far the only large supplier of yellow kiwifruit to international trade, but as cultivation of

'Hort16A' or other *A. chinensis* cultivars starts in the northern hemisphere, they too will be available for much of the year.

'Hayward' kiwifruit store remarkably well. Most other cultivars of *A. chinensis or A. deliciosa* have shorter storage lives. Some other *Actinidia* species are being grown on a small scale, e.g., *A. arguta*, but their fruit generally have a much more restricted storage life.

Industrial Utilization

Processing of kiwifruit into high-quality products is a challenge, as much of the uniqueness of their subtle flavors is lost. Furthermore, if green kiwifruit, such as *A. deliciosa* 'Hayward', are processed, the bright-green color of the chlorophyl is usually modified to an unattractive, sludgy brown. Most juice or nectar products or canned kiwifruit products do not retain their green color unless frozen without heat treatment. Drying likewise usually results in a loss of flavor, green color, and vitamin C. It is therefore not surprising that in most countries kiwifruit are grown primarily for the fresh-fruit market and only fruit that do not reach export quality standards are processed. Extraction of chemical byproducts from waste fruit remains a possibility.

In China, processing of kiwifruit is relatively more important since storage and transport systems for fresh fruit are still being developed. Between 20 and 30% of all Chinese kiwifruit production is currently processed into products such as fruit juices, jams, wines, and spirits. Yellow-fleshed fruit of *A. chinensis* are often preferred for processing because they are sweeter and the color withstands processing better.

Kiwifruit in the Future

Kiwifruit are amongst the most recent of all domesticated fruits. *Actinidia deliciosa* has been cultivated for just on a century, *A. chinensis* for little more than 20 years. Although the kiwifruit currently available commercially throughout the world are promoted for their contribution to health, they probably do no more than set a minimum standard nutritionally for kiwifruit, even if these standards are higher than for most other fruits. The variation within the genus *Actinidia* indicates that it is realistic to predict the development of new kiwifruit cultivars with enhanced nutritional qualities but containing smaller amounts of the compounds having potentially adverse effects on human health.

KWASHIORKOR

C Leitzmann, Justus-Liebig University, Giessen, Germany

Background

Kwashiorkor is a nutritional disease, common in rural areas of developing countries, and it primarily affects children in the second year of life. This typical disease of the weaning period is associated with a diet based on starchy, low-protein staple foods, such as cassava, sweet potatoes, and bananas.

The term 'kwashiorkor' was used in the Gold Coast area of West Africa (present-day Ghana) and describes the 'disease of the weaned child when the next baby is born.' Cecily Williams introduced this term into modern medicine in 1933.

The realization of the close interactions between protein and energy deficiencies led to the introduction of the term 'protein-energy malnutrition' (PEM), which describes a range of clinical disorders in which marasmus and kwashiorkor are the two poles. Between these, there are many forms, with different clinical features, depending on the varying combination of deficiencies of protein, energy, and other nutrients, together with associated infections.

Etiology, Clinical Features, and Physiological Effects

Etiology

Although dietary protein deficiency plays an important role in the causation of kwashiorkor, this alone does not explain the etiology. Kwashiorkor is a complex multifactorial condition in which geographic, climatic, educational, infective, psychological, cultural, agronomical, nutritional, and other factors, frequently in combination, are involved. Kwashiorkor can be considered as the end point of a combination of these adverse factors, in which the body is not able to adapt to these changed conditions, and the characteristic clinical features develop. (*See* **Protein:** Deficiency.)

Clinical Features

The clinical picture can vary, depending on the degree of protein deficiency, accompanied vitamin or mineral deficiencies, age of onset and duration of deficiency, genetic and other factors. Figure 1 shows the typical signs of kwashiorkor.

Edema Edema is the cardinal sign of kwashiorkor and must be distinguished from the edema caused by other diseases such as hookworm infestation or beriberi. Edema causes tissue to swell and may be distributed over the whole body, but it usually appears first in the dorsum of the feet and lower legs. Later, it can also be detected in other parts of the body, including hands, forearms, back, upper extremities, and, in severe cases, in the face, especially the cheeks and around the eyes. Together with increased locally deposited fat in obese variants of kwashiorkor, the edema of the face results in the so-called 'moon-face.' The edema fluid generally represents 5–20% of the body weight. Ascites and other effusions into serous cavities are a late manifestation of edema and may be attributable to the presence of an infection.

Hair changes Kwashiorkor can be accompanied by striking dyspigmentation and changes in the texture of the hair, which can vary greatly from one part of the world to another. Thus, in African children, the dyspigmentation causes a change from black to red, blonde or light brown. In South American children, the 'flag sign,' an appearance of alternating streaks of

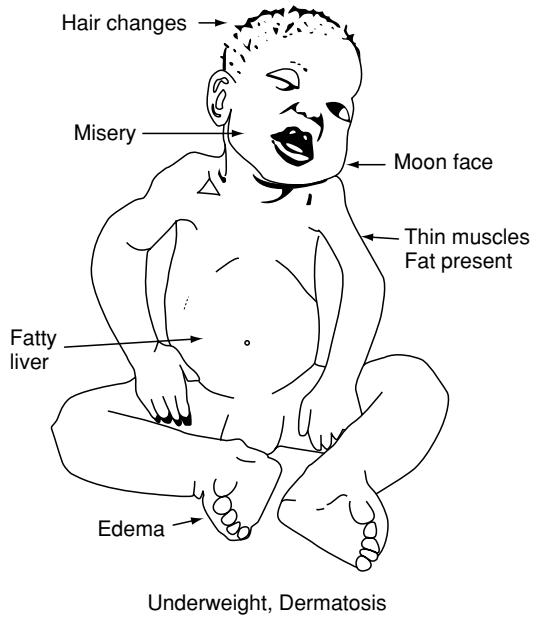

Figure 1 Clinical signs in kwashiorkor. (From Jelliffe DB and Jelliffe EF (1989) *Community Nutritional Assessment with Special Reference to Less Technically Developed Countries*, pp. 273–292. Oxford: Oxford University Press. modified.)

dyspigmented and normal black hair, prevails. The dyspigmented areas reflects periods when the child's nutrition was low in protein, 1–3 months before the color change appears. Nonnutritional environmental and genetic aspects that can also cause dyspigmentation should be excluded. Changes in the texture of the hair can be seen in African children. Curly hair becomes sparse and straight, and the bulbs of the hair roots are reduced in diameter, as a result of which, the hair is easily pluckable.

Dermatosis Dermatoses are characterized by areas of desquamation, ulceration and of both hypo- and hyperpigmentation of the skin. The lesions usually affect the lower limbs, buttocks, and perineum, but may be found anywhere on the body. Whereas the desquamated parts of the skin look as if there has been a burn and resemble 'crazy paving' thehyperpigmented areas resemble 'flaky paint.' Often dermatoses are complicated by associated skin infections.

Fatty liver In many, but not all, cases of kwashiorkor, the liver is considerably enlarged and can be palpated. The enlargement occurs mainly because of an infiltration with fat, especially triglycerides. This is the result of a decreased synthesis of β-lipoproteins, the specific transport agents for triglycerides. The fat accumulates in small droplets within the cells, first in the periphery of the lobules, and then spreads to the center of the lobules. In general, the liver functions are not altered. Severe liver failure is unusual, and cirrhosis only occurs in combination with any hepatic toxin, including aflatoxins. With recovery, the fatty liver is completely reversible. (*See* **Liver**: Nutritional Management of Liver and Biliary Disorders.)

Muscle wasting The muscles are often wasted, and the child regresses in their physical development. The infant becomes weak and is unable either to stand and walk or to hold up their head when lifted from a lying to a sitting position. In many cases, it is difficult to recognize the muscle dystrophy because of edema, which often conceals the wasting, but in the upper arms, where there is less edema, a reduction in circumference is evident.

Subcutaneous fat, which reflects the child's energy intake in the form of starchy food, and psychomotor changes are additional features. The child appears apathetic and miserable, with intermittent crying, and is often anorexic. In many cases, some degree of anemia is present and may be aggravated by malaria, hookworm infestation, or other parasites. Diarrhea is another common finding in kwashiorkor.

Physiological Effects

Kwashiorkor leads to changes in the organs and systems of the body and results in altered physiological functions.

Cardiovascular system Atrophy of the heart (which leads to reduced cardiac output), circulatory insufficiency (associated with prolonged circulation time) and bradycardia have been described. As a result, the extremities of kwashiorkor patients are cold and pale, and the pulse rate is low or even impalpable. Cardiac failure has been postulated as a possible cause of death in these children.

Endocrine organs and hormones The functions of the endocrine glands are not reduced in kwashiorkor. Secretion of human growth hormone from the pituitary appears to be normal or may be increased. Thyroid-stimulating hormone is also elevated. Owing to the prolonged half-life of cortisol, the plasma levels are elevated, with a catabolic effect on nutrients. Thyroid function seems to be normal, but reduced plasma concentrations of thyroxine-binding proteins and a reduced total plasma concentration of thyroxine have been observed. In

general, insulin secretion after oral glucose ingestion is impaired. (*See* **Hormones**: Thyroid Hormones.)

Digestive organs Protein depletion probably plays a predominant role in the pathogenesis of the mucosal changes. Cells of the intestinal mucosa and pancreas are atrophic. The mucous membranes of mouth and tongue are also affected. The synthesis and activity of digestive enzymes are reduced. Most affected are the disaccharidases, lactase, sucrase, and maltase. A reduced absorptive area together with diminished enzyme activities leads to impaired utilization of nutrients. In addition, lactose intolerance is particularly common.

Kidneys There is no specific structural or functional abnormality, but in a state of dehydration, the glomerular filtration rate is reduced. The impaired ability to concentrate urine may be attributable to accompanying electrolyte deficiencies, particularly to potassium. (*See* **Renal Function and Disorders**: Kidney: Structure and Function.)

Immunological system The immune system is still developing in the first 2 years of life and is very sensitive to nutrient deficiencies in early childhood. In kwashiorkor, the lymphoid tissue, primarily the thymus, is atrophic, and the immune response to infectious agents, particularly the cell-mediated immune response, is diminished. Thus, the child becomes more susceptible to infections such as measles or gastroenteritis. These infections themselves exhaust the nutrient stores.

Biochemical and Metabolic Disorders

There is a profound change in the body composition with the onset of kwashiorkor. Total body water increases from 60% to about 80% of the total bodyweight and may be comparable with that of a newborn infant. The high water content is mainly attributable to the reduced body fat stores and to muscle wasting.

The mineral content also changes. In particular, potassium decreases as a result of losses from diarrheal stools. Other minerals, such as sodium, calcium, phosphorus, and magnesium, are also diminished. individual minerals.

Total body protein is severely reduced by up to about 60% of the expected value in a normal child. This reduction is accompanied by a change of collagen protein from 27% in healthy children to about 40% of total body protein in children with PEM. Thus, the noncollagen protein is severely affected.

As a result of diets high in carbohydrates, children with kwashiorkor may still have subcutaneous and other fat stores.

General Metabolism

Protein metabolism In kwashiorkor, protein is adequately digested, and nitrogen retention is much more efficient, as can be seen in a fall of urinary nitrogen output. Whether or not total protein turnover is influenced by the level of protein intake, protein synthesis decreases in individual tissues such as muscle and skin, because they act as buffers in the adjustment of protein metabolism. (*See* **Protein**: Digestion and Absorption of Protein and Nitrogen Balance.)

The pattern of plasma amino acids shows characteristic changes. The concentration of essential amino acids, especially the branched-chain amino acids, is decreased. The plasma concentration of albumin is also decreased, since the rate of synthesis is very sensitive to reduced protein intake and falls immediately at the onset of dietary protein deficiency. The concentration of γ-globulins is usually normal and may even be elevated in the presence of infection. Other plasma proteins, such as transferrin and retinol-binding protein, are lowered and this explains the frequency of accompanying anemia and keratomalacia in kwashiorkor. Reduced concentrations of some plasma enzymes, including cholinesterase, alkaline phosphatase, amylase, and lipase, have also been reported.

Lipid metabolism As a result of decreased ability of the liver cells to synthesize lipoproteins, levels of plasma triglyceride and plasma cholesterol are low. Owing to increased lipolysis in the fatty tissue, the concentration of free fatty acids in the plasma tends to be high. (*See* **Fatty Acids**: Metabolism.)

Carbohydrate metabolism Hypoglycemia and glucose intolerance are frequent occurrences. Glucose intolerance is probably attributable to an impaired insulin release or a peripheral insensitivity to insulin and could predispose to diabetes in later life. (*See* **Carbohydrates**: Digestion, Absorption, and Metabolism; **Glucose**: Maintenance of Blood Glucose Level.)

Effect on Growth and Mental Development

Growth Failure

Compared with adults, young children need high nutrient supplies for rapid growth. Thus, growth failure can be understood as an early adaptation to

reduced dietary energy and protein intake. In contrast to mild forms of malnutrition, where stunted growth is characteristic, growth retardation in kwashiorkor is of less importance. In kwashiorkor, the restricted intake of nutrients together with acute infections, such as measles or gastroenteritis, leads to diminished body weight. Affected children have between 60 and 80% of the expected weight for their age. A decreased weight: height ratio, lowered mid-arm circumference and diminished skinfold thickness are also characteristic signs. (*See* **Growth and Development**.)

Mental Development

It is rather difficult to assess the effects of malnutrition in early childhood on brain and mental development because malnutrition frequently occurs in an unfavorable psychological environment, such as deprivation of parental and social care, with less mental stimulation of the children. Consequently, it becomes difficult to separate these effects from those of malnutrition or other factors.

The development of the human brain occurs mainly between midgestation and the second year of life. In this time, there is a rapid increase in the total cell number, which continues past the first year of postnatal life. The myelination also starts to increase before birth and continues until the second year of life. In this period, the brain development is vulnerable to nutrient deficiencies, which are demonstrated by a reduced number of brain cells in cerebrum, cerebellum, and brain stem, and reductions of total lipid, cholesterol, and phospholipid content. A smaller head circumference, reflecting reduced brain growth, has also been observed in undernourished children.

Although a correlation between anatomical changes of the brain and intellectual development is uncertain, many observations in developing countries have shown correlations between intelligence scores and malnutrition in the first 2 years of life. It seems that acute malnutrition such as kwashiorkor exerts less of an influence on intelligence than chronic malnutrition. The results are somewhat different, and the duration and time of malnutrition, as well as the psychological environment of the children, must also be considered.

Drug Metabolism

Malnutrition is frequently accompanied by infections and other complications, necessitating treatment with drugs such as antibiotics. Present knowledge about drug metabolism in undernourished organisms is limited. In kwashiorkor, the binding capacity for drugs such as salicylates, which are carried in the circulation bound to plasma proteins, is lowered, owing to decreased plasma albumin concentrations. Higher concentrations of free forms of the drug may be toxic. The ability of the liver to detoxicate drugs by oxidizing them may be impaired and can result in a prolonged half-life of the drug. For these reasons, all drugs should be used with caution.

Diagnosis, Treatment, and Prevention

Diagnosis

The diagnosis of kwashiorkor includes the above-mentioned clinical features and anthropometric measurements, such as weight between 60 and 80% of the standard, reduced mid-arm circumference, and triceps skin-fold thickness. A decreased serum albumin concentration below $35\,g\,l^{-1}$ represents the probability of protein deficiency. Other plasma proteins, such as retinol-binding protein, have been used in diagnosis, because they react more sensitively to protein deficiency. (*See* **Nutritional Assessment**: Anthropometry and Clinical Examination.)

Treatment

Children with severe kwashiorkor require treatment in hospital. Table 1 shows the major points of treatment. Since the main causes of death are dehydration and other complications, such as electrolyte disturbances, hypoglycemia, and various infections, the treatment has to start with fluid replacement and treatment of the various complications. After initial resuscitation, refeeding should be started with one- to two-hourly oral or nasogastric feeds of an electrolyte solution. On the second day, a three-hourly milk feed with added sugar (or any similar preparation) should be given. The amount of 90 ml per kilogram of body weight per day can be increased in the following few days. At the same time, the feeding frequency can be reduced to every 4 h. Once the child's appetite has improved, local staple food should be added to the meals to provide an extra source of energy, which can meet the need for catch-up growth.

Severely undernourished children are also likely to be deprived of vitamins (particularly vitamin A, D, folic acid, and some B-group vitamins) and trace minerals; supplements of these nutrients are needed. Refer to individual vitamins.

After the acute phase of illness, the children need several weeks of special feeding and some supervision until recovery is complete. For this period of

Table 1 Synopsis of the major points of treatment of severe PEM

Object of treatment	*Treatment*
Complications	
Dehydration	Plasma 20 ml kg^{-1} in hypovolemia. Half-strength Darrow's solution at 50–100 ml kg^{-1} over 6 h followed by 100–150 ml per kilogram per day for maintenance
Electrolyte disturbance	Potassium: 6 mmol per kilogram per day
	Calcium: 3 g per day
	Magnesium: 2–3 mmol per kilogram per day
Hypoglycemia	Dextrose, 50%, 1 ml kg^{-1} iv stat. and then 10% dextrose solution iv as maintenance
Infection	Antibiotics covering both Gram-negative and Gram-positive organisms, e.g., penicillin 25 000–50 000 units per kilogram per day in four divided doses, iv, im, or orally, and kanamycin 5–15 mg per kilogram per day in two to three divided doses, im
Dietary deficiencies	Initially frequent small feeds, e.g., half-strength Darrow's solution in a dose of 90 ml per kilogram per day in eight divided feeds for 24 h, then full strength milk (90 ml per kilogram per day) increasing to 150 ml per kilogram per day over 2–3 days
	Cereals and other foods are added once improvement occurs
	Vitamin A: 33 000 μg im on admission and then 5000 μg orally per day
	Vitamin K: 5 mg iv or im on admission
	Vitamin D: 10 μg per day
	Ferrous sulfate: 5 mg per kilogram per day once improvement in general condition has occurred
	Folic acid: 5 mg per day for 10 days

iv, intravenous; im, intramuscular.

treatment, nutrition rehabilitation units, where recovery of children is combined with nutrition education for the mothers, are most suitable. Mothers are taught the use of local foods, cooking, feeding practice, and preparation of weaning diets that are more suitable for the children. Moreover, mothers receive instructions for dealing with simple illnesses such as diarrhea. This may help to prevent children who are cured from going back to the conditions that precipitated the malnutrition.

Prevention

In view of its multifactorial causation, the prevention of kwashiorkor cannot be achieved through medical or nutritional means alone. Political, economical, and agricultural measures are also necessary. From the nutritional point of view, the management of weaning is most important. Mothers need educational services in order to understand the special dietary needs of the child at weaning. They should be educated to prepare weaning diets with higher protein and energy contents. (*See* **Infants:** Weaning.)

Owing to lack of time, children are fed only once or twice a day with bulky foods, frequently late at night, when they are too tired to eat. Thus, it is impossible for children to receive their nutrient needs; it is necessary to feed children at least four times a day.

Prognosis

The prognosis of severe kwashiorkor depends on the particular living conditions, including hygiene, which can lead to severe infections, on complications such as cardiac failure, and on the facilities available to treat the sick child. In addition, the conditions to which the child must return after treatment are very important. Prognosis is often unfavorable, with mortality rates between 10 and 25% for severe kwashiorkor cases. (*See* **Malnutrition:** The Problem of Malnutrition; **Marasmus**.)

LABORATORY MANAGEMENT

Contents

Chemical Safety

G Collier, University of Hull, Hull, UK

Background

There are several obvious prerequisites for safe working. These include well-designed buildings, equipment suited to the intended purposes, and carefully planned operating systems that are clearly defined and effectively administered. Moreover, the choice and use of buildings, equipment and systems of work should be strongly influenced by a clear, progressive, and well-publicized safety policy. In addition to defining aims and objectives, the policy statement should specify the persons to whom particular safety responsibilities are delegated; the extent of those responsibilities; the arrangements for advice and instruction on safety matters; and the procedures for reporting defects and making complaints.

It is widely recognized that the same principles that have been adopted within many organizations with respect to total quality management (TQM) are equally applicable to the management of health and safety. Organizations that have applied this approach to their health and safety management systems, often as part of a TQM philosophy, generally achieve high standards of health and safety performance.

The TQM approach seeks to promote continuous improvement in all aspects of an organization's activities. In health and safety terms, the ultimate goal is a harm-free environment. Such an objective is clearly desirable, even in financial terms. Since the staff of any organization is invariably its most valuable asset, ill health and accidents have appreciable financial and operational consequences. An effective system for managing health and safety will reduce what is known, in quality terms, as the cost of nonconformance.

The following paragraphs highlight certain aspects of chemical safety that are of particular relevance.

The Control of Substances Hazardous to Health (COSHH)

Against a background of increasing awareness of a need to provide a general legal foundation for good occupational hygiene practices, the European Commission adopted a Framework Directive (80/1107/EEC) on the protection of workers against chemical, physical and biological hazards. In the UK, this led to the Control of Substances Hazardous to Health (COSHH) Regulations, which may be considered to represent best current practice.

Under these Regulations, no employer may carry out any work that is liable to expose employees to any substance hazardous to health unless he or she has made a suitable and sufficient assessment of the risks created by that work to the health of those employees,

and of the steps that need to be taken to prevent or control exposure. The Regulations are wide-ranging, not least in their definitions of substances hazardous to health.

In practice, there is no single simple way of defining what is, or is not, a hazardous substance. The hazard is the potential of the substance to cause harm to health. Whether that potential is realized, i.e., whether, in other words, there is a risk or danger to health, will depend upon a number of factors: the amount of substance used; its physical state; the likelihood of exposure and the method of entry into the body. All these circumstances need to be taken into account. The hazard, or potential for harm, arises from the intrinsic properties of the substance and, depending upon what those properties are, there may be hazard of a high or low order.

The COSHH Regulations define several categories of hazardous substance as follows:

1. Substances that have been formally designated as very toxic, toxic, harmful, corrosive, or irritant.
2. Substances to which an occupational exposure standard (OES) or maximum exposure limit (MEL) has been assigned. An OES is the concentration of an airborne substance, averaged over a reference period, at which, according to current knowledge, there is no evidence that it is likely to be injurious to personnel if they are exposed by inhalation, day after day, to that concentration. A MEL, however, is a strictly applied limit. It is the maximum concentration, averaged over a reference period, to which personnel may be legally exposed under any circumstances. Furthermore, employers have a duty to ensure that exposure is kept as far below the MEL as is reasonably practicable. So far, MELs have been assigned only to substances that have been generally perceived to present a high level of hazard, including a number of carcinogens, mutagens, and teratogens.
3. Biological agents.
4. Dust, of any kind, in substantial concentrations (see below).
5. Other substances with similar hazards to those in the previous categories.

The risk assessment that is required must be undertaken by a competent person. It involves consideration of all the types of substances to which an employee is likely to be exposed and the effects that such substances can have on the body. The nature and extent of exposure must also be assessed, taking due account of reasonably foreseeable deterioration in, or failure of, control measures. Although inhalation is the main route of entry into the body, some substances may be readily absorbed through the skin, and this needs to be taken into account when designing control measures.

There is a firm requirement to ensure that exposure is *prevented* wherever reasonably practicable. Only where this is not reasonably practicable (i.e., when it cannot be achieved without completely disproportionate expense or trouble) is adequate control an acceptable alternative. Nevertheless, the opportunities for prevention of exposure are often limited, requiring either elimination of the use of the substance altogether or substitution by a less hazardous material.

In most circumstances, effective control is the only practicable option, and this is mainly achieved by enclosure, total or partial, and local exhaust ventilation. The use of personal protective equipment is only acceptable in a minority of situations where adequate control cannot be achieved by other means.

As soon as control measures are introduced, a system of regular maintenance, examination, and testing must be instituted, and the results must be recorded, together with details of any repairs or other remedial work. Defects must be promptly reported by employees, and remedial action must be taken as soon as possible.

Once effective and well-maintained control measures are in place, that is by no means the end of the matter. The TQM approach requires constant feedback to improve performance, and three further lines of action are appropriate.

Where it is necessary to ensure the maintenance of adequate control, a procedure for monitoring for hazardous substances is required. The use of certain specified substances renders this mandatory. Usually, monitoring is not just a matter of atmospheric sampling but requires repeated or continuous measurements in an individual's breathing zone.

Health surveillance may also be called for in certain circumstances, and the results, like those of monitoring exercises, must be recorded. When an individual leaves an employer's service, their health surveillance record should be passed to their new employer.

Above all, there is a requirement to provide continual information, instruction, and training to employees. Success in meeting this requirement is clearly crucial to the success of all other measures. In this connection, one of the notable developments of the last few years has been the ever more stringent requirement for the inclusion of chemical hazard information on labels and packaging.

Sample Handling

Samples of material are presented to the laboratory in many different forms. When submitted for quality assurance or other routine testing, the nature of the

material may be known in some detail. In all other circumstances, the material should be treated as potentially harmful, and appropriate measures should be adopted to control exposure of personnel.

Samples must be adequately labeled, and laboratory workers should always ensure that they have the maximum amount of relevant information before handling the material. Many of the comments made in the following paragraphs in respect of dusts, solvents, and hazardous reagents are equally applicable to materials submitted to the laboratory as samples for examination or other experimental work.

Dusts

Finely powdered materials and dusts can be hazardous to health when present in the environment in substantial concentrations. That which can be said to constitute a substantial concentration is, to some extent, dependent on particle size. This, in turn, governs the aerodynamic diameter and drag, the degree of penetration into the respiratory system, and the region of deposition.

Total inhalable dust (i.e., airborne material that enters the nose and mouth during breathing) includes particles up to 50 μm in diameter. The larger particles are commonly called 'nuisance dusts,' and the body usually expels them by coughing or sneezing. Total inhalable dust of any kind, present at concentrations of 10 mg m^{-3} or greater as an 8-h time-weighted average, is regarded as hazardous to health.

The term 'respirable dusts' is applicable to smaller particles (of average diameter 7 μm or less), which are much more harmful because they can penetrate deep into the respiratory system, reaching the gas-exchange regions of the lungs.

As a general guide:

- particles of diameter > 7 μm will deposit in the mouth and throat;
- particles of diameter 4.7–7 μm will deposit in the pharynx;
- particles of diameter 3.3–4.7 μm will deposit in the trachea and bronchi;
- particles of diameter 1.1–2.1 μm will deposit in the terminal bronchi;
- particles of diameter about 1 μm and less will deposit in the alveoli.

Respirable dusts include grain dust, which may be defined as dust arising from the harvesting, drying, handling, storage, or processing of barley, wheat, oats, maize, and rye, including contaminants. In the UK, grain dust has been assigned a MEL of 10 mg m^{-3} as an 8-h time-weighted average respirable dust of any kind, present at concentrations of 4 mg m^{-3} or greater as an 8-h time-weighted average, is regarded as hazardous to health (see COSHH, 1999). Atmospheric concentrations are determined gravimetrically.

Occupational exposure to respirable dusts can cause asthma and other allergic lung conditions as well as a variety of recognized dust diseases. Such dusts should therefore be considered as respiratory sensitizers, which, when inhaled, can trigger irreversible allergic reactions in the respiratory system. Once this has occurred, subsequent exposure, even to minute amounts, may cause respiratory illness including asthma, rhinitis and extrinsic allergic alveolitis. If exposure is allowed to continue, symptoms are likely to become progressively worse and may result in chronic disease, which may become so severe as to threaten life. The earlier a sensitized person is removed from exposure, the greater the probability of avoiding serious damage to health.

The highest priority should be accorded to prevention of exposure. If this is not reasonably practicable, then effective control measures, such as partial enclosure and local exhaust ventilation, must be instituted. Dust respirators or masks should be used only for short-term tasks where satisfactory dust control cannot be achieved by other means.

Solvents and Toxic Reagents

Many organic solvents present a fire and explosion hazard because of their low flash points. The magnitude of the hazard is dependent upon the quantity of the solvent involved and on other physicochemical properties such as autoignition temperature, explosive limits, vapor density and ability to accumulate electrostatic charge.

Fire or explosion may occur when flammable vapors are mixed with oxygen or air in proportions that lie between certain critical values known as the upper and lower explosive limits (UEL and LEL). For many common solvents, the LEL is only a few per cent in air, and good ventilation is essential to prevent the formation of an explosive atmosphere when significant quantities are used. As most organic solvent vapors are denser than air, low-level ventilation may be required for larger-scale operations in order to avoid dangerous accumulation of vapors at floor level.

In this connection, it is helpful to have some appreciation of the percentage loss of a solvent, by evaporation, when it is used in various laboratory operations. This may range from a loss of about 1% or less of the liquid for a simple decantation, to around 20% or more for hot filtration, but the precise values vary considerably from one solvent to another. Nevertheless, the larger the volume of vapor

liberated, the greater the chance of ignition by a remote heat source.

Ignition may also occur *without* the obvious presence of a high-temperature source. Liquids flowing in pipes can readily generate static electricity, which may result in a spark. It is therefore advisable to dispense large volumes via metal pipes that have been doubly earthed.

Solvents with a low autoignition temperature (e.g., carbon disulfide (100 °C) and diethyl ether (180 °C)) are particularly hazardous. In such cases, the presence of a hot plate in contact with a vapor/air mixture is quite capable of causing violent ignition.

Storage of highly flammable liquids must be in accordance with statutory requirements, which generally limit the total volume to about 50 l within any given working area. The capacity of individual bench bottles must not exceed 500 ml. Many disastrous fires have resulted from inadvertent spillage, and places in which substantial volumes of flammable liquids are used should have clearly defined emergency procedures to ensure rapid evacuation and ventilation of the affected area.

Certain solvents (alcohols and, especially, ethers) have a propensity for peroxide formation on storage, and these may detonate on distillation or on evaporation to low bulk. Such solvents should not be stored for extended periods, once opened. Bottled ether waste should have 100 ml of saturated ferrous sulfate solution added to each 2.5 l before disposal.

Owing to their volatility and the large volumes in common use, many solvents present significant health risks in addition to any fire and explosion hazard. Long-term effects of exposure to high concentrations may include dermatitis, damage to the central nervous system, the liver, the kidneys or the blood, and even cancers. Smoking in the vicinity of chlorinated solvent vapors is particularly hazardous, not because of any fire hazard but because of toxic breakdown products that can be produced by pyrolysis.

Many laboratory reagents in common use are also toxic to some degree and therefore hazardous. The term 'toxic' does not have an absolute quality of the kind that tends to be assumed in common parlance. Almost all chemicals can cause harm in certain circumstances, and, conversely, even highly toxic chemicals can be used safely if adequate precautions and control measures are taken. Most toxicological studies have been undertaken with laboratory animals, and not every species shows the same degree or type of response. Extrapolation of data to the human species is therefore fraught with difficulty. Nevertheless, toxicological data from studies of other mammals can normally be taken as a useful indication of the likely degree of toxic hazard to human beings, and reference works such as the Registry of Toxic Effects of Chemical Substances (NIOSH) can be valuable sources of information.

In toxicology experiments, increasing doses of the test substance are administered to laboratory animals, and the response is observed. The dose level that results in the death of half of the group of animals receiving it is known as the LD_{50} value (a lethal dose for 50%) and is usually expressed as milligrams of the substance per kilogram of body weight of the animal ($mg\,kg^{-1}$). As a rough guide, for oral ingestion by the rat, substances with LD_{50} values lying between 200 and 2000 $mg\,kg^{-1}$ should be regarded as harmful, and those with values between about 25 and 200 $mg\,kg^{-1}$, as toxic. Any substance with an LD_{50} of less than 25 $mg\,kg^{-1}$ should be treated as very toxic. For substances on which extensive toxicological data already exist (by far the minority), formal assignments to one of these categories may already have been made.

Consideration of the toxicity levels of the substances involved, together with the respective amounts of the substances to be used, will be an important aspect of the risk assessment for any operation involving hazardous substances. Such considerations will influence the conditions under which the operation is carried out, whether partial containment in a fume cupboard is necessary, and what degree of personal protection is required.

Many operations are carried out in solution, and in such cases, the solvent may present a greater hazard than the reagents. Very often, however, the fact that the reagent is present in the solution state, together with a solvent that may greatly facilitate absorption through the skin, considerably increases the risks associated with its use.

Waste Disposal

All producers of waste, of whatever kind, have a duty of care to ensure that it is safely disposed of, without risk to others and, as far as possible, without detriment to the environment. The welter of environmental protection legislation throughout the developed world is intended to ensure that this duty is responsibly discharged.

Laboratory waste is regarded as especially hazardous and is usually subject to special controls. Until relatively recently, it was quite common practice to dispose of all aqueous waste down the drains, but this is no longer acceptable, as it can have adverse consequences for the public sewers to which most laboratory drains are connected. In order to avoid causing problems with sewage treatment, no effluent outside the pH range of 5–9 should be discharged into the

public drainage system. It is therefore necessary to neutralize or massively dilute any acid or alkaline wastes before they can be disposed of by such a route.

Similar dilution is also required before even small quantities of water-miscible solvents such as acetone or ethanol can be disposed of down the drain. Accumulation of solvent vapors in sewers would pose a considerable risk to maintenance workers and, indeed, to the system itself. Consequently, only very limited use can be made of the drains for disposal of liquid waste, and it is necessary to ensure that any waste so consigned does not contain significant concentrations of heavy metals or other toxic substances.

In considering discharge to the local environment, discharge of vapors and fumes from local exhaust ventilation and fume cupboard outlets must not be overlooked. Adequate dilution must occur before the fumes are discharged, and, if possible, noxious materials should be trapped at source rather than simply vented to the atmosphere.

Most laboratory waste is now destined either for high-temperature incineration or for burial at a duly licensed landfill site, and the producer of the waste is deemed to be responsible for it right up to the moment of its ultimate disposal. This gives rise to the so-called 'cradle to grave' view of the producer's responsibility.

The onus upon the producer to ensure proper disposal is, in any case, a heavy one. Suitable and separate containers should be available in the laboratory for the collection and segregation of various types of waste. In particular, flammable solvents should be segregated from nonflammables. Halogenated solvents should be collected separately, as far as possible, and must not be mixed with ketones. In general, care must be taken not to bulk waste, especially solvent waste, in such a manner as to create additional hazards by the mixing of incompatible materials.

Producers must ensure that laboratory waste is clearly and adequately labeled as to its nature and hazardous properties, securely packaged, and disposed of via an authorized contractor. Moreover, they should satisfy themselves as to the methods to be employed by the disposer, and this may involve visits to the treatment plant or landfill site. Some types of waste may require separate secondary containment before packaging for transportation, especially highly reactive materials, oxidizing agents and foul-smelling substances. Others may need to be segregated simply because of a high toxicity hazard. This certainly applies to carcinogens, and conspicuous labeling is essential in such cases.

Finally, detailed written records of all waste disposals should be made and retained for at least two years.

Microbiological Safety

V N Scott and I Walls, National Food Processors Association, Washington DC, USA

Introduction

Food laboratories may handle potentially infectious materials, e.g., foods contaminated with pathogenic microoganisms such as *Salmonella* spp., *Escherichia coli* O157:H7, *Listeria monocytogenes*, *Shigella*, and even *Clostridium botulinum*. Numerous published reports have documented laboratory transmission of infectious agents, including those from *E. coli* O157:H7, *Salmonella*, and *Shigella*, although infection occurs primarily in clinical laboratories. The incidence of laboratory transmission of foodborne pathogens is not known but is believed to be very low. Nevertheless, the risk of exposure exists; this risk can be reduced to a very low level by use of good laboratory practices and containment techniques (biosafety level 2), as described in this chapter. Interestingly, laboratory-acquired infections with *Cryptosporidium parvum* have been reported in almost every laboratory working with this parasite; therefore, it is important to adhere strictly to all precautions to prevent transmission of this agent. Good laboratory practices are particularly important when it is recognized that fewer than 20% of

laboratory-associated infections are attributed to a known accident.

The most frequently recognized causes of laboratory infections are oral aspiration due to mouth pipetting, inoculation with syringes and needles, animal bites, spray from syringes, and centrifuge accidents. Other recognized causes include cuts from contaminated glassware and the spilling of pathogenic cultures. Exposure to infectious aerosols is considered to be the most likely source for cases not associated with a known accident.

Biosafety practices relating to sample handling, containment of biological hazards, disinfection and decontamination in the laboratory and personnel practices will be covered in this article. A list summarizing microbiological safety practices can be found at the end. These guidelines should be considered minimal guidelines. They should be customized for individual laboratories after consulting additional references.

Biosafety Levels

There are four biosafety levels for working with microorganisms in the laboratory. These consist of a combination of laboratory practices and techniques, safety equipment, and laboratory facilities that provide increased protection to personnel, the environment, and the community as the level increases. Biosafety level 1 is suitable for work involving well-characterized agents not known to cause illness consistently in healthy persons; work is generally conducted on open benchtops using standard microbiological practices. Biosafety level 2 is suitable for work involving agents of moderate potential hazard to personnel and the environment. The primary differences between biosafety level 1 and 2 is that, with the latter, extreme precautions are taken with contaminated sharp items and certain procedures that may create aerosols are conducted in biological safety cabinets or other physical containment equipment. Biosafety level 3 is applicable to laboratories working with agents that may cause serious disease via the inhalation route, and biosafety level 4 is required for work with dangerous agents that pose a high risk of aerosol-transmitted laboratory infections. Currently all microorganisms expected to be encountered in a food laboratory can be handled with biosafety level 2 in the USA. Some countries may require biosafety level 3 precautions when working with *E. coli* O157:H7. In addition, biosafety level 3 precautions are indicated for *Clostridium botulinum* when activities pose a high potential for aerosol or droplet production and for those activities involving large quantities of toxin.

Sample Handling – Hazards

Laboratory personnel can be exposed to infectious agents through a number of routes (Table 1).

Inhalation Hazards

The generation of droplets and aerosols is considered to be the primary means of laboratory exposure to infectious agents. All laboratory procedures should be performed carefully to prevent the creation of aerosols and droplets. In most instances use of proper containers and equipment will minimize the chance for aerosolization of infectious materials. However, even trivial laboratory operations generate droplets and aerosols: a drop falling off the end of a pipette, streaking the surface of a rough agar plate with a loop, inserting a hot loop into a culture, pulling a cotton plug from a flask or a tube, and many others.

Pipettes should be drained gently with the tip against the inner wall of the receiving tube, bottle, or flask. The liquid should not be expelled forcibly from the pipette. Material should be centrifuged in sealed tubes or using centrifuges with sealed buckets, safety trunnion cups, or sealed heads to prevent the escape of aerosols and material being centrifuged. Only sealed tubes should be used for vortex mixing. Blenders should have leak-proof bearings and tight-fitting gasketed lids. Sonication or homogenization of infectious materials should be done inside a safety cabinet.

Molds pose a potential inhalation hazard, as spores may cause irritation. Moldy food should be sampled with care, to minimize the potential for laboratory contamination. When molds are grown on agar, plates should not be inverted, as mold spores may fall on to the lid of the Petri dish, and if it is opened these can contaminate the laboratory.

Table 1 Routes of exposure of laboratory personnel to hazardous agents

Route	*Procedures resulting in exposure*
Contact	Decanting liquids, pipetting, removal of screw caps, vortex mixing, unsealed containers (spills)
Oral	Mouth pipetting, not washing hands after working with infectious materials
Ocular	Procedures resulting in splashing, aerosol generation (sonication, centrifugation, homogenization)
Inoculation	Use of needles, syringes
Inhalation	Procedures generating aerosols (sonication, centrifugation, blowing out pipettes, heating inoculation loops; streaking inoculum on agar)

Contact Exposure and Inoculation Hazards

Infectious materials should be handled very carefully, especially during sample transfers and decanting of supernatants, to avoid spills. Safety glasses should be used to protect against splashing infectious material into the eyes.

Because of the hazard of self-inoculation, the use of needles and syringes should be restricted to procedures for which there are no alternatives. Needle-locking syringes or disposable syringe-needle units in which the needle is integral to the syringe should be used. Needles should not be replaced in the guard following use, nor should they be clipped.

Care should be taken to avoid cuts when handling sharp objects such as scalpels or broken glass. Broken glass should not be picked up by hand; tongs, forceps, or a brush and dustpan should be used. Dispose of sharp objects in proper receptacles. In laboratories working with animals, training should be given in animal-handling techniques to avoid bites and scratches. Where appropriate, gloves should be worn.

Ingestion Hazards

Mouth pipetting poses such a high risk of exposure that good laboratory practices prohibit this procedure. Only mechanical pipetting devices should be used in the laboratory.

Additional ingestion hazards result from hand contamination and subsequent transfer to the mouth; this can be avoided by appropriate personnel practices such as proper hand washing and wearing gloves (see section on personnel practices and personal hygiene).

Containment – The Biological Safety Cabinet

The most important element of containment is strict adherence to good microbiological practices and techniques. However, appropriate laboratory design and safety equipment are also required for proper containment of microbiological hazards.

The use of proper containment equipment helps minimize the exposure of laboratory personnel to infectious agents. Equipment designed to avoid laboratory hazards includes biological safety cabinets, mechanical pipetting devices, and centrifuges and blenders. Containment is also achieved by use of appropriate closures on laboratory glassware such as test tubes, flasks, and bottles.

The biological safety cabinet is the principal device to provide containment of aerosols. There are three types – class I, II, and III. Class I and II cabinets are generally open-fronted and depend on air flow to protect laboratory personnel.

The class I cabinet (**Figure 1a**) is designed to protect the user; air enters the front work opening and exits at the top through a high-efficiency particulate air (HEPA) filter. This provides no protection against contamination of the work materials, since unfiltered ambient room air flows into the cabinet. A class I cabinet should not be confused with a horizontal laminar flow cabinet in which HEPA-filtered air is blown across the work surface toward the researcher to protect the research/materials against contamination. A horizontal laminar flow cabinet should never be used with infectious agents due to potential worker exposure.

Class II biological safety cabinets (**Figure 1b**) protect the research materials from contamination, as well as the worker, since both the supply and the exhaust air are HEPA-filtered. Room air is drawn through the front work opening into a plenum below the work area by a fan. Air exiting the fan is passed upwards through a channel in the rear into a space between two HEPA filters. A portion of the air is exhausted through one HEPA filter while the rest of the air passes through the second HEPA filter and is directed downward as clean, laminar flow air to the work surfaces. In subclass IIA cabinets 30% of the air is exhausted and 70% recirculated. In subclass IIB cabinets a smaller portion of air (30%) is recirculated or there is total exhaust (no recirculation). In the latter case room air entering through the front opening to protect the researcher against escaping pathogens is drawn into the plenum and is exhausted.

The class III cabinet is a totally enclosed, airtight workspace equipped with protective gloves, and hence is often referred to as a glove box. Such cabinets are used for high-risk biological agents and are not necessary in food microbiology laboratories, although they are sometimes used for work with *Clostridium botulinum*.

Biosafety cabinets should be located in a low-traffic-area free from drafts. The cabinet must be tested and certified at installation, after moving, and annually thereafter. It is desirable that safety cabinets exhaust outdoors since materials such as formaldehyde (used for decontamination), radioisotopes, or chemical carcinogens should not be exhausted indoors. When cabinets are exhausted to the roof the exhaust stack height should insure that discharge occurs above the heads of maintenance personnel. The exhaust stack should not exhaust in close proximity to the air intake. HEPA filters should be disposed of as contaminated biological waste, preferably by incineration.

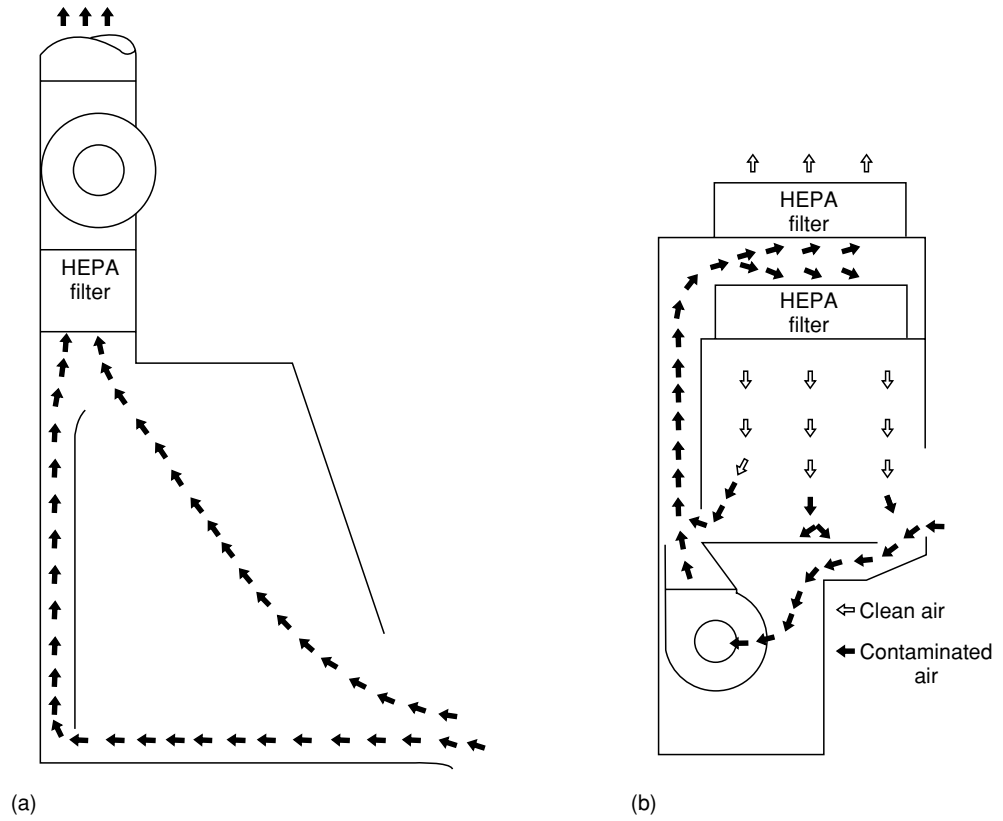

Figure 1 Biosafety cabinets: (a) class I and (b) class II. HEPA, high-efficiency particulate air. Reproduced from Furr AK (ed.) (1995) *CRC Handbook of Laboratory Safety*, 4th edn. Boca Raton, FL: CRC Press, with permission.

Disinfection/Decontamination

Laboratory Waste

Food laboratories generate potentially hazardous infectious wastes during the analysis of samples contaminated by pathogens and during the propagation of pathogenic microorganisms. Biological waste containing viable microorganisms not known to be hazardous to humans is not considered infectious laboratory waste. Nevertheless, it is good laboratory practice to decontaminate all waste containing viable microorganisms and to disinfect work surfaces as if working with infectious agents.

Containment of waste Materials to be disinfected or decontaminated prior to disposal or cleaning should be placed in a centralized area designated for biohazardous waste. A cart clearly labeled 'To Be Autoclaved' is recommended for all laboratories in which infectious organisms are handled. Tubes, bottles, and flasks should be closed. Petri dishes should be placed in trays or biohazard or autoclave bags. Pipettes should be placed in pans or jars with sufficient disinfectant to fill the pipette and cover it completely. Materials to be disinfected and discarded should be separated from those which are to be cleaned and reused. Materials to be discarded can be placed in autoclave bags which are sealed, autoclaved, and then discarded.

Infectious waste (liquid and solid) should be decontaminated at the laboratory facility prior to transport to a disposal site. If this is not possible, adequate physical containment measures (sealed, leak-proof containers) must be taken to prevent subsequent exposure to those handling the waste.

Physical hazards Items with sharp points or edges, such as needles, disposable pipettes, scalpel blades, and broken glass, pose a special problem in decontamination and disposal. These should be placed in puncture-resistant containers either before or after autoclaving. Needles and syringes should be placed directly in the disposal container without replacing the guard on the needle, since replacing the guard is a frequent cause of inoculation of laboratory personnel. After decontamination, special containers that provide a means to cut through both the needle and the plastic syringe should be used to prevent reuse of disposable needles and syringes.

Disinfectants

Disinfection/decontamination in a food laboratory generally occurs by means of chemicals or by heat (usually autoclaving). The type of treatment will depend on the nature of the material to be treated, the level and type of contamination, and the amount of disinfection/decontamination required.

Chemical Chemicals most frequently used for disinfection include quaternary ammonium compounds (0.1–2%), chlorine compounds (0.01–5%), iodophor compounds (0.5–1%), and alcohol (70–95%). Biosafety cabinets are sometimes decontaminated with formaldehyde. Commercial disinfectants should be used according to the manufacturer's directions. Disinfection will depend on selection of the appropriate chemical for the intended use, contact time, concentration, and the presence of interfering substances. For example, although 200 p.p.m. available chlorine is generally adequate for disinfection, organic materials may be present which will combine with chlorine and reduce its effectiveness. Thus it is recommended that discard jars contain 1000 p.p.m. available chlorine; 5% bleach (50 000 p.p.m. chlorine) is recommended for cleaning spills.

Heat Autoclaving is the method of choice for decontaminating cultures, glassware, and pipettes. Autoclaving for 60–90 min at 121 °C (15 psi), depending on the loading conditions, to achieve a waste temperature of at least 115 °C for 20 min is recommended. Effective autoclaving will depend on time, temperature, and steam penetration. Tubes, bottles, flasks, and bags should be loosely closed to allow steam penetration. Tubes should be autoclaved in racks. Glassware should be arranged to allow steam to circulate around the individual containers. The autoclave should never be overloaded. Contaminated glassware should contain liquids to facilitate the sterilization process. Care should be taken when adding water to avoid generating aerosols containing infectious microorganisms. Stainless-steel pans, glass, and heat-resistant plastic can be autoclaved. Metal containers enhance transfer of heat to the waste load, whereas plastic retards steam penetration. Thus with certain materials or with larger volumes of liquids it may be necessary to decrease the size of the load or to increase time to compensate for poor heat transfer/steam penetration. Autoclaved waste can subsequently be disposed of as general waste.

Dry heat may be used to decontaminate some materials, including glassware and instruments, and is recommended for anhydrous materials such as oils, greases, and powders. These should be heated at 160–180 °C for 180–240 min.

Large volumes of infectious wastes, animal carcasses, and contaminated bedding materials should be incinerated. Since most incinerators are off-site, solid waste must be contained in sturdy bags or boxes and liquids in leak-proof containers for transport. Trained personnel should transport the containers to the incinerator.

Inoculating loops are sterilized by heat. Although electric loop sterilizers are available, loops are generally sterilized by holding in a flame until the loop is red-hot. Inoculating loops should be flamed by heating the shaft until the sample has heat-dried before flaming the loop itself. (Alternatively, flaming can be avoided by use of sterile disposable plastic loops.)

Laboratory Decontamination

Frequency Chemical disinfection is used for benchtops, incubators, furniture, and floors which may become contaminated. Work surfaces should be decontaminated at least daily and preferably before and after each use. Biosafety cabinet surfaces should be disinfected before and after each use. Other areas should be cleaned and disinfected at least weekly. Immediate cleaning and disinfection are required when spills occur. Chemicals are also used in disinfecting items placed in discard jars; chemical solutions should be replaced as often as necessary to maintain an effective concentration of disinfectant.

Spills Spills of biohazardous materials require special considerations. Spills can be contained by using enamel or stainless-steel trays as a work surface. If a spill occurs, the entire tray can be autoclaved. Small spills can be cleaned up by pouring a concentrated disinfectant around the edges of the spill and then covering the spill with disinfectant-soaked paper towels. Additional paper towels are used to wipe up the area. Contaminated paper towels are then transferred to a biohazardous waste container for autoclaving. Larger spills, however, can generate significant aerosols which should be allowed to settle for approximately 30 min prior to decontamination. The laboratory should be evacuated and closed during this period. A laboratory worker wearing a lab coat, gloves, and respiratory protection should then clean up the spill with disinfectant and paper towels, sponges, or mops as appropriate. Clean-up materials should preferably be disposable. When there is a large spill in a biosafety cabinet, special disinfection measures may be needed to decontaminate the fan, filters, and air-flow plenums. When infectious agents are spilled on clothing, contaminated garments (lab coats, shoes, etc.) should be removed and decontaminated.

Centrifuge Accidents

If breakage occurs during centrifugation the centrifuge should be turned off and allowed to stand closed for 30 min. If breakage is discovered after the centrifuge is opened, the lid should be replaced and the centrifuge left closed for 30 min. Broken tubes, glass fragments, buckets, trunnions, and the rotor should be placed in an appropriate noncorrosive disinfectant and held for an appropriate time (generally 1–24 h) or autoclaved.

Personnel Practices and Personal Hygiene

The most important aspects of microbiological safety in the laboratory rely on good laboratory practices by the laboratory worker. Persons working with potentially infectious materials should be made aware of the hazards and properly trained in the proper methods for safely handling such materials. Insuring that laboratory personnel are properly trained and informed of potential hazards is the responsibility of the laboratory director.

Access to the laboratory should be limited, especially when working with infectious agents, and doors should be kept closed when experiments are in progress. As noted previously, mouth pipetting should be prohibited. Eating, drinking, smoking, handling contact lenses, and applying cosmetics should not be permitted in the work area. Food should be stored in cabinets or refrigerators designated for this purpose only and food storage areas should be located outside the work area. Drinking-water fountains should also be located outside the work area. Workers should wear laboratory coats or other protective covers. In some cases protective gloves should also be worn. Open-toed shoes or sandals should not be worn in the laboratory. Safety glasses should be worn when filling syringes or when handling certain chemicals such as strong acids. Lab coats and gloves should be removed when leaving the laboratory. Workers should wash their hands following all laboratory activities, after removing laboratory coats and gloves, and immediately following contact with any infectious materials. Workers should develop the habit of keeping their hands away from their face, especially the mouth, nose, and eyes, to prevent self-contamination and infection. This is particularly important when working with agents of low infectious dose, such as *E. coli* O157:H7, where fewer than 10 organisms have been shown to cause illness.

Some employees may have personal health conditions that place them at increased risk in the laboratory, especially when working with certain organisms. For example a pregnant woman may be at increased risk from *Listeria monocytogenes*. Thus most food laboratories do not allow pregnant women to work in a laboratory where *L. monocytogenes* is being handled. Persons who are immunocompromised may be at increased risk not only from *L. monocytogenes*, but also from opportunistic pathogens that may be encountered in foods. Careful assessment of the risk of exposure should be made. If the exposure cannot be eliminated or reduced, consideration should be given to changing jobs. The employee must be informed of the risk and involved in the decision-making process.

Workers with open sores or cuts should not be allowed to handle infectious materials that could potentially contaminate the wound. If sores or cuts are on the hands, bandages and gloves must be worn to protect the worker.

For some infectious agents vaccines that provide an extra level of protection may be available. However for most foodborne disease organisms, vaccines are either not available (e.g., *Shigella* spp., *L. monocytogenes, Campylobacter* spp., most *Salmonella* spp.) or only provide partial protection of short duration (e.g., *Vibrio cholerae*). A pentavalent (ABCDE) botulinum toxoid is available through the US Centers for Disease Control and Prevention as an investigational new drug and is recommended for personnel working with cultures of *C. botulinum* or its toxins. Individuals receiving the toxoid may experience minor side-effects, including redness and swelling at the site of the inoculation; in rare cases more generalized reactions have occurred. Hepatitis A vaccine is available; although laboratory-acquired infection with this virus is not considered a significant risk, the vaccine is recommended for persons who work in laboratories conducting research on this virus.

Other Considerations

All samples and cultures containing infectious materials should be labeled with the universal biohazard symbol and the hazard identified on the label.

Foods for analysis that may be contaminated with pathogens should be assumed to be contaminated and handled appropriately. For example, swollen cans may be contaminated with *C. botulinum* and should be handled, using appropriate safety handling practices, by an individual who is immunized against the toxins. Consideration should be given to the need to open the cans in a safety cabinet.

Laboratories working with infectious agents should have posted on the door the universal biohazard symbol identifying the infectious agent. The sign should also list the name and phone number of the

laboratory supervisor or other responsible party and any special requirements for entering the laboratory. Laboratories dealing with infectious materials should be restricted to authorized persons only.

Hazardous materials should be stored in locked cabinets, refrigerators, or other storage areas and access should be limited to authorized persons only.

Food microbiology laboratories should have safety guidelines posted or a safety manual located in an accessible location. Safety practices appropriate for the specific microbiological hazards that may be encountered should be included, as well as information on chemical and physical hazards.

Summary of Microbiological Safety Practices

1. Avoid mouth pipetting.
2. Handle samples in a manner that minimizes aerosol generation; for procedures known to create aerosols, take steps to contain aerosols.
3. Avoid the use of needles and syringes wherever possible.
4. Decontaminate work surfaces daily and after spills.
5. Keep laboratory doors closed when experiments are in progress.
6. Do not eat, drink, smoke, handle contact lenses, or apply cosmetics in the laboratory.
7. Wear a lab coat when working in the laboratory and remove it when leaving the lab.
8. Wash hands when leaving the laboratory and upon contact with infectious materials.

Human Milk: Composition and Nutritional Value

C M Donangelo and N M F Trugo, Universidade Federal do Rio de Janeiro, Rio de Janeiro, RJ, Brazil

Introduction

It is well recognized that human milk is the most appropriate source of nutrition for infants during the first 4–6 months of life. Human milk provides a balanced composition of nutrients as well as many types of bioactive components which have an important role in infant growth and development. Benefits of breast-feeding for the infant include adequate nutrition, protection against disease, development of gastrointestinal and immune functions, and psychological well-being. It has been recognized recently that breast-fed infants may have an advantage over formula-fed infants as regards long-term cognitive development and lower rates of neurological disorders.

Human milk is a very complex biological fluid that contains numerous constituents distributed into several physicochemical compartments: aqueous phase (mineral ions, lactose, citrate, amino acids, whey proteins, water-soluble vitamins), colloidal dispersion

(casein micelles), emulsion (fat globules, membrane-bound compounds, fat-soluble vitamins), and cells (macrophages, neutrophils, lymphocytes, epithelial cells). This compartmentation of human milk constituents affects binding properties and bioavailability to the infant. Interactions among components in the compartments may influence the accessibility and flow of nutrients to the infant as well as transmission of biochemical messages to the infant via milk.

Human milk composition shows marked inter- and intraindividual variation. Several factors are known to affect composition (Table 1). Stage of lactation is responsible for the largest variation. Remarkable changes in composition occur as lactation progresses from the first few days (colostrum) to over 3 weeks (mature milk) after childbirth. Typical values of selected nutrients in colostrum and mature human milk are shown in Table 2. Nutrients such as protein, sodium, and zinc are present at higher concentrations in colostrum while others, such as lactose and fat, are present in higher concentrations in mature milk. After the first month postpartum, milk composition generally stabilizes and further changes are less dramatic. It has been proposed that alterations of nutrient supply as lactation progresses reflect the changing nutrient requirements of the infant, with a marked decrease in growth rate over time, and also the development of the infant's capability to digest and absorb nutrients.

Maternal diet is an important factor affecting the nutrient composition of milk but the influence varies in magnitude between nutrients. Concentrations of individual fatty acids and of fat-soluble and water-soluble vitamins generally reflect maternal intake. Concentrations of lactose and minerals such as sodium, calcium, phosphorous, magnesium, and iron do not vary with maternal diet. Maternal hormonal adjustments and nutritional stores may contribute to prevent fluctuations depending on the nutrient so that moderate dietary deficiencies or excesses are not always reflected in milk composition. Severe maternal malnutrition may, however, impair milk volume and milk composition.

Several components of human milk, either nutrients or nonnutrients, exert nonnutrient actions which benefit the health and nutrition of the recipient infant.

Data from: [a]Kunz *et al*. (1999); and [b]Atkinson *et al*., [c]Casey *et al*., [d]Canfield *et al*., [e]Lammi-Keefe, [f]Picciano, [g]Prentice (data from outside Europe and the USA) In: Jensen (1995) *Handbook of Milk Composition*, San Diego: Academic Press.

They can be classified in several categories, according to their actions. Since many of these bioactive substances present multiple roles and act synergistically with each other, a particular component may be present in more than one category. A broad category is that of the defense agents, comprising cellular elements (leukocytes) and a variety of heterogeneous soluble compounds, which may act directly or indirectly against pathogens (antiinfectious agents) and/or alter manifestations of infection due to their antiinflammatory properties (antiinflammatory factors), and modulation of the immune responses (immunomodulators). Other categories of beneficial compounds present in human milk are growth factors and hormones, which promote growth and maturation of organ systems; binding proteins for hormones, vitamins, and minerals, which protect and increase the bioavailability of the ligands; and several enzymes, which ensure a better utilization of nutrients and act as defense agents.

Nutritional Components of Human Milk

Protein

Proteins are present in human milk as whey proteins (50–90% of total), casein (10–50%) and milk fat globule membrane proteins (1–3%). Whey proteins include α-lactalbumin, the major protein in this fraction (10–20% of total milk protein), serum albumin, immunoglobulins, and lactoferrin. Casein is mainly composed of two proteins: β-casein (85%), with different phosphorylated forms, and κ-casein (15%), a highly glycolysylated protein containing 40–60% carbohydrate residues (hexoses, hexosamines, and sialic acid). Casein micelles are formed by aggregation of caseins, calcium phosphate, and other ions, depending on both hydrophobic interactions and electrostatic binding. Human milk casein micelles are considerably smaller (30–75 nm in diameter) than bovine casein micelles (about 50–600 nm, mean 120 nm).

The total protein concentration in milk is high during early lactation (colostrum) and gradually declines to a low level in mature milk (Table 2). Protein concentration during early lactation is usually higher in preterm than in term milk. There are pronounced changes in the protein composition of milk as lactation progresses. Whey proteins decrease while casein increases in milk during the first few days of lactation. The ratio of whey proteins to casein is high (about 90:10) in colostrum and declines to 50:50 in mature milk. The pattern in caseins is different for premature milk, colostrum, and mature milk. In general, κ-casein is detectable in human milk only 3–4 days postpartum and may not be detectable in preterm colostrum. β-Casein concentration is higher in colostrum and mature milk of mothers with term compared to preterm infants.

Milk proteins are a source of peptides, amino acids, and nitrogen for the growing infant. In addition, milk proteins serve several nonnutritive roles. Proteins in human milk are not completely nutritionally available to the infant. Proteins with nonnutrient functions must remain intact in the infant gastrointestinal tract and may be largely unavailable for nitrogen metabolism, particularly during early lactation. However, at 6 weeks postpartum, 95% of breast milk protein is considered nutritionally available in term infants. Casein in human milk is an easily digested protein which provides amino acids, calcium, and phosphorus to the newborn. Casein phosphopeptides in human milk have been shown to keep calcium (and probably also bound iron, zinc, copper, and manganese) in soluble form in the infant intestinal tract, thus favoring absorption. α-Lactalbumin in human milk has a very high nutritional value (protein quality) and its amino acid composition is similar to the estimated amino acid requirements of young infants.

Nonprotein nitrogen

The nonprotein nitrogen (NPN) fraction of human milk comprises 20–25% of the total nitrogen and remains relatively constant during lactation. This fraction consists of more than 200 compounds, including free amino acids, urea, uric acid, ammonia, carnitine, choline, taurine, amino sugars, amino alcohols, nucleic acids, nucleotides, and polyamines. Many of these components, such as taurine, choline and nucleotides, are considered conditionally essential for the young infant. For example, human milk is a source of purine and pyrimidine bases as well as preformed nucleotides that are required by young infants due to their high need of nucleic acid formation but limited capacity for *de novo* synthesis of nucleotides.

Components of human milk NPN that contribute to infant protein metabolism include some peptides, free amino acids and, mainly, urea. Urea nitrogen is a significant part (30–50%) of total NPN in human milk, and it may contribute to infant protein synthesis. Free amino acids represent 3–5% of the total amino acids in human milk with higher levels in colostrum than in mature milk. Glutamate/glutamine and the nonprotein sulfonic acid, taurine, are the predominant free amino acids in mature human milk. Levels of urea and free amino acids in human milk seem to reflect protein quality and protein intake in the maternal diet. Increased urea and free amino acid levels have been observed in women receiving

high-versus low-protein diets. In mothers consuming diets low in lysine, methionine, and/or tryptophane, milk levels of these amino acids in the free form are also low.

Carbohydrates

Lactose is the major carbohydrate and, after water, is the second major constituent in human milk (*c.* 70 g l^{-1} in mature milk). Other carbohydrates in human milk include nucleotide sugars, glycolipids, glycoproteins, and oligosaccharides, many of which have several nonnutrient functions. Total oligosaccharide content in human milk is 5–8 g l^{-1}. Low levels of free galactose and minor levels of glucose are also found in human milk (*c.* 3 and 0.3 g l^{-1} in mature milk, respectively).

Lactose is one of the most stable constituents of human milk, with variation in levels reflecting mainly heterogeneity of individuals. Levels in milk increase (slightly) during the first few days postpartum but remain quite stable in mature milk (Table 2). Its concentration decreases during nursing but no variation occurs if levels are corrected for the increase in fat. Lactose levels may be low in preterm colostrum and in colostrum of women with insulin-dependent diabetes mellitus. Lactose in human milk is readily available to the infant and has been reported to stimulate the absorption of calcium, magnesium, and manganese.

Lipids

Human milk lipids are the major energy source for the infant, as well as a source of essential fatty acids (linoleic, 18:2 *n*-6 and α-linolenic, 18:3 *n*-3), and their long-chain polyunsaturated fatty acid metabolites such as arachidonic acid (20:4 *n*-6), eicosapentaenoic acid (20:5 *n*-3), and docosahexaenoic acid (22:6 *n*-3).

Lipids are present in human milk in the form of globules with a hydrophobic core consisting of triacylglycerols, cholesteryl esters, and retinyl esters and other neutral lipids, coated with bipolar compounds, phospholipids, proteins, cholesterol, and enzymes, formed into a loose layer called the milk lipid globule membrane. The diameter of the globules ranges from 1 to 10 μm, with most of the globules at 1 μm, giving a large surface area for efficient binding to lipolytic enzymes, thus facilitating lipid digestion and absorption in the infant gastrointestinal tract.

Triacylglycerols account for at least 98% of the milk lipids, followed by phospholipids (0.7%), cholesterol (0.5%), and minor amounts of free fatty acids, and mono- and diacylglycerols. The major fatty acids in triacylglycerols are 18:1 and 16:0 (*c.* 30% and 20% of total, respectively). The structure of the triacylglycerols in human milk is unique with most of the 16:0 at *sn*-2, 12:0 at *sn*-3, 18:0 at *sn*-1, and 18:1 and 18:2 at *sn*-1 and *sn*-3. Structure is an important factor controlling products formed by the action of lipases and their intestinal absorption in the infant.

Lipids are the most variable constituents of human milk. Total milk fat increases with the stage of lactation (Table 2) and during nursing; it decreases with parity, maternal infection, and long-term maternal undernutrition; it shows diurnal rhythm, and may vary with maternal diet and body composition (adiposity). With the increase in total milk fat during the first month of lactation, there is an increase in the average size of the milk fat globules and a reduced ratio of phospholipids and cholesterol (membrane lipids) to triacylglycerols (core lipids).

A major proportion of human milk fat is formed from circulating lipids derived from maternal diet, and from maternal body stores. A small proportion is synthesized *de novo* in the mammary gland from glucose, primarily as saturated fatty acids with medium-chain length (10–14 carbon atoms). Both maternal diet and maternal adipose tissue affect the composition of human milk triacylglycerols.

Maternal diet has a considerable influence on the fatty acid composition of human milk. Long-chain polyunsaturated fatty acids (such as 20:4 *n*-6, 20:5 *n*-3 and 22:6 *n*-3) which are synthesized by the maternal organism from their essential precursors (18:2 *n*-6 and 18:3 *n*-3), respond to changes in the diet. For example, levels of eicosapentaenoic acid (20:5 *n*-3) and docosahexaenoic acid (22:6 *n*-3) in human milk are increased by consumption of fish such as herring, mackerel, and salmon. The contents of *trans* isomers of fatty acids in milk reflect maternal intake of partially hydrogenated food fats and oils, deep-fried foods, and dairy products.

Typical western and nonwestern diets affect the fatty acid composition of human milk (Table 3). On high-fat (western) diets, fatty acid composition reflects dietary fatty acid pattern with high levels of unsaturated fatty acids related to consumption of vegetable oils. In this condition, only about 10% of the milk fatty acids are synthesized by the mammary gland. On high-carbohydrate low-fat (nonwestern) diets, the proportion of fatty acids originating in the mammary gland increases, resulting in higher levels of medium-chain fatty acids in milk. On low-energy diets, much of the milk fat is derived from adipose tissue and the composition of milk triacylglycerols reflects maternal depot fat. Maternal diet does not affect total cholesterol and phospholipids levels of milk.

Vitamins

All nutritionally essential vitamins are found in human milk. Fat-soluble vitamins are present in the core of milk fat globules (vitamin A, vitamin K) or bound to membrane or specific binding proteins (vitamin E, vitamin D). Water-soluble vitamins such as folate and vitamin B_{12} are bound to specific whey proteins.

Typical levels of vitamins in colostrum and mature human milk are presented in Table 2. Stage of lactation and particularly maternal nutritional status are the most important factors affecting the vitamin content of human milk (Table 4). In general, when maternal vitamin intakes are low, milk levels are also low and respond to supplementation; when they are high, milk levels approach a plateau and are less responsive to maternal supplementation. For many vitamins, such as folate and vitamin E, levels in milk are largely preserved through maternal regulation even, if maternal status is poor. For others, such as vitamin A, vitamin D, and vitamin B_{12}, levels in milk may be very low with maternal deficiency, and in this situation, inadequate for infant nutrition. Premature delivery is another factor affecting vitamin levels in human milk. Preterm milk has a high content of ascorbic acid, vitamin B_{12}, and pantothenic acid but may not be sufficient to meet the needs of the preterm infant for thiamin, vitamin B_6, vitamin E, and vitamin D.

Fat-soluble vitamins Vitamin A is present in human milk mainly as retinyl esters (95%) and as free retinol. Vitamin A activity is also provided as β-carotene which accounts for up to 30% of total carotenoids in milk. Other carotenoids present in human milk are lycopene, lutein, and cryptoxanthin, which have no provitamin A activity. The total level of vitamin A shows a rapid decrease over the first month postpartum. Vitamin A milk level is responsive to increased maternal intake, particularly in mothers with poor vitamin A status. The retinol:retinyl esters ratio in mature milk does not change after loading with vitamin A in well-nourished mothers but it may rise up to 30% in vitamin A-deficient mothers. Poorly nourished mothers have a low level of vitamin A in their milk and are thus at risk of providing insufficient amounts to the infant. Clinical evidence of vitamin A deficiency has been found after weaning in infants reared on breast milk containing 30 μg dl^{-1} vitamin A or lower.

Vitamin E is present in human milk mainly as α-tocopherol (*c.* 80%); the β-, δ-, and γ-isomers are also present in small quantities. The level is very high in colostrum and quite stable in mature milk; generally, it does not respond to maternal supplementation,

Table 3 Fatty acid composition of human milk lipids with different diets

	Western diets		*Nonwestern diets*

Table 4 Effects of stage of lactation and maternal diet on vitamin content of human milk

Vitamin	*Advancing lactation*[a]	*Maternal diet*[b]
Fat-soluble vitamins		
Vitamin A	↓	+
Vitamin D	=	+
Vitamin E	↓	=
Vitamin K	=	=
Water-soluble vitamins		
Ascorbic acid	↑	+
Thiamin	↑	+
Riboflavin	↑	++
Niacin	↑	+
Folate	↑	+
Vitamin B_6	↑	++
Vitamin B_{12}	↓	+
Pantothenic acid	↑	+
Biotin	↑	+

[a]Mature milk levels (> 1 month postpartum) compared to colostrum (1–5 days postpartum): higher (↑), lower (↓), or no change (=).
[b]+ indicates that maternal intake of the vitamin influences milk vitamin content primarily in deficient women; ++ indicates that maternal intake influences milk content even when vitamin status of mother is adequate; = indicates no influence of maternal intake on milk content.
Adapted from: Picciano MF Human milk: nutritional aspects of a dynamic food. *Biology of the Neonate* 74: 84–93. In: Jensen (1995) *Handbook of Milk Composition*, San Diego: Academic Press.

and is similar between populations with different vitamin E status, suggesting that maternal vitamin E stores are mobilized during lactation to insure vitamin E supply to the neonate.

Vitamin D-active compounds in human milk are the 25-hydroxylated forms, cholecalciferol and ergocalciferol, present in the nonlipid fraction of milk at 1.5–6% of their concentration in maternal plasma. The level of vitamin D in milk responds to maternal intake and exposure to sunlight. The level may be very low in women with poor vitamin D intake (e.g., strict vegetarians) and in those who live at northern latitudes. Exclusively breast-fed infants in areas of poor sunlight exposure may be at risk of vitamin D deficiency.

Vitamin K in human milk occurs mainly as phylloquinone. Levels in milk do not change consistently with stage of lactation and do not relate with maternal dietary intake. The level can be increased by maternal supplementation of vitamin K at very large doses. In general, it appears that the content of vitamin K in human milk is low and may not be sufficient to meet the needs of all newborns. In many countries, it is recommended that newborns receive vitamin K after birth.

Water-soluble vitamins Except for vitamin B_{12}, concentrations of water-soluble vitamins are lower in colostrum than in mature milk. In general, levels of water-soluble vitamins in mature human milk are several-fold greater than those in maternal plasma. For example, levels of ascorbic acid, thiamin, vitamin B_6, and folate in milk are 7–10 times the corresponding plasma levels. This suggests that the mammary gland actively transports and metabolizes these vitamins and regulates secretion, but mechanisms remain largely unknown.

The impact of maternal nutrition on the concentration of water-soluble vitamins in milk depends on the specific vitamin, the maternal status, and stage of lactation. Milk levels of vitamin B_{12} are very low in strict vegetarian women. The level of folate in milk is maintained with the concomitant depletion of maternal folate. Maternal supplementation of vitamins such as niacin, riboflavin, and vitamin B_6 affects levels in milk only when maternal status is inadequate. In well-nourished mothers, maternal supplementation at high doses has either no effect (i.e, ascorbic acid, folate, riboflavin) or little effect (other water-soluble vitamins) on levels in milk. The content of vitamin B_6 in human milk responds to maternal supplementation during established lactation but not during early stages. The level of vitamin B_6 in milk is greatly reduced in women with long-term use of oral contraceptive.

Minerals

Major minerals in human milk are the monovalent ions – sodium, potassium, and chloride – and the divalent species – calcium, magnesium, phosphate and sulfate – followed by the trace minerals, all distributed among the different physicochemical compartments of milk in a highly specific manner. Several studies have demonstrated a high bioavailability of most minerals in human milk, related to compartmentation and specific binding, as well as their favorable interrelationship with other milk nutrients for efficient utilization by the infant.

In general, mineral constituents in human milk do not correlate with maternal diet or maternal blood levels. Exceptions are the levels in milk of anionic elements such as iodine, fluoride, and selenium, which strongly reflect maternal status and intake, and also show marked geographic differences. Stage of lactation affects levels of all minerals in milk, with most rapid changes occurring during the first few days postpartum. Typical levels of minerals in colostrum and mature human milk are presented in Table 2.

Major minerals Electrolytes in milk (sodium, potassium, and chloride ions) are at much lower concentrations than those in maternal plasma, and collectively contribute to 10% of the total osmolarity of human milk. Variation in levels of electrolytes from colostrum to mature milk are inversely related to changes in lactose concentration. Levels are not influenced by nutritional factors or by maternal systemic diseases such as diabetes, but increase two- to three fold during mastitis.

Calcium is found in human milk mainly in the aqueous phase (80%), both as a free ion and associated with low-molecular-weight species such as citrate and phosphate, and bound to casein (20%). The concentration of ionized calcium in human milk is quite constant ($3\,\text{mmol}\,l^{-1}$) throughout lactation. Total calcium levels in milk increase markedly during the first days postpartum, stabilize in mature milk, and decline gradually in extended lactation. Magnesium is present mainly in the aqueous fraction of human milk (90%) and in the lipid globule membrane (10%). The total concentration of magnesium in human milk falls gradually during lactation. Maternal diet has no effect on calcium, magnesium, phosphate, and citrate levels in milk. Preterm milk may not be sufficient to meet the infant needs for calcium and phosphorus.

Trace minerals Iron in human milk is distributed in various compartments, about one-third associated

with low-molecular-weight compounds in the aqueous fraction, one-third with the milk fat, mainly the outer fat globule membrane, and about 10% in the casein fraction. At least some of the 20–30% in the whey protein fraction is bound to lactoferrin, a glycoprotein with two high-affinity binding sites for ferric iron, but only 3–5% of the total iron-binding capacity is used. Lactoferrin has been frequently proposed to account for the high bioavailability of iron in human milk.

The total concentration of iron in human milk is highest during the first few days after birth, with a 30% decrease during the first month of lactation followed by more stable levels. Neither iron supplementation of nursing women with adequate iron status nor poor maternal iron status has been shown to affect the level of iron in milk. There are reported geographic differences in human milk iron levels not related to maternal diet or nutritional status. The concentration of lactoferrin is higher in colostrum (5–6 mg ml^{-1}) than in mature milk (1.5 mg ml^{-1}). Lactoferrin content may be elevated in milk of women with very high iron intakes, and is reduced in generally malnourished women.

Zinc in human milk is distributed between the aqueous (40–70%), lipid (10–30%), and casein (10–45%) fractions. Serum albumin and citrate, followed by glutamate and picolinate, are the major zinc-binding ligands in the whey fraction; alkaline phosphatase, present in the fat globule membrane, appears as the major zinc-binding protein of human milk fat; and phosphoserine residues are the primary zinc-binding sites in caseins. Zinc in human milk is utilized very efficiently by infants. Breast-fed infants were shown to maintain high plasma zinc values compared to formula-fed infants even if the concentration of zinc in the formula was about three times that in breast milk. Human milk has therapeutic value in treating infants suffering from acrodermatitis enteropathica, a hereditary zinc-deficiency disease.

The concentration of zinc is very high in human colostrum, then declines throughout lactation. The most marked decrease (three- to fivefold) occurs during the first 2 weeks postpartum. Levels do not appear to be directly related to maternal nutritional status. Values reported from developed and developing countries are very similar. The effect of maternal zinc supplementation on milk zinc levels may depend, however, on maternal zinc status. For example, in lactating women with marginal zinc intakes it was shown that the decline in zinc concentration in milk over 1–9 months postpartum was significantly less in zinc-supplemented compared to nonsupplemented women.

Most (75%) of the copper in human milk is in the whey fraction, mainly associated to serum albumin and citrate; 15–20% is in the fat phase and the remainder (5%) is bound to casein. Citrate and free amino acids are believed to contribute to the efficient absorption of copper from human milk. The concentration of copper is generally high in colostrum and falls mainly during the first month but less markedly than that of zinc. The concentration of copper in human milk does not appear to be affected by maternal dietary intake or nutritional status of copper. The copper content of human milk may not be sufficient to meet the needs of the preterm infant.

Bioactive Components of Human Milk

Defense agents

The defense agents in human milk provide protection for the infant not only against infections, but also against diseases such as insulin-dependent diabetes mellitus, Crohn's disease, and atopic and allergic diseases. The mucosal surfaces of the intestinal and respiratory tracts of the infant are the major targets for their action, but some may also have a systemic effect after being taken up into the circulation. In general, the concentrations of the defense agents in human milk decrease with the progression of lactation. They are thus higher in a period when the defense system of the infant is immature and when there is a low production of immune agents in mucosal secretions. In order to play their roles in the infant's intestinal tract, these defense agents have to survive digestion, at least partially. Compartmentation and the presence of antiproteinases in milk, resistance to digestion, and low secretion of hydrochloride and pancreatic enzymes are mechanisms that allow survival of the defense factors in the gastrointestinal tract of the infant.

Leukocytes Leukocyte levels are high in colostrum and decrease in mature milk (less than 10% of the colostrum value). Neutrophils and macrophages represent about 90%, and lymphocytes about 10%, of the leukocytes in human milk. Leukocytes in human milk may transmit immunocompetence and promote maturation of the gastrointestinal tract of the infant through the secretion of cytokines, immunoglobulin A (IgA), and growth factors. They may also protect the breast against infection.

Soluble antiinfectious agents Many are effective mainly as antibacterial factors but some may be antiviral, antifungus, and antiprotozoan factors

also. They may act by direct inhibition of the growth of pathogens, inhibition of binding of bacterial pathogens and toxins to mucosal surfaces, and promotion of the growth of protective microorganisms. The main antiinfectious agents in human milk are:

1. Lactoferrin: most of it (> 90%) is present in milk in the form of apolactoferrin, which competes with siderophilic bacteria for ferric iron, thus impairing the proliferation of pathogenic microorganisms. However, lactoferrin may have a more complex antimicrobial effect since it can sensitize microorganisms to antibiotics and to the attack of lysozyme by the release of lipopolysaccharides from bacterial cell walls.
2. Digestive products of milk lipids: products of human milk lipid digestion, especially medium-chain, mono- and polyunsaturated fatty acids and monoacylglycerols, exert antiviral, antibacterial, and antifungal activity *in vitro*. The bile salt-stimulated lipase of human milk appears to be important in the production of these antimicrobial lipids.
3. Enzymes: peroxidase, which is produced by milk leukocytes, catalyzes the oxidation of thiocyanate ions to products with bacteriostactic activity. Lysozyme cleaves peptidoglycans in the cell wall of susceptible bacteria, causing their lysis.
4. Secretory IgA and other immunoglobulins (IgG, IgM, and IgD): secretory IgA (sIgA) is the principal immunoglobulin in human milk, secreted as dimeric IgA bound to a secetory component. Its concentration is higher in colostrum than in mature milk. sIgA protects the infant against mucosal pathogens in the maternal environment, and its antibody specifity reflects the maternal immunological experience. It causes agglutination of bacteria, blocks adhesion of several bacteria, viruses, and parasites to mucosal surfaces in the intestinal and respiratory tracts, neutralizes toxins, and prevents translocation of gut bacteria through the epithelial barrier.
5. κ-Casein and mucin: like other glycoproteins, including sIgA, they interact with pathogenic bacteria and viruses, possibly through their carbohydrate side chains, inhibiting their adhesion to epithelial cells, thus preventing microbial colonization and invasion of intestinal tissue.
6. Oligosaccharides: human milk contains several complex oligosaccharides, which are monomers of glucose, galactose, *N*-acetylglycosamine, fucose, and neuraminic acid. Almost all carry lactose at the reducing end. Oligosaccharides act as soluble receptor analogs of epithelial cell surface carbohydrates and are therefore potent inhibitors of bacterial adhesion to epithelial surfaces. Their biological functions are closely related to their conformation. The nitrogen-containing oligosaccharides also favor the proliferation of intestinal bifidobacteria and lactobacilli, resulting in an acidic intestinal environment, which aids in suppressing the growth of enteric pathogens. Glycoproteins, such as lactoferrin and κ-casein, exert a similar effect, ascribed to their oligosaccharide moiety. Glycoconjugates, such as monosialogangliosides, are receptor analogs for heat-labile toxins produced by bacteria, thus inhibiting binding of toxins.

Anti-inflammatory factors They protect the infant's intestinal tract against inflammatory damage and modulate inflammatory process. Several antiinfectious agents in human milk also have antiinflammatory activity. For instance, lactoferrin inhibits the formation of oxygen radicals by scavenging free iron, inhibits the complement system, and suppresses cytokine release from macrophages stimulated with bacterial products. Lysozyme interferes with the production of superoxide anion. Enzymes such as catalase and glutathione peroxidase act by degrading and removing hydrogen peroxide. Somatostatin-like immunoreactivity has been detected in human milk and may act as an antiinflammatory factor due to its immunosuppressive properties. Other antiinflammatory factors present in human milk are cortisol, epithelial growth factor, polyamines, antioxidants (ascorbate-like compound, uric acid, β-carotene, tocopherol), and inhibitors of nonoxidative inflammatory systems (prostaglandins and platelet-activating factor).

Immunomodulators Human milk components, besides providing passive protection for the neonate, may also directly modulate the immunological development of the infant. The immunomodulators in human milk include bioactive substances which have other primary biological functions, such as hormones and growth factors, substances that present an overlapping of their antiinfectious or antiinflammatory properties, and those that are actual immunological factors, such as cytokines and chemokines. Some examples of the major immunomodulators in human milk are prolactin, which may modulate differentiation and function of gut-associated lymphoid tissue (e.g., intraepithelial lymphocytes); antiidiotypic sIgA, which can provide natural immunization to the infant by sensitizing it against foreign antigens and microbial agents; lactoferrin, which suppresses *in vitro* antibody production and T-lymphocyte proliferative

response to antigens; nucleotides, which can act locally at the respiratory and alimentary tract, or systemically, enhancing T-cell maturation and function, and providing partial resistance to bacterial infection; β-casomorphins, which are derived from casein digestion and have opioid-like activity, and may be able to regulate intestinal motility and immunostimulating functions.

Several cytokines (interleukin (IL)-1β, IL-6, IL-10, interferon-γ, tumor necrosis factor-α), chemokines (IL-8, growth-related peptide, monocyte chemotactic protein) and granulocyte- and macrophage-colony-stimulating factors are present in human milk. These substances are protein hormones which mediate both natural and specific immunity and direct the development and functions of the immune system. The potential role of the immunological factors present in human milk, which would have to retain their biological activity in the gastrointestinal tract and to be transferred to the circulation of the infant, could compensate for the developmental delay of the neonate immune system, both at the mucosal and systemic sites.

Growth factors and hormones

Several nonpeptide hormones and hormonally active peptides are present in human milk. Among the former are the thyroid hormones, cortisol, progesterone, and estrogens. Examples of peptide hormones and growth factors, which promote the development and maturation of organ systems, are insulin, epithelial growth factor (EGF) and insulin-like growth factors (IGF-1 and 2). Both EGF and IGFs stimulate the growth of intestinal tissue. Other substances in human milk, such as lactoferrin and nucleotides, also have similar epithelial growth-promoting activities of intestinal cells *in vitro* or in animal models. The growth and maturation of the gut epithelial barrier would benefit the infant by limiting the penetration of foreign antigens in the intestinal mucosa. Gastrointestinal regulatory peptides (gastrin, gastric inhibitory peptide, gastrin-releasing peptide, neurotensin, somatostatin, etc.) and hypothalamic and hypophyseal hormones (prolactin, growth hormone, thyrotropin-releasing hormone, thyroid-stimulating hormone, gonadotrophin-releasing hormone, etc.) are also present in human milk. Leptin, a peptide hormone secreted by adipocytes and involved in the regulation of energy metabolism and food intake, is also present in human milk, as a result of the possible transfer from maternal plasma and also of the secretion by mammary epithelial cells.

Binding proteins for vitamins, minerals, and hormones

The binding proteins in human milk may improve solubilization and protect the ligands throughout their passage in the gastrointestinal tract of the infant and may increase the bioavailability of the vitamins and minerals attached to them. Binding proteins for vitamin D, thyroxine, and corticosteroids are present in human milk. Cobalamin- and folate-binding proteins in human milk show antimicrobial effects *in vitro* and enhance folate and cobalamin absorption in the neonatal period through specific receptors in animal and in intestinal membrane models. However, their role in cobalamin and folate absorption in infants is still not known. The role of lactoferrin from human milk in enhancing iron absorption by the infant is still controversial, but it might act as a regulator of iron absorption when iron stores are adequate and as an enhancer of iron absorption in deficiency states.

Enzymes

Several enzymes present in human milk are important in neonatal development. Proteinases, which could aid in hydrolysis of milk proteins, thus improving their bioavailability, may have their action limited by the antiproteinases also present. The antiproteinases would nevertheless have a beneficial effect by protecting bioactive milk proteins against hydrolysis in milk and in the infant's intestine. α-Amylase facilitates the digestion of polysaccharides by the infant, and its concentration in milk increases with the stage of lactation, reaching a plateau at 6 months. This is important, since salivary and pancreatic α-amylase only reaches adequate levels in the infant by 2 years after birth. Lysozyme, peroxidase, and glutathione peroxidase are all defense agents in human milk.

In addition to the lipoprotein lipase, human milk contains another lipase that is bile salt-dependent. It is called milk digestive lipase or bile salt-stimulated lipase and it is the most extensively studied enzyme in human milk. It facilitates the hydrolysis of milk fat in the intestine in the neonatal period, aiding the incipient endogenous lipid digestive function of the newborn, especially in premature infants. It acts on lipid substrates and also on water-soluble esters and its concentration is lower in colostrum than in mature milk. The milk digestive lipase completely hydrolyzes triglycerides, since it lacks positional or fatty acid specificity. The contribution of milk lipases to the newborn's endogenous lipases results in an enhancement of antibacterial and antiviral effects due to the production of free fatty acids and monoglycerides that have antiinfective properties.

Physiology

M Neville, UCHSC, Denver, CO, USA

Background

The provision of a specialized maternal body fluid, milk, for neonatal nutrition frees the mother from the necessity of providing a specific environment for rearing of the young. It allows birth to occur at an early stage of development and provides a time of intense maternal interaction with the newborn during early behavioral development. In addition, the nutritional reserves of the mother may be able to sustain the suckling through a period of famine. For all these reasons, lactation allows mammals to adapt to a wide variety of environments. It is becoming increasingly clear that breast milk is the most appropriate source of nutrition for human infants at least up to the age of 6 months. Many components of human milk, including, but not-limited to, the protein lactoferrin, growth factors, long-chain polyunsaturated fatty acids (LCPUFA), bile salt stimulated lipase, and anti-infectious oligosaccharides and glycoconjugates are not duplicated in formula. These components may be particularly important for the challenged infant (e.g., the preterm infant, infants with feeding problems, and infants in homes lacking adequate sanitation) but are increasingly being shown to be beneficial to healthy infants in well-protected environments as well.

After reviewing the macronutrient composition of milk, we will summarize the anatomical structure of the mammary gland at both the gross and microscopic levels to provide a basis for discussion of the processes of milk secretion and ejection. The stages of mammary development will be summarized briefly. The process of lactogenesis, the onset of copious milk secretion around parturition, will be discussed as it relates to milk composition, the provision of colostrum to the infant, and the relative roles of hormones and milk removal in initiating milk secretion. We will examine the regulatory mechanisms that help adapt the milk supply both to maternal food supply and to the requirements of the infant. The effects of dietary composition and maternal metabolic status on milk composition and secretion will be summarized, followed by a brief discussion of the involution of the mammary epithelium after the termination of suckling.

Milk Composition

After the period of colostrum formation, the composition of human milk is relatively constant, although some nutrients vary significantly within the feed and with duration of lactation. Breast-feeding can provide adequate nutrition for at least 4 months after birth; whether human milk alone provides sufficient nutrients after this period is currently a matter of controversy. The major macronutrients in milk are the sugar, lactose, (a disaccharide unique to milk), oligosaccharides, milk fat (mainly in the form of triglyceride), proteins, including casein, lactoferrin, secretory immunoglobulin A (sIgA), α-lactalbumin and many others present at lower concentrations, and minerals including sodium, potassium, chloride, calcium, and magnesium. The secretion mechanisms for most of these milk components are not as well understood. There are many minor components, including enzymes, vitamins, trace elements, and growth factors whose function and secretion are less well understood. The concentrations of the major components of human milk are compared with those of bovine milk in **Table 1**.

The major differences between human and bovine milk can be related to the specific needs of the young of the two species. For example, the concentration of lactose is higher and that of the mono- and divalent ions lower in human than in cow's milk. The high concentration of lactose provides a large amount of 'free water' – that is, water that does not need to be obligatorily excreted by the kidneys with salts, providing a reserve for temperature regulation via

Table 1 Comparison of the macronutrient contents of human and bovine milk

Component	*Human milk*	*Bovine milk*
Carbohydrates (g dl^{-1})		
Lactose	7.3	4.0
Oligosaccharides	1.2	0.1
Proteins (g dl^{-1})		
Caseins	0.2	2.6
α-Lactalbumin	0.2	0.2
Lactoferrin	0.2	Trace
Secretory IgA	0.2	Trace
β-Lactoglobulin	0	0.5
Milk lipids (%)		
Triglycerides	4.0	4.0
Phospholipids	0.04	0.04
Minerals and other ionic constituents (mM)		
Sodium	5.0	15
Potassium	15.0	43
Chloride	15.0	24
Calcium	7.5	30
Magnesium	1.4	5
Phosphate	1.8	11
Bicarbonate	6.0	5

sweating in human infants. The high concentration of casein in bovine milk provides protein and associated calcium and phosphate to support the very rapid growth of the young calf. In general, casein is removed when bovine milk is used to produce infant formula designed for the much more slowly growing human infant. There are a number of agents in human milk that protect against gastrointestinal and respiratory infections, including the oligosaccharides that recently have been shown to interact specifically with pathogen receptors, lactoferrin, and secretory IgA. These compounds are present at very small concentrations in bovine milk and infant formula.

The Anatomy of the Breast

The secretory apparatus of the breast consists of 15–25 ducts extending from the nipple and coursing through the mammary fat pad to terminate in grape-like clusters of alveoli (Figure 1). Each duct serves a specific lobule. The lobules are separated and supported by thick connective tissue septa and, in the nonpregnant nonlactating breast, by large amounts of adipose tissue. Blood vessels, nerves, and lymphatics run in the septa, which merge imperceptibly with the fascia at the anterior thoracic wall. The nipple, which serves as the termination point for the lactiferous ducts, is surrounded by an area of pigmented skin, the *areola*, containing sebaceous glands and sweat glands. The areola serves as the termination point for the fourth intercostal nerve, which carries sensory information about suckling to the spinal cord and brain. This is extremely important in the regulation of oxytocin secretion from the posterior pituitary and prolactin from the anterior pituitary. The mammary ducts expand slightly to form sinuses beneath the areola.

Figure 1 Camera lucida drawing of a sagital section through the breast of a 19-year-old nulligravida. From Dabelow A (1941) Die postnatale Entwicklund der menschlischen Milchdruse und ihr Korrelationen. *Morphology Journal* 85: 361–416, with permission.

Histologically, the secretory compartment of the breast consists of ducts and alveoli. The larger ducts appear to have two layers of cuboidal epithelium. Smaller ductules and alveoli have a single luminal epithelial layer surrounded by a discontinuous layer of contractile cells, the *myoepithelium* (Figure 2). This latter network of cells forms a basket-like framework around the alveoli and runs longitudinally along the ducts. Myoepithelial cells contract in response to oxytocin, ejecting milk from the alveoli, where it is stored after secretion by the luminal

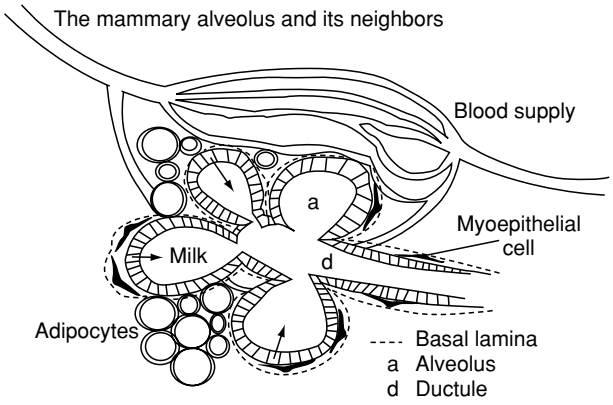

Figure 2 Cartoon showing the relation of the mammary epithelial compartment composed of mammary ducts and alveoli to the other anatomical compartments of the gland: the myoepithelial cells, the stroma composed of adipocytes and fibroblasts, and the extensive blood supply. Milk secretion by the epithelial cells into the alveolar lumen is indicated by arrows.

epithelial cells. Adipocytes are intimately associated with the glandular elements, as is a prominent blood supply.

Although the location and external form of the mammary glands differ from one species to another, the mechanisms of milk production are remarkably similar. Milk is produced and stored in alveolar units like that shown in Figure 2. Removal of the milk is accomplished by a process called *milk ejection*, during which, milk is forced from the alveoli by contraction of surrounding myoepithelial cells. Milk ejection is often called the 'let-down reflex,' and the milk exits through ductules into ducts draining several clusters of alveoli. In the human, the small ducts coalesce into 15–25 main ducts that drain sectors of the gland. The main ducts dilate into small sinuses as they near the areola, where they open directly on the nipple. For milk removal, the entire areola with the underlying milk sinuses is drawn into the infant's mouth, and the milk is withdrawn by the stripping action of the tongue.

In comparison with related dermal glands such as the salivary and sweat glands, the rate of milk secretion is slow, about 1.5 ml of milk per gram of tissue per day, and the secretory product is stored in the alveolar spaces until it is forced out by myoepithelial cell contraction. The larger ducts play a passive role in milk secretion, merely transferring the milk from the alveolar stores to the subareolar sinuses, where it is available to the suckling infant. Because the composition of the aqueous phase of milk changes very little during a feed or milking, it is unlikely that reabsorptive processes, like those important in the formation of saliva or sweat, play a significant role in determining milk composition.

Although the mammary epithelial cells are ultimately responsible for converting most precursors into milk constituents and transporting them to the mammary lumen, other cell types are also intimately involved in milk production, as illustrated in Figure 2. We have already mentioned the myoepithelial cells responsible for milk ejection from the breast. The mammary ducts and alveoli are embedded in a stroma that contains fibroblasts, adipocytes, plasma cells, and blood vessels. Blood flow is greatly expanded during lactation to make available the large amounts of substrate required for milk synthesis. During lactation, B lymphocytes 'home' in to the mammary gland, where they become plasma cells and settle in the interstitial space producing the immunoglobulins that ultimately find their way into milk. Stromal cells synthesize the growth factor IGF-1, which may promote survival of mammary epithelial cells. The mammary epithelium should, therefore, be viewed as an integrator of the activities of many cells and organs that contribute in a coordinated fashion to the synthesis and secretion of milk and its ejection from the gland.

Mechanisms of Milk Secretion

Figure 3 shows a single mammary epithelial cell in a lactating mammary gland. It is positioned on a basement membrane, and processes of myoepithelial cells course along its basal surface. Tight junctions join this cell to its neighbors, and in lactation, they prevent the direct transfer of interstitial fluid

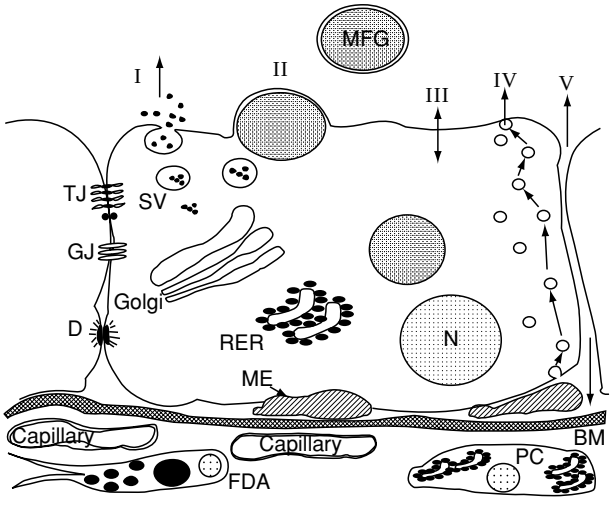

Figure 3 Mammary epithelial cell showing the pathways for the secretion of milk components. See text for further information. SV, secretory vesicles; RER, rough endoplasmic reticulum; ME, myoepithelial cell process; TJ, tight junction; GJ, gap junction; D, desmosome; BM, basement membrane; FDA, fat-depleted adipocyte; PC, plasma cell.

components to the alveolar lumen. Four major *transcellular* pathways are responsible for the secretion of milk components during lactation. The *paracellular* pathway is open during pregnancy and, under certain other conditions, allowing movement of interstitial fluid components into the milk space and the flux of milk components in the other direction.

Pathway I: Exocytosis

The exocytotic pathway secretes milk components by a mechanism similar to exocytotic secretion in all endocrine and exocrine glands. Casein and α-lactalbumin are synthesized and secreted via this largely constitutive secretory pathway, which is also responsible for the secretion of lactose, calcium, phosphate, citrate, and most other components of the aqueous phase of milk. Lactose is synthesized in the terminal portion of the Golgi vesicles from glucose and UDP (uridine diphosphate)-galactose by the enzyme galactosyl transferase using α-lactalbumin as an essential coenzyme. Lactose contributes two-thirds of the osmolarity of human milk. Various glycosyl transferases responsible for the formation of the wide variety of complex oligosaccharides present in human milk are also found in the terminal Golgi.

Pathway II: Lipid Secretion

The mechanism for the secretion of lipid is unique to the mammary epithelium. Triacyglycerols are synthesized in the mammary alveolar cell from glycerol and free fatty acids. The free fatty acids are derived from the plasma lipid using the enzyme lipoprotein lipase, from plasma free fatty acids carried there on albumin or by synthesis within the alveolar cell from glucose. Free fatty acids synthesized in the mammary alveolar cell are medium-chain fatty acids with 12 or 14 carbons rather than the long-chain fatty acids derived from the plasma. Once synthesized, the triacylglycerols form droplets, merge, and gradually move to the apical membrane. When they reach the apical surface of the cell, they press on the membrane, gradually becoming enveloped, and eventually pinch off as membrane-bound milk fat globules. The membrane of the milk fat globule prevents coalescence of the fat droplets and serves to deliver both triglycerides and phospholipids to the infant.

The composition of milk triglycerides depends on the diet. On the usual high-fat diet consumed by the American woman, the fatty acid composition reflects dietary lipid with long-chain fatty acids predominating and a fair proportion of unsaturated fatty acids reflecting the consumption of vegetable oils (Table 2). In this condition, only about 10% of the milk fatty acids are synthesized in the mammary gland itself as medium-chain fatty acids (C8–C14). On high-carbohydrate, low-fat diets, the proportion of fatty acid synthesized in the mammary gland from carbohydrate increases, leading to an increase in medium-chain fatty acids, as can be seen from the data from the milks of Nigerian women in Table 2. The milks of the Nigerian women also contained a higher proportion of *n*-3 LCPUFA. On reduced- or low-calorie diets, much of the milk fat is derived from adipose tissue; in this case, the composition of the triglycerides resembles depot fat.

Table 2 Major fatty acids of human milks (wt%)

Fatty acid		*Human milk*[a]	*Human milk*[b]
Saturated fatty acids			
Intermediate- and medium-chain (formed in mammary gland)			
8:0	Octanoic acid	0.46	
10:0	Decanoic acid	1.03	0.54
12:0	Lauric acid	4.40	8.34
14:0	Myristic acid	6.27	9.57
Long chain			
16:0	Palmitic acid	22.00	23.35
18:0	Stearic acid	8.06	10.15
Monounsaturated fatty acids			
16:1 *n*-7 (*cis*)	Palmitoleic acid	3.29	0.91
18:1 *n*-9 (*cis*)	Oleic acid	31.30	18.52
18:1 *n*-9 (*trans*)		2.67	0.86
Polyunsaturated fatty acids (PUFA) (essential fatty acids)			
18:2 *n*-6	Linoleic acid	10.76	11.06
18:3 *n*-3	Linolenic acid	0.81	1.41
Long-chain PUFA (n-6)			
18:3 *n*-6	γ-Linolenic acid	0.16	0.12
20:2 *n*-6		0.34	0.26
20:3 *n*-6	Dihomo-γ-linolenic acid	0.26	0.49
20:4 *n*-6	Arachidonic acid	0.36	0.82
Long-chain PUFA (n-3)			
20:5 *n*-3	Eicosapentaenoic acid	0.04	0.48
22:5 *n*-3		0.17	0.39
22:6 *n*-3	Docosahexaenoic acid	0.22	0.93

[b]Data from Nigerian women who also had a diet high in fish, as reflected in the *n*-3 LCPUFA.

Pathway III: Transmembrane Transport

There are transport mechanisms for only a few milk components in the apical membrane of the mammary alveolar cell. This membrane is known to be permeable to monovalent ions such as sodium, potassium, and chloride, as well as to glucose. It is impermeable to divalent cations and disaccharides such as lactose. The mechanisms that control the substantial concentration gradients of monovalent cations across this membrane are not understood.

Pathway IV: The Transcytotic Pathway

Proteinaceous substances from the interstitial space find their way into milk via *transcytotic* pathways.

One of these pathways, that for the secretion of IgA, is well understood. An IgA receptor on the basolateral membrane of the cell interacts with dimeric IgA made by plasma cells residing in the interstitial spaces of the mammary gland. The IgA is endocytosed and transported in a vesicle to the apical membrane, where it is secreted with a piece of its transporter (called 'secretory component') into the milk. The secretory component renders the protein resistant to protease, and the IgA thus has a reasonable survival time in the infant's intestine, where it may contribute to protection from infectious agents. Many other proteins that are not synthesized in the mammary alveolar cell enter milk via transcytosis, e.g., hormones such as insulin and prolactin, growth factors such as IGF-1 and even serum albumin.

Pathway V: Paracellular Transport

During lactation, tight junctions (Figure 3) form a seal between alveolar cells, closing the paracellular pathway and completely isolating the alveolar lumina from the interstitial spaces. In pregnancy, after involution and during mastitis, these junctions open by mechanisms that are not well understood. At these times, even large proteins can be transferred between the milk space and interstitial space. Under these conditions, plasma components like sodium, chloride, and albumin enter the milk space directly from the interstitial space, milk components like lactose enter the blood stream, and the concentrations of sodium and chloride in milk are high.

Cells from the immune system pass into milk via the paracellular pathway. They appear to be able to squeeze even through the tight junctions of the lactating gland.

Mammary Development

The mammary gland is one of the few organs that undergoes almost the entire cycle of development, differentiation, function, and involution in the adult animal. Each of these stages has different control mechanisms, only some of which are understood despite decades of study. The developmental cycle of the mammary gland is usually divided into four stages: (I) mammogenesis, or development, (II) sensory differentiation (III) secretory initiation, and (IV) lactation and (V) involution. Mammogenesis takes place in the embryo, and at puberty. Sensory differentiation may begin at late puberty and is completed during pregnancy. Secretory initiation begins at parturition and is completed during the first 3–5 days after birth in the human. Lactation lasts as long as milk continues to be removed from the breast after birth of the infant. Involution is the regression of the gland after suckling has been discontinued. Each phase has its own unique control mechanisms.

Embryogenesis

The mammary gland begins to develop in the fourth week of fetal life as a thickening of the epidermis that gradually begins to invade the underlying parenchyma forming an epithelial bud. This bud branches and canalizes forming about 15–20 rudimentary ducts consisting of a lumen surrounded by a layer of ductal epithelium with an underlying layer of myoepithelial cells. The entire process requires about 28 weeks, during which time, a fully committed epithelial rudiment and an underlying fat pad are formed, as well as the nipple. It is becoming clear that interactions between the epithelium and the underlying stroma are critical in determining the morphology of the structures formed. Towards the end of pregnancy, the mammary epithelium of the infant may become secretory under the influence of the maternal steroid hormones, and at birth, many infants secrete a small amount of milky fluid called 'witches' milk.

Postnatal Development

During childhood, the mammary gland does little more than keep pace with the general growth of the body.

Pubertal Development

One of the earliest signs of puberty in girls is enlargement of the breast. This enlargement involves both the epithelium and the adipose stroma, *an obligatory substratum for epithelial growth*. Transplant experiments in rodents have shown that the mammary epithelium grows only in white adipose tissue fat pads and best in the mammary fat pad. Under the influence of *estrogen* from the developing ovary, the ducts begin to elongate. The most direct evidence that estrogen is essential for ductal development comes from experiments in which time-release pellets were used to deliver drugs directly into the developing gland. Implantation of estrogen pellets enhances ductile development, whereas implantation of pellets that release antiestrogens into the local tissue environment inhibits ductal growth. Estrogen receptors are found in the stroma as well as in scattered epithelial cells.

Pregnancy

During pregnancy, the increasing concentrations of sex steroids along with prolactin and placental lactogen bring about maximal development of the breast. Lobular development intensifies until the fat pad is completely filled with epithelial structures. By midpregnancy, the alveolar cells have differentiated

sufficiently to be capable of secreting milk, a point in time called lactogenesis, Stage I. However, milk secretion is held in check by the high concentrations of progesterone from the placenta.

Secretory Initiation, Lactation, and Involution

With the birth of the young, the hormonal support for mammary growth and inhibition of milk secretion are withdrawn, and secretory initiation begins. This process involves the terminal differentiation of the mammary cells through a carefully programmed series of events that result in copious secretion of milk 4 days after birth. Milk secretion is maintained until regular removal of milk from the gland ceases, at which point, the mammary epithelium begins to involute. Many of the alveolar cells undergo apoptosis, and the gland returns to its prepregnant state.

Secretory Initiation

Although the mammary epithelium becomes fully competent to secrete milk sometime in midpregnancy, the term secretory initiation is used to describe the *onset of copious milk secretion in the first few days after parturition* and will be so used in the rest of this discussion. Withdrawal of progesterone and estrogen in the presence of sustained prolactin secretion brings about a complex series of well-programmed events that lead to the secretory activity of differentiated mammary cells. Immediately after birth, the tight junctions between the cells begin to close, and the paracellular pathway is no longer available for the exchange of components between the milk space and the interstitial space. The concentrations of sodium and chloride in the milk fall, and the milk lactose concentration increases (Figure 4). Next, secretion of IgA oligosaccharides and lactoferrin increases, adding large quantities of these protective substances along with high concentrations of lymphoid cells to the mammary secretion, now called *colostrum*. Beginning about 40 h postpartum, the alveolar cells increase their secretion of lactose, casein, and the other components of mature milk, and milk volume production goes from about 100 ml per day on the second day postpartum to about 500 ml per day on day 5. The corresponding feeling of fullness of the breast is often referred to as the 'milk coming in.' Suckling by the infant is not required to initiate the process; however, milk secretion cannot be maintained if milk is not removed shortly after the secretory activity increases.

Lactation

At the end of secretory initiation, the breast enters the stage of lactation, sometimes referred to as

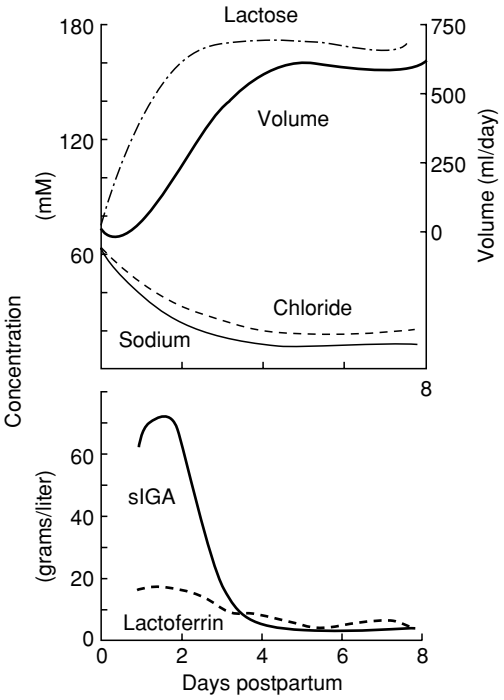

Figure 4 Changes in milk composition and volume during secretory activation in the woman.

galactopoiesis. This stage persists as long as the infant continues to suckle at least twice a day. The daily milk volume transferred to the infant increases on average from 500 ml on day 5 to about 650 ml at 1 month and about 750 ml at 3 months. Milk volume is largely regulated by infant demand. Infants who are larger at a given age tend to take more milk; if breast milk is supplemented with other foods or formula, milk volume decreases. In most women, the breast appears to have the capacity to secrete much more milk than is needed for nourishment of a single infant. In fact, wet nurses who removed milk from their breasts using a breast pump have been recorded as producing up to 3500 ml per day, and some women are able to breast-feed triplets!

Regulation of Milk Secretion

Prolactin is necessary for milk secretion, and suckling promotes its secretion. However, the volume of milk secretion is not directly regulated by the concentration of prolactin in the blood. Rather, local mechanisms within the mammary gland related to the amount of milk removed by the infant are responsible for the day-to-day regulation of milk volume. A protein factor called *feedback inhibitor of lactation* is secreted with other milk components into the alveolar lumen. If milk is not removed from the gland, this substance, whose identity is not yet entirely clear,

interacts with the mammary alveolar cell and inhibits milk secretion possibly by altering the sensitivity of the cells to prolactin.

Regulation of Milk Ejection

Suckling initiates a neuroendocrine reflex essential for removal of milk from the breast. Afferent impulses travel via sensory neurons from the areola to the hypothalamus, where they stimulate magnocellular neurons to fire, sending an impulse down their axons into the posterior pituitary where the hormone *oxytocin* is released. This hormone travels through the blood stream to the breast, where it causes contraction of the myoepithelial cells, forcing the milk from the alveoli into the mammary ducts and sinuses whence it can be removed by the sucking infant. Without an adequate let-down reflex, complete removal of milk from the breast is not possible. The activity of the magnocellular neurons can be profoundly influenced by higher brain centers. For this reason, emotional distress can inhibit let-down. Conversely, let-down is subject to conditioning, so that a woman often releases oxytocin at the sound of her (or someone else's) infant's cry or in response to a picture of her infant.

Interactions of Lactation with Maternal Conditions

The lactating breast is largely an autonomous organ, depending only on permissive levels of prolactin and other hormones such as insulin and hydrocortisone necessary for continued milk secretion. The amount of milk produced is under local control and depends on the rate of milk removal from the breast, as discussed above. The gland removes nutrients from the plasma according to its needs for substrate to synthesize milk components and is usually only marginally affected by acute changes in maternal dietary intake and other maternal factors such as fluid intake, body composition, illness, and exercise. The limits to which lactation is maintained in starvation are unknown, since experimental observations in this area are difficult. A single case report suggests that 7 days of total fasting does not impact milk secretion. The composition of the diet does, however, affect some milk components, most notably certain vitamins such as vitamin C, vitamin A, vitamin B_{12}, vitamin D, and possibly others. Vitamin B_{12} deficiency has been reported in infants of mothers consuming a vegetarian diet. The milk levels of some trace elements, for example, selenium are also affected by maternal dietary status. The effects of the lipid composition of the diet on milk fat composition have been discussed above. Fluid intake is not directly linked to milk production, as women who take no water during the day during Ramadan produce normal volumes of slightly hypertonic milk. It is likely that hydration severe enough to threaten maternal metabolism would also threaten milk production. The total fat content of milk does not appear to be affected by dietary intake but is inversely proportional to body fat. Diabetics may have difficulty initiating lactation, but once lactation is established, they have no problem nursing an infant. Mastitis alters milk composition by opening the tight junctions, so that the sodium and chloride content of the milk is increased and the protein content decreased. Pregnancy anecdotally reduces milk volume, although there are no good data on this point. Exercise has not been observed to alter either milk volume or composition.

The impact of lactation on maternal nutritional and reproductive status is more notable. Exclusive breast-feeding inhibits the release of gonadotropin-releasing hormone from the hypothalamus, postponing the return of reproductive function after birth of the infant. However, even full breast-feeding does not necessarily offer protection against a subsequent pregnancy, particularly in well-nourished women. Bone calcium has been shown to decline during lactation in several studies, probably owing to the lack of estrogen during the period of postpartum amenorrhea, but appears to recover to normal values once the menses have resumed. Women with marginal protein nutrition may suffer some deterioration of their protein status. During lactation, the folate stores of women with marginal folate status may be depleted of the vitamin, a situation that may have a negative impact on a subsequent pregnancy. However, compared with species like rodents or dairy animals, whose body lipid reserves are depleted within a short time after lactogenesis by their very copious milk production, metabolic adaptations to lactation in the woman are relatively small, because feeding a single infant does not place an enormous metabolic load on the lactating women compared with rodents or dairy animals.

LACTIC ACID BACTERIA

J A Narvhus, Agricultural University of Norway, Aas, Norway
L Axelsson, MATFORSK, Norwegian Food Research Institute, Aas, Norway

Introduction

Lactic acid bacteria (LAB) are responsible for a great diversification in the flavor and texture of food products due to their fermentation of food raw materials. However, in some circumstances they can be responsible for food spoilage. Food fermentation technology, along with drying and salting, is one of the most ancient food-preserving techniques known to humans. Fermented foods are less perishable than the original raw materials, their nutritional value may be enhanced, and the safety of these foods may be improved due to the inhibition of pathogenic bacteria by the low pH and the presence of organic acids and antimicrobial compounds. The ubiquity of LAB in nature often results in opportunistic inoculation of food raw materials. Humans have, since prerecorded times, aided such natural events by purposely adding a portion of previously fermented food to the new batch of raw materials (so-called 'back-slopping') in order to promote successful fermentation. In addition, specific traditional technologies often lead to the dominance of particular types of LAB, which gives the product special characteristics. (*See* **Fermented Foods**: Origins and Applications; **Traditional Food Technology**.)

Today, many traditional fermentation technologies have been industrialized and form large commercial enterprises. Examples of these are the production of cheese and other fermented dairy products, fermented sausages such as salami, and fermented cabbage – sauerkraut. LAB are only weakly proteolytic and lipolytic, which is also important since breakdown products from protein and fat are often organoleptically unpleasant in high concentrations. LAB also inhabit the mucous membranes of the intestinal and reproductive tracts of humans and animals and incorporation of selected strains into certain fermented foods has gained increasing interest in recent years. LAB have a reputation of being 'generally recognized as safe' (GRAS). However, some species are pathogenic and the recent developments in the field of probiotics have brought safety aspects of LAB into focus. Aside from the known pathogens, LAB are rarely isolated from disease and in almost all cases are associated with underlying illness which increases the susceptibility of the host.

LAB were amongst the very first bacteria studied. In 1873, Joseph Lister isolated the first bacterial pure culture which he called *Bacterium lactis*. This lactic

acid bacterium is now called *Lactococcus lactis* and is used for fermenting milk to produce hundreds of different dairy products. Early work on LAB was mainly concentrated on those associated with dairy products and, with time, many commercial starter cultures were developed. However, LAB were soon discovered in other habitats and a broader view of the group developed. From concentrating on the reactions of the organisms in milk, interest was diverted into more diverse attributes and the taxonomy of the group was gradually mapped. (*See* **Cheeses**: Starter Cultures Employed in Cheese-making; **Fermented Milks**: Types of Fermented Milks; **Yogurt**: The Product and its Manufacture.)

However, the relationships between different LAB genera have seen many changes. Orla Jensen described seven genera in 1919, but only the name of one of them, *Streptococcus*, remains valid today. The LAB group now comprises 16 genera, 12 of which are associated with food (Table 1). All LAB have a G+C% under 50. Morphologically, they are cocci, coccobacilli, or rods and, with the exception of the tetrad-forming genera *Aerococcus, Pediococcus*, and *Tetragenococcus*, chain formation is common. LAB are Gram-positive, nonsporing, and most species are nonmotile. They have complex nutritional requirements and are dependent on the presence of a fermentable carbohydrate for active growth. As an end product of this fermentation, LAB produce copious amounts of lactic acid either homofermentatively (> 95% lactic acid from glucose) or heterofermentatively (producing acetic acid, ethanol, and carbon dioxide in addition to lactic acid). Under conditions of limiting carbohydrate, fermentation by homofermentative strains may become mixed. The group lacks the ability to synthesize porphyrin groups and they thus have a nonrespiring (cytochrome-negative) metabolism and are catalase-negative in standard laboratory media. It should be mentioned here that the genus *Bifidobacterium* is often regarded as being a member of the LAB group as it fits the general description above. In addition, certain strains of bifidobacteria are used in probiotic applications, much in the same way as some LAB. However, bifidobacteria are phylogenetically unrelated to LAB and also differ physiologically in that they utilize a sugar fermentation pathway unique to the genus. (*See* ***Bifidobacteria* in Foods**.)

The separation of the various genera of LAB from each other using conventional biochemical tests has always been problematic, since a certain overlapping of properties exists (Table 1). Nevertheless, the allocation of most LAB isolates to the correct genus should be possible by the use of the characterization tests shown in the table.

Within each genus, classical division of LABs into species relies heavily on carbohydrate fermentation profiles and some other simple physiological tests such as growth at particular temperatures and tolerance of salt and extremes of pH. However, the development of genotyping techniques has to a certain extent revolutionized our understanding of the relationships within the group. Some of these techniques can also be used to identify and characterize isolates down to species and even strain level. Figure 1 shows the changes in nomenclature within LAB important in foods, from 1980 to 2000. Figure 2 shows a schematic, unrooted phylogenetic tree of the lactic acid

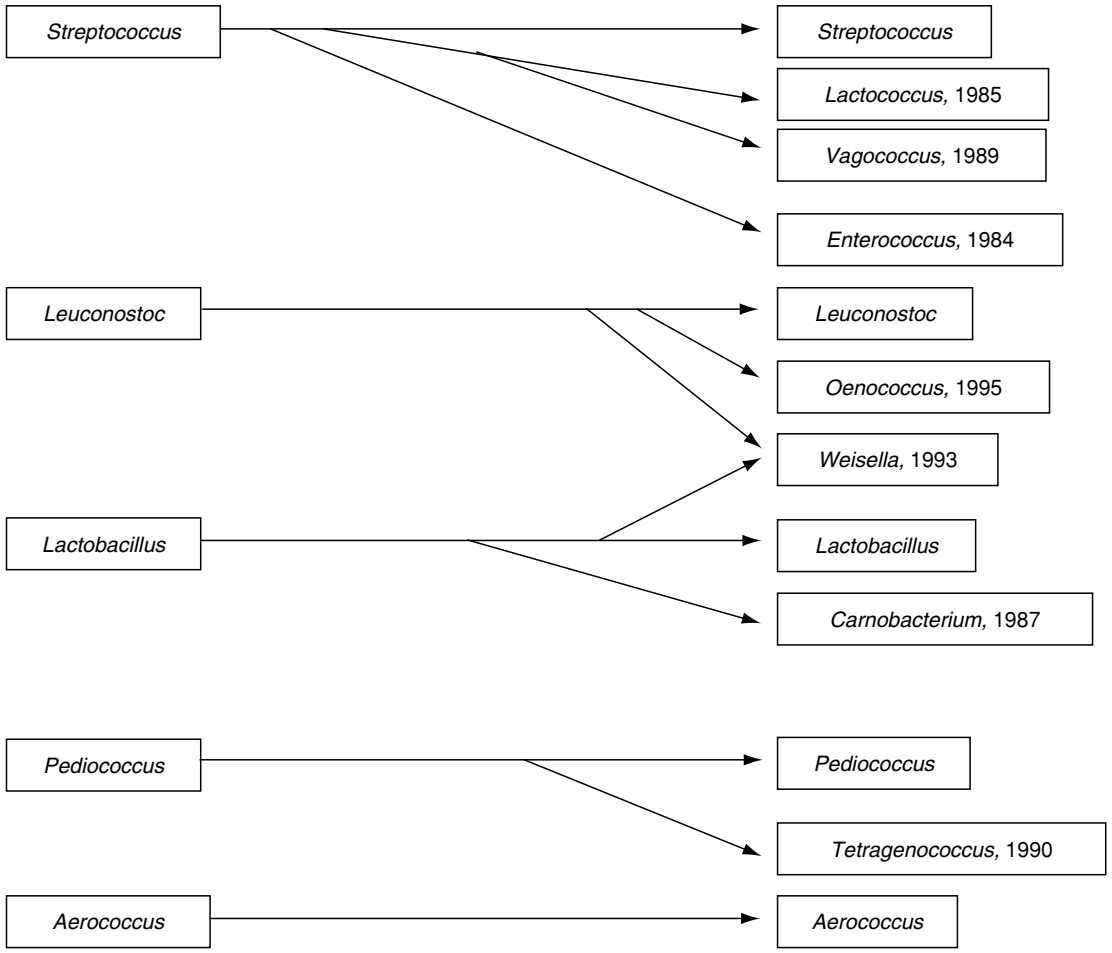

Figure 1 Genera of lactic acid bacteria important in food, showing changes in nomenclature from 1980 to 2000.

bacteria. Phylogenetically, LAB belong to a cluster of Gram-positive bacteria which also includes aerobic and facultative anaerobic genera such as *Bacillus* and *Staphylococcus*. So far, not one genotyping method has achieved universal acceptance but these methods are gradually partially replacing the traditional characterization tests. However, molecular biological techniques alone have the disadvantage that they give no information concerning the properties of the organisms under study. For this reason, studies of the metabolic properties of LAB, especially with relation to food product characteristics, are also receiving increasing attention.

Descriptions of Selected Genera

The Genus *Streptococcus*

The genus *Streptococcus* is one of the original genera of LAB and was heterogeneous. Taxonomic studies in the 1980s, however, supported the unofficial subgrouping of the genus and concluded that the fecal and lactic species were sufficiently different to deserve allocation to their own genera of *Enterococcus* and *Lactococcus*. However, most streptococci are not food organisms; most are commensals of humans and animals and, indeed, many are pathogens or opportunistic pathogens. The notable exception to this is *Streptococcus thermophilus*. This species is characterized by its rapid growth at high temperatures and active fermentation of milk. It is used, together with *Lactobacillus delbrueckii* ssp. *bulgaricus*, for the production of yogurt and is found in many indigenous fermented milks, where it may occur along with a variety of other LAB and yeasts. It is also used as a starter culture for a variety of Italian cheeses, including Parmesan. No other species of *Streptococcus* is reported to be important for either the manufacture or spoilage of food stuffs. (*See* **Yogurt**: The Product and its Manufacture.)

The Genus *Lactococcus*

Some species of the genus *Lactococcus*, previously grouped within *Streptococcus* and having the group N

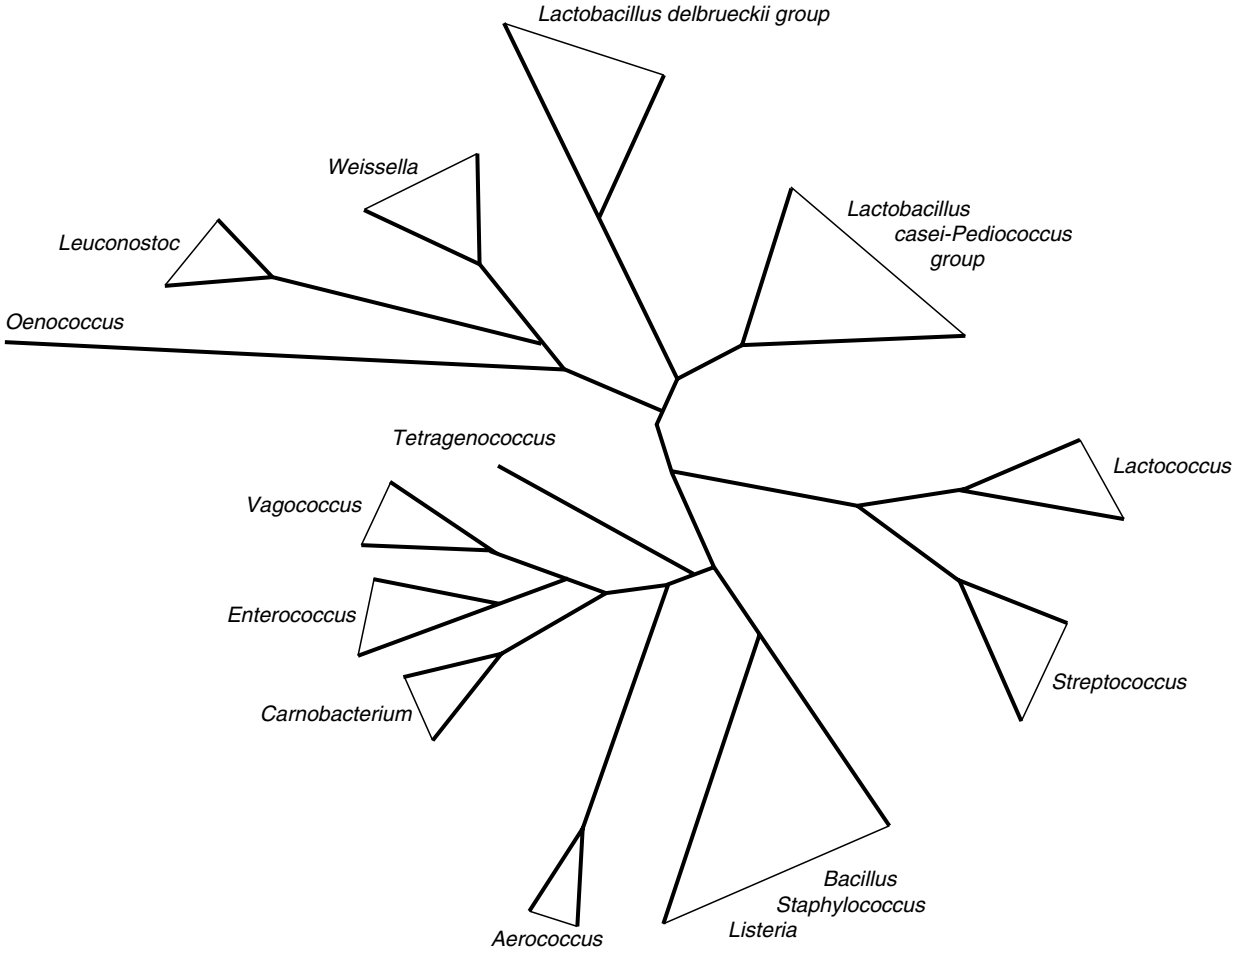

Figure 2 Schematic, unrooted phylogenetic tree of the lactic acid bacteria, including some aerobic and facultative anaerobic Gram-positives of the low G+C subdivision. Note: evolutionary distances are approximate. Reproduced from Axelsson L (1998) Lactic acid bacteria: classification and physiology. In: Salminen S and von Wright A (eds) *Lactic Acid Bacteria. Microbiology and Functional Aspects*, 2nd edn. New York: Marcel Dekker with permission from Marcel Dekker.

antigen, are extremely important in the dairy industry. They can be isolated from spontaneously fermented milks and, more importantly, are an essential part of commercial dairy starter cultures used for the manufacture of fermented milks, sour cream, fermented butter, unripened cheeses (such as cottage and cream cheeses), and also for a multitude of vastly varying matured cheeses. Lactococci are often used in coculture with *Leuconostoc* strains. *L. lactis* is the most commercially important *Lactococcus*. It has two subspecies – *cremoris* and *lactis* – and the latter subspecies has a biovariant – *diacetylactis*. The two subspecies differ from each other in a variety of biochemical characterisation tests; the subspecies *cremoris* is markedly less reactive than *lactis* but it has the reputation of being a better flavor producer in cheese. In the nondairy environment, strains of *lactis* are isolated more frequently than *cremoris*. Some strains of *cremoris* form extracellular polysaccharides and are found in traditional Scandinavian ropy milks. (*See* **Cheeses:** Starter Cultures Employed in Cheese-making; **Fermented Milks:** Types of Fermented Milks; **Starter Cultures.**)

The biovariant *diacetylactis* deserves a special mention since its one distinguishing feature – the ability to metabolize citrate – results in the formation of diacetyl in fresh fermented milk products and in the production of carbon dioxide which forms eyes in Gouda-type cheeses. Other species of *Lactococcus* are not considered important in the food industry.

The Genus *Vagococcus*

The genus *Vagococcus* is phenotypically indistinguishable from lactococci and also possesses the group N antigen. However, vagococci are often motile; they have been isolated from chicken feces, water, and diseased fish.

The Genus *Enterococcus*

Cocci which are Gram-positive, catalase-negative, possess the group D antigen, and are able to grow in

6.5% salt and in the presence of 0.4% sodium azide, can be identified presumptively as enterococci. This genus was previously grouped within *Streptococcus*. Certainly all the classical species of *Enterococcus* fall into this category, but some newly described species have some aberrant properties which has resulted in the unofficial division into five subgroups. Several species of *Enterococcus* are naturally found in the intestinal tract of humans and animals. The role of enterococci in food is unclear and much debated. These organisms have been isolated from many indigenous fermented foods, but their possible positive contribution has not been elucidated since such products commonly contain several species of LAB. The tolerance of members of the genus for extremes of pH, salt, and temperature makes their survival in fermented foods unproblematic. The fecal original of many species, such as *E. faecalis* and *E. faecium*, however, means that their presence in foods is regarded as being an indication of poor hygiene. Further complications are the opportunistic pathogenicity of some species of *Enterococcus*, their ability to decarboxylate amino acids and thereby produce amines in foods, and finally their propensity to be resistant to antibiotics and to transfer such traits by means of mobile genetic elements. A new area of debate concerns the advisability of using these organisms as probiotics.

The Genus *Leuconostoc*

All leuconostocs are heterofermentative cocci. Their main habitat is on plants and, to a lesser extent, in meat, milk, and dairy products. As in other genera of LAB, the member species in this genus are continually being revised, but this is a comparatively small genus, with about 11 species. The most common species are *Leuconostoc mesenteroides*, which has three subspecies: *mesenteroides, cremoris*, and *dextranicum*, and *Leuc. lactis*. Several other species at present placed in the genus *Leuconostoc* show poor genotypic homology with the above species, and also with each other. Leuconostocs play an important role in the early stages of the fermentation of vegetable products such as dill pickles, olives, and sauerkraut. They take over from the initial, mainly Gram-negative flora and are important for the development of the characteristic flavor of the products. Later in the fermentation other more aciduric LABs dominate.

Several leuconostocs produce extracellular polysaccharides which can be used as food-thickening agents or stabilizers. However, these dextrans cause problems in sugar factories and also in fermented sausages, where the production of slime is undesirable. Some mesophilic dairy starter cultures contain leuconostocs. They produce flavor compounds (diacetyl and acetate) from the metabolism of citrate and reduce acetaldehyde to ethanol. In addition, production of CO_2 from both citrate and carbohydrates is important for the eyes in Gouda-type cheeses and the slight effervescence in cultured buttermilk.

The Genus *Oenococcus*

Oenococcus oeni (previously *Leuconostoc oenos*) is the only member of this new genus. It is found in wine and is responsible for the malo-lactic fermentation which occurs during the maturation of wine. *O. oeni* converts L-malic acid to L-lactic acid, thus increasing the pH by 0.1–0.3 pH units, and rendering the wine microbiologically stable. Traditionally present as a natural contaminant in wine, this organism may be purposely introduced to some wines to insure the desired maturation.

The Genus *Lactobacillus*

Members of the genus *Lactobacillus* are rod-shaped and number over 60 species. Despite the fact that several species have recently been removed to two new genera (*Weissella* and *Carnobacterium*), the genus is still heterogeneous. Lactobacilli are found in a variety of habitats and vary considerably in their characteristics. In 1919, Orla-Jensen grouped the lactobacilli into three subgenera: *Thermobacteria, Streptobacteria*, and *Betabacteria*. These subgenera are currently not taxonomically valid, but this subdivision is still useful to divide the genus into three primary phenotypic groups: the obligately homofermentative; the facultatively heterofermentative; and the obligately heterofermentative.

Lactobacilli are naturally found in nutritive and carbohydrate-rich habitats such as plants or material of plant origin, meat, milk, and dairy products. They are also found in manure, silage, and sewage. The mucous membranes (intestinal, vaginal, and oral) of humans and animals are often dominated by lactobacilli, where they are thought to have a probiotic function. (*See* **Microflora of the Intestine: Probiotics.**)

In the food industry, lactobacilli may be responsible for the desired fermentation of some products but also for the spoilage of others. In dairy foods, *Lb. delbrueckii* ssp. *bulgaricus* is used as a starter culture for yogurt and a variety of cheeses, particularly those manufactured using a high cooking temperature. During the ripening of most cheeses, so-called 'non-starter' lactobacilli (NSLAB) develop and are important for the development of the cheese flavor. Present research focuses on identifying useful strains with the prospect of greater control over cheese ripening. Heterofermentative lactobacilli may cause unwanted openness in some cheeses due to CO_2 production from residual carbohydrate.

Lactobacilli play an important role in the fermentation of many cereal products, such as sourdough, Tanzanian *togwa* and Nigerian *ogi*, where they produce certain flavor compounds and reduce the pH to as low as 3.5. Several species of lactobacilli are naturally found in fermented sausages such as salami, and commercial starter cultures for such products commonly contain *Lb. plantarum*. However, they may also cause the spoilage of refrigerated fresh and cooked meats kept in a CO_2-enriched atmosphere. Although this may inhibit the growth of other spoilage organisms and also pathogens, defects such as slime, green color, gas, and acidic taste may develop. Various fermented vegetables also contain lactobacilli. The early stages are dominated by leuconostocs and/or heterofermentative lactobacilli, but the final product is usually dominated by more acid-tolerant, homofermentative species.

The Genus *Carnobacterium*

The genus *Carnobacterium* is comparatively new, comprising some former lactobacilli which do not grow on acetate agar or at pH 4.5. Phylogenetically, however, they are most closely related to enterococci. They have so far been isolated from five habitats: meat (and meat products), cheese, fish, poultry, and sea water. Most reports are of isolates from meat that is stored vacuum-packed or in a CO_2/nitrogen atmosphere at refrigeration temperatures.

The Genus *Weissella*

Weissella was created when some aberrant species of *Leuconostoc* and heterofermentative *Lactobacillus* were found to be genotypically related. Species within this genus have been isolated from habitats such as meat and dairy products, sewage, and plants.

The Genera *Pediococcus, Aerococcus*, and *Tetragenococcus*

Pediococci, along with aerococci and tetragenococci, divide in two perpendicular directions (often wrongly described as 'dividing in two planes'), and thereby form tetrads of cells rather than chains. *Tetragenococcus* contains strains formerly regarded as *P. halophilus*. This species is characterized by its extreme tolerance to salt (>18%) and is important in the fermentation of high-salt-containing foods such as soy sauce. Aerococci are of minor interest in food technology and will not be further described here. Pediococci are found, along with other LAB in fermented vegetables, meat and fish. *P. damnosus* (also called *P. cerevisciae*) is of considerable nuisance in the brewing industry where it can cause 'ropy' beer due to capsular material and flavor defect due to diacetyl production. Pediococci do not grow well in milk but can be isolated from milk and dairy products. They may possibly be significant in the maturation of cheese where they can be found as part of the NSLAB community.

Commercial Applications of LAB in the Food Industry

The occurrence of specific LAB in various fermented foods has been outlined above. It is important to emphasize that there is a great difference in the degree of sophistication in the use of these bacteria. As quality control regulations for all foodstuffs become more stringent, the demand for control of fermented foods is also increasing. Whilst in the dairy industry commercial starter cultures have been available for many decades, their introduction into other fermented food products is either relatively new or is not yet in evidence. (*See* **Starter Cultures**.) This applies in particular to the countless varieties of fermented foods produced at artisan level in developing countries. Many of these products have not yet been scientifically described and the microorganisms responsible for the fermentation processes have not been identified. Despite considerable research into the metabolism of LAB, details of their various important metabolic activities in well-known products are only partially mapped.

The use of starter cultures in the dairy industry is a special case since milk pasteurization results in the destruction of the indigenous LAB. To achieve a successful fermentation it is therefore necessary to add suitable cultures of LAB. The development of the commercial starter culture industry has led to greatly increased quality and stability of dairy products and also for the few other fermented foods where they are utilized.

There is currently considerable research on so-called 'indigenous' fermented foods. These products are produced by natural fermentation and usually the responsible organisms create a complex mixture of various LAB, sometimes also interacting with other bacteria and/or fungi. Present studies are gradually elucidating the LAB present in these products, their interactions, and attempting to identify them. Although many of the strains isolated from these products resemble known species of LAB, they often have special properties which may make them a useful source of gene material for modifying known commercial cultures.

Bacteriophage Infection of Cultures

In 1935, fermentation problems in the dairy industry were diagnosed as being due to virus particles –

bacteriophages – attacking and destroying the starter culture. This has remained one of the most persistent problems in the dairy industry, despite the introduction of many innovative technological procedures to prevent their introduction to the process, and despite the wealth of research into phage–host interactions and phage resistance systems. The mode of action of phages, at a molecular level, is now known and the future will probably see the development of commercially available cultures that have been engineered to be resistant to phage attack. This methodology will also be of use in the future development of new starter cultures for controlled fermentations of other products where the availability of a selection of strains showing identical fermentation properties, but different phage susceptibility, may be problematic.

Instability of Starter Cultures

Variation in the properties of starter cultures has been a problem since their introduction, and has two main causes.

Natural, heterogeneous starter cultures, often produced by commercialized back-slopping techniques, show a certain variation in their fermentation properties from production to production. This is due to the variation in the balance of strains in the mixture, which may be caused by differences in food raw materials or culture media, in fermentation conditions or by interreactions between the composite strains. Since the different strains present in the culture may well have specific roles to play in product characteristics, an imbalance between the strains will result in unstable product quality.

Many LAB bear some of their genetic material on extracellular DNA particles called plasmids. Plasmids in lactococci have been extensively studied and they have also been found in many other LAB. Although the function of many plasmids is cryptic, in lactococci they code for technologically important properties such as bacteriophage resistance mechanisms, proteinase activity, and the ability to break down lactose and citrate. Loss of plasmids may occur during cell division, and this naturally results in the loss of the specific gene and the culture becomes commercially useless. In the commercial preparation of starter cultures the propagation conditions are carefully controlled so as to minimize the risk of plasmid loss.

Bacteriocins from LAB

Strains from almost all genera of LAB have been shown to produce many different proteinaceous antimicrobial substances, collectively called bacteriocins. Most of these are cationic, amphipathic peptides and will insert into the cell membrane of closely related bacteria, thereby leading to inhibition of growth by pore formation. The best known bacteriocin is nisin, and this is used as a food preservative in more than 50 countries. (*See* **Nisin**.) The 1990s have seen considerable research in this field, aimed at finding bacteriocins active against foodborne pathogens. Many bacteriocins have been thoroughly characterized and the genetics of their biosynthesis has been elucidated. However, commercial application of these compounds – or the bacteria producing them – has, apart from nisin, so far not materialized to any large extent.

Probiotic LAB

Since Metchnikoff's work in 1908, the LAB normal microbial flora of the body has been believed to have a beneficial effect on the well-being of the host. There is increasing interest worldwide for developing food products which contain strains of LAB which have been isolated from the human gut – so-called probiotic products. The majority of products on the market are fermented dairy products, and some fermented cereals have been developed. The commercial potential of such products is dependent upon the availability of convincing scientific documentation of the positive effect of ingesting these organisms. When based on well-designed double-blind experiments, there have been many recent reports showing significant effect on the balance of the gut microflora and also some that indicate that probiotic bacteria can promote a general stimulation of the immune system. Most countries demand documented proof of the efficacy of such products before claims can be made in promotion advertising. (*See* ***Acidophilus*** **Milk**; ***Bifidobacteria*** **in Foods**; **Probiotics**.)

Genetic Modification of LAB

Most LAB can now be genetically modified through recombinant DNA technology, although the degree of advanced modification that can be done varies between species and strains. For *Lactococcus lactis*, the most studied and probably the most economically important species, the available techniques are very advanced indeed. Essentially any protein of choice can be highly expressed in a controlled way, and this can be done by chromosomal integration in a so-called food-grade manner (i.e., no antibiotic resistance markers or other unwanted genetic elements are used in the procedure). It is now possible to change the properties of starter strains, for instance aroma formation capability or enhanced antimicrobial activity against pathogens. The introduction of

such strains into the market depends more on legislation and consumer acceptance than the construction of the strains. It should be noted that some properties can be transferred between strains by classical genetic methods, e.g., conjugation, and that this is still an important tool in starter development since these techniques are unproblematic from a legislative and consumer point of view.

LACTOSE

J M Johnson and F D Conforti, Virginia Polytechnic Institute and State University, Blacksburg, VA, USA

Introduction

Lactose may be found as a naturally occurring compound of foods containing dairy products, or it may be isolated from such products and added for specific functional properties. This article discusses the recovery of lactose and the importance of lactose as a food ingredient. Many of the properties of lactose make it a useful food ingredient, but some may be at a disadvantage and require special control. The sensory and dietary considerations of lactose are also discussed.

Sources

Lactose is one of the main constituents of human and animal milk (**Table 1**). As a disaccharide consisting of glucose and galactose, lactose acts as an energy-carrier in milk. Due to its physiological and functional characteristics, industrially manufactured lactose is used today in a large number of foodstuffs as well as in the pharmaceutical industry. Lactose is produced from whey, a byproduct of cheesemaking and casein production, by crystallizing an oversaturated solution of whey concentrate. Global demand for lactose has grown appreciably over the last 10 years, the lactose industry having adapted accordingly, especially in the USA and Europe. The world production amounts to approximately 500 000 tons, the tendency still being upwards.

Physical and Chemical Properties

Lactose is a disaccharide practically unique to milk. It consists of a D-glucose and a D-galactose molecule joined in a β-1,4-glycoside linkage. Its systemic name is β-*O*-D-galactopyranosyl-(1-4)-α-D-glucopyranose (α-lactose) or β-*O*-D-galactopyranosyl-(1-4)-β-D-glucopyranose (β-lactose). Lactose has two isomeric forms, α- and β-lactose, which differ in the steric configuration of the hydroxyl group of C-1 moiety of glucose.

Table 1 Lactose content of selected dairy foods

Food item	*Amount (g)*	*Lactose (g)*
Milk (skimmed, low-fat, whole)	245	8.5–12.8
Lactose reduced milk	244	2.5–3.5
Nonfat dry milk	30	11.6
Cheese (cured, natural)	28	0.4–0.8
Processed cheese	28	0.4–4.1
Yogurt	227	4.3–17.6
Butter	15	0.1
Icecream/icemilk	99	5.5–14.4

Lactose may appear in different crystal polymorphs, depending on the crystallization conditions. Each polymorph has its specific properties. As an example, α-lactose (which crystallizes as a hydrate containing equimolar amounts of lactose and water) has very hard crystals and is not hygroscopic, as with β-lactose. However, a hydrous β-lactose (which crystallizes at temperatures above 93.5 °C) forms small crystals with a solubility up to 10 times higher than that of α-lactose. Because of this higher solubility, β-lactose is experienced sweeter than α-lactose.

The solubility of α-lactose is more temperature-dependent than that of β-lactose, and the solubility curves intersect at 93.5 °C. A solution at 60 °C contains approximately 59 g of lactose per 100 g of water. Therefore, if a 50% solution of lactose (approx. 30 g of β- and 20 g of α-) at 60 °C is cooled to 15 °C, then at this temperature, the solution can contain only 7 g of α-lactose or a total of 18.2 g per 100 g of water at equilibrium. Therefore, α-lactose will crystallize very slowly out of solution as irregularly sized crystals, which give rise to a sandy, gritty texture.

α- and β-lactose differ considerably in solubility and in the temperature dependence of solubility. If α-lactose is brought in water, much less dissolves at the outset than later. This is because of mutarotation: α-lactose is converted to β, hence the α-concentration diminishes, and more α can dissolve. If β-lactose is brought in water, more dissolves at the outset than later (at least below 70 °C): on mutarotation, more α-lactose forms than can stay dissolved, and α-lactose starts to crystallize.

The solution of lactose is temperature-dependent, and solutions are capable of being highly supersaturated before spontaneous crystallization occurs, and even then, crystallization may be slow. In general, supersolubility at any temperature equals the saturation (solubility) value at a temperature of 30 °C higher. The low solubility of lactose, coupled with its capacity to form supersaturated solutions, is of considerable practical importance in the manufacture of concentrated milk products. This is of prime importance in sweetened condensed milk, and crystal size must be controlled if a product with a desirable texture is to be produced. (*See* **Carbohydrates**: Classification and Properties.)

Usually, α-lactose crystallizes as a hydrate containing one molecule water of crystallization. The crystals are very hard, slightly hygroscopic, often fairly large, and dissolve slowly. The water of crystallization is very strongly bound. Above 93.5 °C, anhydrous β-lactose crystallizes from an aqueous solution. β-lactose is not very hydroscopic, and it dissolves quickly; its solubility is good. Therefore, dehydrating α-hydrate is difficult. It may cause problems when determining the dry matter of milk and milk products; this determination implies evaporation of water at elevated temperatures. Maintaining the temperature > 93.5 °C during the assay is paramount to prevent the formation of α-lactose hydrate crystals.

Amorphous lactose is formed during rapid drying, as in a spray drier. It is present in the glassy state, which means that many properties, including hardness, density, and specific heat, are similar to those of crystalline sugar but that the packing of the molecules does not show perfect order. Amorphous lactose contains at least a few percent of water and can quickly dissolve on addition of water. But then, α-lactose hydrate may start to crystallize. If the water content of the amorphous lactose is low, say 5%, crystallization is postponed. However, the product attracts water from moist air, and when moisture content rises about 8%, α-lactose hydrate starts to crystallize (at room temperature). The postponed crystallization is an important factor in relation to spray-dried powders made from skim milk or whey because it leads to hard lumps in the powder, and eventually, the whole mass of powder turns into one solid cake.

This caking is caused by the crystallization of lactose, as it causes the powder particles, largely consisting of lactose, to grow together (to sinter). Since water is needed for crystallization of α-lactose, caking does not occur at a low a_w, below 0.4. At a higher temperature, crystallization can occur far more readily, a_w being higher; moreover, the viscosity of the highly concentrated lactose solution (essentially the continuous phase of the powder particles) is lower, leading to a more rapid nucleation, hence crystallization. The susceptibility of caking, especially higher in whey powder, is considerably reduced if most of the lactose is crystallized before the drying (in the concentrate). Such precrystallized powder is usually called 'nonhygroscopic,' which may be a misnomer because the powder concerned does not attract less water (this is determined by its a_w in relation to that of the air), but the effects differ.

Sensory Properties and Digestibility

Lactose is a disaccharide that yields D-glucose and D-galactose on hydrolysis. Lactose occurs in both α- and β-forms, which differ in the steric configuration on the H and OH around the C-1 glucose. Lactose is not as sweet as sucrose or fructose. For example, 1.08, 2.2, and 4.91% sucrose are of equivalent in sweetness to 3.75, 7.5, and 15% equilibrium lactose solutions. β-lactose is 1.05–1.22 times as sweet as α-lactose, but this small difference in sweetness is of no practical value because equilibration of the anomers occurs rapidly in solution.

The low sweetness of lactose compared with other saccharides may be due to a weaker binding of the molecule to the tongue papillae when compared with fructose, sucrose, or glucose. To take advantage of the fact that the β-form is sweeter than the α-form, methods have been developed to convert the monohydrate α-form to the β-form by treatment with methanol and sodium hydroxide. However, when the β-form is in solution, mutarotation occurs quickly, and the solution becomes a mixture of α- and β-anomers and must be utilized in quick dissolving applications if only the β form is specified.

The sweetness of lactose syrups is increased with partial hydrolysis to form a solution of galactose, glucose, and lactose. The three sugars have a synergistic effect on sweetness when mixed in solution.

Hydrolysis of lactose to glucose/galactose markedly changes the two properties of greatest commercial importance in sugar, i.e., sweetness and solubility. The hydrolyzed lactose syrup is expected to find applications in nonalcoholic beverages, ice cream, yogurt, salad dressings, jams, pectin jellies, toffees, fudge, and boiled sweets. The technology exists for the commercial conversion of glucose (from starch hydrolysis) into fructose *via* immobilized glucose isomerase. Thus, using two linked immobilized enzyme reactors, it is possible to produce sweet glucose–fructose–galactose syrup from lactose:

$$\text{Lactose} \xrightarrow{\beta\text{-galactosidase}} \text{glucose} + \text{galactose} \xrightarrow{\text{glucose isomerase}} \text{glucose} + \text{fructose} + \text{galactose}$$

Low levels of intestinal lactase activity occur in many otherwise healthy adults and children in various population groups. Current evidence indicates that these low levels are normal for most populations of the world, notable exceptions being peoples of northern European extraction: approximately two-thirds of the world's adult population are believed to be lactose malabsorbers. Individuals who have genetically acquired low lactase levels as adults were able to drink milk without any ill effects as infants.

Clinically identifiable lactose malabsorption evolves over time and may be classified into three distinct periods: the initial period is characterized by a decline in lactase activity through childhood; the second phase in this continuum is noted when the decline in lactase activity is sufficient to result in a level of undigested lactose quantitatively high enough to cause symptoms associated with the ingestion of a lactose load; and the third phase occurs when the level of lactase declines to the point that it is no longer sufficient to digest even the modest levels of lactose usually consumed.

Diarrhea, intestinal cramps, and abdominal swelling are the symptoms experienced by individuals with lactose malabsorption when foods containing milk products are consumed. The unhydrolyzed lactose passes to the large intestine and is fermented to lactic acid by microflora, contributing to diarrhea. People experiencing lactose intolerance should limit their consumption of milk and milk products or select lactose-modified milk. (*See* **Food Intolerance**: Lactose Intolerance.)

Lactose-hydrolyzed milk is a viable product of enzyme technology, but its manufacture must be conducted optimally in terms of adaption to milk processing and lactase efficiency. Possibilities for the widespread production of lactose-modified dairy products have been opened up by the development of commercial sources of the enzyme lactase. Lactose-modified nonfat dry milk may be manufactured for the use as a food ingredient, and cultured products such as yogurt may be prepared successfully from lactase treated milk. Lactose-modified whey may be condensed to high-solid noncrystallizing syrups for use in soft drinks, confections, and ice cream.

A rare, and possibly fatal, condition of lactose intolerance is galactosemia, in which an infant is found to have a deficiency of galactose-1-phosphate uridyltransferase, which converts galactose to glucose for absorption. Infants with this condition must be diagnosed early and given substitute milk products that have fructose or sucrose added for energy and sweetening properties.

Isolation and Purification

The principal raw material for lactose production is cheese whey, although casein may be used. With the application of new membrane processing techniques in dairy technology, ultrafiltration permeate from the production of cheese and whey protein is now becoming a major dairy waste in the USA, Canada, Europe, and New Zealand. In membrane processing operations, the problem of waste is reduced almost entirely to milk salts and lactose. Expansion in the use of ultrafiltration will depend largely on the profitable use of permeate. A general solution to the problem of utilizing permeates rests with the human food industry.

The whey protein byproduct of lactose serves as a functional ingredient for other foods. The recovery of lactose and protein from whey resolves two problems: (1) an economical source of a functional ingredient and (2) the utilization of a product (whey) in abundance from cheese production that otherwise is a disposal problem. (*See* **Whey and Whey Powders**: Protein Concentrates and Fractions.)

The manufacture of lactose is similar to that of sucrose. It is basically a five-step process:

concentration, coagulation and removal of whey, further concentration, crystallization, and recovery of crystals (usually by centrifugation). The crystals are usually washed and may be dissolved and recrystallized to yield a product of high purity. The normal form of commercial lactose is α-monohydrate, but there is a limited market for β-lactose that is produced by crystallizing above 93.5 °C. Commercial lactose is available in a number of grades.

The addition of β-galactosidase to milk for cheese manufacture shortens the time needed to produce cheese. The hydrolysis of lactose by the enzyme stimulates the action of the microorganisms by converting the monosaccharide to glucose and galactose, which are more readily available for fermentation. However, this limits the suitability of whey for lactose recovery and poses a problem of disposal of whey that cannot be used for lactose recovery. (*See* **Cheeses**: Chemistry and Microbiology of Maturation.)

Food Applications

One of the oldest uses of milk sugar is as a constituent of baby food to adapt cow's milk to the composition of human milk. Due to its flavor-enhancing properties and low sweetening powers, lactose is primarily used now in numerous foodstuffs. Particularly worth mentioning here are: baby food, cakes and biscuits, chocolate and chocolate products, sugar confectionery, soups, and sauces.

The presence of lactose can affect a number of properties of confectionery systems that can have implications for the processibility of the system and for the overall product characteristics, such as flavor, mouth feel, texture, color, and stability. The changes observed when lactose is used in confectionery formulations would be expected to be a function of (1) the concentration, type and physical characteristics of the lactose, (2) the function and physical characteristics of the ingredient that is substituted by lactose, and (3) the processing parameters used in the products' manufacture.

Typically, at least 10% lactose can be used in most systems as a part-substitute for sucrose or skimmed milk powder without altering the textural acceptability of a product to an unsatisfactory degree, whereas up to 20% substitution is possible in certain cases. The tendency for lactose to crystallize and grain the confection appears to be a factor limiting the use of higher levels in many cases, whereas the difference in viscosity behavior compared with sucrose also inhibits the preparation of textural attributes similar to products containing sucrose. These observations, however, suggest that modifications to the manufacturing procedure to account for these properties could enable even higher levels to be incorporated successfully.

Human milk contains ~7.0% of lactose (bovine *sim*5.0%) and 1.0% of protein (bovine *sim*3.5%). Most baby formulas are essentially 'humanized' cow's milk, i.e., the lactose content is increased and the protein content reduced. Most of the lactose used in baby food preparations is added in the form of demineralized whey powder. Lactose may be used as an additive in powdered foods as a free-flowing agent. The hygroscopicity of lactose glass may be exploited to advantage as a means of absorbing free moisture from low moisture foods and fixing it as water of crystallization of lactose. For example, food particles may be coated in a solution of flavoring and/or coloring materials and then the coated particles tumbled in a powdered lactose glass that absorbs surface moisture and forms a capsule around the food particles. Lactose glass is used in 'instantizing' or increasing the dispersibility of certain foods. Products are prepared containing 5–50% lactose, spray-dried, and then 'instantized' by moistening and redrying. Alternatively, powdered lactose glass is added to the powdered food, which is then wetted slightly, causing the lactose to crystallize and form agglomerates that entrap the other food components. Such products are free-flowing and capable of dispersing rapidly, similar to instant milk powders.

Lactose is used extensively in the formulation of various types of candy, fudges, and caramels. It has certain advantages in these products, e.g., less sweetness, better color binding and better mouth-feel particles, but it also has the disadvantage of tending to crystallize and causing grittiness. Lactose, along with sucrose, may be used to sugar-coat chocolate buttons and hazelnuts: the lactose suppresses sucrose crystallization, thereby allowing the coating to be effected at relatively low temperatures, and reduces the sweetness of the coating.

Lactose is difficult to crystallize and can be a disadvantage in food applications. α-Lactose has a very low solubility and cannot be used in partially prepared food products that are rehydrated without heating such as instant puddings. Large crystals may form in the manufacture of ice cream when the mix is cooled to a low temperature. The result is a sandy texture or crystals large enough to be felt by the tongue and palate. The problem can be overcome by inhibiting crystal formation by the addition of gums or by seeding with additional crystal nuclei to keep the crystal size small. (*See* **Ice cream**: Methods of Manufacture.)

The concentration of lactose in sweetened condensed milk is critical in protecting the texture of the milk product. Condensed milk has 60% of the water removed and sucrose added to produce a product with a total carbohydrate concentration of 56%.

Too much lactose results in a product that is grainy, and too little lactose produces a product that is slimy in texture. (*See* **Condensed Milk**.)

Lactose is used in the bakery and confectionary industries, where it reacts with protein amino groups to give Maillard browning, for color and flavor. Lactose enhances the emulsifying and creaming properties of shortenings, which improves product quality, facilitates baking operations, gives increased loaf volume and external appearance score, and extends the shelf-life freshness by 50–100% compared with the shelf-life of standard formulations. Lactose may also be used in sugar coating and as a humectant in bakery products. If proper precautions are taken, lactose is a very suitable icing sugar for many purposes: it gives a reduced sweetness and better body with less chipping and cracking.

The vulnerability of lactose in the Maillard browning reaction is a problem in the manufacture and storage of dried milk and dried whey powder. Both products brown when stored at ambient temperature, making them undesirable in terms of solubility for rehydration and nutritional value. Dried milk that has browned is difficult to reconstitute, and browned milk is deficient in available lysine, the ε-amino group of which takes part in the Maillard reaction. Dried milk and whey solids should be stored under dry, cool conditions and rotated when in stock to avoid browning during storage. (*See* **Browning**: Nonenzymatic.)

Background

Lead (Pb) is a highly toxic trace element with no recognized biological requirement in organisms and no established threshold concentration for sublethal toxicity. Moreover, lead concentrations in the biosphere have been substantially elevated by industrial releases of lead over the past five millennia. These contaminant lead emissions have been difficult to quantify accurately, and many measurements of lead in the biosphere have been biased by undetected contamination during sampling, storage, and analysis.

Occurrence in Foods

The relative magnitude of environmental lead contamination is unparalleled among the elements. Approximately 350 million tonnes of lead have been produced since the advent of cupellation (a smelting process that separates precious metals from lead ores) five millennia ago (Figure 1), and most (> 50%) of it has been dispersed as an environmental contaminant on a global scale. Production rates of ~3.4 million tonnes of lead per year were estimated to release ~1.6 million tonnes of contaminant lead into the environment annually during the preceding decade. These inputs included atmospheric emissions of industrial lead aerosols (3×10^8 kg year^{-1}), which were nearly two orders of magnitude (10^2) greater than the sum of all natural atmospheric emissions of lead (4.5×10^5 kg year^{-1}). These industrial emissions increased average lead concentrations in the biosphere by approximately

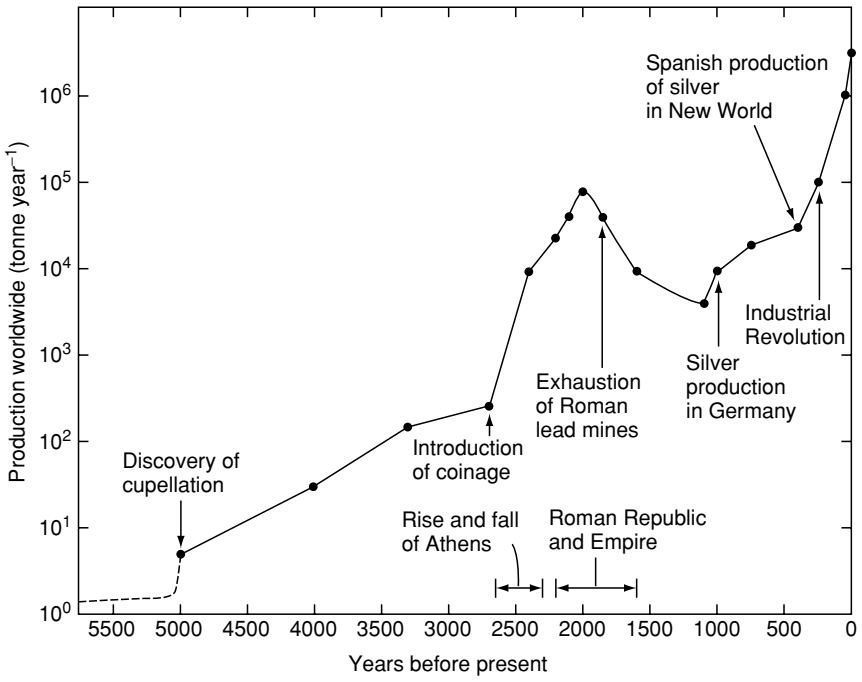

Figure 1 Industrial production of lead over the past five millennia. From Settle DM and Patterson CC (1980) Lead in albacore: Guide to lead pollution in Americans. *Science* 207: 1167–1176, with permission.

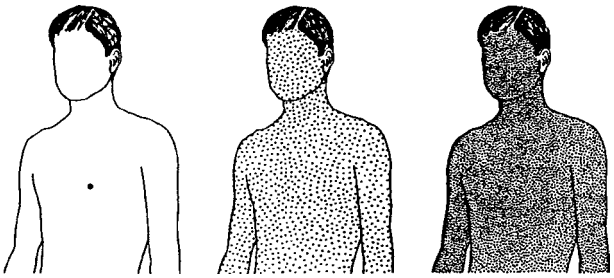

Figure 2 Relative amounts of lead contamination in adult humans. Each dot represents 40 μg Pb per 70-kg person. The figure on the left with one dot represents the natural concentration of lead in humans (40 μg per 70 kg). The figure in the center represents the current average lead concentration of adults in urban environments (40 000 μg per 70 kg) in previous decades; recent studies of ambient blood lead concentrations indicate that average lead concentrations in children and young adults are now substantially lower (Pirkle *et al.*, 1998). The figure on the right represents the minimum concentration that will actuate classical lead poisoning in a significant fraction of the population (160 000 μg per 70 kg). From Patterson CC (1980) An alternative perspective – lead pollution in the human environment: Origin, extent and significance. In: National Research Council. *Lead in the Human Environment*. Washington, DC: National Academy of Sciences.

one order of magnitude above natural levels. However, there have been measurable reductions in environmental lead concentrations that closely correlate with reductions in industrial lead emissions over the past three decades.

One consequence of industrial lead emissions into the biosphere has been a 500–1000-fold increase in the lead body burdens of older (>40 years) adults of industrialized countries, since most (>90%) of that lead is in bone, where its biological residence time is relatively long (Figure 2). Contemporary baseline lead concentrations of those individuals are estimated to be still approximately 40 000 μg of Pb per 70-kg person, which is ~1000-fold (10^3) higher than natural levels in prehistoric individuals (40 μg of Pb per 70-kg person), and only fourfold lower than levels in individuals with overt, clinical lead poisoning (160 000 μg Pb per 70-kg person). The body burdens of younger adults and children are now estimated to be much lower (~10 000 μg of Pb per 70-kg person), since they have had less exposure to industrial lead.

Presumably, there have been comparable decreases in the lead concentrations of other components of the biosphere, including foods in human diets. Yet, contaminated foods are now a principal source of elevated lead concentrations in humans living in regions where the use of leaded gasolines has sharply declined (Table 1). The dietary intake of lead by adults in those areas is estimated to account for approximately two-thirds of their baseline daily consumption of lead (~50 μg day^{-1}).

From Flegal AR *et al*. (1990) Lead contamination in food. In: Nriagu JO and Simmons MS (eds) *Environmental Food Contamination, Advances in Environmental Science and Technology*. New York: John Wiley.

Background lead concentrations in basic food crops and meats range from 2 to 45 p.p.b. ($ng\ g^{-1}$) fresh weight (FW) (Table 2). Most (50 to >99%) of that lead is derived from direct and indirect atmospheric inputs of industrial lead aerosols. The rest (<1 to 50%) is derived from soils (primary minerals, humic substances, and soil moisture), which have natural lead concentrations of <8 to 25 p.p.m. ($pg\ g^{-1}$). Consequently, contemporary background lead concentrations in foods are two- to 100-fold above natural concentrations, which are estimated to range from 0.1 to 20 $ng\ g^{-1}$ (FW).

Leafy crops are most susceptible to contamination from atmospheric deposition of industrial lead (Table 2). These crops include wheat, rice, spinach,

and lettuce, whose contemporary baseline lead concentrations are five- to 100-fold above natural concentrations. Contaminant lead concentrations in foods not directly exposed to atmospheric depositions (e.g., root crops, nuts, beans, and some fruits) are approximately twofold lower. Atmospheric industrial leads are also a primary (>90%) source of lead contamination of some livestock and poultry. This occurs initially through the ingestion of contaminated forage, feed, and soils, and subsequently during the processing of meat products.

Current baseline lead concentrations of foods are several orders of magnitude lower than lead concentrations of foods in some industrial areas (Table 3). For example, lead levels in some plants are at sub-part-per-million concentrations in remote, rural environments ($0.2\ \mu g\ g^{-1}$) and part-per-thousand concentrations in some highly contaminated urban areas ($950\ \mu g\ g^{-1}$) as a consequence of local emissions of industrial lead aerosols (e.g., automobile exhausts of leaded fuels). Lead concentrations of consumer organisms (herbivores, omnivores, and carnivores) may also be increased by one to two orders of magnitude above baseline concentrations by the ingestion of contaminated foods and soils.

Numerous other sources of lead contribute to the lead ingested by humans. For example, lead solder may contribute approximately 40% of the dietary lead accumulated by adults through the contamination of both drinking water and foods. It is estimated that 42 million people in the USA are exposed to drinking water with elevated lead levels ($>20\ \mu g\ l^{-1}$) due to the lead solder in pipes. Lead solder also accounts for >99% of the lead in some foods packaged in lead-soldered cans. Lead-glazed ceramics may increase lead concentrations in foods to parts-per-million concentrations, and are a notable source of acute lead toxicity. Leaded crystal, pewter, potions, and sealants are other sources of lead contamination to foods. Finally, dirt may be ingested inadvertently as a food contaminant or directly through pica. A child that ingests as little as 1 g of soil and 200 mg of lead paint chips a day may be consuming 2600 µg of lead per day and absorbing 550 µg of lead per day.

Chemical Properties

Lead has the most stable divalent (+2) oxidation state of the group IVB elements, though it also occurs in a tetravalent (+4) oxidation state. Coordination numbers for its divalent compounds range from 2 to 7. Those for its tetravalent compounds range from 4 to 8. The stereochemistry of lead is usually octahedral or tetrahedral. The divalent oxidation state dominates the inorganic chemistry of lead, while its organic chemistry is dominated by the tetravalent (+4) oxidation state.

Divalent lead, Pb^{2+}, is a B-type or soft sphere metal cation. Lead's classification, which is based on the number of electrons in its outer shell, indicates that Pb^{2+} ions tend to form covalent bonds, in sharp contrast to the mainly ionic binding of hard sphere ions, such as Ca^{2+}. This is evidenced by the tendency of Pb^{2+} to form strong bonds with groups containing nitrogen and sulfur (e.g., CN, R-S, -SH, and imidazol) in biological systems. It is also apparent in mineral deposits, where galena (PbS) is the most abundant lead ore and where anglesite ($PbSO_4$) and cerrusite ($PbCO_3$) are less common minerals.

Despite differences in their chemistries, lead is introduced and cycled in biological systems as an analog of calcium. Most (70 to >90%) of the lead

in vertebrates is associated with calcareous tissues, where lead can substitute for calcium in apatite matrices. In addition, lead competes with Ca^{2+} for sites in cellular and subcellular systems. These include synaptosomes, mitochonrdria, membrane vesicles, protein kinase C, calmodulin and other Ca^{2+}-binding proteins. This ionic substitution is associated with some of the primary mechanisms of lead toxicity, which are attributed to the alteration of calcium-mediated cellular processes and the mimicry of Ca^{2+} binding to regulatory proteins.

Since lead is a biogeochemical analog of calcium, lead concentrations are normalized to calcium concentrations (atomic ratios) to quantify distributions and fluxes of lead within organisms and food chains. This normalization indicates a systematic decrease in the atomic ratio of lead to calcium at higher trophic levels, a process referred to as biopurification. The biopurification of calcium relative to lead is attributed to the selective transport of Ca^{2+} across cell membranes, the selective retention of Ca^{2+} in metabolic processes, and the selective removal of Pb^{2+} in detoxifying processes. These biopurification processes may be circumvented by the direct assimilation of contaminant lead by organisms, which occurs in addition to the ingestion of lead within food. As a result, atomic ratios of lead to calcium in humans may exceed the ratios in their diets.

Isotopic Composition

Lead (atomic number 82) has an atomic weight of 207.19, based on the relative abundance of its four stable isotopes: ^{204}Pb (1.5%), ^{206}Pb (23.6%), ^{207}Pb (22.6%), and ^{208}Pb (52.3%). The latter three isotopes (^{206}Pb, ^{207}Pb, and ^{208}Pb) are formed by the radioactive decay of the long-lived natural isotopes ^{238}U, ^{235}U, and ^{232}Th, respectively, while ^{204}Pb has no radioactive progenitor. Since each parent isotope has a different half-life, the relative natural abundance of stable lead isotopes in a geological deposit varies systematically with the age and evolution of the formation. Different geological formations may, thus, be distinguished by their characteristic (but not necessarily unique) stable lead isotopic ratios.

Ratios of stable lead isotopes may also be utilized to identify and trace different sources of lead in the environment. Natural differences in stable isotopic compositions of lead, which are characteristic of different geological formations, persist in the environment because there is no measurable physical, chemical, or biological fractionation of lead isotopes within the biosphere. This allows sources of industrial lead inputs into the atmosphere, water, soils, and organisms to be distinguished by their isotopic composition. Additionally, stable lead isotopic tracer techniques may be utilized to investigate lead exposure and uptake by organisms, as well as the cycling and therapeutic manipulation of accumulated lead.

However, most lead tracer studies, to date, have used man-made radiolead isotopes. One radioisotope of lead, ^{210}Pb (with a half-life ($t_{½}$) of 22 years), is commonly used to characterize and date relatively short (< 100 years) geological events. It is also employed as a radiotracer in biological systems, as are three other radioisotopes with shorter half-lives: ^{211}Pb ($t_{½}$ = 36.1 min), ^{212}Pb ($t_{½}$ = 10.64 h), and ^{213}Pb ($t_{½}$ = 26.8 min). The applicability of of those radioisotopes is constrained by their half-lives, which often are not suitable for analyses of many metabolic processes, the relative insensitivity of radiometric measurements, and increasing controls on the use of radioactivity in human health studies. Conversely, the applicability of stable lead isotopic tracers has been rapidly increasing with the development of high-resolution inductively coupled plasma mass spectrometers.

Analysis – Isolation and Concentration

Analyses of lead concentrations in environmental matrices have been plagued by problems of contamination during sampling, storage, and analysis. Unrecognized or poorly documented contamination have invalidated most environmental lead data reported prior to 1980 and indicated that many subsequent data are highly questionable. This has been demonstrated by numerous comparisons of data from traditional laboratories and those using ultraclean analytical techniques. Perhaps the most celebrated of those comparisons were analyses of lead in tuna, which demonstrated that the lead concentration of fresh tuna (0.3 $\mu g\,g^{-1}$ FW) was three orders of magnitude lower than the concentration (400 $\mu g\,g^{-1}$ FW) measured with previously accepted techniques.

Numerous procedures have been developed to isolate and concentrate lead for analysis. One of the most common procedures is liquid/liquid extraction, which typically involves a water-immiscible solvent, an aqueous solution, and a complexing agent that forms a nonionic or neutral chelate with lead. Another common procedure is an ion-exchange extraction, which sequesters lead ions on a chelating functional group immobilized on a solid substrate. A third is electrodeposition, which concentrates lead on to an electrode for direct electrochemical analyses or to preconcentrate it for other instrumental analyses.

Total lead concentration measurements usually require a rigorous acid digestion prior to these isolation and concentration procedures. They are required for

most of the following analytical methods, because they do not have the requisite selectivity, sensitivity, or freedom from matrix interferences to accurately and precisely measure trace concentrations of lead in complex matrices. Measurements of lead concentrations in different fractions or phases typically have the same constraints.

Colorimetric Methods

Historically, lead concentrations were measured by colorimetric methods, including spectrometry. The primary spectrometric method for measuring lead now is with the reagent dithizone (diphenylthiocarbazone). It is a relatively simple and inexpensive technique, with a relatively low (pg) level of sensitivity. The accuracy and precision of this method is highly dependent upon the skills of the analyst and the utilization of rigorous trace metal clean techniques. The same qualification applies to the following techniques, which involve much more elaborate instrumentation.

Spectrometric Methods

The most common method of measuring lead concentrations in a variety of matrices is atomic absorption spectrometry (AAS). This method measures lead concentrations by the absorbance of lead spectra emitted from a source lamp by vaporized lead atoms. While flame AAS techniques may still be appropriate for measurements of relatively high ($pg\,g^{-1}$) concentrations of lead, most AAS analyses of lead are now by graphite furnace AAS. Evolving AAS methodologies include the development of alternatives to graphite furnaces (e.g., heated quartz tubes) and couplings with chromatographic separations for species composition measurements. (*See* **Spectroscopy**: Atomic Emission and Absorption.)

Atomic emission spectrometry (AES) is similar to AAS, except that lead is measured by the light emitted by excited ions rather than by the light they absorb. The primary advantage of AES is that numerous elemental concentrations may be measured simultaneously in a relatively small sample. This methodology is being improved with the development of inductively coupled plasma (ICP) systems, which increase sensitivity and decrease analytical interferences. Current ICP–AES systems now provide the sensitivity required for analyses of lead in most biological matrices.

The most accurate method of measuring lead concentrations in biological matrices is with isotope dilution thermal ionization mass spectrometry (TIMS). This definitive method is yield-independent, extremely sensitive, and precise. It is, also, the most accurate and precise method for measuring stable lead isotopic compositions.

However, other rapidly evolving mass-spectrometric methods provide comparable or complementary measurements of lead concentrations and isotopic compositions in different matrices. All of these mass spectrometric methods involve the electromagnetic and physical separation of lead ions within an instrument flight tube. The most prominent of these is inductively coupled plasma mass spectrometry (ICP-MS), which includes both the quadrapole ICP-MS and the high-resolution magnetic sector ICP-MS. The latter's sensitivity, accuracy, and precision now rival those of TIMS. Additional mass-spectrometric methods which have evidenced potential for analyses of lead in biological matrices include secondary ion mass spectrometry, glow-discharge mass spectrometry, and laser microprobe mass analysis.

Nuclear magnetic resonance (NMR) techniques are being developed for diagnostic analyses of lead. These focus on the resonance frequencies of ^{207}Pb, which are influenced by the molecular environment around the isotope. NMR provides a measure of lead speciation in both environmental and clinical settings. For example, NMR has been used to simultaneously measure intracellular free calcium and lead concentrations in erythrocytes. (*See* **Spectroscopy**: Nuclear Magnetic Resonance.)

Electrochemistry

Electrochemical methods are used to measure both lead concentrations and its organic complexation in aqueous systems. These measurements are based on the current produced as lead is reduced or oxidized by varying the potential of a working electrode in an electrochemical cell containing the sample. The sensitivity of total lead concentration measurements, which are determined after digesting the sample, can be increased by a preconcentration step. Organic complexation is determined by titrating the sample with lead and measuring the current produced after each lead addition.

The two principal electrochemical methods for determining lead in environmental samples are differential pulse polarography and anodic stripping voltammetry. The first method measures the faradaic current produced by the reduction of Pb(II) to Pb(0), while the potential on the working electrode is scanned to negative potentials. In the second method, lead is preconcentrated on a mercury electrode by the reduction of Pb(II) to Pb(0) during a reducing step. The potential is then scanned positive, and the oxidation current is measured.

Chromatography

Chromatography separation techniques can detect a wide range of molecular species containing metals or metalloids. This method involves isolation of the species of interest from the sample in a sufficiently volatile, thermally stable, and physicochemically resistant form for separation by gas–liquid or high-performance liquid chromatography. These methods are coupled with elemental detectors, principally flameless atomic absorption spectrometers, which provide low (< 50 pg) detection limits. Other detectors include flame atomic absorption spectrometers, thermal conductivity detectors, flame ionization detectors, electron-capture detectors, thermionic specific detectors, and atomic emission spectrometers. (*See* **Chromatography**: High-performance Liquid Chromatography; Gas Chromatography.)

There have been numerous applications of chromatography methodologies to investigate the speciation of lead in the environment, because of its widespread dispersion, diverse chemical forms, and toxicity. Gas chromatography has been used to detect organolead compounds, including trialkyllead chlorides, in the environment. Gas–liquid chromatography was initially used to measure tetraalkyl derivatives of lead in the environment, and it has since been used to investigate the biomethylation of inorganic and ionic alkyl lead by microorganisms. Additional speciation measurements may be obtained with high-performance liquid chromatography coupled with GFAAS, mass spectrometry, and NMR.

X-ray Fluorescence

A rapidly evolving methodology for measuring lead concentrations *in situ* is with X-ray fluorescence (XRF). Sufficient incident radiation from an X-ray generator or a radioactive source is provided to excite an inner shell electron, with the resultant emission of a fluorescent X-ray. The emitted energy is characteristic of the element that absorbed the original X-ray, and the amount of energy released is proportional to the mass of element present.

Two types of XRF are applicable for noninvasive analyses of lead concentrations. L-line techniques require 10.5 keV to remove an L-shell electron, and K-line techniques require 88 keV to remove a K-shell electron. These XRF techniques are most appropriate for analyses of bone lead concentrations of individuals. This is significant because bone is the major reservoir of lead in humans and accounts for > 90% of their total lead content.

Toxicology

A L Ehle, University of Chicago, Chicago, IL, USA

Introduction

Lead occurs widely throughout the environment. Naturally occurring forms and lead contributed from human activities constitute the potential source for human exposure. Lead was one of the first metals to be used by humans. Almost half of the world's production of lead is consumed by the storage battery industry. Lead pigments, chemicals, and metals

account for the remainder. Of importance to the food industry has been the past use of lead for water pipes, as a lining for containers, and in solder used in the manufacture and sealing of steel cans. Most inorganic lead compounds, with the exception of lead acetate and lead chloride, are not readily soluble in water. Solubility of lead compounds is enhanced in acidic solutions.

Absorption and Distribution

Human studies indicate that, in adults, approximately 10% of ingested lead in the diet is absorbed from the gastrointestinal tract. The fraction absorbed is greater if a solution of lead salts is ingested in a fasting state, compared to the same amount of lead ingested with food. In children, evidence suggests that the fraction absorbed may be as high as 40–50%. Absorption appears to be increased if the diet is deficient in protein, calcium, or iron. In addition to gastrointestinal absorption, significant lead absorption can occur through the respiratory system from inhalation of lead particles.

Absorbed lead is transported by blood, predominantly in red blood cells. It is initially rapidly distributed throughout the various soft tissues and organs. It is then slowly redistributed into two pools, a rapidly exchangeable pool in blood and soft tissue, and a less mobile pool in bone. In humans, about 90% of the total body burden is in bone. Placental transfer of lead occurs and there is a relatively good correlation between blood lead concentrations of mothers and newborn infants; the levels in infants are 5–10% lower than those in the mothers.

Excretion of absorbed lead is primarily through the kidneys; about 75% of the loss is through this route. The mechanism of urinary excretion appears to be essentially a filtration process. Gastrointestinal losses account for about 16% of the loss. The remainder of the loss is through hair, skin, and sweat.

The body half-life of lead is approximately 10–30 years. The half-life in the blood and soft-tissue compartment is about 20 days. The bone pool has a much longer half-life, 10–30 years, and accounts for the long total body half-life.

Lead in blood is generally accepted as the best indicator of exposure and body burden for soft tissues and organ systems. Average blood lead levels in the general population of industrial countries are typically found to be between 5 and 15 $\mu g\,dl^{-1}$.

Toxic Effects

Lead has toxic effects on several organ systems. The blood cell-forming system is the first to be affected by lead exposure. Frank anemia begins to occur in adults with blood lead above 60 $\mu g\,dl^{-1}$. Children are more sensitive to lead effects and begin to show anemia with blood levels above 30 $\mu g\,dl^{-1}$. At levels as low as 10 $\mu g\,dl^{-1}$, reversible biochemical changes in the hemoglobin synthetic pathway occur that are without clear adverse effects. This early change consists of progressive inhibition of δ-aminolevulinic acid dehydrase activity. Abdominal pain or 'lead colic' occurs at somewhat higher levels of 80–100 $\mu g\,dl^{-1}$ in adults.

Acute central nervous system toxicity can occur when blood levels are above 100 $\mu g\,dl^{-1}$ in adults, and are above 80–90 $\mu g\,dl^{-1}$ in children. This syndrome is an acute encephalopathy, characterized by coma, convulsions, and death or irreversible loss of function. Lead encephalopathy is much more common in children than adults. There is evidence that a chronic intellectual impairment may occur at lower blood levels, with children again being significantly more sensitive to these effects. The extent of intellectual impairments and the blood lead levels at which they occur are still a matter of controversy. In the USA blood lead levels above 10 $\mu g\,dl^{-1}$ in children are felt to be potentially harmful by public health authorities. Concern over this potential effect has been the prime motivator behind environmental regulatory efforts to reduce lead exposure for the general population.

Lead can also produce a peripheral neuropathy, resulting in significant weakness in some individuals. This effect is usually seen at relatively high blood levels. Electrophysiological changes in peripheral nerve function in the absence of any clinical symptoms have been reported at blood lead levels below 70 $\mu g\,dl^{-1}$ in some studies of lead-exposed workers. The significance of these findings is controversial in terms of indicating a clear toxic effect. Lead encephalopathy and neuropathy may be reversible if adequate treatment is instituted early in the evolution of these symptoms.

A prolonged high-level exposure is associated with kidney disease in some individuals. This takes the form of an interstitial fibrosis and a loss of renal function, which appears to be irreversible. Reversible change in renal function is more common and is characterized by mild elevation of blood urea nitrogen or creatinine, blood tests that indicate altered kidney function. There have been reports that serum concentration of 1,25-dihydroxy vitamin D, the active form of vitamin D, is depressed in children with moderate blood lead levels. This metabolite is formed in the kidneys. Recent studies suggest that the effect may only be seen against a background of nutritional deficiency, or low vitamin D intake.

In a given individual the manifestations of these toxic syndromes are variable at any given level of lead in the body. The factors responsible for the variability are poorly understood. Children, in general, are more sensitive to the toxic effects of lead.

Other possible toxic effects of lead in humans are less well defined and remain unsubstantiated. Although long-term high-level lead exposure in rodents can produce kidney tumors, there is no conclusive evidence that lead is carcinogenic in humans. In some studies an association between increasing blood lead levels and small increases in blood pressure were noted. Other investigators believe that confounding factors may account for the blood pressure changes. Although there are experiments indicating that high doses of lead are toxic to the reproductive functions of both male and female laboratory animals, data in humans are limited and inconsistent. There is no clear association of lead with the frequency of congenital anomalies in humans. There has been concern that *in utero* lead exposure may have harmful effects on brain development, in view of the toxic syndrome seen in children.

Lead toxicity is treated by identification and elimination of the source of exposure if symptoms are mild. In more severe toxicity, treatment with a chelating agent such as calcium ethylenediaminetetraacetic acid, D-penicillamine, or succimer is used to increase lead excretion.

Lead in the Food Chain

Lead is ubiquitous throughout the food chain. Table 1 is a compilation from a World Health Organization (WHO) document illustrating the typical lead content of various foods. Plants subject to the effects of air pollution potentially have the highest lead concentration, followed by root and tuberous plants. The lowest lead concentrations are found in plants in which the edible portion is above ground and shielded from airborne lead deposits. In animal food sources, muscle tissue has the lowest concentration of lead; the concentration in visceral organs, such as liver or kidney, is considerably higher. Concentrations of lead in all raw foodstuffs will vary, depending on the environment in which they were produced. Tetraethyl lead, where it is still in use as a gasoline additive, can be a significant source of airborne lead.

Food processing and preparation can contribute significantly to the lead content of foodstuffs. As noted in Table 1, lead concentrations in canned foods are noticeably higher in this study, primarily as a result of the lead contamination from solder used in steel cans. Alternative packaging can eliminate this. Significant reduction in dietary lead intake in the USA is attributed to increased consumption of fresh and frozen foods and elimination of lead-soldered cans for foods. Lead contamination of food may occur, beyond lead migration from soldered cans, from other sources during food processing. Water with a high lead content that is used in processing would be one such source of contamination. Contact with lead or lead-containing substances would be another potential source of contamination. The likelihood of this type of contamination is increased if the food in contact with the lead source is acidic. A common source for this form of lead contamination has been the use of pottery dishes or containers with improperly fired glazes that contain lead. Acidic food can leach large amounts of lead from such glazes, and

cases of clinical lead poisoning continue to be reported from this source of contamination. Despite awareness of this potential problem improperly fired pottery with lead-containing glazes continue to be produced, predominantly in developing countries.

Total food-related lead intake can be highly variable, depending on the dietary pattern. Estimates of average daily lead ingestion from food in western cultures where studies have been performed have typically ranged from 25 to 200 $\mu g\,day^{-1}$, although intakes as high as 400 $\mu g\,day^{-1}$ have been reported for some populations. The current US recommended daily intake from all sources is 75 $\mu g\,day^{-1}$ or less for adults and 6 $\mu g\,day^{-1}$ or less for children under 6 years of age. These amounts are one-tenth the daily intake estimate to produce blood lead levels of 30 $\mu g\,dl^{-1}$ in an adult and 10 $\mu g\,dl^{-1}$ in a child.

Dietary lead intake accounts for approximately 70% of the total daily lead absorption from all sources in most studies. More recent studies, from the US Food and Drug Administration, have found significant reductions from these figures that are attributed to almost complete elimination of lead-soldered food cans and reduced airborne lead contamination from leaded petrol. In these studies, dietary lead was found to be less than half of the daily lead intake.

Monitoring and Surveillance

Monitoring of the lead content of foods is not routinely performed. Avoidance of lead contamination in food preparation and food processing should be sought as a part of an integrated public health program to minimize lead exposure of the population. While lead exposure from the diet is normally far below that associated with toxic symptoms, it should be remembered that dietary lead is a major source of an individual's total lead intake. Although it is not clear at what level harmful effects first occur in humans, it is clear that lead is not an essential dietary component and it is prudent to avoid the addition of lead to food during its processing or preparation. This begins with the obvious exclusion of food contact with any lead-containing alloy in food processing and preparation. It also means attention to more subtle details, such as the exclusion of lead-based solder from the repair of food-handling equipment and being aware of the potential risk of lead contamination from improperly glazed pottery containers.

LEAVENING AGENTS

J L Vetter, Technical Assistance Services, Leawood, KS, USA

History of Chemical Leavening

Bakery foods that depend on chemical leavening systems for their appearance, texture, and taste are relatively recent developments. Whereas yeast-leavened products have nourished humans for over 4000 years, chemically leavened products have been available for less than 200 years. We have come to enjoy a wide variety of chemically leavened products as part of our daily menu. Some are sweet, e.g., cakes, doughnuts, and biscuits, whereas others are more bland, e.g., baking powder biscuits and many types of crackers (see **Figures 1** and **2**).

Leavening with Yeast

The word 'leaven' comes from the Latin word '*levare*' or '*levo*,' which means 'to raise' or 'to make light by aeration.' Leavened or aerated baked foods can be

Figure 1 Leavening agents: machine-cut doughnut production. (Courtesy of Rhone-Poulenc, New Jersey.)

Figure 2 Examples of chemically leavened baked goods.

traced as far back as 2000 BC, when Egyptians used yeast to leaven bread. (*See* **Bread**: Breadmaking Processes; **Yeasts**.)

Chemical Leavening

Yeast was the primary source of leavening gas to raise baked foods until late in the eighteenth century, when it was discovered that sour milk or buttermilk would release carbon dioxide gas from sodium bicarbonate (baking soda) during baking of a dough or batter to which these ingredients had been added. Carbon dioxide from baking soda is the same gas as that released by yeast during fermentation of a dough.

Sour milk and buttermilk were replaced in many recipes with cream of tartar after about 1835. Cream of tartar (potassium bitartrate) was obtained as a byproduct from wine-making. There were early attempts to combine the baking soda and cream of tartar into a more convenient blended product, and this led to the development of baking powders. A US chemist by the name of Hoagland, living in Fort Wayne, Indiana, originated the cream of tartar baking powder in 1850 and founded the Royal Baking Powder Company.

Sour milk, buttermilk, and cream of tartar all had one thing in common: they released the carbon dioxide from baking soda very rapidly, and much of the leavening gas was actually lost during the mixing of a dough or batter, resulting in a baked product with less volume than desired. There was a need for a material that would not react so quickly and allow sufficient time for mixing and forming products before the leavening gas was released. This led to the development in the mid-1800s of monocalcium phosphate (MCP; also known as acid calcium phosphate, ACP) as an alternative to cream of tartar. Although MCP is considered a 'fast-acting' leavening acid, it is a little slower than cream of tartar. A patent was issued in 1864 for such an acidic phosphate leavening agent. However, better agents for controlling or delaying leavening activity were still required, and this need led to the development of a number of alternatives to cream of tartar and MCP for use with baking soda. Sodium aluminum sulfate (SAS) was developed in the early 1890s, sodium acid pyrophosphates (SAPPs) in the early 1900s, and sodium aluminum phosphates (SALPs) around 1960.

Design of Leavening Systems

There are three primary factors to consider in designing a chemical leavening system for a specific product. These are:

1. How much leavening gas is needed to produce the desired finished product?
2. What leavening acid is needed to achieve the desired product characteristics?
3. What other effects might the leavening acid have on the dough, batter, or finished product?

This article will discuss these three factors and describe the characteristics of commercially available chemical leavening agents and their application in specific bakery foods.

Mechanisms of Chemical Leavening

Air and Water as Leaveners

Although air and water are 'chemicals' in the truest sense of the word, they are generally not considered 'chemical leavening agents.' Nevertheless, air and water do provide leavening activity in a number of bakery products. Air, which is incorporated into a dough or batter as small gas cells during mixing, will expand during baking and cause some leavening of the product. In fact, air is the primary leavening agent in a fat-free sponge cake. During baking, water contained in the dough or batter will

be vaporized by the heat of the oven and cause a leavening – or raising – of the product. Water is the primary leavening agent for saltine crackers, contributing to the tender, flaky texture of the product. The contributions of air and water to the leavening and characteristics of baked products should not be overlooked in designing a leavening system based on more traditional 'chemical' leavening agents.

Leavening by Decomposition

There are two primary chemical leavening agents that can release carbon dioxide gas by decomposition during baking. These are sodium bicarbonate (baking soda) and ammonium bicarbonate. Heat is required for these materials to decompose, and the temperature of baking is generally adequate for this purpose. Sodium bicarbonate decomposes when dissolved and heated to release carbon dioxide according to eqn (1).

$$2NaHCO_3 \xrightarrow{\text{Heat}} H_2O + CO_2 + Na_2CO_3. \quad (1)$$

Ammonium bicarbonate decomposes when dissolved and heated according to eqn (2).

$$NH_4HCO_3 \xrightarrow{\text{Heat}} NH_3 + H_2O + CO_2. \quad (2)$$

Both ammonia and carbon dioxide are gases and contribute to the leavening of the baked product.

Leavening by Chemical Reaction

The vast majority of chemical leavening systems are based on the reaction of an acid with sodium bicarbonate to release chemically the carbon dioxide from the soda, and it is with these systems that the majority of this article is concerned. A general equation for the reaction is shown in eqn (3).

$$HX + NaHCO_3 \xrightarrow[\text{Heat}]{\text{Moisture}} \underset{\text{(Neutral sodium salt)}}{NaX} + H_2O + CO_2. \quad (3)$$

In addition to the carbon dioxide leavening gas, water is released, and a sodium salt of the leavening acid is formed. The nature of the neutral sodium salt depends on the leavening acid being used.

There are a number of leavening acids from which to choose in formulating a chemical leavening system. They differ in the amount required to release completely all of the carbon dioxide in the soda, the speed with which they release this leavening gas, and their effects on doughs, batters, and finished product characteristics.

Neutralizing value The neutralizing value (NV) is a term used to describe the amount of leavening acid needed to react completely with the amount of baking soda used in formulating a bakery product. If all of the soda reacts with the leavening acid, the finished product should be close to neutral in pH, which is desired in most products. Higher (alkaline) or lower (acidic) pHs can be achieved, if desired, by adjusting the amount of leavening acid and/or soda from the amounts needed for complete reaction.

The NV is defined as the weight of soda neutralized by 100 parts of leavening acid. Since most formulae for bakery products begin with a given weight of soda (the weight needed to give the desired amount of leavening gas), the NV is most commonly used to determine the amount of leavening acid required for the amount of soda used according to the following equation:

$$\%\ \text{Leavening acid} = \frac{\%\ \text{Soda} \times 100}{\text{NV}}. \quad (4)$$

The NVs for commonly used leavening acids are listed in Table 1. It should be noted that larger amounts of leavening acids with low NVs are required for a given amount of soda than for those leavening acids with higher NVs. This could be a factor in the economics of developing a leavening system.

Rate of reaction The speed with which a leavening acid reacts with baking soda to release carbon dioxide leavening gas is very important in controlling the characteristics of the finished baked product. If the acid reacts too rapidly with the soda, all of the leavening gas could be released during mixing and, therefore, would not be available to raise the product during baking. In this case, the finished product would be low in volume and dense in texture. However, if the acid reacts with the soda too late in the baking process, the structure of the product will be 'set' by the heat of baking, and the leavening gas cannot raise the product without causing cracks or splits.

The release of some leavening gas, or incorporation of some air, during mixing is desirable for the formation of small air or gas cells in the dough or batter. This process, called 'nucleation,' is responsible for the development of a fine and uniform grain in the final

Table 1 NVs of commonly used leavening acids

Cream of tartar	45
Glucono-δ-lactone	45

product. However, most of the leavening gas should be reserved for release at the proper time during baking in order to achieve the total volume desired.

A number of factors affect the proper time for release of gas during baking. Product size is certainly important. A small product will heat, and the structure will set, faster than a larger product. Oven temperature obviously affects the rate at which a product's temperature rises to the point of setting the structure. Other ingredients in the formula can affect the temperature at which a product sets. The amount of time to mix fully a dough or batter and the time required to form or deposit the product to be baked will influence the time at which the leavening acid should react with the baking soda.

The manufacturers of leavening acids have attempted to meet all the diverse needs of the household, institutional and large-scale wholesale baker by developing and marketing products with a wide range of 'reaction rates.'

Some materials have essentially no delay in their reaction with baking soda. They react as soon as they dissolve in the water present in the formula; the soda has probably already dissolved. These materials include the lactic acid in sour milk or buttermilk, cream of tartar, and MCP monohydrate.

Anhydrous monocalcium phosphate (AMCP) has a time delay, which, although relatively short, does allow time for preparing doughs and batters for baking. A major use for AMCP has been self-raising flour, which is often used to prepare baking powder-type biscuits. The time delay of AMCP allows sufficient time for mixing, rolling, and cutting the dough prior to baking.

Manufacturers of SAPPs have been able to vary the amount of time delay of these leavening acids from a few minutes to as much as an hour or more. This is done by controlling the conditions under which the SAPP is manufactured.

SAS, SALP, and dicalcium phosphate dihydrate (DCP) are basically heat-triggered leavening acids. They have essentially no reaction with soda until the temperature of the product is raised by the heat of baking. In some baked products, this delay may be too long, and SAS, SALP, and DCP perform better when used in combination with a faster-acting leavening agent such as MCP or AMCP. Of course, all leavening agents are essentially 'heat triggered,' since they dissolve and react with soda faster as the temperature of the dough or batter increases. Nevertheless, the term 'heat triggered' is usually reserved for those materials that have an almost indefinite time delay until the temperature rises to a certain point, in contrast to those leavening agents that are both time and temperature triggered.

Table 2 Rates of reaction with baking soda for commonly used leavening acids

Leavening acid	*Rate of reaction*
Cream of tartar	Rapid
Monocalcium phosphate monohydrate	Intermediate
Anhydrous monocalcium phosphate	Intermediate (slower)
Sodium acid pyrophosphates	Slow
Sodium aluminum phosphate	Very slow
Sodium aluminum sulphate	Very slow
Dicalcium phosphate dihydrate	Very slow
Dimagnesium phosphate	Slow
Glucono-δ-lactone	Slow

Glucono-δ-lactone (GDL) does not fit any of the above categories of no delay, time delay, and temperature triggered. GDL reacts continuously, but slowly, with baking soda. The speed of reaction, of course, increases with temperature and becomes quite rapid during baking. The steady release of carbon dioxide in a dough containing GDL is very similar to the release of carbon dioxide by yeast in a fermenting dough. Therefore, GDL has been popular in the development of chemically leavened bread.

The rates of reaction of commonly used leavening acids are listed in Table 2.

Ionic effects of leaveners Although the primary function of chemical leavening systems is to leaven, or raise, a product, leavening agents can also affect characteristics of doughs, batters, and the finished baked product. These effects are due to reactions between the leavening agents and components (particularly starch and protein) of the dough or batter. These are called 'ionic' effects, since the leavening agents dissolve in the water of the dough or batter and dissociate into positive cations and negative anions. In some cases, it is the cation (such as calcium ions) that is responsible for the observed effect. In other cases, it is the anion (such as pyrophosphate) that causes a change in the dough, batter, or finished product.

The calcium and aluminum cations in phosphate-based leavening acids provide more resiliency to cake products than the sodium cation in other phosphate-based leavening agents. Therefore, if resiliency is a property desired in a cake product, the formulator may choose a leavening system containing calcium and/or aluminum ions. Calcium ions tend to stiffen doughs and thicken batters; they also tend to dry out moist or slightly sticky doughs. These properties of doughs and batters are important considerations in handling and processing, particularly in high-speed, automated commercial bakeries. (*See* **Bread**: Dough Mixing and Testing Operations.)

The pyrophosphate anion in SAPP leavener interacts with proteins from other ingredients in the formula. This tends to result in a moister texture, which is usually desirable. Unfortunately, the pyrophosphate ion also imparts a slightly bitter aftertaste when used at higher levels. Therefore, the product formulator must try to balance such desirable and undesirable effects in developing a leavening system for a specific product.

Final product pH can affect the color of a baked product, and the pH can be controlled by the leavening system. In white products such as white layer cakes, a pH that is slightly below neutral accentuates whiteness. This lower pH can be achieved by adjusting the balance between leavening acid and baking soda (more acid, less soda) or by selection of leavening acid. Pyrophosphate leavening acids tend to buffer pH in the range 7.3–7.5 and it is somewhat difficult to lower the pH by adjusting the pyrophosphate and soda balance. Calcium phosphates, however, do not have the pH buffering capacity of the pyrophosphates, and pH can be manipulated more easily by adjusting the acid/soda balance. The color and flavor of chocolate products are enhanced by higher pH. Again, this can be achieved by selection of leavening acid and/or adjustment of the acid/soda balance (less acid, more soda).

The development of a suitable leavening system is a highly complex activity. The formulator has a number of objectives to meet, and fortunately, there is available a number of leavening agents with varying properties to help meet these objectives.

Characteristics of Leavening Agents

Sodium Bicarbonate (Baking Soda)

As mentioned previously, the heat of baking can cause baking soda to decompose, giving off carbon dioxide leavening gas without reacting with a leavening acid. The sodium carbonate formed by the decomposition of baking soda is very alkaline and will tend to give the baked product a high pH. This is desirable in some applications, because the high pH enhances certain flavors, such as chocolate. Many recipes for chocolate chip cookies call for leavening only with baking soda.

Ammonium Bicarbonate

Ammonium bicarbonate will also decompose during baking and release ammonia and carbon dioxide leavening gases without reacting with a leavening acid. Unlike sodium bicarbonate, which leaves a residue of alkaline sodium carbonate, ammonium bicarbonate leaves no residue when it decomposes by heat. It, therefore, has no effect on the pH of the baked product. If there is more than about 5% moisture in the baked product, however, the ammonia gas will dissolve in this water and impart an ammoniacal flavor to the product. For this reason, ammonium bicarbonate is used only in low-moisture products such as crackers.

Cream of Tartar

Cream of tartar (potassium acid tartrate) reacts very rapidly with soda in a dough or batter, releasing 70–80% of the leavening gas within 2 min of completion of mixing. For this reason, it has little application in commercial production of bakery foods, since there is insufficient time to process the dough prior to baking.

Sodium Aluminum Sulfate

SAS is a very slow-reacting leavening agent and does not release leavening gas until the product is in the oven, and its temperature rises. SAS is most often used in combination with a faster-acting leavening acid such as MCP. This combination (SAS and MCP) is the most popular composition of household baking powders. SAS is not used extensively in commercial baking.

Monocalcium Phosphates

Monocalcium phosphate leavening acids are available in two forms: the monohydrate (MCP) and the anhydrous product (AMCP). The monohydrate is fast-acting, although slightly slower than cream of tartar. It is usually used in combination with slower-acting leavening agents. MCP will release leavening gas from baking soda during mixing, which is desirable in achieving a fine, uniform grain in the baked product as long as a slower-acting leavener is present to provide leavening gas during baking. AMCP is coated with a slowly dissolving phosphate material that delays its reaction with baking soda. This delay is relatively short, but sufficient for some products that are baked in the home. These products include biscuits, pancakes, and waffles.

Sodium Acid Pyrophosphates

SAPPs are available with a range of reaction rates from slow to very slow. SAPPs are used almost exclusively in some applications such as cake doughnuts and canned, refrigerated biscuit doughs. They are one of several options available to the formulator of cakes, biscuits, pancakes, etc. The aftertaste, to which many people are sensitive, somewhat limits the use of

SAPPs, particularly since the development of SALP leavening agents.

Sodium Aluminum Phosphates

SALPs are the most recently developed chemical leavening agents. They are very slow-reacting with baking soda and are often marketed as blends with a faster-acting leavener such as MCP or AMCP. SALPs have become quite popular with product formulators, because of their high NV, relatively low cost, lack of undesirable flavors, and ability to be blended with other leaveners to achieve optimized properties for specific applications.

Dicalcium Phosphate Dihydrate

DCP is not technically a leavening 'acid,' because it is an alkaline phosphate salt. However, when incorporated into a dough or batter and subjected to the heat of baking, DCP decomposes to MCP and tricalcium phosphate (TCP). The TCP is insoluble, precipitates out of the system, and leaves MCP – a fast-acting leavening agent – to react with baking soda. The temperature at which DCP decomposes is relatively high (55–60 °C), so that decomposition occurs rather late in the baking process. For this reason, DCP is classified as a very slow-acting leavening agent and is commonly used in combination with a fast-acting leavener.

Dimagnesium phosphate

Magnesium phosphate is a new leavening acid that is slow-acting and is activated by heat (40 °C). It has a clean flavor profile, provides a uniform cell structure, and imparts moistness to baked product crumbs. It is particularly useful in frozen and fresh baked cakes, muffins, biscuits, and pizza crusts.

Glucono-δ-lactone

GDL is an organic compound that forms gluconic acid when dissolved in water. It reacts slowly, but steadily with baking soda. The rate of reaction, of course, increases as the temperature of the dough or batter increases during baking. GDL has a low NV of about 45, requiring about two parts of GDL for every one part of soda. It is, therefore, relatively expensive to use and finds limited application in specialized products.

Summary

The technology of chemical leavening is quite complex, because of the varying requirements of different products and processes. It is made even more complex by the availability of a variety of chemical leavening agents, each with its own set of properties, advantages and disadvantages.

An understanding of the technology of chemical leavening should lead to the production of even better, cost-effective, and consumer-satisfying bakery foods.

LEGISLATION

Contents

History

P Berry Ottaway, Berry Ottaway & Associates Ltd, Hereford, UK

Background

The history of food legislation can be traced back over millennia. Laws have been introduced into all civilized society for one or more of four main reasons. The first is food safety and protection of the population; the second is fiscal, for the collection of taxes; the third covers various aspects of the adulteration of food; and the fourth is concerned with weights and measures.

Food Safety

Although food safety now predominates in the legislation of our modern society, it was not until the nineteenth century that food laws protecting public health became important in western Europe and North America. However, laws based on early experience of food safety problems go back many thousands of years. The detailed Jewish dietary laws (kashrut) can now be rationalized with our knowledge of food safety, microbiology, and parasitology. The dietary laws are mainly written down in Deuteronomy and Leviticus in the Old Testament in the Bible.

In these works, the Israelites were given the rules on permitted and forbidden foods. The only animal (mammal) meat allowed was from those species that chewed the cud, parted the hoof, and were cloven-footed. This meant that sheep and deer were allowed as food but the pig was strictly forbidden. It had already been deduced that the meat from grazing herbivores was likely to be safer than that from a scavenging omnivore.

Similar explanations can now be applied to the rest of the detail of the early Jewish food law. All birds of prey, such as vultures, eagles, seagulls, and owls, had to be excluded from the diet. Of the lower orders of animals, none which were creeping and go on all-fours, or winged, swarming animals were allowed, except if the legs of the swarming beasts were jointed so that they could jump. Within the insects these definitions separated the disease-carrying flies and cockroaches from the grasshoppers and locusts; locusts are still a common food in many parts of the world.

Among the aquatic animals only those fish that possess both scales and fins were permitted. Crustaceans such as prawns, lobsters, and crabs, and all shellfish may not be eaten. Again, the scavengers with their higher risk of disease are excluded.

Even with the permitted animal foods there are further rules. No animal that has died naturally or from the result of an attack from another animal must be eaten and complex laws were developed on the separation of meat and dairy products and the use of utensils. These strict dietary laws originated thousands of years ago and many are still strictly observed today by followers of both Judaism and Islam.

It was not until the second half of the nineteenth century that legislation relating to the public health and safety aspects of food began to be generally established in Europe.

In the UK the 1860 Adulteration of Food and Drink Act prohibited the sale of impure food and food to which materials or ingredients injurious to health had been added. This was strengthened in 1872 by the Adulteration of Food and Drugs Act which required the appointment of public analysts and empowered local enforcement officers to take samples and bring prosecutions.

The Sale of Food and Drugs Act, passed in 1875, increased the scope of the previous legislation by making it an offence to sell, to the prejudice of the customer, food which was not of the nature, quality, or substance demanded by the consumer. In the same year, the Public Health Act 1875 permitted the local enforcement authorities to take preemptive action by inspecting food. That which was considered to be 'diseased or unsound, or unwholesome or unfit for

the food of man' could be officially seized and taken before a justice of the peace.

It was over 50 years later, in 1928, that significant changes were made to the 1875 Acts, and in 1938 a consolidation took place and the appropriate sections of the Sale of Food and Drugs Act and the Public Health Act were brought together in the Foods Act 1938. The 1938 Act introduced the offence of applying false or misleading labels to food and also contained the powers to make regulations to govern the preparation, storage, and sale of food. This Act brought most of the British food safety legislation into place. The 1938 Act was further consolidated in 1955 (Food and Drugs Act), by the Food Act 1984, and the Food Safety Act 1990.

During the second half of the nineteenth century and first half of the twentieth century, the developments in food safety legislation in the UK had a very significant influence on the introduction of similar legislation into the British dominions and colonies at the time.

Fiscal Laws

The idea of levying taxes on foods goes back more than two millennia in Europe. Import and export duties (*portoria*) on goods, including food commodities, formed an important part of the well-organized taxation system of the Roman Empire.

In the UK the earliest written reference to customs dues being levied is to be found in a charter dated 743. In a document from 979 there is evidence of duty to be paid on cheese, butter, and eggs coming into England through the port of Billingsgate. Until the beginning of the thirteenth century, there were specific grants giving permission to individual ports to charge duties on imported foods. Introduction of a nationally organized English customs service started in the reign of King John (1166–1216). In 1203 a duty of one-fifteenth of the value was placed on all imports and exports, including food. This was called the quindecima. It was decreed that the duty raised be paid direct to the treasury and removed the permission for it to be retained by the ports. This established a basic centralized system of customs control at the ports, which has survived in the UK with very little change to the present day.

For a number of centuries, most of the food-related laws in what is now the UK were based on the need to raise taxes and at one time or another a wide variety of food and drink has been subject to tax. It is interesting to reflect that a tax imposed on tea by the English in 1773 initiated the American War of Independence and the American colonies breaking away from the control of Europe, eventually to become the USA.

The Adulteration of Food

Sadly, history shows that where food is traded there is the temptation to adulterate or misdescribe the food to make illicit profits. It would appear that in all ages and societies the temptation has been irresistible. An Indian law dated to about 300 BC prohibited the adulteration of grain, scents, and medicines.

Documents in the UK show that food adulteration has been a problem for nearly a thousand years. For centuries the methods of adulteration, and methods of detection, were very crude and adulterated foods often caused illness and even death.

In England during the Middle Ages, the trade guilds took the first positive actions against adulteration of the foods for which their members were responsible. This was voluntary regulation by the tradesmen in the guilds to insure their reputation and also to insure a trading advantage. As time went on, the voluntary controls began to be replaced or supplemented by statutes.

In each age to the present day it has been the case that the more expensive items of food and drink are at risk of adulteration and manipulation. Thus, sugar, spices, tea, coffee, wine, beer, and spirits have all been the targets of malpractice. Milk was commonly diluted with water and a proportion of butterfat removed from the top of the milk. Bread was also commonly adulterated and records show that in a number of towns in medieval England bakers were pilloried. In the more serious cases, where widespread illness or death resulted from the malpractice, the tradesmen were sent to the gallows.

During the eighteenth century, legislation was introduced (in 1718) to prevent the adulteration of coffee. This was followed by a similar law on tea in 1730 and one on bread in 1758. The weakness of these laws at the time was due to the lack of effective analytical methods. Most methods that had been developed for the detection of adulteration were based on taste, smell, or texture.

It was not until 1860 that the Adulteration of Food and Drink Act was passed in England. This was more broad-based than the previous commodity-related legislation and it created an offence of knowingly selling food containing injurious material. Between 1860 and 1870, similar laws were passed in Germany and Sweden.

In the USA, Professor GW Wigner won a Board of Trade prize in 1880 for a paper recommending legislation to combat food adulteration. The US Congress failed to pass the first act drafted on the basis of the paper, but between 1880 and 1890 several states passed laws based on Wigner's work.

Weights and Measures

From the earliest days of human communities bartering or trading food, there has been a requirement for a mutually acceptable system of weights and measures.

The oldest weights identified by archeologists are believed to be between 9000 and 10 000 years old. There is also evidence that trade in weighed products was used by the Indus civilization and in Sameria about 5000 years ago. A little later, weighed trade was adopted by the Babylonians and then by the Egyptians about 4500 years ago.

There are also references in the Bible (Old Testament) to the importance of weights and measures in a structured society. They appear where Moses is told the laws for the Israelites in Leviticus: 'Ye shall do no unrighteousness in judgment, in metyard, in weight or in measure. Just balances, just weights, a just ephah and a just hin, shall ye have' (ephah and hin were measuring equipment of that time). Also the Book of Proverbs states: 'A just weight and balance are the Lord's; all the weights of the bag are his work.'

The Romans introduced an organized system of weights and measures into all the countries which became part of the Roman Empire. The Roman libra was almost the same weight as a standard measure used by the Egyptians and another used by the Babylonians. For a number of centuries after the collapse of the Roman Empire, practically every country in Europe had a weight with its name derived from either the word *libra* or *pondus*, the latter being the origin of the word pound. The pound was the principal unit of measure in UK law until it began to be phased out in the mid-1980s in favor of metrication and as part of the UK harmonization with the rest of the European Community. It was finally abolished as a measure of food in 2000. The pound is still retained in the USA.

In the Dark Ages that followed the collapse of the Roman Empire, the system of weights and measures deteriorated and in northern Europe there was a gradual return to the primitive ways of measuring, for example, with the human body. The situation developed where almost every main town had its own standards which could differ from those of its neighbors. This resulted in considerable confusion in trade.

In England, the earliest law to introduce and enforce consistent standards of weights and measures was introduced during the reign of King Edgar (AD 959–975). To quote from a translation: 'And let one money pass through the King's Dominions and that let no man refuse; and let one measure and one weight pass, such as is observed at London and Winchester.'

A major change in the weighing and measuring of food began in France during the Napoleonic period, with the introduction of the metric system. The principal unit of weight became the gram, and that for volume became the milliliter.

The metric system originated in 1791 when a committee of the French Academy made a report to the National Assembly on proposals for a new scientifically based method of measurement. These proposals were subsequently adopted in France. The report defined the standard of length as the meter (metre), which was one ten-millionth of the earth's meridian quadrant at sea level.

The unit of weight, the gram (g), became a secondary standard based on the centimeter (one-hundredth of a meter), and the density of water at a given temperature. Minor inaccuracies were encountered in the measurement of length and in 1875 the International Bureau of Weights and Measures was established at Sèvres in France. The meter was redefined as 1 650 763.73 wavelengths of the orange-red light emitted when a gas consisting of pure krypton-86 is excited in an electrical discharge. A standard kilogram (1000 g) was produced from a platinum-iridium alloy and is carefully preserved at Sèvres.

Through the twentieth century, the metric system was adopted by more and more countries and has now become the main system of measurement for science and also for trade. One of the main areas still retaining the imperial measurements of pounds, ounces, and gallons is the USA.

Early Development of Food Law in the USA

During the late nineteenth and early twentieth centuries, the development of food legislation in the USA was complex. Congress did not have constitutional authority over the regulation of manufacturing processes or the provision of pure and safe food. The federal laws were primarily concerned with interstate and international trade. Early federal food legislation was mainly concerned with the export and import of meats such as a law in 1890 requiring the inspection of salted pork and bacon. This was introduced to facilitate exports as a number of European countries were concerned about contamination with trichinae.

Towards the end of the nineteenth century, there was an intermingling of state and federal laws. Among laws passed by individual states was the California pure food and drug law of 1850; the Massachusetts law prohibiting milk adulteration in 1856; the New York food and drug law in 1881; and the District of Columbia food and drug law of 1891.

Chiefly as a result of a campaign by Dr Harvey W Wiley, chemist for the US Department of Agriculture, against adulterated and misbranded foods, President Theodore Roosevelt signed the Food and Drug Act in 1906. This was after 12 similar bills had failed over the previous 20 years.

In 1927 a separate enforcement agency covering food was constituted as the Food, Drug and Insecticide Administration. This became the Food and Drug Administration in 1931.

In 1939 the Federal Food, Drug and Cosmetic Act was passed which, whilst retaining most of the provisions of the 1906 Act, added new provisions such as the definition of food, food standards of identity, and making truthful labeling mandatory.

The Hale Amendment in 1954 allowed for a more simplified method of promulgating food standards, and the Food Additive Amendment of 1958 required that any substance added to food must be proved to be safe by the manufacturer before being offered for sale. It also permitted the use of food chemicals for technological purposes where they were safe at the intended level of use. The Delaney proviso prohibited the approval of any food additive shown to induce cancer in humans.

Following the enactment of the Food Additives Amendment, the Food and Drug Administration published the first list of substances generally recognized as safe (GRAS) in the Federal Register. This list contained nearly 200 substances.

In 1960 the Color Additive Amendment was enacted requiring manufacturers to establish the safety of all color additives intended for use in foods, drugs, and cosmetics. This was also subject to the Delaney proviso prohibiting the approval of any color additive shown to induce cancer in humans or animals.

With the establishment of the Environmental Protection Agency in 1970, the program for setting limits and tolerances for pesticides was transferred from the Food and Drug Administration to the new agency.

Food Law of the European Union

The most ambitious and comprehensive program to develop new food law was that undertaken in the European Union in the second half of the twentieth century.

From the signing of the Treaty of Rome, which brought the European Economic Community into existence in March 1957, it was realized that in order to insure freedom of trade in foodstuffs it was essential to establish common rules on the presentation, control, and in some cases the composition of the foods.

Of particular concern in the first years of the Community were the diverse national laws regarding the use of additives in foods and the first directive in the food sector was that on food colors which was adopted in 1962. During the early 1960s, work was in progress on directives to control other groups of food additives.

The first real step towards the harmonization of the food legislation was a European Commission recommendation published in 1965 which required prior notification from the member states of any intended new legislation or amendments to existing legislation on foodstuffs.

Four years later, in 1969, the European Council issued a resolution which included the drawing-up of a program for the elimination of technical barriers to trade in foodstuffs. The program that emerged as a result of this resolution was ambitious as it was divided into priority groups covering 70 subjects with a time schedule built around five phases, with completion in 1971, 2 years after the publication of the program. As very little of the program had been accomplished by the 1971 deadline, a new resolution in 1973 revised the program and extended the deadline to 1978. Again, progress was slower than anticipated and a further revised program was adopted in 1977.

One of the main objectives of the harmonization program during the 1970s was the development of compositional or 'recipe' legislation, covering specific groups of foodstuffs. This 'vertical' legislation, as it came to be known, was considered essential for free movement of foods and a large number of directives were envisaged, each concerned with the composition and control of a product category. By the mid-1970s, over 30 categories of foodstuffs had been identified as requiring recipe or vertical legislation.

The first of these directives was that on cocoa and chocolate products, which was still in force in 2000, having been amended 12 times. Although work commenced on over 25 vertical directives during the first half of the 1970s, very little of this proposed legislation had been adopted by 1977. Most of the delays were caused by lack of agreement between the member states as to what was important for the control of the product category. One of the problems associated with the vertical legislation was that, to a considerable degree, it restricted product development and the introduction of technological innovation.

A major turning point in the progress towards harmonization and an important influence on the revised programs for the 1980s was the European Court of Justice judgment on the Cassis de Dijon case. This concerned a German prohibition on the import of the blackcurrant liqueur Cassis de Dijon

from France as the alcohol content was lower than that permitted by German law. The Court ruled that the barrier created by the German regulation was incompatible with the Treaty of Rome and that quantitative restrictions on imports should be prohibited. This judgment provided a general principle for the trade in foods between member states which was that, provided a foodstuff complies with the regulations in force in the member state in which it is manufactured, it should be permitted on the market of any other member state.

The Cassis de Dijon judgment is now regarded as being pivotal in the major change of approach by the European Council and Commission to the harmonization program. There was a shift of emphasis away from the vertical directives and it was determined that future Community legislation on foodstuffs should be limited to provisions which are justified by the need to protect public health, provide consumers with necessary information about foods, provide for necessary public controls, and insure fair trade.

The new approach to harmonization was given an additional impetus in mid-1985 with the publication of a white paper from the Commission to the Council entitled *Completing the Internal Market*. The white paper addressed the fact that there has been a significant imbalance between the 'horizontal' food legislation (e.g., labeling and additives) where considerable progress had been made and the 'vertical' legislation covering composition in which there had been relatively little progress.

The white paper, and a Commission Communication which followed it, defined a new approach in which the vertical system was to be replaced by a horizontal one. The procedures were also simplified to reduce the work involved and to speed up the harmonization process.

The new program was to be centered on five framework directives that were considered crucial to the single market in foodstuffs. These were:

1. Additives
2. Food labeling and presentation
3. Materials and articles in contact with food
4. Official control of foodstuffs
5. Foods for particular nutritional uses

The framework directives were required to lay down the general principles for control in the relevant areas and specific technical directives were to be developed as adjuncts to these framework directives.

As some of the five key areas had already been covered by earlier directives, priority was to be given to revising them and bringing them into line with the new requirements. However, even with the more simplified and streamlined program, progress was slow and much of the essential proposed legislation was not adopted by the introduction of the single market in January 1993.

At the end of 1999, the European Commission published a white paper on food safety which included proposals to set up a centralized European Food Authority and which also set timetables for the completion of over 80 outstanding items of food legislation.

In anticipation of their eventual incorporation into the European Union, a number of states in the former Soviet Union, particularly Hungary, Poland, and the Czech Republic, have been revising their food laws in line with those of the European Union.

Codex Alimentarius

Since the mid-1960s, the Codex Alimentarius Commission has played an increasing role in shaping the future of international food law.

Codex was instituted as a joint Food and Agriculture Organization (FAO) and World Health Organization (WHO) initiative to develop internationally accepted standards and codes of practice for food commodities. All member nations and associate members of the FAO and WHO can become members of Codex. By 2000, the number of member countries had reached 165, representing 97% of the world's population. Over the years a wide range of standards covering a number of food categories have been agreed, and in some countries these standards form the basis for national laws.

The Codex Alimentarius has gained a greater significance since the formation of the World Trade Organization (WTO). The Agreement on the Technical Barriers to Trade (TBT) that was introduced following the Tokyo Round on World Trade in 1979 had a substantial impact on the establishment of policies on food control. The TBT Agreement did not specifically mention Codex but dealt with aspects of food not directly related to safety, such as labeling, quality, and packaging, and thus impinged on Codex. The WTO, however, has recognized Codex as the preferred international organization for the arbitration and settlement of disputes related to food trade.

International Standards

J A Smith, Leatherhead Food Research Association, Leatherhead, Surrey, UK

Standards

The initial object of standardization was to provide a means of communication between the supplier and the user. Standards are, in principle, voluntary instruments but, as legislation began to deal with more complex technological developments, legislators referred to standards as a means of achieving the desired objectives of legislation. Before the advent of detailed food labeling, food standards provided the only way to guarantee the consumer that the desired quality in terms of product characteristics was maintained, and they thus became frequently referred to in legislation or laid down under mandatory acts.

Food standards generally lay down requirements for the composition of a food in terms of percentage and quality of ingredients and may include provisions on food additives. They may also specify physical properties, such as water content, particle size, density, or processing methods.

The Codex Alimentarius Standards of the Food and Agriculture Organization/World Health Organization (FAO/WHO) are, in effect, model laws for use in international trade; by granting full acceptance of a Codex standard, a country or trading bloc engages to accept conforming products on its market.

Food standards have generally been established for more basic food commodities, such as flour, bread, and meat products, in order to insure minimum standards are met, but have also been widely applied to products such as soft drinks and chocolate, which are consumed by a mass market. In insuring that basic standards are met, food standards have partly a social function in guaranteeing the quality of basic necessities. Composite products, the appeal of which depends on diversity, are rarely the subject of standards. Standards are usually tied to a product denomination or name and, since they reflect national tradition and characteristics, there can be different standards in different countries for the same product descriptor.

Nowhere has this been more evident than in the European Union (EU) with its variety of culinary traditions. Examples include use of durum wheat only in pasta in France and Italy, differences in composition of sausages in the UK and Germany, and the use of vegetable fat in chocolate throughout the EU.

Attempts during the 1980s to harmonize compositional food standards were unsuccessful due to the unwillingness of the then European Community (EC) member states to broaden the scope of their own standards and come to a common level with others. It is for this reason that the establishment of compositional standards *per se* is no longer actively pursued at EC level; the emphasis now is on public safety, removal of barriers to trade, and prescribed food labeling in order to allow the consumer to make an informed choice.

This trend away from prescribed standards of composition has become international in recent years, as such standards are seen as restrictive in terms of product development and obstructive to trade. However, a large number of food standards are still in force worldwide and are still a significant factor when considering the scope of technical food legislation.

In this article, to illustrate the role typically played by food standards, the situation is described first under EC law, in the UK as an EU member state, and then in the USA, with is totally different system of food legislation.

The EC

A number of food standards were set by so-called vertical directives (i.e., directives applying to a specific product sector) in the 1970s and 1980s; products such as jams, coffee and chicory extracts, fruit juices, cocoa and chocolate products, honey, preserved milks, sugars, caseins and caseinates were included. In order to reach agreement on some of these, it was necessary to allow certain national derogations or exemptions to be maintained, the most famous being the use of vegetable fat in chocolate (UK, Denmark, and Ireland at the time allowed vegetable fat to be used up to 5% of the total weight of the product in chocolate manufacture, whereas other member states were of the opinion that the use of vegetable fat rendered the product a 'chocolate substitute'). Some issues were left open to the member states to make a decision, for example, the addition of vitamins for nutritional purposes to fruit juices. These directives included provisions on additives and labeling as well as minimum levels of required ingredients.

Key to the change in emphasis in EC food law was the 'cassis de Dijon' case, which was a case brought under Article 30 of the EEC Treaty concerning the composition of a blackcurrant liqueur. Under this Article, no EC member state may refuse a product legally made in another member state provided its exclusion cannot be justified in terms of public health or provision of information. In the absence of compositional standards at EC level for the majority of foods manufactured the impact of this was highly significant, as the concept of mutual recognition of another EU member state's products began to be widely accepted. Certain of the member states began writing mutual recognition clauses into any new legislation on compositional standards to insure they did not fall foul of EC law.

Today EC directives on these foods are still in existence, although work has been continuing for some years to simplify them and bring them more into line with trends in modern food legislation. Examples of this are the removal of provisions on additives (now covered by horizontal (i.e., applying to all foods) additives directives) and the bringing of labeling requirements into line with those required by the general food-labeling directive, 2000/13/EEC. Revised directives have been agreed on coffee and chicory extracts and fruit juices and similar products; after many years' discussion, agreement has finally been reached on a revised cocoa and chocolate products directive. The key issues of vegetable fat and the naming of milk chocolate made with a lower percentage of cocoa solids have largely been resolved by requiring more detailed labeling, as well as restricting the types of vegetable fat that can be used.

However, variations on compositional standards are still being produced under EC law and are deemed necessary in order to insure the market in key agricultural sectors. Marketing standards have been produced for tuna, poultry, and a number of fruit and vegetables. Of other EC regulations, the one which is probably most familiar to many in the food industry is that on spreadable fats. This standard details the product descriptions that can be used for dairy, animal, and mixed-fat spreadable fat products with differing fat contents between 10 and 90%. Another important regulation is that on drinking milk, which lays down fat contents and descriptions for the different types of milk. As EC regulations, and not directives, such legislation is binding on the individual member states.

A new type of legislation has been introduced during the 1990s. Although not generic standards in the true sense, regulations on certificates of specific character for agricultural products and foodstuffs and on the protection of geographical indications and designations of origin for agricultural products and foodstuffs requires that names of the registered products may only be used when the product in question complies with approved specifications. Only products that are traditional or are produced in a traditional way will be able to be registered and protected by their specific character; mozzarella cheese is thus protected. PGIs/PDOs are intended to insure that a product's name is linked with its qualities and characteristics that may be due to environmental factors. Generic names (such as Cheddar cheese) may not be registered; however, a range of meat products (including Parma ham), olive oils, cheeses (including West Country farmhouse Cheddar cheese and Parmesan cheese) and other foods have been registered. Following a European Court ruling in March 1999, the name 'feta' has been deleted from the register, but the name will remain protected at a national level in the meantime.

The UK

Over the last 10 or so years, the number of food standards still in force under UK law has been significantly reduced. In some cases (for example, mayonnaise and soft drinks) revocation has been total; in other cases (for example, cheese, icecream) key definitions have been included in revised regulations on food labeling to insure that a minimum quality of product is still maintained when a product descriptor is used. To illustrate this, the minimum fat content of icecream and milk fat content of dairy icecream are still laid down, together with fat contents for named cheeses. Standards still remaining include those on bread and flour and meat and spreadable fish products, as well as on basic foods such as drinking milk, jams, honey, and other EC-derived standards.

Typically, a standard includes a definition of terms used in the regulations in order to aid interpretation; any exemptions that may apply; minimum compositional requirements for named foods; specific labeling requirements that are relevant for named products; penalties and enforcement, and any revocations of existing standards. An explanatory note finishes the text, summarizing the main points of the regulations. The requirements detailed in regulations may be backed up by codes of practice or guidelines, or by decisions reached by case law, which can aid in the interpretation of particular points contained within the regulations, or by advice issued to enforcement officers.

Are other EU member states similar to the UK? Certain have undergone a similar extensive deregulation exercise, most noticeably The Netherlands;

detailed guidelines are still used as indicators of consumer expectation in Germany. Spain still has in existence a large number of compositional standards across a wide range of food products, which contrasts with the Scandinavian countries, which tend to have fewer standards. But throughout the EU the concept of mutual recognition in terms of compositional requirements insures that national standards of the future can only be justified on the grounds of consumer information or public health/safety needs.

The USA

Establishment of Food Standards

Mandate for the production of standards for food comes from the Federal Food, Drug and Cosmetic Act (FFDCA), as amended. Section 401 of this Act, concerning definitions and standards for food, states that wherever, in the judgment of the Secretary of Health and Human Services, such action will promote honesty and fair dealing in the interests of consumers, regulations shall be made fixing and establishing for any food, under its common or usual name so far as practicable, a reasonable definition and standard of identity, a reasonable standard of quality, and/or reasonable standards of fill of a container.

Section 401 states that no definition and standard of identity, and no standard of quality, may be established for fresh or dried fruits, fresh or dried vegetables, or butter, with the exception that definitions and standards of identity may be established for avocados, cantaloupes, citrus fruits, and melons; however, these may relate only to maturity and the effects of freezing.

In prescribing any standard of fill of container, due consideration must be given to the natural shrinkage in storage and in transit of fresh natural food and the need for necessary packing and protective material. In the prescribing of any standard of quality for any canned fruit or canned vegetable, consideration must be given and due allowance made for the different characteristics of the varieties of that fruit or vegetable. When prescribing a definition and standard of identity for any food or class of food in which optional ingredients are permitted, the optional ingredients that must be named on the label will be designated, for the purpose of promoting honesty and fair dealing in the interests of consumers.

Agencies Responsible for Food Standards

The major federal agencies responsible for food standards in the USA include the Food and Drug Administration (FDA), the US Department of Agriculture (USDA) and the National Oceanic and Atmospheric Administration (NOAA), which is directed by the US Department of Commerce.

Food and Drug Administration The FDA, by delegation from the Secretary of the Department of Health and Human Services, regulates food other than red meat, poultry, and eggs. These standards of identity, established by the FDA for these products in Title 21 of the Code of Federal Regulations (21CFR), must be followed in every respect.

US Department of Agriculture The USDA is responsible for the control of red meat, poultry, and eggs and also for the quality assurance of other foods. Within the USDA, specific responsibilities are delegated to other agencies. Those involved in establishing standards for food include the following:

- Food Safety and Inspection Service (FSIS)
- Agricultural and Marketing Service (AMS)
- Federal Grain Inspection Service (FGIS)

The AMS is primarily responsible for standardizing the quality and grading of meat, poultry, dairy products, horticultural products, and certain other commodities. The grade standards established for these commodities are published in 7CFR. The majority of the functions of the AMS are voluntary, as are the grade standards. Federal law does not require that a food processor or distributor use the grade standards; however, they are widely used in wholesale and retail sale to enable the purchaser to select the required grade or level of quality.

The Meat and Poultry Inspection regulations, established by the FSIS and published in 9CFR, include compositional standards and labeling requirements for meat and poultry products. Definitions and standards of identity or composition established in 9CFR, 319 and 381 subpart P, for meat and poultry products, respectively, are mandatory and the producers covered must meet the provisions laid down to be legally manufactured and sold.

National Oceanic and Atmospheric Administration The National Marine Fisheries Service (NMFS) is one of the major services administered by the NOAA and is involved in the development of specifications and standards for the quality, grade, and identity for fishery products and the establishment of grade standards for processed fishery products.

Procedure for Establishing Standards

The procedure for establishing a food standard, referred to in section 401 of the FFDCA, is governed by the FDA in 21CFR. Any petition for a food standard

must show that the proposal, if adopted, would promote honesty and fair dealing in the interests of consumers. A petition includes an application or other document requesting the Commissioner of Food and Drugs to establish, amend, or revoke a regulation or order, or to take, or not, any other form of administrative action under the laws administered by the FDA.

Review of Codex Standards All food standards adopted by the Codex Alimentarius Commission are reviewed by the FDA. These Codex standards will be accepted without change, accepted with change, or not accepted. This review is accomplished in one of several ways, according to the procedures detailed in 21CFR. The review is officially published in the *Federal Register* for comments. After reviewing these comments the FDA makes a decision on the standard. A partial adoption of a standard makes it legally enforceable in the USA.

The FDA encourages all interested parties to confer with different interest groups such as consumers, industry, academia, and professional organizations in formulating petitions or comments.

Rule making Legal and scientific knowledge is used by the FDA to formulate regulations on compositional and processing requirements for food. There is considerable interaction between the FDA and the food industry during the establishment of regulations and the FDA is often dependent on industry for adequate scientific data on which to base regulatory decisions. Petitions from industry may initiate regulations. When federal agencies intend to issue a new regulation, or amend an existing one, they publish a notice of intent in the *Federal Register*; this stage is often omitted by the FDA. This rule-making notice gives the text of the proposed regulation, describes the issues involved, and invites comment within a specific period of time. If, after comments have been received, the change is favorably viewed, a proposed rule will be published, inviting comments, upon which the final rule is judged. When the final rule is published the background to the change and a summary of the comments is given.

Type and Scope of Standards

The FDA issues three types of standards, as prescribed by the FFDCA, namely standards of identity, quality, and fill of container, for a number of food products.

Standards of identity are the basic food standards issued by the FDA and their purpose is to protect consumers from being cheated by inferior products or confused by misleading labels. These standards establish or define the food product, e.g., by specifically stating the ingredients that the food may contain. They specify the correct name of the food and other mandatory label information, including the type and amount of certain vitamins that must be present in foods labeled 'enriched.' Required amounts of certain ingredients and maximum limits of others are specified. The standards are based on the assumption that food represented as, or purported to be, a food for which a standard of identity has been established must comply with the specification of the standard in every respect. However, temporary permits may be issued for interstate shipment of experimental packs of food varying from the requirements of definitions and standards of identity.

Certain of the standards of identity are supplemented by standards of quality and fill of container. Standards of quality establish specifications for quality requirements or factors for canned fruits and vegetables and are minimum standards. Standards of quality must not be confused with standards for grades that are published by the USDA for agricultural products and by the NMFS for fishery products. The standards for grades may classify the products from average to excellent in quality.

Standards of fill of the container designate the quantity in terms of solid or liquid components, or both for products such as canned fruits and vegetables, and certain fish products. If a food for which a standard of quality or fill has been established falls below that standard, it must bear a label statement in the prescribed size and style of type, stating that the product is substandard.

Comparison of certain food standards Table 1 is intended to illustrate some of the current differences in composition between certain food products in different countries. The product categories chosen (icecream and chocolate products) have been selected to show the contrast in these products. Similar product designations are used, but the composition is quite different. The tables include information concerning the major mandatory compositional requirements for the products covered; they are not intended to cover complete compositional data for these products.

The Future of Food Standards

The EC

New standards of composition in the traditional format are no longer relevant in the legislative arena of the twenty-first century. However, reference has been made to EC marketing standards that have an impact on all of the member states. The introduction of legislation requiring the declaration of the quantity

Table 1 Comparison of certain UK and USA standardized foods

	UK	*USA*
Icecream	Minimum 5% fat, minimum 2.5% milk protein	Minimum 1.6 lb total solids/gallon, weighs not less than 4.5 lb to the gallon
	Minimum 5% milk fat for 'dairy icecream'	Minimum 10% milk fat (milk solids, not fat content, may vary depending on the milk fat content)
	Food Labelling Regulations 1996, as amended	Title 21 CFR Part 135.110
	Milk fat only in dairy icecream, other than that present as a result of using egg, flavoring, emulsifier, stabilizer, or vegetable fat in nondairy icecream	Milk-derived fats only, except those natural components of flavoring or incidental ingredients
Chocolate (EC) Sweet chocolate (USA)	Minimum 35% total dry cocoa solids, including minimum 14% dry nonfat cocoa solids and minimum 18% cocoa butter	Minimum 15% chocolate liquor, less than 12% milk solids
	EC Directive 73/241/EEC, as amended	Title 21 CFR Part 163

CFR, Code of Federal Regulations.

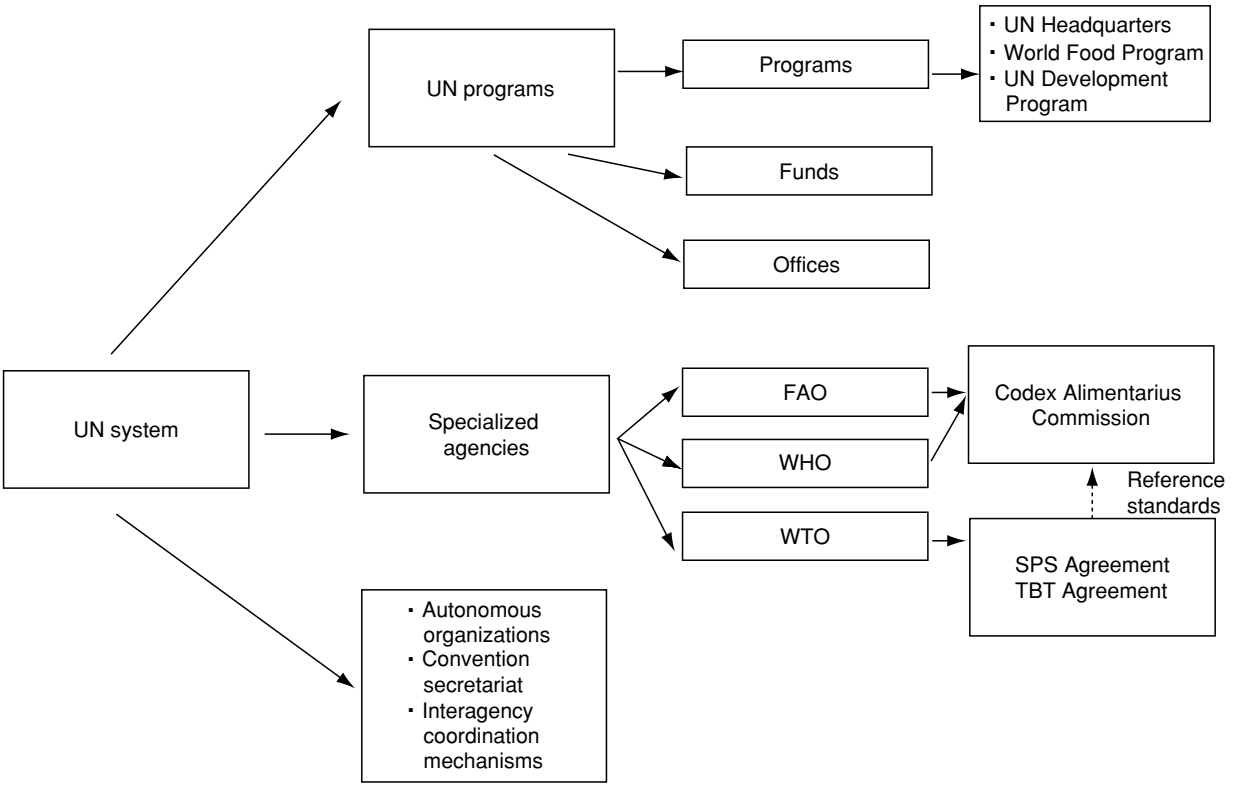

Figure 1 United Nations system of organizations. FAO, Food and Agriculture Organization; WHO, World Health Organization; WTO, World Trade Organization; SPS, Sanitary and Phytosanitary Measures; TBT, Technical Barriers to Trade.

of the characterizing ingredient(s) of foods (so-called QUID legislation) has made compositional standards irrelevant to a large degree; by requiring the content of the key ingredient to be declared on a label there is no need to set a minimum level as consumers can make their own choice. The QUID labeling requirement will largely determine the future format of revised legislation on meat products and spreadable fish products in the UK. However, it is clear that the revised EC standards on coffee, cocoa and chocolate, preserved milks, and other named foods will be here to stay for some time, particularly after the intensity of debate in reaching agreement.

USA

In October 1995, the FDA published its policy on the development and use of standards with respect to international harmonization of regulatory

requirements and guidelines. The FDA established that its main goals in standard-setting activities is to preserve and to enhance its public health mission, increase its efforts in harmonizing regulatory requirements with foreign governments, including setting new standards that better serve public health, and respond to laws and policies that encourage agencies to use international standards that provide the desired degree of protection.

The FDA policy lays down the criteria it uses for participating in standards development. For example, the expected standard would be required to stress product safety and effectiveness, thereby contributing to safe, effective, and high-quality products.

Codex Standards

In 1995, two agreements of the World Trade Organization gave a new significance to the work of the Codex Alimentarius Commission (CAC). These were the Agreement on the Application of the Sanitary and Phytosanitary Measures (SPS) and the Agreement on Technical Barriers to Trade (TBT). Both agreements formally recognized that international standards, guidelines, and recommendations, including the Codex Alimentarius, are reference points that can be used to facilitate international trade and resolve trade disputes in international law. The SPS agreement goes a step further and specifically identifies Codex texts as scientifically recognized and as a means of harmonization.

The adoption of Codex texts as scientifically justified standards for the SPS and TBT agreements is of immense significance (Figure 1). Codex texts are now an integral part of the legal framework within which international trade is being facilitated through harmonization. They can be used as benchmarks in international trade disputes and to evaluate the relevance of national measures. This formal recognition has awakened considerable interest in CAC activities and attendance at Codex meetings has increased markedly in recent years.

Until now, the individual commodity standards, which dealt with the quality aspects of foodstuffs, were the most important part of the Codex Committee's work. However, interest in these recipe standards is shifting to a more horizontal approach. It can already be seen that work from the so-called horizontal committees, such as labeling and additives, are attracting more interest and gaining in importance and profile. Moreover, topical issues, such as those concerning the use of biotechnology, are attracting the interest of both consumer groups and the food industry. The CAC is already examining consumer protection against health hazards and food safety in this key area. These provide an insight into the direction that the CAC activities are likely to take in the future.

Codex texts have formed the basis for food standards legislation in certain countries, for example the Middle Eastern countries. They have often been used as a guide in many other countries throughout the world. This role is still significant and, in the light of the SPS and TBT agreements, is likely to increase further as Codex texts are used as reference in international trade disputes.

Additives

P Berry Ottaway, Berry Ottaway & Associates Ltd, Hereford, UK

Introduction

The addition of chemical substances to food for technological purposes such as preservation or for organoleptic purposes such as color and flavor can be traced back over millennia. Salt was valued in early civilizations not only as a condiment but also for its ability to increase the stored life of meat and fish. There is evidence that the Egyptians used colorants in their foods nearly 4000 years ago.

The use of chemical additives to foods increased considerably during the twentieth century, partly due to the globalization of trade in food and partly to the increasing knowledge of food technology.

Many hundreds of substances have been researched for use as food additives for either technological or organoleptic purposes, often not without

controversy, and one of the challenges to international organizations such as the Codex Alimentarius Commission (Codex) is to try and achieve harmonization in the use of food additives throughout the world. Codex is an organization, set up under the auspices of the Food and Agriculture Organization (FAO) and the World Health Organization (WHO), which is charged with developing a food code to be used on a truly international basis.

Definition of a Food Additive

The definition of a food additive is, by necessity, closely linked to a definition of food. Unfortunately, there is no agreement between the food laws of a number of the developed countries on the actual definition of food.

In 1966, in the early days of the Codex, there was an attempt to define food, as follows:

> Food means any substance, whether processed, semi-processed or raw, which is intended for human consumption and includes drink, chewing gum, and any substance which has been used in the manufacture, preparation or treatment of food, but does not include cosmetics or tobacco or substances used only as drugs.

This definition can be found in many modified forms in the legislation of different countries. Even though the European Union (EU) has been developing its harmonized food legislation since the mid-1960s, it has not yet been able to obtain agreement between its member states on the precise definition of 'food' or 'foodstuff,' even though both terms are used extensively in EU legislation. It is likely that an agreed definition will not be dissimilar to that of Codex.

The Codex defines a food additive as:

> Any substance not normally consumed as a food by itself and not normally used as a typical ingredient of the food, whether or not it has nutritive value, the intentional addition of which to food for a technological (including organoleptic) purpose in the manufacture, processing, preparation, treatment, packing, packaging, transport or holding of such food results, or may reasonably be expected to result (directly or indirectly) in it or its by-products becoming a component of or otherwise affecting the characteristics of such food. The term does not include contaminants or substances added to food for maintaining or improving nutritional qualities.

In the legislation of the EU, the definition of a food additive is contained in European Council Directive 89/107/EEC. This definition is similar to the Codex definition and is given as:

> For the purpose of this directive 'Food Additive' means any substance not normally consumed as a food itself and not normally used as a characteristic ingredient of food whether or not it has nutritive value, the intentional addition of which to food for a technological purpose in the manufacture, processing, preparation, treatment, packaging, transport or storage of such food results, or may be reasonably expected to result, in its by-products becoming directly or indirectly a component of such foods.

The directive specifically excludes:

1. processing aids;
2. substances used in the protection of plants and plant products in conformity with Community rules relating to plant health;
3. flavorings for use in foodstuffs, falling within the scope of Council Directive 88/388/EEC;
4. substances added to foodstuffs as nutrients (e.g., minerals, trace minerals, or vitamins).

Extraction solvents are also not considered to be food additives in the EU and are subject to specific legislation on both their use and residual levels.

A processing aid is further defined in European law as:

> any substance not consumed as a food ingredient by itself, intentionally used in the processing of raw materials, foods or their ingredients, to fulfill a certain technological purpose during treatment or processing and which may result in the unintentional but technically unavoidable presence of residues of the substance or its derivatives in the final product, provided that these residues do not present any health risk and do not have any technological effects on the finished product.

In European law one of the key differences between a food additive and a processing aid is that the latter must not have any technological effect in the finished product. For example, residues of a mold-release agent for a confectionery product are unlikely to have a technological effect on the final product, whereas an antioxidant or preservative added to protect ingredients during processing could still exert a technological function if carried over into the finished product. The former would be considered a processing aid whilst the latter could be considered a technological additive.

In the USA, the Food Additives Amendment 1958 to the Federal Food, Drug and Cosmetics Act contains a more complex definition:

> The term food additive means any substance the intended use of which results or may reasonably be expected to result, directly or indirectly, in its becoming a component or otherwise affecting the characteristics of any food (including any substance intended for use in producing, manufacturing, packing, processing, preparing, treating, packaging, transporting, or holding food, and including any source of radiation intended for any such use), if such substance is not generally recognized,

among experts qualified by scientific training and experience to evaluate its safety, as having been adequately shown through scientific procedures (or, in the case of a substance used in food prior to January 1, 1958, through either scientific procedures or experience based on common use in food) to be safe under the condition of intended use; except that such a term does not include

1. a pesticide chemical in or on a raw agricultural commodity; or
2. a pesticide chemical to the extent that it is intended for use or is used in the production, storage, or transportation of any raw agricultural commodity; or
3. a color additive; or
4. any substance used in accordance with a sanction or approval granted prior to the enactment of this paragraph pursuant to this act, the Poultry Products Inspection Act (21 U.S.C. 451 and the following) or the Meat Inspection Act of March 4, 1907 (34 Stat. 1260), as amended and extended (21 U.S.C. 71 and the following).

This amendment categorized food chemicals as: (1) those generally recognized as safe (GRAS); (2) those with prior sanction; and (3) food additives. Pesticides on raw agricultural products and food color additives were excluded from the legal definition as they were covered by other legislation.

Joint FAO/WHO Expert Committee on Food Additives (JECFA)

Since it was established in 1955 the Joint FAO/WHO Expert Committee on Food Additives (JECFA) has played an international role in providing a review and opinion on food additives, particularly on safety in use.

JECFA was originally set up to consider the chemical, toxicological, and other aspects of contaminants and residues of veterinary drugs found in foods intended for human consumption.

The committee is composed of an international group of independent scientists appointed in their own right for their expertise in food additives, veterinary drug residues, and contaminants. The members are not appointed as government representatives. The committee is administered jointly by the FAO and the WHO. JECFA provides scientific advice directly to member countries of FAO and WHO and also to two committees of Codex; the Codex Committee on Food Additives and Contaminants (CCFAC) and the Codex Committee on Residues of Veterinary Drugs in Foods (CCVDF).

In relation to Codex, the Codex committees identify the additives, contaminants, and residues that should receive priority evaluation and refer them to JECFA for assessment before considering them for incorporation into Codex Standards.

The JECFA reports on their toxicological evaluations are published so that the information becomes widely available.

In its interaction with the Codex Committees, JECFA is independent of Codex and is able to provide impartial and independent advice without political influence.

With the advent of the World Trade Organization (WTO) in 1995, Codex has taken on a greater international significance as the WTO recognizes Codex as the preferred international organization for the arbitration and settlement of disputes related to food trade.

As a consequence of the WTO and also the involvement of Codex in setting international standards for foods and commodities, Codex now has a major influence on food additive legislation worldwide.

Approval of Additives

As part of the assessment of an additive, the JECFA examines the available toxicological data and chemical specifications of the additive and establishes an acceptable daily intake (ADI). The ADI is the amount that can be taken daily in a human diet for a lifetime without risk. Unless stated to the contrary, ADIs are expressed as mg kg^{-1} body weight, one of the exceptions being flour treatment agents that have been given as parts per million.

The ADI is normally derived from the 'no observed adverse effect' level (NOAEL) determined from long-term animal (*in vivo*) studies. The ADI is calculated by applying a safety or uncertainty factor, which is commonly 100, to the NOAEL obtained from the most sensitive test species. The 100-fold safety factor is based on the need to take into account both the differences in species and differences in toxicokinetics and toxicodynamics. Although most commonly used, the factor of 100 may be varied depending on the nature of the toxic effect and the availability of relevant toxicity data.

Approval for the use of an additive is given on the understanding that the additive will be kept under surveillance and reevaluated as necessary in light of changing conditions of use or new scientific evidence. The ADI value may be qualified in five different ways:

1. *Not limited*, which means that there is no explicit indication of an upper limit: this is assigned to substances of very low toxicity (this category has now been superseded by 'not specified').
2. *Not specified*, which means that on the basis of available data the total daily intake required to

achieve the desired additive effect does not represent a hazard to health. For this reason the establishment of an ADI is not deemed necessary. However, the usage of an additive in this category must conform to good manufacturing practice (GMP).

3. *Unconditional status* is allocated to those substances for which the biological data include favorable results from appropriate long- and short-term toxicological studies and/or biochemical and metabolic studies.
4. *Conditional* is allocated when the committee has considered that the quality of the available data is inadequate for an unconditional ADI and further work is required, or if there are other reasons such as those arising from dietary requirements. The reasons and the restrictions imposed on the use of the substance are stated in the evaluation.
5. *Temporary acceptance* means that there are insufficient data to establish whether or not the substance is toxic and further evidence must be submitted within a stated period of time. Details of the requirements are included in the evaluation.

After the JECFA has completed its assessment of an additive and issued its opinion, Codex is responsible for the formal approval or disapproval.

When Codex gives approval for the inclusion of the substance in the list of additives, in many cases the approval is limited, as far as possible, to specific foods for specific purposes at the lowest effective level of use. Any judgments are determined on the basis of the ADI of the additive and its probable intake from all dietary sources.

Classification of Additives

Food additives can perform a number of technological functions during food processing and storage and in a few cases the same substance may have more than one function.

A comprehensive, but not exhaustive, list of additive functions is given in the Codex Standard on Food Labeling (Table 1). This list illustrates the diversity of functions covered by additives and in most countries it forms the basis for the classification of approved additives.

Legislative Controls on Additives

Most countries, and particularly those which are members of Codex, have introduced legislation for the control of food additives. Whilst the details of the legislation differ from country to country, the basic requirements of only using approved additives tend to be consistent. There is, however, no complete consistency between the lists of different countries.

Table 1 Codex Alimentarius additive classes for labeling. Codex standard 1–1985 (revised 1–1991)

Acidity regulator	Flavor enhancer
Acids	Flour treatment agent
Anticaking agent	Foaming agent
Antifoaming agent	Gelling agent
Antioxidant	Glazing agent
Bulking agent	Humectant
Color	Preservative
Color retention agent	Propellant
Emulsifier	Raising agent
Emulsifying salt	Stabilizer
Firming agent	Sweetener
	Thickener
The following class titles may also be used for food additives falling into the respective classes:	
Flavor(s) and flavoring(s)	Modified starch(es)

Table 2 Categories of food additives in the European Union (Directive 89/107/EEC)

Color	Preservative
Antioxidant	Emulsifier
Emulsifying salt	Thickener
Gelling agent	Stabilizer
Flavor enhancer	Acid
Acidity regulator	Anticaking agent
Modified starch	Sweetener
Raising agent	Antifoaming agent
Glazing agent	Flour treatment agent
Firming agent	Humectant
Sequestrant	Enzyme
Bulking agent	Propellant gas and packaging gas

A significant group of countries now working to one of the most complex laws on food additives are those in the EU. A complete review and revision of the European legislation on food additives took place from the late 1980s to the mid-1990s.

Within the EU the framework legislation is found in Directive 89/107/EEC which lists 24 categories of food additives (Table 2). Whilst essentially similar, the EU list differs in detail from that of Codex (Table 1) in that the EU list includes sequestrants, antifoaming agents and enzymes, whilst the Codex list has color-retention agents that are not in the EU list. These categories are further defined in the specific directives, such as those on colors, sweeteners, and the directives on additives other than colors and sweeteners (Directive 95/2/EC).

Also detailed in the legislation (Directive 95/2/EC, Article 1,5) are substances or groups of substances not considered to be food additives under European food law (Table 2). This includes edible gelatin, caseinates, inulin, and chewing gum bases. Since the

middle of the 1990s, the detailed European legislation on food additives has centered on three directives:

- Directive 94/35/EC on sweeteners for use in foods (as amended);
- Directive 94/36/EC on colors for use in foods (as amended);
- Directive 95/2/EC on food additives other than colors and sweeteners (as amended).

The interpretation of all three directives has become complex, as in many cases the additives are not only restricted to defined categories of foods, but can also be subject to varying upper limits on their use depending upon the food category in which their use is intended. Thus a color, sweetener, or technological additive may appear in a list of permitted additives, but its use may be severely restricted to a small number of foods and its usage levels laid down as g or mg of the additive per kg or liter of the product as consumed. An example is given in Table 3. This table clearly illustrates the way the controls are imposed. The maximum levels of each additive are related to both technological need and the degree of likely exposure of the consumers to the additive in terms of the relative proportions of the food consumed as part of a diet. Thus, in case of propane-1,2 diol alginate, the additive is restricted to $100\,mg\,l^{-1}$ in beer, $300\,mg\,l^{-1}$ in nonalcoholic flavored drinks, but allowed up to $10\,g\,l^{-1}$ in an emulsified liqueur.

The introduction of these directives consolidated and harmonized the legislation on food additives across the EU and all food and drink products on

Table 3 Example of European Union food additive legislation showing food categories and maximum levels

EC no.	*Name*	*Food*	*Maximum level*
E355	Adipic acid	Fillings and toppings for fine bakery wares	$2\,g\,kg^{-1}$
E356	Sodium adipate	Dry powdered dessert mixes	$1\,g\,kg^{-1}$
E357	Potassium adipate	Gel-like desserts	$6\,g\,kg^{-1}$
		Fruit-flavored desserts	$1\,g\,kg^{-1}$
		Powders for home preparation of drinks	$10\,g\,l^{-1}$
			Expressed as adipic acid
E363	Succinic acid	Desserts	$6\,g\,kg^{-1}$
		Soups and broths	$5\,g\,kg^{-1}$
		Powders for home preparation of drinks	$3\,g\,l^{-1}$
E385	Calcium disodium ethylene diamine tetraacetate (calcium disodium EDTA)	Emulsified sauces	$75\,mg\,kg^{-1}$
		Canned and bottled pulses, legumes, mushrooms, and artichokes	$250\,mg\,kg^{-1}$
		Canned and bottled crustaceans and molluscs	$75\,mg\,kg^{-1}$
		Canned and bottled fish	$75\,mg\,kg^{-1}$
		Minarine	$100\,mg\,kg^{-1}$
		Frozen and deep-frozen crustaceans	$75\,mg\,kg^{-1}$
E405	Propane-1,2-diol alginate	Fat emulsions	$3\,g\,kg^{-1}$
		Fine bakery wares	$2\,g\,kg^{-1}$
		Fillings, toppings, and coatings for fine bakery wares and desserts	$5\,g\,kg^{-1}$
		Sugar confectionery	$1.5\,g\,kg^{-1}$
		Water-based edible ices	$3\,g\,kg^{-1}$
		Cereal- and potato-based snacks	$3\,g\,kg^{-1}$
		Sauces	$8\,g\,kg^{-1}$
		Beer	$100\,mg\,l^{-1}$
		Chewing gum	$5\,g\,kg^{-1}$
		Fruit and vegetable preparations	$5\,g\,kg^{-1}$
		Nonalcoholic flavored drinks	$300\,mg\,l^{-1}$
		Emulsified liqueur	$10\,g\,l^{-1}$
		Dietetic foods intended for special medical purposes-dietetic formulae for weight control intended to replace total daily food intake or an individual meal	$1.2\,g\,kg^{-1}$
		Dietary food supplements	$1\,g\,kg^{-1}$
E416	Karaya gum	Cereal- and potato-based snacks	$5\,g\,kg^{-1}$
		Nut coatings	$10\,g\,kg^{-1}$
		Fillings, toppings, and coatings for fine bakery wares	$5\,g\,kg^{-1}$
		Desserts	$6\,g\,kg^{-1}$
		Emulsified sauces	$10\,g\,kg^{-1}$
		Egg-based liqueurs	$10\,g\,l^{-1}$
		Dietary food supplements	*quantum satis*
		Chewing gum	$5\,g\,kg^{-1}$

sale in the EU must now comply with the requirements of this legislation. The introduction of the new laws between June 1996 and March 1997 resulted in a number of products having to be reformulated as the new requirements in some cases differed significantly from the internal legislation of some of the member states of the EU. In Germany, for example, the options open to manufacturers for the selection and use of a number of additives increased, whereas in the UK, manufacturers were confronted with more restrictions, particularly in the use of colors and sweeteners.

During the development of the directives on additives, there was considerable discussion about which foods should be allowed to contain which additives. The categories of foods and drinks were modified a number of times during the debates, with the end result that there was no pattern to the product categories finally agreed. Thus, in the section dealing with food preservatives, there are general groupings such as 'nonalcoholic flavored drinks' or 'dried fruit,' and very product-specific rules such as those for gnocchi or polenta.

All applications for the extension of the conditions of use to allow other categories of foods to contain additives, or applications for new additives, are referred by the European Commission to the Scientific Committee on Food of the EU (SCF). The SCF has published guidelines on the data required for applications for new additives and this was updated in July 2001. One of the conditions is that a new additive must exhibit a technological function or a significant advantage (i.e., considerably improved function or organoleptic properties) over those already approved for the technological purpose. Extensive toxicity studies are required to establish the safety of the additive. Since the EU directives on colors, sweeteners, and miscellaneous technological additives were adopted in the mid-1990s, there have been relatively few additions to the lists.

Labeling of Food Additives

The legal requirements for the labeling of food additives can vary from country to country.

The Codex standard on the Labeling of Prepackaged Foods lays down guidelines for the labeling of additives. These guidelines are closely followed in the EU directive on Food Labeling (2000/13/EC). Codex requires that for food additives falling into the respective classes (Table 1), the class titles given in the table should be used together with the specific or recognized name or a recognized numerical identification of the additive. The EU already has a recognized numerical classification of food additives commonly described as the 'E number' system. Thus, in the EU sulfur dioxide can be labeled as either: preservative: sulfur dioxide or preservative: E220.

Codex also requires that a food additive that is carried over into a food in a significant quantity or in an amount sufficient to perform a technological function in a food as a result of the use of raw materials or ingredients containing the additive shall also be included in the list of ingredients on the label. This means, for example, that if a significant ingredient in a food product contains an antioxidant or preservative, which is in sufficient quantity in the final product to continue to play its additive role, it must be added to the ingredients list. Excluded from this requirement are processing aids that do not have a technological function in the final product.

In the USA there are a number of specific rules for the labeling of additives. Substances that perform a functional purpose (i.e., technological additives) may be declared in the ingredients list using a collective or generic term followed by the function in parentheses. Alternatively, the function can be listed followed by the substance(s) performing that function, e.g., soy lecithin (emulsifier) or emulsifier (soy lecithin).

When a chemical preservative or antioxidant is used, American law requires both the common or usual name of the preservative and the function, using terms such as 'preservative,' 'to retard spoilage,' or 'to preserve (or retain) freshness.'

There is also a specific requirement in the USA for the listing of colors. Food and Drug Administration (FDA)-certified colors and their lakes must be listed specifically by their complete or abbreviated name for all food products except butter, cheese, and icecream.

Mixtures of colorings may be listed as 'artificial color' followed by a sublisting of the certified colors in parentheses, e.g., artificial color (FD and C yellow FD and C red 40).

Other additives used for coloring (termed noncertified), such as caramel, may be listed by their specific, usual or common name, e.g., caramel coloring or colored with caramel.

The differences in approach between the USA and EU can lead to complications with transatlantic trade in food products.

For countries other than the USA and those in the EU, there are a number of instances where there are requirements for the labeling of additives which are specific to that country. For many countries, however, the general principles of the Codex standard on labeling apply.

The Future

The complexities of international control on food additives together with the high costs of the toxicological

studies have been instrumental in reducing the number of food additives coming on to the market.

The rate of food additive developments appears to have peaked in the mid-1970s and by the early 1980s there were consumer reactions and food scares related to additives, particularly intolerances to the azo food colors, preservatives, and antioxidants.

Future developments will, in general, be focusing on improvements to the efficiency or functionality of additives and on reducing the overall intake of those found to have relatively low ADIs.

It is likely to be some years before there is truly international harmonization on the additives that are permitted and their maximum levels of use in foods.

Contaminants and Adulterants

C M Stansfield, Leatherhead Food International, Leatherhead, Surrey, UK

Introduction

Despite the fact that we now have a more tightly controlled, and therefore safer, food supply than ever before, there is a noticeable increase in consumer awareness and interest in food quality and safety, and one cannot exclude from this context adulterants, contaminants, and residues. This article outlines the way in which such areas of major public concern are regulated and controlled, including pesticide and heavy metal residues, microbiological contamination, foreign substances, and others.

General Overview

In addition to specific legislative acts on food safety issues, all modern food law embodies the fundamental concept that food should be of the nature, quality, and substance demanded by the consumer. This implies that, even where a country lacks specific legislation on a particular area, it is able to take action against adulteration or contamination of food.

To achieve the objective of protecting the consumer, each country has its own way of regulating the occurrence of contaminants and adulterants in foodstuffs. Some countries control food contamination at commodity level, i.e., levels for heavy metals and microbiological criteria or other contaminants are laid down in food standards of composition. In contrast, other countries insure that food quality and safety are achieved throughout the food process, as opposed to being concerned with the examination and control of the final product only.

In recent years, new technological developments, consumer awareness, and demand for a healtheir diet have resulted in an increase in the amount of new legislation, either already in force or in circulation as proposals, and much of this is related to food safety. In addition to these factors, the increase in new legislation in Europe is mainly a result of the need to harmonize the area of food safety at European Union (EU) level.

Food Adulteration

In Europe, an adulterant is a substance added to food in order to defraud the consumer, whereas in the USA, food containing any substance that is not supposed to be in the food is said to be adulterated. Deliberate adulterants are frequently inferior, cheaper ingredients that are used for economic advantage, e.g., water in milk, and are not dangerous, but constitute fraud.

The addition of mineral oil to cooking oil in Spain in 1979 was a dangerous adulterant that caused injury to some hundreds of people, and this incident incited the EU to set up a rapid alert system between the control authorities of member states. The task of such alert systems is to insure that affected food is identified and removed from the market and to return the trading system to normal as soon as possible. Some countries have powers to seize and destroy adulterated food but others operate by warning the trade and the public. Since lack of immediate action by the trade could not only lay them open to prosecution but also lead them to disrepute, it is extremely unusual for them not to cooperate with the authorities.

The presence of foreign bodies such as stone, glass, metal, rubber, wood, human hair, and parts of

clothing usually arise from lack of care, and are dealt with under general legal provisions on food. Unfortunately, there have been cases of deliberate addition of foreign bodies to food, usually by tampering with food on display, with intent to inflict economic damage, either for personal gain or as a threat against the manufacturer or trade, and such action is dealt with under criminal law. Food alert systems have again proved their worth in limiting risk and economic damage.

Contaminants

Contaminants are defined by the World Health Organization/Food and Agriculture Organization (WHO/FAO) Codex Alimentarius as follows:

> 'Contaminant' means any substance not intentionally added to food, which is present in such food as a result of the production (including operations carried out in crop husbandry, animal husbandry and veterinary medicine), manufacture, processing, preparation, treatment, packing, packaging, transport or holding of such food or as a result of environmental contamination. The term does not include insect fragments, rodent hairs and other extraneous matter.

It is interesting to note that the consumer would certainly regard the first two exclusions as contaminants. Legislation on contaminants has been developed in response to specific concerns and is therefore largely incoherent and in many cases outdated. Substances that accumulate in the environment, polluting air, farmland, and sea, eventually become present in foodstuffs. Specifying levels for the intake of environmental contaminants in foods must create a balance between encouraging the reduction of their presence through good manufacturing practices and consideration of conditions beyond the control of the producer that may determine the achievable level; for example, aflatoxin levels in cereal-based foods reflect climatic conditions during maturation and storage. However, within the EU, harmonization of certain areas is a continuing process. The Codex definition of contaminant has been adopted by the EU in an overriding framework regulation, Council Regulation (EEC) no. 315/93, which lays down a general prohibition on the marketing of foods containing contaminants in unacceptable amounts. In this way, levels are controlled through good manufacturing practice; however, there is also provision for the establishment of maximum tolerances, analytical methods and detection limits and references to sampling. There are separate committees that consider industrial contaminants, such as heavy metals and dioxins, and agricultural contaminants, such as nitrates, mycotoxins, and inherent plant toxins. This has resulted in the setting of maximum levels for certain contaminants in foodstuffs. However, existing limits on contaminants in each member state apply where no level is laid down by the EU.

Heavy Metals

Heavy metals represent an important group of inorganic contaminants that may be present in food products as a result of (1) their natural occurrence in food products in the raw materials used; (2) contamination of raw materials; or (3) undesirable transfer during the processes of manufacturing and packaging. The heavy metals most commonly covered by restrictive legislation are arsenic, copper, lead, mercury, zinc, and tin.

Regulations on heavy metals are frequently product-specific in nature, owing to susceptibility of certain foodstuffs to contamination by particular metals. For example, maximum levels for mercury in fish and fish products are often laid down because these products have been identified as principal sources of this element in the human diet. Levels of 0.5 p.p.m., or 1 p.p.m., depending on fish species, have been established by Codex Alimentarius and the EU. Similarly, levels of tin are of primary concern in canned foods, for obvious reasons. Tolerances for tin in canned foods normally fall in the range of 100–250 mg kg^{-1} (Table 1).

Most commonly, legislation on heavy metals is covered by regulations specifying maximum tolerances for named metals in a range of foodstuffs when the presence of a substance reaches a level known to present significant risk; this is the case for Canada, the UK, Australia, and South Africa. In some cases, a general tolerance is also laid down for foodstuffs not specifically listed, as in the UK, and Poland.

The limits for mercury in fish, and for lead and cadmium in a range of food categories, are the only heavy-metal limits set, at present, by the EU.

Some member states have approaches that differ from the one outlined above. Certain countries, including Spain, Austria, and Greece, lay down provisions in individual standards of composition, as does Israel.

Recommendations of the Codex Alimentarius Commission are often considered in the formulation of legislation on heavy metals but, as Table 2

Table 1 Permitted levels of tin (p.p.m.) in canned solid foods

demonstrates for wine, there may still be variations in levels set worldwide.

The situation for lead in wine has been rectified partly by action by the EU and the US Food and Drug Administration (FDA), which have banned the use of lead capsules on wine bottles, the major source of lead in wine. Amongst efforts to reduce their presence in other foods has been a prohibition on or general phasing out of the use of lead solder in food cans.

Heavy metals may also be indigenous in food, and their presence in water can derive partly from the rocks of the aquifer. In this case they are referred to as undesirable substances and are regulated, in the EU, the USA, and elsewhere, by legal provisions on the quality of drinking water and bottled mineral water, for which a Codex standard also exists.

Polychlorinated Biphenyls and Dioxin

Various inert organic compounds with industrial applications may pose a threat to food safety. Polychlorinated biphenyls (PCBs) are examples of such compounds; their presence is now widespread and uncontrolled in the environment. These have a tendency to accumulate in animal feeds, particularly those of animal and marine origin, and are subsequently introduced into food.

At EU level, there are no limits at present for PCBs in foods and, in general, the regulations of most countries do not make specific provisions for the control of PCBs in foodstuffs. However, certain countries (e.g., Germany and the USA) have set maximum tolerances for PCBs in a range of foodstuffs. In some other countries, The Netherlands and France included, maximum tolerances are laid down for fish and fish products, which are particularly susceptible to PCB contamination (Table 3). Concern over PCB contamination led the UK and the USA to discontinue their manufacture in 1977. In some countries, the use of PCBs in industrial applications is restricted where they may constitute a threat to food safety. For example, in Denmark, the use of PCBs in heating installations for foodstuffs is prohibited.

Dioxin, a contaminant from chemical manufacture, has caused concern in recent years, as it can accumulate in the fatty tissue of animals and humans. In 1999 contamination from dioxin resulted in widespread infection of poultry and eggs in various European countries. This was believed to have originated from an oils- and fats-processing company in Belgium, which supplied feed manufacturers. Protective measures were established by the EU, and in the longer term they are evaluating the risk of dioxins and PCBs. 'It has emerged that more than 90% of human dioxin exposure derives from foodstuffs, with a large portion of this derived from foodstuffs of animal origin. Council Regulation (EC) No. 2375/2001 lays down maximum limits for dioxins in products from meat, milk, fish and oils and fats. Levels for the types of PCBs that exhibit toxicological properties to dioxins have not been set due to limited data available on their presence. The European Commission intends to review situation by the end of 2004.'

Nitrates

Concern over the harmful properties developed from the reduction of nitrate to nitrite has led the EU to set levels for nitrates in water, and for spinach and lettuce, depending on the season in which they are harvested. Currently, levels for fresh spinach range from 2500 to 3000 mg kg^{-1}, for processed spinach 2000 mg kg^{-1}, and a range of 2500–4500 mg kg^{-1} is set for lettuce. It has been estimated that, in many European countries, vegetables contribute most of the nitrate exposure, and some member states, such

as Austria and The Netherlands, have introduced upper limits for other types of vegetables. In Austria, guideline levels are laid down for a range of other vegetables, including carrots, cabbage, and parsley. Switzerland has levels for nitrates in cheese and infant foods as well as vegetables. Outside Europe, Argentina sets levels for nitrates in various milk products.

Radioactivity

Natural radioactivity occurs in all foods, arising from the radioactive isotopes carbon-14 and potassium-40. The specific activity of carbon-14 is relatively low; however, potassium-40 gives rise to specific activities of 40–50 Bq kg^{-1} in cows' milk, 400–500 Bq kg^{-1} in milk powder, 600–800 Bq kg^{-1} in concentrated fruit juice, and over 1000 Bq kg^{-1} in instant coffee. There is no legislation governing this radioactivity since it cannot be eliminated, and consumption of such foods does not significantly alter the potassium content, and hence the potassium radioactivity of the body.

Human exposure to radiation is laid down in law and national measures are usually based on recommendations of the International Committee for Radiological Protection (ICRP). Drinking water contributes a very small radiation dose to total population exposure and is largely due to naturally occurring radionuclides in the uranium and thorium decay series. WHO has established guideline levels for radioactivity in drinking water, based on ICRP recommendations and available data on risk exposure. Some countries lay down limits for radionuclides in bottled waters, for example in the USA, Sweden, Israel, and Switzerland.

Before the accident at Chernobyl nuclear power station in 1986, very few countries had radioactivity limits for food since the policy was, and still is, to control emission and waste at source, with local incidents being handled by monitoring of food and population. Contamination of food on a continental scale arising from Chernobyl required immediate action and resulted in the EU setting limits for radioactive contamination of imports from outside its member states. Since then, contamination levels have decreased to a negligible risk of health, and later rules exclude a number of products from the scope of the original regulation. There is a maximum tolerance of 370 Bq kg^{-1} for combined cesium-134 and cesium-137 in milk, milk products, and special infant foods, and a single level of 600 Bq kg^{-1} for other food products concerned. In 1999, the EU established procedures for carrying out checks on the radiocesium content of such foods. A number of countries followed the EU post-Chernobyl regulation. Infant foods, milk, and milk products, and animal foods are among the most widely regulated commodities in this regard. The EU has also established a regulation setting maximum permitted levels for radioactive contamination of foodstuffs, which could be applied in the event of a future nuclear accident or other radiological emergency potentially involving radionuclides other than cesium.

Mycotoxins

The concern over the carcinogenic hazard of mycotoxins has also increased in recent years. Mycotoxin contamination is most often related to the susceptibility of certain crops, especially grains and nuts, during storage, to the attack by toxin-producing fungi, in particular *Aspergillus flavus*, which produces a group of highly toxic metabolites called aflatoxins.

Specific mycotoxin legislation was developed in several countries as a result of the discovery of aflatoxin in the early 1960s; it was later extended to other mycotoxins, including patulin, ergot, ochratoxin A, and pomphsin. Currently, levels for some mycotoxins are regulated at EU level, namely aflatoxins B_1, B_2, G_1, G_2 in nuts, dried fruit, cereal products, and spices and a level of aflatoxin M_1 in milk, and limits for ochratoxin A in cereals and vine fruit. Limits for mycotoxins in infant foods and patulin in fruit juices have been proposed, and further categories for ochratoxin A are under review at EU level. Certain countries may control the presence of aflatoxins in other foods, as is the case in Germany, where limits are laid down for enzyme preparations, dietetic foods for babies and infants, milk, and other foodstuffs. Regulations on aflatoxins in non-EU countries, where they exist, usually determine levels for peanuts and peanut products and milk, or lay down a general level for all foodstuffs. Table 4 gives examples of maximum levels of aflatoxins in foodstuffs, especially nuts and nut products, in major countries worldwide.

Inherent Toxic Substances

If present in excessive amounts, certain inherent toxins pose a threat to human health. Whilst such toxins are not widely regulated, some countries have laid down product-specific tolerances in certain instances. For example, Finland has levels for solanidine glycosides in potatoes and for indole in crustaceans; however, in general, natural toxins can be controlled through regulations that establish species and strains that are for food use.

Levels for shellfish toxins have been established by a number of countries, including Japan and the USA, as well as in the EU. The adverse health implications associated with erucic acid content in some rapeseed

Table 4 Examples of maximum levels of aflatoxins in nuts and nut products, in major countries

Country	*Food*	*Aflatoxin*	*Maximum level ($\mu g\,kg^{-1}$)*
European Union member states	Groundnuts, nuts, and dried fruit and their processed products, intended for direct human consumption or as an ingredient in foodstuffs	$B_1 + B_2 + G_1 + G_2$	4[a]
		B_1	2[a]
	Groundnuts to be subjected to sorting, or other physical treatment, before human consumption or use as an ingredient in foodstuffs	$B_1 + B_2 + G_1 + G_2$	15[a]
		B_1	8[a]
	Nuts and dried fruit to be subjected to sorting, or other physical treatment, before human consumption or use as an ingredient in foodstuffs	$B_1 + B_2 + G_1 + G_2$	10[a]
		B_1	5[a]
USA	Peanut and peanut products, Brazil nuts and pistachio nuts, other foodstuffs (except milk)	Aflatoxins	20
Australia	Peanut and tree nuts and the nut proportion of products containing nuts	Aflatoxins	15
Japan	Peanut and peanut products, pistachio nut, almond, Brazil nut, cashew nut, hazel nut, macedemia nut, walnut, and giant corn	B_1	10
South Africa	Grains, nuts, and their products and all other foodstuffs	Aflatoxins	10 of which M_1 is maximum 5

[a]Maximum limits apply to the edible part of groundnuts, nuts, and dried fruits. If nuts 'in shell' are analyzed, it is assumed when calculating the aflatoxin content that all contamination is on the edible part.
Data from Legislation Unit (2000, updated March) *Contaminants in Foodstuffs – An International Review of Maximum Limits Part 2*. Leatherhead, UK: Leatherhead Food RA.

and mustard oils led the EU to set maximum levels for erucic acid in oils and fats intended for human consumption and for foodstuffs containing the same. EU regulations on flavorings include a list of maximum limits for certain potentially toxic substances, such as thujone and coumarin, which may be present in a foodstuff as a result of the use of flavorings. 3-monochloropropane-1, 2-diol is created during food processing under certain conditions. At EU level maximum levels have been set for its presence in hydrolyzed vegetable protein and soy sauce.

Microbiological Contamination

The contamination of foodstuffs by pathogenic and spoilage microorganisms has always been one of the major concerns of consumers and enforcement authorities, owing to the great risk that this poses to human health.

Countries may differ in the way in which they approach this problem; however, most governments have the single philosophy of seeking to insure protection of public health. This is usually achieved by provisions of food acts that exist in most countries to insure food safety and quality by making it an offence to sell food that is injurious to health and does not conform with the quality demanded by the purchaser. This means that in most countries it is an offence to sell foodstuffs contaminated with pathogenic organisms (*Salmonella, Staphylococcus aureus*, sulfite- reducing *Clostridium*, *Listeria monocytogenes*, and others) or spoilage microflora. Through the enforcement of food acts, powers may be given to the relevant authorities to impose emergency control measures in order to prevent the circulation and sale of contaminated food at any time should they consider that the public health is at risk. The UK Food Safety Act 1990 illustrates this clearly in that powers are given to ministers and other relevant authorities to act immediately upon cases that endanger the public health, e.g., to issue emergency orders, to close down food premises, etc.

In addition, microbiological criteria may be set which can be achieved throughout food processing by means of the application of good manufacturing practice. Microbiological criteria are generally expressed as three main categories:

1. Microbiological standards: these are applicable to the final product and have legal force; they are mandatory.
2. Microbiological guidelines: these are guides intended to help manufacturers to insure good hygiene practice; although guidelines are optional, it is strongly recommended that they are followed in the absence of microbiological standards.
3. Microbiological end-product specifications: these are generally contractual agreements between manufacturers and purchasers to check that the goods concerned are of the quality required.

Where a microbiological standard exists, sampling and analytical methods are required in order to monitor, in qualitative and quantitative terms, the criteria laid down.

Microbiological Criteria

The development and application of microbiological criteria for foods are carried out by international bodies and national authorities, including the WHO, the International Commission on Microbiological Specifications for Foodstuffs (ICMSF – a voluntary specific body, which provides basic information on the microbiology of foods based on extensive studies) and the EU.

Certain countries place more emphasis on the microbiological standard for the final product; in other words, microbiological criteria are laid down in food standards of composition. Examples include Spain, The Netherlands, Australia, Sweden, and Argentina, amongst others. In contrast, other countries follow a more systematic approach, where food quality and safety are achieved by the identification of hazard and assessment of risk throughout the processing, from the raw material stage to the final product. This is usually carried out by means of the Hazard Analysis Critical Control Point (HACCP) system or equivalent process, which is used in conjunction with good manufacturing process. The UK is an example of the latter trend, where there are very few specific microbiological standards; instead, the approach to food hygiene is that of prevention backed up by codes of practice and microbiological guidelines. In the USA, HACCP is mandatory in meat plants, seafood and juices used for beverages. Good manufacturing process regulations are laid down for foodstuffs in general, dietary supplements, low-acid canned foods, and acidified foods, and there are pathogen-reduction performance standards for *Salmonella* in slaughter plants and raw ground products.

The EU general hygiene directive was established in 1993 with the aim of insuring confidence in the standard of safety of all foods in circulation, particularly in respect of hygiene, through all stages from production to sale to the final consumer. While this does not establish criteria, the principles of HACCP are required and the directive makes provisions for future criteria concerning microbiological criteria and temperature control, requirements for food business operators to insure appropriate training for food handlers, and general hygiene requirements for premises. EU microbiological criteria are laid down for mineral water, milk and milk products, mincemeat, and meat preparations. The European Commission is revising its food hygiene rules to streamline and harmonize existing requirements. The new rules would apply to all food and all food operators throughout the food chain, and requires HACCP systems to be implemented by all food business operators.

Residues

Residues of pesticides and veterinary pharmaceuticals in food are not legally regarded as contaminants but are permitted to safe levels defined at the time that each product is authorized.

Pesticides

The use of pesticides in agriculture has contributed to the worldwide increase in food production. As well as improving the efficiency or productivity of agricultural practices, their use has also raised concern over their side-effects on animal and human health.

In most countries the use of pesticides is strictly controlled by regulatory bodies, whose responsibility is to insure that their use is safe and that any residues present in foodstuffs do not constitute any risk to public health. The WHO/FAO Joint Meeting on Pesticides Residues (JMPR) plays a major role at international level in assessing the safety of pesticides and by setting standards, and its recommendations and rules are taken into account by most countries.

Legislation on pesticides at EU level is extensive and the increasing tendency to use pesticides on certain crops, and the continuous formulation and commercialization of new substances for pesticide use, have resulted in a frequent revision of their safety and a subsequent need to review the legal provisions. Existing directives set mandatory maximum limits for pesticide residues in and on fruits and vegetables, cereals, and foods of animal origin, dried processed and composite products, infant formulae, and baby foods. Another directive prohibits the placing on the market and use of plant protection products containing certain active substances, including ethylene oxide. Methods of analysis for the detection and monitoring of fixed maximum limits are required to be established by these directives.

In comparison with the EU, non-EU countries may have a similar approach to the way in which they control residues of pesticides in foodstuffs, in that their legislation is based on lists laying down maximum levels for certain pesticide residues in and on specific food commodities. For example, in the USA, tolerances are set for a wide range of foods, processed foods, and animal feeds. Changes in the overall framework of their regulation mean that all pesticide tolerances must be reevaluated by 2007, establishing safe tolerance levels for groups of pesticides with similar mechanisms.

The overall trend observed in legislation on pesticides is that they are drawn up on a very restrictive basis; only those pesticides in the lists may be used and maximum levels should not exceed those laid down, unless special authorization is granted.

Veterinary Medicines

'Veterinary medicines' is a generic term embracing all substances that have an effect on the functioning of the organisms of the animal, whether administered by injection or through animal feed. Concerns over human health relate to possible immunological effects of repeated exposures to antibiotic residues, the possible development of antibiotic-resistant strains of pathogens, and the possible adverse effect of animal hormones on humans. The trend observed across major countries worldwide is for the prohibition or restriction of residues of veterinary medicines in foodstuffs. This may be made under the power of food acts, general health regulations, or under specific food commodity standards. For example, the EU, USA, Canada, and South Africa have regulations setting maximum residue levels of antibiotics for a wide range of foodstuffs of animal origin.

In addition to the indirect presence of antibiotic residues in foodstuffs, certain substances having an antibiotic effect may be intentionally added to foods as preservatives. Examples of the most widely regulated and used are natamycin and nisin, which are permitted in processed cheese in a great number of countries worldwide.

The concern over use of growth promoters in the treatment of animals intended for human consumption results from possible carcinogenic and teratogenic effects. There is a great deal of legislation in the EU in this regard, including directives on the following:

1. The trade in animals treated with certain substances having hormonal action and their meat.
2. Methods to detect residues of substances having a hormonal and thyrostatic action.
3. Prohibiting the use in livestock farming of certain substances having a hormonal action.

The legislation of non-EU countries also tends to concentrate on the control of the use of hormones in animal feed and meat for human consumption.

Codex

P Berry Ottaway, Berry Ottaway & Associates Ltd, Hereford, UK

Introduction

From the mid-1960s, the Codex Alimentarius (Codex) has grown in importance as the forum for the development of international standards and codes of practice for food commodities and products. Codex now has an enhanced role in the international trade in food as it is the preferred organization for the arbitration of disputes under the World Trade Organization (WTO) agreements.

Background

The Codex Alimentarius Commission was inaugurated in 1963 as a subsidiary body of the World Health Organization (WHO) and the Food and Agriculture Organization of the United Nations (FAO). The name Codex Alimentarius was derived from the Latin and can be translated as 'food code.' In the early 1960s, when the Commission was established, there was already a perceived need to facilitate world trade in food and food commodities and it was believed that this could be helped by the development of internationally accepted standards.

Although most of the developed countries had detailed food legislation, sometimes for centuries, there was a diversity of approach to food control. Barriers to international trade in foods were developing at a time when improvements in food preservation techniques and transport meant that international trade in food was no longer being limited by either the perishability of the food or the means to transport it safely.

The Codex Alimentarius, or Codex system, as it is now more commonly known, was set up to facilitate trade by establishing internationally acceptable standards and codes of practice for the production and handling of food. The objectives were to provide added protection for consumer health and to promote fair practices in the food trade. To accomplish these objectives, Codex has to try and harmonize the best features of ideas and concepts devised by its various national members.

Membership of the Codex Alimentarius Commission

All member nations and associate members of the FAO and WHO can become members of Codex. The membership has increased over the years and 165 countries were Codex members in 2000, representing 97% of the world's population. The activities are funded by the regular budgets of both the FAO and WHO. There are no other financial obligations on members except that an important contribution, mainly in terms of services, is made by those member states who act as host countries for the meetings of the Codex Committees. As there is no requirement for a financial contribution from the individual members, it means that the poorer nations can participate in Codex activities on equal terms with the wealthier ones.

Codex and the World Trade Organization

The beginning of 1995 marked the start of a new era in world trade with the establishment of the WTO. The aims of WTO are 'to provide the common institutional framework for the conduct of trade relations among its members in matters related to the agreements and associated legal instruments.' The actual functions of the WTO are to facilitate the implementation and operation of the Multilateral Trade Agreements; to provide a forum for trade negotiations concerning multilateral trade; to administer trade disputes; to monitor national trade policies; and to cooperate with the International Monetary Fund and the World Bank.

The Codex Alimentarius has gained a greater significance since the formation of the WTO. The Agreement on the Technical Barriers to Trade (TBT) that was introduced following the Tokyo Round on World Trade in 1979 had a substantial impact on the establishment of policies on food control. The TBT agreement does not specifically mention Codex but dealt with aspects of food not directly related to safety such as labeling, quality, and packaging and thus impinged on Codex. The WTO, however, has recognized Codex as the preferred international organization for the arbitration and settlement of disputes related to food trade.

The Codex Alimentarius

The Codex Alimentarius used to consist of 25 volumes, of which 17 consisted of the agreed Codex standards and the remainder of the recommended codes of practice and guidelines. In the 1990s these were revised into 13 volumes (Table 1). The published volumes of the Codex are available in English, French, and Spanish. Individual standards

Table 1 Structure of the Codex Alimentarius

Volume	*Subject matter*
1A	General requirements
1B	General requirements – food hygiene
2A	Pesticide residues in foods (general texts)
2B	Pesticide residues in foods (maximum residue limits)
3	Residues of veterinary drugs in foods
4	Foods for special dietary uses (including foods for infants and children)
5A	Processed and quick-frozen fruits and vegetables
5B	Fresh fruits and vegetables
6	Fruit juices
7	Cereals, pulses (legumes), and derived products and vegetable proteins
8	Fats and oils and related products
9	Fish and fishery products
10	Meat and meat products; soups and broths
11	Sugars, cocoa products, and chocolate and miscellaneous products
12	Milk and milk products
13	Methods of analysis and sampling

are being made available on the worldwide web and CD-ROM.

Codex Standards

The purpose of a Codex standard is to set out the required qualities of a food or commodity as sold. The standard has to be set out in objective terms and the required features should be able to be verified. Where necessary, procedures for the verification of a given parameter are included. When a standard has been adopted, the Codex Alimentarius Commission will recommend it to the governments of its member states and invite them to accept the standard and embody it in their national law. The governments are also asked for their reactions to the standard and all their responses are collated and published as part of the Codex Alimentarius.

Codex standards are by nature quantitative in that they have to give limits for most of the parameters such as the minimum required or the maximum allowed and, in some cases, both. If such limits are to have any validity, it must be possible to check the product's compliance by agreed measurements or analysis. A test must be capable of being carried out to similar degrees of accuracy by different laboratories across the world. In the development of testing methods there are always a number of issues surrounding the validity of tests, including the sampling procedures and the problem that food products are not always sufficiently homogenous. These problems have to be considered and resolved by the Codex Committee on Methods of Analysis and Sampling (CCMAS).

The CCMAS has established methods that may be used as agreed procedures by producers, processors, quality examiners, enforcement agencies, and trades worldwide. In summary, these methods:

- define what is being measured and the units in which the answers are to be expressed;
- describe in detail and with precision how measurements are to be made;
- specify how the results should be interpreted (i.e., to determine whether or not the sample complies with the requirement of the standard).

The methods are normally devised from those developed in various countries and they have to be validated to international satisfaction through practical evaluation in a number of different laboratories. It is important that all methods become internationally accepted procedures and there is the advantage that, by developing them through the Codex system, the high cost of development can be shared by a number of countries. This also has a direct benefit for the smaller member countries with limited resources.

Once a standard together with its methods of analysis and sampling has been agreed, the next step in the Codex system is to get the standard accepted by the governments of the member countries. There are various levels of acceptance and each type, together with its attendant obligations, is detailed in the Codex Procedural Manual.

The acceptances fall into three sets of conditions: full acceptance; acceptance with specified deviations; and free distribution. Under the conditions of full acceptance, the products to which the Codex standard and criteria apply, both home-produced and imported, should comply with all relevant requirements. A country may also accept the standard with specified deviation. In such cases statements giving the reasons for the deviations from the standard or required limits are necessary. A country may also determine that a product conforming to the standard and defined limits may be allowed unrestricted distribution.

The conditions of acceptance are slightly different for certain types of standards. There are differences between those for general standards such as nutrition labeling and those for specific commodity standards. For some, such as the Codex Maximum Limits for Residues of Pesticides and Veterinary Drugs in Food, acceptance with specified deviations is not allowed.

Governments are formally requested to indicate which form of acceptance they are adopting and their responses form part of the Codex Alimentarius. This section is regularly updated and permits those involved in international trade to determine the current state of the various national regulations for those foods that are covered by Codex standards.

As the current voluntary adoption procedure with its options does not appear compatible with the WTO system, and as the Codex Alimentarius is the officially recognized reference for international standards in terms of food safety, changes to the acceptance procedure are being discussed.

Codex Codes of Practice and Guidelines

Whilst the development and use of Codex standards effectively produces product specifications, it is also important that issues such as hygiene and good manufacturing practice (GMP) are also addressed, preferably in the context of the Codex Alimentarius. A series of Codex codes of practice and guidelines have been compiled from the collective knowledge and experience of members and observers. Such compilations include the general principles of food hygiene and recommended international codes of practice for a wide range of foods, including fishery products, low-acid canned foods, egg products, frozen fruits and vegetables, and dried milk.

The objectives of the codes of practice and guidelines are fourfold. They provide checklists on GMP for the established processors and also guidance for new or expanding processors in the setting-up of production operations in terms of premises, equipment, manufacturing methods, and control.

The codes and guidelines also assist the food control and monitoring agencies by providing guidance on internationally recommended methods and provide the food industry with grounds for supporting recommended practices and for rebuttal of criticism. As they are codes or guidelines, as opposed to clearly defined standards, they can allow for adjustment to meet particular local circumstances but still provide the essential requirements to support GMP.

Before a code of practice and guideline can be adopted within Codex, representatives of the member governments must give their assent. This level of national recognition should encourage the authorities within the countries to develop their criteria in an internationally accepted rather than an arbitrary manner.

The Codex Organizations

The development of Codex standards, codes of practice, and guidelines are coordinated by the Codex Alimentarius Commission and its Executive Committee. The Commission is also supported by the Secretariat of the Joint FAO/WHO Food Standards Programme in Rome, Italy.

The detailed work on Codex is divided between a number of committees. The committees have been set up so that some focus on 'horizontal' issues such as food labeling, whilst others are concerned with 'vertical' issues such as specific requirements for foods for special dietary uses. During the development of a standard it will be considered by both types of committee as necessary.

In addition, there are five regional coordinating committees covering Africa, Asia, Europe, Latin America and the Caribbean, and North America and South-West Pacific. The Commission and its committees can receive advice from FAO and WHO Expert Committees such as the Joint FAO/WHO Expert Committee on Food Additives.

There are also three other intergovernmental bodies dealing with specific groups of commodities which report to the Codex Alimentarius Commission. These are a Joint FAO and WHO Committee of Government Experts on the Code of Principles Concerning Milk and Milk Products, a Joint United Nations Economic Commission for Europe (UNECE)/Codex Group of Experts on Fruit Juices, and a Joint UNECE/Codex Group of Experts on Quick Frozen Foods.

The Codex committees are grouped as either specific or general subject committees, of which there are currently nine dealing with horizontal subjects such as food additives, labeling and pesticide residues. The other committees are responsible for specific groups of commodities such as fats and oils or vegetable proteins. There have been 15 Codex Commodity Committees, some of which have been adjourned, leaving seven active in 2002 (**Figure 1**).

As part of Codex policy, each committee has a host country. The governments of the host countries are responsible for hosting the meetings of their allocated committee and for providing the administrative infrastructure for the meetings. As the host country also takes financial responsibility for the meetings held in its territory, the current host countries are mostly in North America or western Europe. New Zealand hosted the Meat Hygiene Committee from 1972 until its adjournment in 1983 and Hungary took over the Methods of Analysis and Sampling Committee from Germany in 1972, and the Committee on Tropical Fresh Fruits and Vegetables, which was formed in 1988, is hosted by Mexico.

Due to rapid developments in biotechnology, and particularly genetic engineering, Codex has formed a task force on biotechnology. This task force held its first meeting in March 2000 during which it agreed to develop principles for the risk analysis of foods obtained through modern biotechnology and to develop guidelines for the safety assessment of foods obtained by such processes.

Development of Codex Standards

The present procedures for the development and adoption of Codex standards have evolved from a number of years of practical experience. The basis on which the mechanism relies is the requirement for objectivity at all stages of the development of a standard. The procedure must also be sufficiently robust to accommodate a dichotomy of views and approaches and to bring them together to an agreed standard. Due to the often very large attendance, the committee meetings have to be structured to allow the business to be conducted efficiently. The procedure has been broken down into eight discrete steps:

Step 1

A decision is taken by the Commission to elaborate a standard on a particular subject. The requirement may be either horizontal (e.g., requirements for the nutrition labeling of foods), or vertical (e.g., requirements for the composition of a specific category of food products). After the decision is made by the Commission, the work is assigned to the appropriate

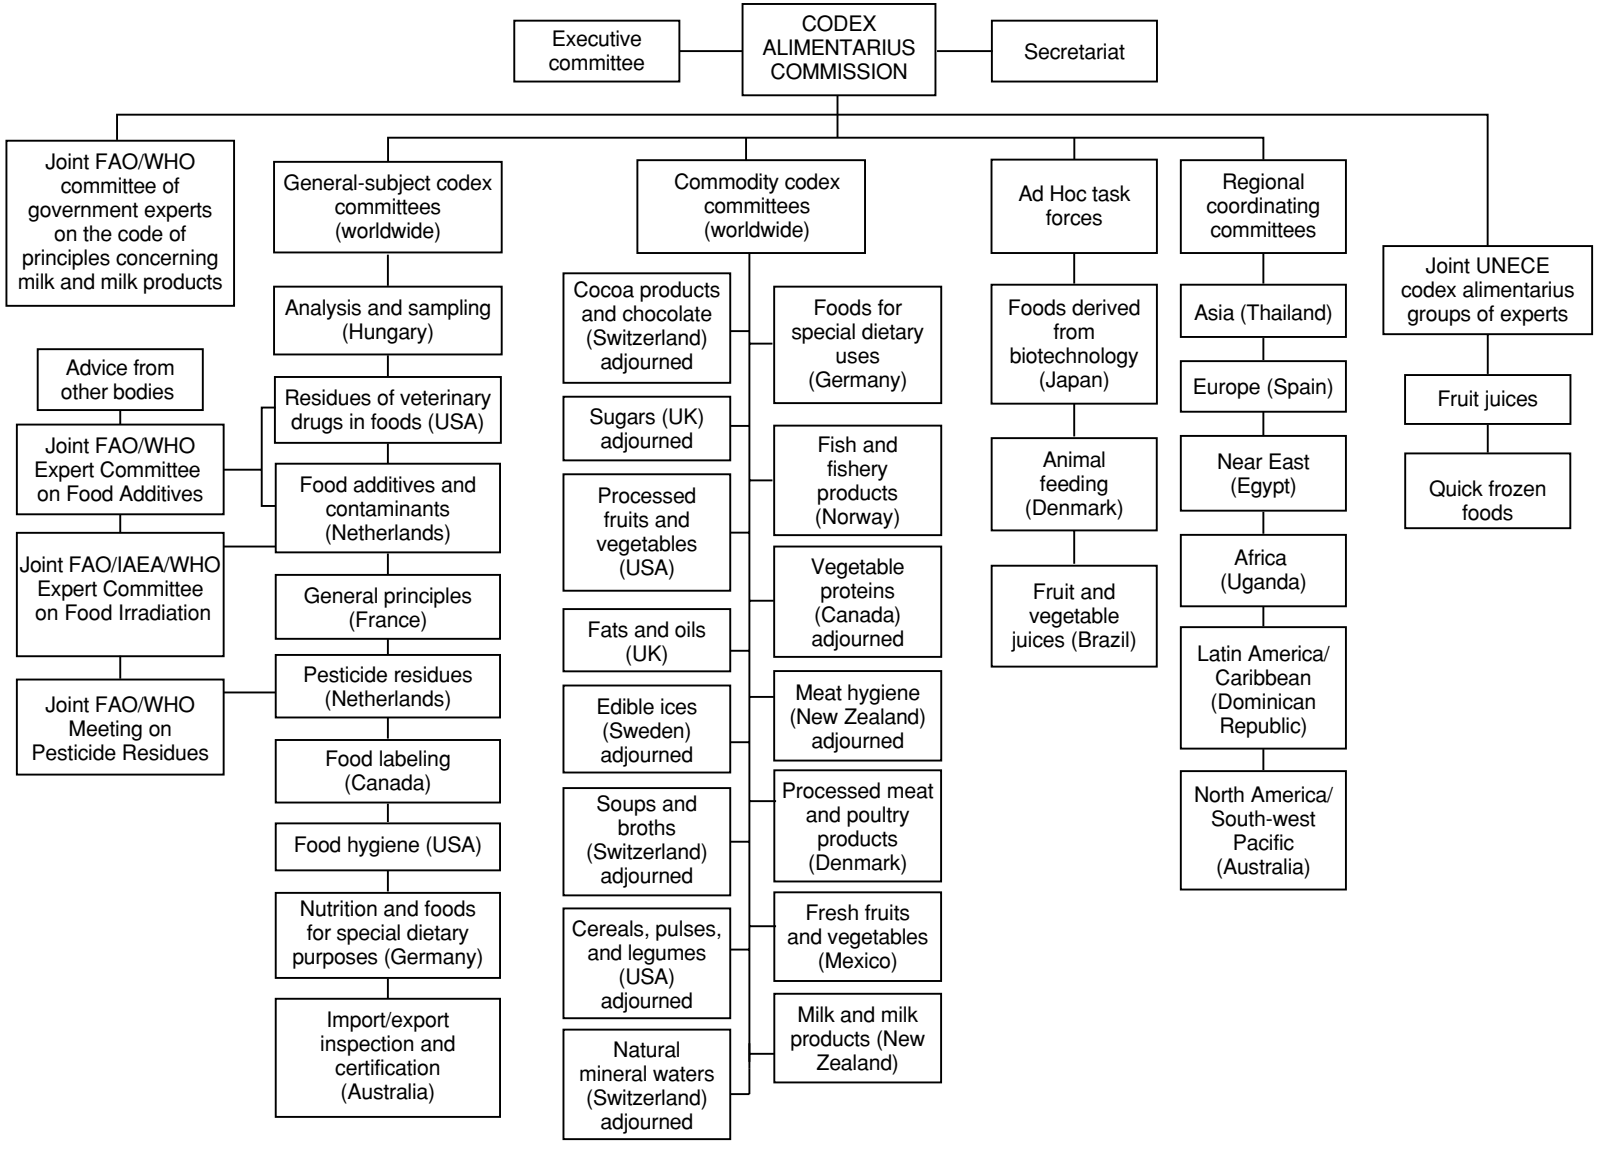

Figure 1 Organization of the Codex Alimentarius Commission. FAO, Food and Agriculture Organization; WHO, World Health Organization; IAEA, International Atomic Energy Agency; UNECE, United Nations Economic Commission for Europe.

committee. In some circumstances the decision may also be taken by the committee and endorsed by the Commission.

Step 2

The Secretariat arranges for a proposed draft standard to be drawn up. This will include consultation with the Committee and the relevant experts and interests in the particular field.

Step 3

The proposed draft standard is sent to all the member governments and international organizations for comments.

Step 4

The Secretariat collates the comments and forwards then to the Committee.

Step 5

Once agreed, the proposed draft standard is sent through the Secretariat to the Commission for adoption as a draft standard. The Commission adopts the proposal as a draft standard on the basis of a majority of the votes cast.

Step 6

The adopted draft standard is sent to the governments and international organizations for comment.

Step 7

The Secretariat collates and forwards the comments to the Committee.

Step 8

When finally agreed, the draft standard is returned to the Commission for adoption as a Codex standard, which is then sent to the governments for their acceptance.

When a proposal is adopted by the Commission as a draft standard (step 5), in certain circumstances the Commission may, on the basis of a two-thirds majority of the votes cast, decide on a simplified procedure which takes the draft directly to Step 8. A decision to go to the simplified procedure can be taken in the case of urgent problems related to trade or public health; the revision or updating of existing Codex standards; or in the case of matters concerning new scientific information or technology.

The proposed draft standard and draft standards are considered in detail at the biannual committee meetings to which the member governments are encouraged to send delegates. The meetings are run in a democratic way and the national delegates have an equal say regardless of the size of their country. Unlike the European Union, where the development of legislation is governed by a weighted voting system whereby the larger countries have more votes than the smaller members of the Community, consensus in Codex committees is reached with all member countries having an equal say.

For each Codex or Commission meeting the agenda is effectively set by the status of the draft standard following the previous meeting. In preparation for each meeting the Secretariat will send out, some months in advance, circular letters to the governments and interested organizations with notification of the specific items in the draft which require an opinion or comment. Those replies which are received in time are made available before the meeting so that all members can assess the range and nature of the opinions.

At the meetings verbal argument can supplement or discuss the written opinions and it is not unusual for divergent views to be presented during the first stages of the development of a standard. These are often due to serious differences of interest. A section dealing with consumer interest in one country may have a social or economic impact upon another. A good example of this would be where a proposal put forward by an importing country for unrealistically low levels of pesticides in a food could lead to serious economic problems for a producing country. The advantage of the meetings is that it provides a forum in which the various views can be aired and where views on both the risks and benefits of proposals can be discussed and objective solutions agreed.

Before each meeting adjourns, a draft report on the meeting and its conclusions is discussed, amended, and adopted. The agreed report is then circulated.

The procedure for the development of a Codex standard normally takes between 7 and 10 years to accomplish. Although a few Codex committees meet annually, the Commission and most of the committees only meet biannually. This has the limitation in that the time scale can make it difficult for the Codex to keep pace with a rapidly changing scientific and political environment. As a consequence, additional working groups may have to be convened to consider urgent matters reflecting a changing environment, such as international concerns over the trade in genetically modified foods.

Codex and Food Safety

There are a number of areas of consumer protection and health where Codex has already played a significant role. One of these areas is food safety. Food

safety is multifaceted and each aspect may need a particular approach.

For example, poor food hygiene is a major cause of human illness worldwide and exceeds by manyfold the effects on the consumer from other aspects of food safety. Most food hygiene problems are due to faulty handling of the food, often through ignorance. Whilst establishing good hygiene practices is relatively easy in principle, the realities of life are that it is far more difficult to maintain the standards.

Codex has, therefore, developed a number of international codes of hygiene and/or technological practice. These cover the requirements for premises, equipment, and handling procedures. In addition to the general principles of food hygiene, Codex has specific codes relating to commodity groups such as fish and fishery products, egg products, meat and poultry products, and dried milk. These Codes are complemented by the Codex General Principles for the Establishment of Microbiological Criteria in Food. These principles have been developed with their practical application in mind and include clear advice on how microbiological testing can be used to check ingredients and processes and to determine the necessary actions or changes before problems develop. It is also indicated that the testing can be adapted so assurance can be obtained that the provisions in the codes have been observed. This latter aspect has relevance to imported foods. In addition, the principles are laid down by which to determine those instances or foods where the presence of specific microorganisms in excessive numbers means that the food should not reach the consumer. These specific provisions were developed as it was recognized that in the absence of such guidelines it was possible that the control authorities in some countries might place excessive importance on numerical data for some microorganisms, which might lead to needless rejection of a food without any increase in consumer protection.

Other areas of food safety where Codex is directly involved are contaminants and additives. The term contaminants is used in this context to denote the presence in food of small quantities of undesirable substances such as dioxins or polychlorinated biphenyls (PCBs), and the elements that can cause health hazards such as lead, mercury, and cadmium. The Codex Committee on Food Additives has the responsibility of setting achievable limits for these contaminants.

Although the use of agricultural chemicals such as pesticides has become essential to modern agricultural and horticultural practices, their residues in food have consistently given rise to concerns. Lists of pesticides which should be authorized for use have been drawn up by the Codex Committee on Pesticide Residues. These lists have been developed from the work of the Committee of Experts of the FAO/WHO Joint Meeting on Pesticide Residues. As a result of this work, over 2000 maximum residue limits have been defined based on advice from the Expert Committee on Toxicity and also the procedures of good agricultural practice. In a similar way, committees are considering the complex problems of veterinary drug and hormone residues in foods.

Food additives play an important part in the quality and safety of much of the processed food. The Codex Committee on Food Additives (CCFA) has responsibility of implementing the reports of the Joint Expert Committee on Food Additives (JECFA). JECFA is a group of independent and internationally recognized experts which is appointed jointly by WHO and FAO to review and report on the safety of additives.

The CCFA has, as a primary task, to consider the technological need for an additive on the one hand and the JEFCA safety evaluation on the other. To accomplish this, it has to elicit from the Codex Commodity committees both the degree of usage of the additive and its importance to the various sectors of the industry. It is the responsibility of both the CCFA and JECFA to treat all additives on an equal and objective basis and to give equal consideration to those of both natural and synthetic origin.

In dealing with additives it is important for the governments, enforcement agencies, and the public that any of the additives listed as permitted in foods have been considered by a group of independent and respected experts who have provided an impartial consensus opinion that can be accepted with confidence. One of the strengths of Codex is that it provides the structure by which this can be accomplished.

The Future of Codex

The recognition by the WTO and the greater involvement of the developing countries are contributing to the strength of Codex. The Codex Commission is aware of the need to keep pace with changing food quality and safety concepts and developments such as the application of genetic engineering to the food supply. The strength of Codex has been and will continue to be its truly international base.

LEGUMES

Contents

Legumes in the Diet

M A Uebersax and L G Occeña, Michigan State University, East Lansing, MI, USA

Introduction

Legumes are a vital food resource which contribute to the nutritional well-being of diverse human diets. They provide essential nutrients and high levels of protein with moderate levels of energy and dietary fiber. This article discusses the structural features, chemical composition, handling, storage, processing, and utilization of legumes.

General Features

The term legume is derived from a Latin word *legumen*, meaning seeds harvested in pods. Alternative terms for the edible seeds include grain legumes and pulse, from the Latin *puls*, meaning pottage. Food legumes refer to those species of the plant family Leguminosae (pea or bean family) that are consumed directly as mature dry seeds, as immature green seeds, or even as green pods with the immature seeds enclosed. The plants vary in size from tiny wild vetches to large trees. Most of the important legumes in the human diet are mainly herbaceous, often annuals, and grow throughout the world. **Table 1** lists some of the more important food legumes with their scientific and common names. Two categories of grain legumes are: (1) oilseeds such as soy beans and groundnuts, grown for their protein and oil content; and (2) pulses, or grain legumes, including common beans and peas, which are grown principally as a protein source and used either as boiled whole grain in different preparations or as split seeds.

Only about 20 out of approximately 13 000 species of legumes are commonly consumed, with most of the consumption occurring in Central and South America, Africa, and Asia. World consumption (percentage of total) of common beans has been characterized by regions as follows: Latin America 46.6%; Africa 24.3%; western Europe 6.3%; eastern Europe 7.0%; Asia 4.5%; Middle East 4.0%; and North America 7.5%. The pattern of consumption and preference for one type of legume over another depends upon the availability in the area. The annual per capita supply for 1998 is highest for Central America (13.7 kg), followed by South America (10.3), sub-Sahara (8.8 kg), Africa (8.2 kg), North America (7.2 kg), Asia (5.4 kg), Oceania (4.8 kg), and Europe (2.7 kg). However, the annual per capita consumption of legumes of some Mediterranean countries (except Lebanon 14.5 kg; Turkey 13.5 kg) is more than twice as much as the rest of Europe.

World production of major food legumes exceeds 59×10^6 t per annum **Table 2**. India is the world's leading producer, as well as the world's leading importer of pulses. Canada is the leading world exporter of pulses; Australia, Myanmar, China, and the USA are also world exporters outside the European Community (EC). India, China, and the USA are the major peanut-producing countries, with India contributing nearly 30% of total world production.

Table 1 Important food legumes with their scientific and common names

Scientific name	*Common name*
Arachis hypogea L.	Arachide, groudnut, peanut, earthnut, goober pea, Philippine pink, mani
Cajanus cajan L. *Millsp.*	Pigeon pea, Congo pea, gandul, guandu, red gram, Angola pea, yellow dhal, catjang pea
Cicer arietinum L.	Chickpea, gram pea, Egyptian pea, pois chiche, Bengal gram, gram, chana, garbanzo, alter, shibu
Cyamopsis tetragonolaba L.	Guar gum
Dolichos uniflorus	Horse gram, horse grain, Madras gram, kallu
Glycine max (L.) *Merr.*	Soybean, soya bean, soya, haba soya, preta
Lablab purpureus (L.) *Sweet*	Hyacinth bean, Egyptian bean, val
Lathyrus sativus L.	Khesari, chickling vetch, grasspea
Lens culinaris Medik	Lentil, masur
Lupinus albus L.	White lupine
Lupinus angustifolius L.	Blue lupine, New Zealand blue lupine
Lupinus luteus L.	European yellow lupine
Macrotyloma uniflorum (Lam.) Verdc.	Horse gram, Madras gram, kulthi
Phaseolus lunatus L.	Lima bean, butter bean
Phaseolus vulgaris L.	Common bean (field bean, haricot, pinto, navy, kidney, dry bean), garden bean, frijol, caraota, poroto
Pisum arvense sativum L.	Pea, pois, arveja, Alaska pea, common or garden pea, dry peas, guisante, muttar
Psophocarpus tetragonolobus (L.) *DC*	Winged bean, Goa bean, four-angled bean, Manila bean, princess bean
Vicia faba L.	Broad bean, faba bean, horse bean
Vigna aconitifolia (Jacq.) Marechal	Moth bean, mat bean
Vigna angularis Wild	Adzuki bean
Vigna aureus	Green gram, golden gram, mung bean, Oregon pea, chickasano pea, mungbean
Vigna mungo (L.) *Hepper*	Urd, black gram
Vigna radiata (L.) *Wilczek*	Green gram, golden gram, mung bean
Vigna umbellata (Thunb.) Ohwi and Ohashi	Rice bean, mambi bean
Vigna unguiculata (L.) *Walp. ssp. Unguiculata*	Cowpea, black-eyed pea, crowder pea
Voandzeia subterranea (L.) *Thouars*	Bambarra groundnut

Structural and Anatomical Features of Legume Seeds

The seeds of leguminous plants differ in color, size, shape, and seed coat thickness. The seed coat (testa) is the outermost layer of the seed that protects the embryonic structure from damage caused by water absorption and microbial contamination. Figure 1 illustrates the anatomical features of a legume seed. The hilum (large, oval attachment scar) and the micropyle (minute opening in the seed coat) regulate seed water imbibition. The internal structure of the seed includes the shoot (leaf tissue), consisting of two cotyledons and the embryonic axes, including the epicotyl (stem tip), hypocotyl (stem), and the radicle (root). Seed coat thickness, seed volume, hilum size, and protein and starch content all influence water absorption.

The seed coat comprises between 6% and 8% of the total seed weight. The major components of the seed coat of legumes include the waxy cuticle layer (hydrophobic barrier), intermediate layer (palisade and hourglass cells) and the thick-cell-walled parenchyma cells that appear spongy and swell dramatically during hydration.

The cotyledon, which contains reserve starch and protein, is the largest component of the dry bean by both weight and volume. Processed texture and nutrient availability of beans are both influenced by the dimension and arrangement of the cotyledon cells. The outermost layers consist of epidermal cells, containing granular protein structures with limited starch, and the hypodermis, which has larger, elliptically shaped cells. The parenchyma cells comprise the largest portion of the cotyledon. These cells are bound by a distinct cell wall and middle lamella with a few vascular bundles. Thick walls, in the longitudinal section, give rigidity to the cotyledon. The secondary walls, found only in mature parenchyma cells, are very thick and contain pits that facilitate the diffusion of water during soaking. Within each parenchyma cell, starch granules are embedded within a protein matrix; between adjacent cells, the middle lamella, composed mainly of pectic substances, adds potential rigidity to the tissues.

Comparative Chemical Composition

Carbohydrates

The total carbohydrates of legumes range from 24.0%, on a dry-weight basis (dwb) in winged beans to 68% in cowpeas. Oligosaccharides of the raffinose family (raffinose, stachyose, verbascose, and ajugose)

Table 2 World production of important food legumes

	Year	World production (Mt)	Production (Mt)	
			Developing countries	Developed countries
Soybeans	1996	130 206 297	61 229 828	68 976 469

Data adapted from FAO (1996–2000). (http://apps.fao.org/page/form?collection = Production. Crops. Primary&Domain = Production&servlet = 1&language = EN&hostname = apps.fao.org&version = default)

account for 31.1–76.0% (dwb) of the total sugars. Starch makes up a larger portion, ranging from 24% to 56% (dwb) of total carbohydrate. These variations in reported starch contents result in part from differences in cultivars and analytical procedures. The physiocochemical properties and internal molecular structures of bean starch differ depending on the original source, maturation, and environmental factors. The majority of legume starches have molecular weights higher than 2×10^4, and over 90% of them have molecular weights about 4×10^4. (*See* **Carbohydrates**: Classification and Properties.)

The amount of amylose, ranging from 10% to 66%, may influence starch solubility, lipid binding, and other functional properties. The variability between amyloses from different legumes may be the result of: (1) maturity of seed; (2) genetic control of amylose synthesis; (3) cultivar differences; and/or (4) seed storage history. A degree of amylose polymerization may confer structural stability on the granule but may also be partially responsible for its resistance toward *in vitro* α-amylolysis.

Most legume starches have gelatinization temperatures of 60–90 °C and are characterized by no distinctive pasting peak, but rather a very high viscosity which remains constant or increases during cooling. The restricted and single-stage swelling patterns of legume starches are explained by the crystalline and

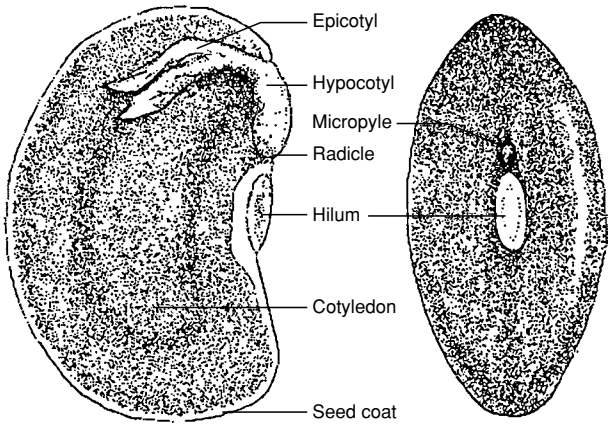

Figure 1 Anatomical structure of a legume seed.

amorphous regions of the starch granules and the presence of strong binding forces which relax within one temperature range.

Large variation in nonstarch polysaccharides (NSP), including fiber content (1.2–13.5%), has been observed in selected types of legumes. A significant proportion (80–93%) of the fiber is localized in the seed coat. Beans possess relatively high levels of soluble and insoluble fiber, and significant levels of pectin. Cellulose is the major component of fiber in smooth and wrinkled peas, red kidney, and navy beans, while in other legumes (lupins, lentils, broad beans, etc.), hemicellulose predominates. Cotyledon cell walls contain higher levels of pectin than cellulose. The seed coats are primarily composed of cellulose (29–41%) with small amounts of lignin (1.2–1.7%). Total dietary fiber is higher in cooked beans than in raw beans. Water-soluble fractions can be lost with cooking water, even though the beans are intact, while long boiling may cause modifications in certain constituents of other fiber fractions. (*See* **Dietary Fiber**: Properties and Sources.)

Proteins

Legumes are dense sources of plant protein that ranges from 20% to 40% (dwb). The bean storage (reserve) proteins are predominant in the globulin fractions, while the metabolic (enzymatic) proteins are primarily found in the albumin fraction. The storage proteins have high affinity for water and contribute dramatically to the nutritional and functional properties of the cooked seed. Bean proteins are relatively high in essential amino acids, in particular lysine, threonine, isoleucine, leucine, phenylalanine and valine. However, they are deficient in sulfur-containing amino acids, in particular methionine and cystine. This explains their association with cereal grains that are deficient in lysine, but are a substantial source of methionine. (*See* **Protein**: Food Sources.)

The globulin fraction can be subdivided into globulin I (GI: high salt solubility) and globulin II (GII: low salt solubility). Phytohemagglutinin (PHA), the lectin of dry beans, is identified as GII with two general types of subunits: an erythrocyte reactive subunit, E, and a lymphocyte-stimulating subunit, L. PHA has relatively high levels of aspartic acid and serine, but possesses very little cystine and methionine. It has the ability to agglutinate red blood cells, disrupt the internal mucosa, and reduce nutrient absorption. Leguminosa lectins will bind both the storage protein and the glycosidase enzymes. It has been suggested that lectins act during the maturation of the plant to contribute to an orderly arrangement of the storage proteins in the protein bodies.

Total biological utilization of the legume protein is relatively low, with digestibility less than 76%. Protein digestibility may be impaired by the presence of numerous antinutritional compounds that must be removed or destroyed during processing. There is considerable variability in protein digestibility among different commercial classes of *Phaseolus vulgaris*, and also among cultivars within a class. Heating for longer than 30 min at 121 °C results in lowered protein quality and decreased available lysine in *P. vulgaris*. The protein efficiency ratio (PER) of raw and cooked legumes is approximately 0 and 1.2, respectively.

Minor Constituents

Ash and minerals The total ash content of *P. vulgaris* ranges from 3.5 to 4.1% (dwb). Beans are generally considered to be substantial sources of calcium and iron. They also contain significant amounts of phosphorus, potassium, zinc, and magnesium. Differences among bean classes and environmental factors influence variability. Ash content decreases after cooking because of leaching, with losses ranging from 10% to 70%. The wide range of reported losses could be due to different soaking and cooking methods. (*See* **Minerals – Dietary Importance**.)

Vitamins Dry edible beans provide several water-soluble vitamins (thiamin, riboflavin, nicotinic acid, and folic acid) but very little ascorbic acid. However, variability of vitamin content is high. Commercial methods of preparation of canned beans cause a significant loss of water-soluble vitamins. (*See* **Vitamins**: Overview.)

Lipids Neutral lipids are the predominant class and account for 60% of the total lipid content. Phospholipids comprise 24–35%, while glycolipids account

for up to 10% of the total lipid content of legume seeds. Most dry beans possess relatively low total fat content, generally 1–2%. The fatty acid composition of legumes demonstrates a significant amount of variability; however, legume lipids are generally highly unsaturated (55–85%), with linoleic acid present in the highest concentration. Palmitic acid is the predominant saturated fatty acid. (*See* **Fats**: Classification.)

Tannins and polyphenols The procyanidin and condensed tannin content of dry beans ranges from 0.4% to 1.0%. These compounds are localized in the bean seed coat, with low or negligible amounts present in the cotyledon. The hydroxyl groups of the phenol ring enable the tannins to form cross-links with proteins that may be implicated in postharvest seed hardening or decreased digestibility. During cooking, polyphenolic compounds are partially leached into the cooking medium and may interact with cotyledon constituents, yet complete destruction of the tannins does not occur during heat processing. (*See* **Tannins and Polyphenols**.)

Grading, Handling, and Storage

Various genetic, cultural, and environmental factors, including variety, seed source, agronomic conditions, handling, and storage of the dry product, critically affect the final quality of legume food products. Seed germination and vitality are extremely vulnerable to damage during handling and storage.

Beans are not ready for harvest until the moisture level drops to about 20%. Conditions best suited for threshing (removal of seed from pod and separation of plant residue) are seed moisture of 16–20% (on a wet-weight basis) and pod moisture at least 4% lower than seed moisture. Moisture content is also an important factor influencing postharvest storage stability. Accumulation of moisture will result in high seed respiration rates (heat) and subsequent mold development can be a storage problem. Aeration of seeds during storage provides moisture equilibration and ability to inhibit localized 'pockets' of moisture. The seed is vulnerable to mechanical damage, which can result in split seed coats, so design of handling systems (conveyors and augers) must minimize seed dropping.

Bean moisture control, storage temperature, and relative humidity exert a major influence on dry bean quality and on the final product. High moisture and high temperature during storage will result in brown, discolored, and off-flavored beans ('bin burn'). Beans subjected to adverse storage conditions may undergo cooked-seed textural defects which severely limit their food use. Legume seeds that will not soften sufficiently because of a failure to imbibe water during soaking are termed 'hard-shell.' Legume seeds that absorb adequate water during soaking, but will not soften sufficiently during a reasonable cooking time, are designated as hard-to-cook (HTC).

The most noticeable structural changes caused by HTC defect is a failure of cotyledon cells to separate during cooking. Disintegration of cytoplasmic organelles, with inclusions and loosening of attachments between the cell wall and the plasmalemma, are observed in HTC beans. Loss of plasmalemma integrity is considered to be responsible for increases in electrolyte leakage observed in HTC beans. Much research has been directed toward understanding and controlling these reactions.

Processing and Uses

Food legumes are an economical source of supplementary protein for many populations lacking animal protein. Legumes are currently of interest to the consuming public because they provide high nutrient levels without supplying excessive calories, and the perception of their food values has dramatically shifted from the 'poor man's steak' label.

The major physical constraints limiting the use of dry beans are as follows:

1. Preparation: time, convenience, expense
2. Postharvest storage changes: seed hardening – hard shell and HTC; moisture absorption; mold growth; seed discoloration; flavor and odor changes.

The major biological constraints limiting utilization of dry beans are as follows:

1. Antinutrients: protease inhibitors and trypsin inhibitors, lectins and PHA; amylase inhibitors; phytic acid (mineral chelation and malabsorption).
2. Digestibility: procyanidin interactions (tannins and condensed polyphenols, binding of proteins); protein (limited proteolysis, amino acid balance); starch (resistant granules, limited amylolytic degradation).
3. Flatulence factors: oligosaccharides; nonstarch polysaccharides; proteins; retrograded starch.

Figure 2 summarizes the processing and edible byproducts of dry beans.

Soaking

Soaking of legume seeds may be used to moisten and soften the seed to reduce cooking time or aid in seed coat removal. Soaking also reduces the toxin content and surface contamination. The time needed for

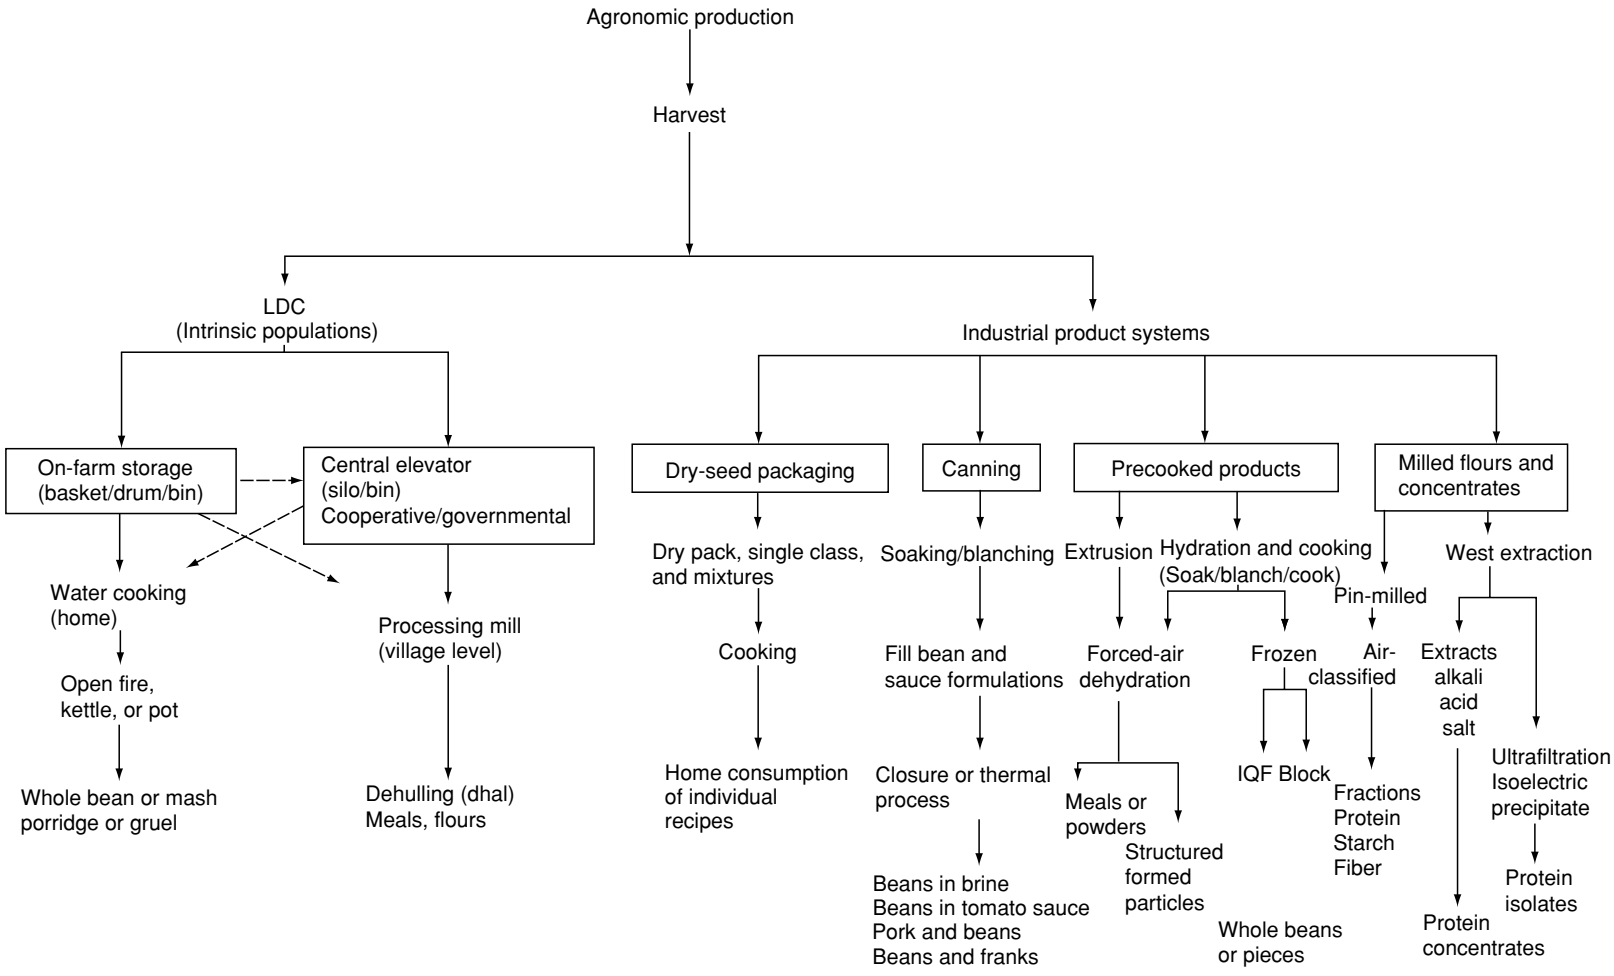

Figure 2 Outline of primary dry-bean processing and end products. LDC, less developed countries; IQF, individually quick-frozen.

soaking varies with variety and species, and with length and conditions of storage. Traditionally, dry beans have been soaked overnight (8–16 h) in cold water. High-temperature soaking accelerates hydration. Experimental methods designed to accelerate seed hydration and tenderization include vacuum, ultrasonic sound, the use of soak-water additive (phosphates) and gamma-irradiation. Cracking or scouring seeds with tough seed coats before soaking assists moisture penetration. The degree and rate of hydration of the starch–protein matrix influences the cooking rate and final texture of cooked beans. The content of total soluble sugars (reducing and non-reducing) and soluble minerals in legumes decreases during soaking because of leaching losses. In many less developed countries (LDC), dry beans are cooked without soaking because of water quality limitations.

Germination, Sprouting, and Fermentation

Soaking legume seeds and holding at ambient temperatures will facilitate germination. Germination has profound effects on the physicochemical composition changes and improves the nutritional quality of legumes by increasing vitamins such as ascorbic acid, riboflavin, choline, thiamin, tocopherol, and pantothenic acid. The sprouted grains may be consumed fresh or, if followed by seed coat removal, can be roasted or ground for use in soups or side dishes.

In Asian countries, soybeans have been fermented to produce a variety of nutritious food products. Some important soybean-based foods are tofu (soybean curd), natto (Japanese product), miso (soy paste), tempeh (Indonesian product), shoyu (soy sauce) and tamari. Fermented foods that are traditional in India include idly (steamed) and dosai (fried) from black gram, and dhokla (steamed) and khaman from Bengal gram. Groundnuts are also fermented with a mold to make ontjom, an Indonesian product similar to tempeh.

Dehulling and Roasting

Dehulling and splitting the cotyledons reduces cooking time considerably. The ease of removing the hull depends on the thickness of the seed coat and can be achieved via wet or dry methods. The wet method involves soaking the grain in water for a few hours, draining, drying, milling, and winnowing to remove the seed coat. In a large-scale dry method, oil is mixed with the seeds by passing through emery-coated rollers to abrade the surface. This is common practice for legumes with particularly tough seed coats, including velvet, hyacinth, and winged beans.

Dehulling and splitting the cotyledons into halves is a process traditionally practiced in Asia and Africa. In India, nearly 70% of food legumes are milled to make dehulled split cotyledons (referred to as dhal), which is prepared by cooking until soft, mashing, mixing with water, then boiling again to give a porridge of uniform consistency. In addition, dhals are cooked with vegetables, spice, and condiments. Roasting and puffing involve the application of dry heat to legume seeds using a hot drier at a temperature of 100–200 °C for a short time (1–5 min) or by direct heating with hot sand. Dhal or whole seeds are roasted to obtain an appealing flavor and maintain maximum protein quality.

Pigeon peas are usually consumed as dehulled splits or dhal. The dhals are cooked until soft and served as a sauce or boiled with rice. They are also incorporated in cereal legume mixtures to feed infants and young children in LDC. Mature seeds can also be soaked before boiling or pounding, then steamed and fried. However, the green seeds, pods, or sprouts may be eaten directly or canned.

Thermal Processing

Heating increases tenderization of the cotyledon, improves flavor, and inactivates enzymes and intrinsic toxic factors of legume seeds.

Cooking Whole legumes may be cooked either with or without the seed coat, in boiling water or steam. Traditionally, cold-water-soaked beans are simmered at subboiling temperatures for several hours or until adequately tender for eating. Cultivar variability, hard-shell, and HTC storage defects may dramatically alter cooking time. The use of 'crock-pot' cookers has also generated interest for preparing beans, although this low-temperature cooking procedure may not adequately inactivate PHA. There is loss of solids from beans during cooking, with the amount depending on species, variety, and cooking method. Although cooking is essential in order to render the beans palatable and inactivate toxic substances, excessive cooking results in loss of protein biological value in the form of lysine and methionine.

Canning Industrial canning overcomes the long period of time and high fuel costs involved in home preparation of legumes. Hot-water hydration (final moisture 53–57%) can be accompanied via serial rotator blanchers with differential temperatures, or continuous pipe blanchers. Hydrated beans may be processed in a standard rotary water blancher for 3–8 min, then continuously washed with cold-water sprays, utilizing rod washers or vibrating sieves to facilitate removal of broken beans and skins. Beans are generally processed in water or brine, tomato sauce, or molasses. The beans will further hydrate during the thermal process and equilibrate with the

sauce or brine to a final moisture content of 65–70% within 2–4 weeks.

Food Ingredient Preparation: Bean Meals, Legume Flours, Concentrates, and Powders

Flours and concentrates made from legumes other than soybeans have had little commercial success. Initial efforts to produce bean ingredients were focused to minimize cell rupture in order to retain the same texture, appearance, and taste of conventionally prepared beans. The compartmentalization of protein and starch enables size reductions and fractionation of dry beans into coarse and fine fractions containing high starch and high protein, respectively. Examples of high-protein food ingredient products are flour processed by pin milling and air classification, and concentrates and isolates processed by alkali, salt, and acid extraction together with isoelectric precipitation or ultrafiltration. Bean protein concentrates containing 72–81% protein, protein isolates containing about 90% protein, and fractions containing 50% starch have all been produced using water extraction techniques. Instant precooked bean powders have been prepared by soaking, cooking, slurrying, and drum- or spray-drying. Recent product development has included the use of spray-dried powders from pea, imitation milk replacers from pea and lentil, and protein curd similar to tofu from pea. Ingredients from dry beans, peas, and lentils have been used in pasta, noodles, and spaghetti. Legume meals and concentrates have been blended into ground-beef preparations. In addition, the high-fiber or high-protein bean flour fractions have been successfully substituted (20%) for wheat flour to produce quality biscuits, doughnuts, quick breads, and leavened doughs.

When raw legumes are ground without pretreatments, they develop undesirable odors and flavors. Lipoxygenase has been held responsible for the appearance of off-flavors by catalyzing formation of hydrogen peroxides from unsaturated fatty acids. However, treatment with dry heat for 6–8 min at 105 °C completely inactivates this enzyme. It is therefore advantageous to apply a rapid heat treatment to beans prior to bean flour production. The attractions of conventional air heating are ease of handling and lack of product contamination, but air does not provide a high rate of heat transfer. Instant navy bean powders, obtained by roasting dry beans in a bed of heated ceramic beads, followed by grinding, resulted in functional food ingredients which showed: (1) stable gel-forming capacity; (2) low trypsin inhibitor and hemagglutinin activities; (3) increased water-holding capacity and cold paste viscosities; (4) no changes in available lysine; (5) limited degree of starch damage; and (6) reduction of water-soluble nitrogen content. Air classification of roasted beans produced high fiber, starch, and protein fractions that are suitable as food ingredients in a variety of food products.

Groundnuts or peanuts are eaten raw, roasted, or pounded into peanut butter, or processed as salted peanuts, sweets, and snacks. They are also incorporated in soups and stews. In Africa, India, China, and South-east Asia, the peanut crop is converted to oil and cake. Edible peanut flour is prepared by grinding peanut kernels in a hammermill or bar-cracking machine. The ground seeds are conditioned to 10% moisture and cooked in a stack cooker for 45–60 min to attain an exit temperature of 116 °C. An expeller is used to reduce the oil content of the cooked meal to 8–12%. The meal is then ground, conditioned to 10% moisture, flaked, and extracted with hexane. The defatted flakes are desolventized, then cooled and ground to either flour or grits. Nutritious, low-cost, peanut-flour-enriched wheat noodles have been developed in Thailand.

Processing of full-fat, partially defatted or fat-free flakes from peanut kernels includes grinding low-moisture (6%) kernels to a flour consistency, mixing with water to form an emulsion suspension, heating this to 93–116 °C to reduce lipoxygenase activity, and drum-drying to form the peanut flakes. Peanut protein concentrate is prepared using defatted peanut flour or meal with protein content between 45% and 60%. The processes or techniques which can be used to isolate peanut protein concentrate include immobilization of the major protein fraction, air or solvent classification, and wet milling.

Bambarra groundnut seeds have lower oil content compared to groundnut, but are richer in protein and calories. They are consumed fresh, grilled, or broiled, or made into flour to form cakes. Immature shelled or unshelled nuts are pounded and boiled into a stiff porridge. They are also served as appetizers and relishes.

Convenience Bean Products

Preparation and cooking time is a major constraint to bean utilization, but numerous chemical and physical processing techniques have been initiated to alleviate this problem.

Quick-cook beans Bean products which cook in less than 15 min have been developed using vacuum infiltration of a solution containing sodium chloride (NaCl), pentasodium tripolyphosphate ($Na_5P_3O_{10}$), sodium bicarbonate ($NaHCO_3$), and sodium carbonate (Na_2CO_3). Further soaking of the beans in this solution is followed by rinsing, drying and cooking or

freezing, depending on the intended use. These products have not been commercially developed, in part because of the elevated sodium level associated with the process.

Frozen or dehydrated beans Numerous precooking and dehydration procedures have been developed which enable production of rapidly reconstituted beans, bean pieces, or bean powders. Fully cooked, dehydrated bean flours, bean 'crumbles' and refried bean mixes are prepared for use in institutional food service systems. Main-dish retail products with a wide variety of styles and seasonings (barbecue, Cajun, *al presto*) have recently entered the market.

Partially or fully cooked beans marketed as individually quick-frozen (IQF) or as a block-frozen product are suitable as institutional food ingredients or for direct retail distribution. Appropriate hydration and softening under low-temperature cooking conditions prior to freezing provide products that are readily suitable for use in recipe-based foods, such as chilli con carne and acidified three-bean salad dishes.

Extrusion Extrusion utilizes continuous high-pressure and high-temperature cooking of starch or flour from legumes and cereals. The use of this technology and proper ingredient formulation may provide precooked or quick-cook legume products. Starch gelatinization occurs primarily during the later stages of cooking of the beans. The amount of water available is critical to the gelatinization process. When the cooking and extrusion processes are combined, the increased pressure differential will facilitate expansion of the final product. This formed product, of open porosity, may require additional air-drying to assure shelf-stability. The dry formed 'bean' will readily hydrate and soften when reconstituted. Die configuration can be designed to produce a variety of intricate product shapes that can be further optimized to produce simulated beans. Appropriate binders and coating agents can be added to improve the appearance of precooked or quick-cook bean products, resulting in promising prototypes of extrusion-cooked formed 'beans.' (*See* **Extrusion Cooking**: Principles and Practice.)

Microwave heating/cooking Several frozen bean and refried bean products, as well as instant bean flour mixtures for sauces and salsa, are commercially available and can be prepared using a microwave oven. Microwave treatment of whole soybeans after soaking to prepare soy flour or soy grits without a burnt odor was reported completely to inhibit trypsin activity. Proper microwave treatment also reportedly increased the *in vivo* digestibility and the metabolizable nitrogen of soybeans.

Legumes are prepared, processed, and consumed using a variety of locally and culturally adapted methods or styles, and are important in subsistence and industrialized economies. Research directed to improve utilization of legumes has included removal of constraints such as postharvest storage defects, cookability, digestibility, and inactivation of antinutritional and flatulent factors. New processes and products may enhance the utility and acceptability of these valuable food resources.

Dietary Importance

Y Lam, Bio-Rad Laboratories, Hercules, CA, USA
B O de Lumen, University of California, Berkeley, CA, USA

Introduction

Since man settled down to practice agriculture, the human diet has consisted mainly of cereals or starchy roots and fruits, which are poor sources of protein. With few exceptions, these classes of food crops have been the basis of the human diet throughout recorded history, and this is still true today. As shown in Table 1, legume cultivation and consumption are widespread throughout many countries and cultures, suggesting that legumes might have evolved to fulfill human needs for proteins and other nutrients, complementing cereals.

North America

Common bean, lima bean, soybean, peanut, pea, and lentil are the main legumes used in this region. Common bean and lima bean are typically processed commercially and canned or cooked at home. Peanut is used roasted as whole seeds or as ingredients in various products such as peanut butter. Pea is sold commercially as green immature seeds in frozen form or as dry mature seed. Lentil is usually used as dry seeds and incorporated into a number of dishes. Soybean is a major cash crop in the USA, where the soymeal that remains after oil extraction is used mainly for animal feed. The USA and Brazil are the biggest producers and exporters of soybean. Soybean in the USA is a major source of cooking oil, protein concentrate, and protein isolates, which find uses in many different products including meats. The market for soy products is increasing at a rapid rate owing to the health benefits attributed to consumption of soy products such as reduction of cardiovascular disease and prevention of cancer. Tofu (soybean curd), soy sauce, miso, and nato are consumed by an increasing number of the US population in addition to the Asian American population already consuming them in large quantities.

The kidney bean is the principal legume of Mexico, occurring in several varieties. The dietary patterns of the Native American population in Arizona and New Mexico are similar to those of Mexico and Central America. The average daily intake of the Pima Indians in Arizona is 70 g per person, about four times the average US daily intake, providing a high percentage of the total protein. Kidney bean is again the principal legume, but other beans such as lima are also eaten.

Latin America

The common bean is the major legume in this region, making up about 90% of the total legume production, excluding soybean, which is produced in large quantities in Brazil as an export cash crop. In South and Central America, cowpea, pea, pigeon pea, and lupine are also grown. Common bean is typically used

Table 1 Cultivation of economically important legumes in different regions of the world

Common names	*Latin name*	*Areas of cultivation*
Peanut, groundnut, monkey nut, pigeon pea	*Arachis hypogaea*	Tropics and subtropics
	Cajanus cajan	Tropics and subtropics in Asia and Africa; widely cultivated in India and Pakistan; introduced into tropical America, Pacific Islands, and Australia
Chick pea, Bengal gram	*Cicer arietinum*	Tropics and subtropics in Asia and Africa; widely cultivated in India and Pakistan mainly as a cold weather crop; also cultivated in Mediterranean countries and South America
Soybean	*Glycine max*	South and East Asia, particularly in China and Japan (but not in India) and USA; other countries only on a limited, experimental scale
Lentil, split pea	*Lens esculenta*	Near east, North Africa, India, Burma, central and southern Europe
Lima bean, butter bean	*Phaseolus lunatus*	Tropical America, West Indies, tropical Africa, Madagascar, New Guinea, and north Australia
Golden gram, green gram	*Phaseolus aureus*	South and East Asia, particularly India, East Africa
Black gram, mung bean	*Phaseolus mungo*	India, Africa, West Indies, South and East Asia
Kidney bean, French bean, haricot bean	*Phaseolus vulgaris*	Throughout the world, particularly in the Americas
Pea, garden pea	*Pisum sativum*	Throughout temperate zone; in warm countries as a cold weather crop or at high altitudes
Broad bean, horse bean	*Vicia faba*	Temperate zone, particularly Mediterranean region, highlands in Asia, Africa, and Central and South Americas
Cowpea, blackeye pea	*Vigna unguiculata*	Tropical Asia and Africa, West Indies, southern Europe, and the Americas
Bambara, groundnut, earth pea	*Voandzeia subterranea*	Tropical Africa

as a dry bean, cooked at home, and included in a number of dishes.

Tropical Africa

In addition to the dry seeds, other forms of legumes are also consumed, such as the tender green shoots, leaves, and immature green pods. The three major legumes that are consumed locally are cowpea, common bean, and pigeon pea. Peanut is also grown but mostly exported.

Asia

Legumes are the only high-protein sources of the average diet in India, where they are eaten mainly with rice, wheat, and other minor cereals. Chickpea and pigeon pea make up 60% of the total legume production in India, followed by pea and khesari (*Lathyrus sativus*). The term 'gram' is applied to dry legume seeds with the husk, whereas the split, dehusked seeds are called 'dhal.' The most common way of preparing dhal is to cook until soft, after which they are mashed, mixed with water, and boiled again to give a soup or gruel of uniform consistency. These are eaten as part of meals composed of the staple cereal of the locality, which is usually boiled rice or chapatties made from wheat, sorghum, or millet.

Soybean, peanut, common bean, adzuki bean, black gram, horse gram, green gram, fava bean, and lima bean are grown and consumed to different degrees in China, Taiwan, Japan, Korea, Myanmar, Vietnam, Philippines, Malaysia, Indonesia, and Sri Lanka. The legumes are consumed as dry seeds, immature pods, sprouted and fermented. The winged bean (*Psophocarpus tetragonolobus* L) is mainly eaten as a green vegetable in the Philippines, Malaysia, Indonesia, Vietnam, and Sri Lanka. Because its chemical composition is similar to that of soybean, the winged bean has been promoted in its dry form as a rich source of protein and oil.

Soybean is the principal legume of East Asia (China, Japan, and Korea) and is also widely used in South-east Asia. It is consumed in forms that have been used for centuries such as green, dry seed, fermented, and germinated. Green immature soybean has an attractive flavor, and the pods are usually boiled in salted water, so that the beans can be easily removed. Immature beans are used in salads or cooked in vegetables dishes or in soups. The popularity of green soybean in the USA is increasing, together with other soy products.

Sprouted soybeans are among the most popular of Chinese vegetable dishes, which are either eaten raw as a salad or included in cooked dishes. Tofu is the most popular form of soy products in Asia. Typically, the whole beans are soaked overnight, ground into an emulsion, and strained to remove coarse particles, and the mash is boiled or steamed and passed through cloth filters. The curd is then precipitated from the milky fluid, allowed to settle, transferred to boxes lined with cloth filters, pressed with weights, washed, and dried to various extents. The final product, with a white color and delicate texture, contains 6–17% moisture and is sold in slices or slabs. The curd is included in a variety of dishes and is widely used as food for children.

A number of fermented soybean products are widely used in Asia. Soy sauce (shoyu) is produced in large quantities in Asia and the USA. It is made with a long, elaborate fermentation process with various fungi, bacteria, and yeast. Soybean paste (miso) is made from fermenting a mixture of soaked and cooked soybean plus steamed rice inoculated with *Aspergillus oryzae*. The final product, with a paste-like consistency and containing about 10% protein, is made into soups or served with rice and other foods as a side dish or condiment. Natto is a Japanese product made by fermenting whole soybeans through the action of *Bacillus subtilis* using an ancient method said to have been invented by Buddhist monks. The finished product, which is eaten with rice, has a musty flavor and gray color. A similar fermented product is hamanatto, which originally came from Korea. Here, the fermenting agent is a mold. Tempeh, an Indonesian product, is made by treating soybeans with the fungus *Rhizopus oryzae*. This highly nutritious product contains about 25% protein and is rich in amino acids produced by the fermenting fungus. (*See* **Fermented Foods**: Origins and Applications.)

Soy beverage is prepared as a white emulsion, which has the appearance of milk. Typically, the soybeans are soaked and passed through a mill, emerging as an emulsion. The emulsion is filtered, transferred to a boiler, and boiled for 20 min after adding supplements such as vitamins, sugar, salt, calcium, and flavorings. The boiled mixture is finally passed through a special emulsifier. The milk contains about 3.2% protein, 3.4% fat, and 4.5% carbohydrates, with contents of vitamins and calcium according to the amounts added. In Asia, soy milk is used as a beverage for adults but not for infants. Various proprietary formulations of soy milk are produced in the USA mainly for use in feeding infants and young children allergic to cows' milk.

Middle East, North Africa, and Mediterranean Countries

Populations in these regions consume legumes such as fava bean, pea, lentil, lupine, and some species of *Lathyrus*. In Africa, groundnut, mainly cultivated as

an oil-yielding cash crop, is also used directly as human food. Cowpea is the next most widely used legume in Africa. The common beans, particularly kidney beans, are also grown extensively in hilly regions with a good rainfall. Stewed broad beans are commonly eaten as the first meal of the day in the Middle East.

Europe

Pea and lentil are produced and used extensively in European countries. Common bean is also used in all of Europe but is usually imported from Canada and the USA. Lentil is also often imported.

Macronutrients

The energy value and proximate composition of 10 species of legume seeds are shown in Table 2. The largest component by weight in legume is carbohydrate averaging 53%. The second largest component in legumes is protein, varying from 19.5 to 39.7% by weight and contributing significantly to the seed energy value. Lipids comprise on average 7% of the seed weight. Most legumes are low in lipids, with the exception of peanut and soybean, which are low in carbohydrate but high in protein and lipids.

Protein

Methionine is the first limiting essential amino acid in legumes because the major storage proteins, the globulins, are low in this amino acid (Figure 1). Cysteine, although not an essential amino acid, is included with methionine, because it has a sparing effect on methionine when added to the diet. This limitation, together with its high lysine content, makes legumes nutritionally complementary with cereals, which is first limiting in lysine and relatively high in methionine. This makes the overall protein quality of cereal–legume mixtures better than that of either protein source alone. (*See* **Protein**: Food Sources.)

Supplementation of legumes with free methionine improves their value in supporting animal growth and increases the efficiency of utilization of dietary protein. In the feeds of poultry and swine, where soybean is the main protein source, methionine is used as a supplement. Little practical use of supplementation in human diets has been made, despite clinical studies with humans demonstrating their effectiveness. (*See* **Amino Acids**: Metabolism.)

Bioengineering (genetic engineering) is another strategy to enhance the protein quality of legumes. The sulfur amino acid requirements of humans vary with age, with infants requiring the most, adults requiring the least, and growing pigs requiring more than human infants (Figure 1). The FAO recommends using the essential amino acid requirement pattern of 2–5-year-old children to evaluate protein quality for all ages, except infants. The methionine + cysteine content of legumes has to be increased to approximately 25 mg per gram of protein for humans except infants, to 42 mg per gram of protein for human infants and to about 48 mg per gram of protein for swine. The digestibility of legume protein, which varies from 72 to 98%, also needs to be considered.

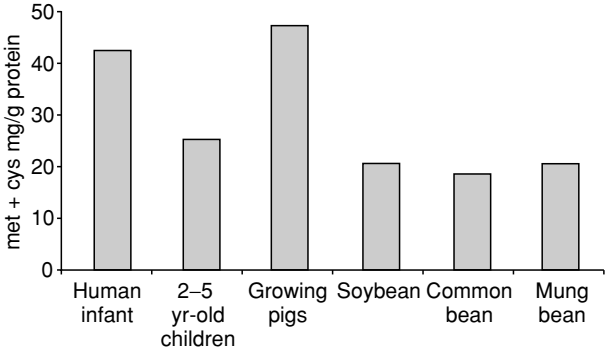

Figure 1 Methionine and cysteine contents of some legumes compared with methionine and cysteine requirement for human infants, 2–5 year-old children and growing pigs.

Table 2 Macronutrients contents per 100 g of edible legume seeds

Common names	*Energy (kJ)*	*Water (g)*	*Protein (g)*	*Lipid (g)*	*Crude fiber (g)*	*Ash (g)*	*Carbohydrate (g)*
Soybean	1735	9.0	34.3	18.7	3.8	5.1	31.6
Peanut	2306	6.5	27.6	52.1	2.0	2.4	13.3
Pea	1453	10.5	24.5	1.1	4.0	2.5	62.0
Lentil	1453	10.5	27.7	1.0	4.1	2.6	61.2
Cowpea	1453	11.7	22.0	1.3	4.5	3.3	63.4
Chickpea	1546	10.7	19.5	5.7	4.0	2.7	61.7
Pigeon pea	1449	9.9	19.5	1.3	1.3	3.9	65.5
Fava bean	1470	10.6	24.8	1.4	7.0	3.3	60.4
Lupine	1596	10.7	39.7	9.0	12.5	3.5	35.0
Winged bean	1701	9.7	32.8	17.0		4.1	36.5
Mean	1537	10.0	25.8	7.0	6.0	3.4	52.3

Taking soybean as an example with an average methionine+cysteine content of 22 mg per gram of protein, this value has to be increased by 14% (for humans), by 91% (for infants), and by 118% (for swine). Figures would have to be higher if protein digestibility is taken into consideration and for other beans (Figure 1), whose methionine+cysteine contents are generally lower than those of soybean. In any case, animal feeding trials need to be carried out to establish the actual nutritional value of transgenic seeds.

Soybean is a primary target for genetic engineering, since it is the single largest source of protein in animal feed. In feed formulations where corn is added to soybean meal to provide methionine, increasing the methionine content of corn would be desirable, although its protein quality would not be significantly improved. Other legumes that are lower in methionine content than soybean should also be targeted.

There are basically four types of bioengineering strategies to increase the methionine content in legumes: (1) introduce methionine residues or methionine-rich peptides into nonconserved, and presumably noncritical, regions of storage protein; (2) transfer genes coding for methionine-rich protein (MRP) from other species, i.e., heterologous genes into legume of interest; (3) increase the level of nonabundant, endogenous MRP in the target plant; and (4) manipulate the key enzymes in the biosynthetic pathways of essential amino acids. The transfer of heterologous MRP genes into legumes is the most widely used and has been successful in increasing the methionine content of soybean by 26% and lupine by 94%. The transgenic soybean containing the Brazil nut MRP is allergenic to individuals who are allergic to Brazil nut, demonstrating that the Brazil nut MRP is a major allergen in Brazil nut and that allergens can be transferred from one food source to another through bioengineering. In feeding trials with rats, the transgenic lupine seeds have statistically significant increases in live weight gain, true protein digestibility, biological value, and net protein utilization compared with wild-type seeds. The strategy of cloning nonabundant, MRP in soybean led to the discovery of lunasin, a unique soybean peptide that has been shown to have anticancer properties (see section Bioactive Phytochemicals).

Digestibility of Legume Proteins

While the amino acid pattern of legumes is the most important index of protein quality, digestibility and bioavailability of the constituent amino acids are the next important factors. Differences in protein digestibility may be due to the nature of the protein, the presence of nonprotein components (dietary fiber, tannins, phytates), the presence of antinutritional factors, and processing conditions. The true digestibility of legumes varies from 73% (canned pinto beans) to 98% (soy protein isolate). Recognizing the importance of digestibility in evaluating protein quality, the recommended method is to combine amino acid score with digestibility data in what is called protein digestibility-corrected amino acid score. (*See* **Protein:** Quality.)

Carbohydrates

The total carbohydrate content of legumes is typically 60%, and these carbohydrates are generally well absorbed and utilized. Starch accounts for the major portion of legume carbohydrates, ranging from 24 to 56%. The oilseeds have lower carbohydrates content, with values such as 14% for peanuts and 32% for soybean. Oligosaccharides of the raffinose family (raffinose, stachyose, verbascose, and ajucose) account for 31–76% of the total sugars. The resistance of the raffinose oligosaccharides to human and monogastric animal digestion presents a problem to certain individuals sensitive to flatulence. It is estimated that reducing the raffinose oligosaccharide content of soybean used for livestock feed by 1% would result in an additional total value of $101 million per year (1990 value) owing to improved nutrition and reduced flatulence. (*See* **Carbohydrates:** Classification and Properties.)

Lipids

The lipid content of legumes is generally 7%. Exceptions are the oilseeds peanut and soybean, which contain about 52 and 20% oil, respectively. Soybean oil is the most widely used cooking oil. Winged bean is potentially a rich source of oil because of its similarity with soybean in chemical composition, but has not been exploited commercially. Peanut and soybean oils provide essential fatty acids to the human diet. Peanut contains 22% linoleic, whereas soybean has 54% linoleic and 8% linolenic. (*See* **Fats:** Classification.)

Micronutrients

Selected mineral and vitamin contents of 10 species of legume seeds are shown in Table 3.

Vitamins

Legume seeds are excellent sources of folate, which, in addition to being an essential nutrient, is thought to reduce the risk of neural tube defects. One serving of beans provides more than half of the current recommended dietary allowance (RDA) for folate. Beans are also good sources of thiamin and pantothenic

Table 3 Micronutrients contents per 100 g of edible legume seeds

Common names	Ca (mg)	Fe (mg)	Zn (mg)	Vitamin A (IU)	Thiamin (mg)	Folate (μg)	Vitamin C (mg)
Soybean	277	15.7	4.89	24	0.874	375.1	6
Peanut	92	4.58	3.27	0	0.64	239.8	0
Pea	43	2.08	0.27	145	0.15	41.7	60
Lentil	51	9.02	3.61	39	0.475	432.8	6.2
Cowpea	110	8.27	3.37	50	0.853	632.6	1.5
Chickpea	105	6.24	3.43	67	0.477	556.6	4
Pigeon pea	130	5.23	2.76	28	0.643	456	0
Fava bean	37	1.55	1.00	333	0.133	148	3.7
Lupine	176	4.36	4.75	23	0.64	355	4.8
Winged bean	440	13.44	4.48	0	1.03	44.6	0

acids. On average, 100 g of legume seeds provides 23% of the nicotinic acid, 50% of the thiamin, 15% of the riboflavin, 20% of the vitamin B_6, 195% of the folate, and 30% of the pantothenic acid requirement of an adult (based on US RDAs). Among the legumes, peanut is particularly rich in B vitamins. In general, legume seeds are poor sources of fat-soluble vitamins and vitamin C, but the leaves and immature seeds of some legumes contain high amounts of carotene, vitamin C, and vitamin E. For example, immature soybean seed is a good source of vitamin C, whereas mature soybean seed contains virtually no vitamin C. (*See* **Vitamins**: Overview.)

Minerals

Legumes are high in iron, with one serving of legume providing around 2 mg of iron. This compares favorably with the iron RDAs of 10 and 15 mg for adult men and premonopausal women, respectively. However, iron bioavailability from legumes is poor, and thus their value as a source of iron is diminished. In contrast, zinc bioavailability from legumes is relatively good at around 25%. Also, many beans are good sources of calcium, providing on average 50 mg of Ca per serving. Calcium bioavailability from soyfoods is essentially equivalent to that from milk, but the balance of calcium to phosphorus is inadequate, since the ratio is 1:2, whereas the ideal is 2:1. Legume seeds contain very low amounts of sodium. (*See* **Minerals – Dietary Importance**.)

Bioactive Phytochemicals

The correlation between diets rich in soybean and reduced incidence of certain types of cancer and cardiovascular disease has led to studies on identifying the responsible substances.

Effects on Heart Disease

Animal studies have shown clearly that soy protein lowers serum cholesterol and triglycerides, but the results in humans have not been consistent. However, a metaanalysis of a number of human studies using strict criteria, concluded that soy protein reduces serum cholesterol and triglycerides. The US FDA approved a health claim that diets low in saturated fat and cholesterol that include 25 g of soy protein may reduce the risk of heart disease. The mechanism of action remains to be elucidated.

Effects on Cancer

A number of soybean compounds are being studied for their anticancer properties. These include phytosterols, phytates, saponins, protease inhibitors, isoflavones, and a recently discovered unique peptide termed lunasin.

Phytic acid may play a role in reducing cancer risk, possibly because of its antioxidant effects. Specifically, it has been suggested that phytic acid may lower the risk of colon cancer and perhaps breast cancer.

Saponins have been shown to have anticancer properties, as suggested by a recent rodent study that a saponin-containing diet inhibited by about two-thirds the development of preneoplastic lesions in the colon. However, given that the human intake of saponins is much less than the experimental amount, it is not clear to what extent these results in rodents are relevant to humans.

Bowman–Birk inhibitor (BBI) is a protease inhibitor found in soybean and many other types of legumes. BBI in the form of BBI concentrate (BBIC) has shown the greatest suppression of carcinogenesis in animal models so far. BBIC is now being tested in human clinical trials. (*See* **Trypsin Inhibitors**.)

Isoflavones, which are found in plants but are especially high in soybean, belong to the class of phytoestrogens. Isoflavones offer potential alternative therapies for a range of hormone-dependent conditions that include cancer, menopausal symptoms, cardiovascular disease, and osteoporosis. Epidemiological evidence and animal experiments strongly suggest beneficial effects of isoflavones on human health. Large-scale human clinical trials are needed to confirm limited but promising pilot studies.

Lunasin is a 43-amino acid peptide with a polyaspartic acid carboxyl end, a cell adhesion motif (-RGD- or arg–gly–asp), and a predicted conserved helical region. The peptide was isolated and sequenced 14 years ago, and a few biological effects were proposed, but none was proven until the lunasin gene was isolated. Transfection of the *lunasin* gene into mammalian cells leads to the arrest of cell division, enlargement of the cells, and eventually cell death, resulting in cell lysis and chromosome fragmentation. The expressed lunasin peptide binds preferentially to chromatin. This suggests the use of the *lunasin* gene as a chemotherapeutic agent in conjunction with a specific delivery system that targets cancer cells. While the *lunasin* gene is potentially a chemotherapeutic agent, the lunasin peptide has been shown in *in vitro* experiments using mammalian cells to suppress transformation of normal cells to cancer cells caused by chemical carcinogens and oncogenes. The first *in vivo* experiment using a mouse skin cancer model shows that topical application of lunasin peptide suppresses skin tumorigenesis.

Anti-nutritional Factors

Amylase and Protease Inhibitors

Protease inhibitors from legumes can interfere with protein digestion, leading to growth retardation and, in some species of animals, can cause pancreatic enlargement and enhance chemically induced pancreatic tumors. Two types of trypsin and chymotrypsin inhibitors have been identified in soybean: Kunitz trypsin inhibitor and BBI. Boiling dry beans generally reduces the protease inhibitor content by 80–90%, and there is little reason to think that the amount of trypsin inhibitors obtained by eating commonly consumed beans would exert any adverse effects in humans. (*See* **Plant Antinutritional Factors:** Characteristics.)

Lectins

Lectins, also known as hemagglutinins, are found in many legume seeds. Lectins are toxic to animals by causing lesions in the intestinal mucosa, malabsorption of nutrients, weight loss, and eventually death. Symptoms of lectin toxicity in humans include nausea, vomiting, diarrhea, and abdominal pain. Proper cooking of beans until a soft texture is achieved eliminates lectin toxicity. (*See* **Hemagglutinins (Haemagglutinins)**.)

Goitrogens

Goitrogenic compounds are found in soybean and peanut. Consumption of unheated soybean or peanut can lead to enlargement of the thyroid gland in rat and chicken. Iodine administration and heat treatment are common ways of eliminating goitrogens.

Cyanogenic Glycosides

Cyanide poisoning from lima beans in humans has been reported. However, once lima beans are ground and cooked, the enzymes responsible for the liberation of the cyanogenic compounds are generally denatured.

LIGNIN

M T Holtzapple, Texas A&M University, College Station, TX, USA

Introduction

Lignin is the world's most abundant noncarbohydrate biological material. An estimated 35 000 million tonnes is produced annually, a daily production of about 16 kg per person.

Lignin is derived from the Latin *lignum*, meaning wood. It is an important component of wood and other higher plants, serving as nature's 'glue.' Not only does it hold plant cell walls together, its hydrophobic properties prevent water loss from plant vascular systems. Lignin is highly resistant to enzymatic degradation, so it protects plants from invading insects and microbial attack.

Because lignin is nondigestible, it is an important component of dietary fiber. Lignin resists decay and thus forms a large fraction of soil humus. When subjected to geological forces, lignin and other plant components are transformed into lignite and, ultimately, bituminous and anthracite coals. (*See* **Dietary Fiber:** Properties and Sources.)

Pure lignin does not occur in nature because it always accompanies plant polysaccharides as a composite material called 'lignocellulose.' Lignin removal is required to manufacture paper, so tree lignin – particularly softwood lignin – is well studied. (*See* **Carbohydrates:** Classification and Properties; **Cellulose**; **Hemicelluloses**.)

Structure

Monomers

The three phenylpropylene lignin monomers – *trans*-coniferyl alcohol, *trans*-sinapyl alcohol and *trans-p*-coumaryl alcohol – are shown in Figure 1. The monomers are essentially the same, differing only in the number of methoxyl groups. In softwoods, coniferyl alcohol is the dominant monomer (94% coniferyl, 1% sinapyl, 5% coumaryl alcohols). In hardwoods, both coniferyl and sinapyl alcohols are

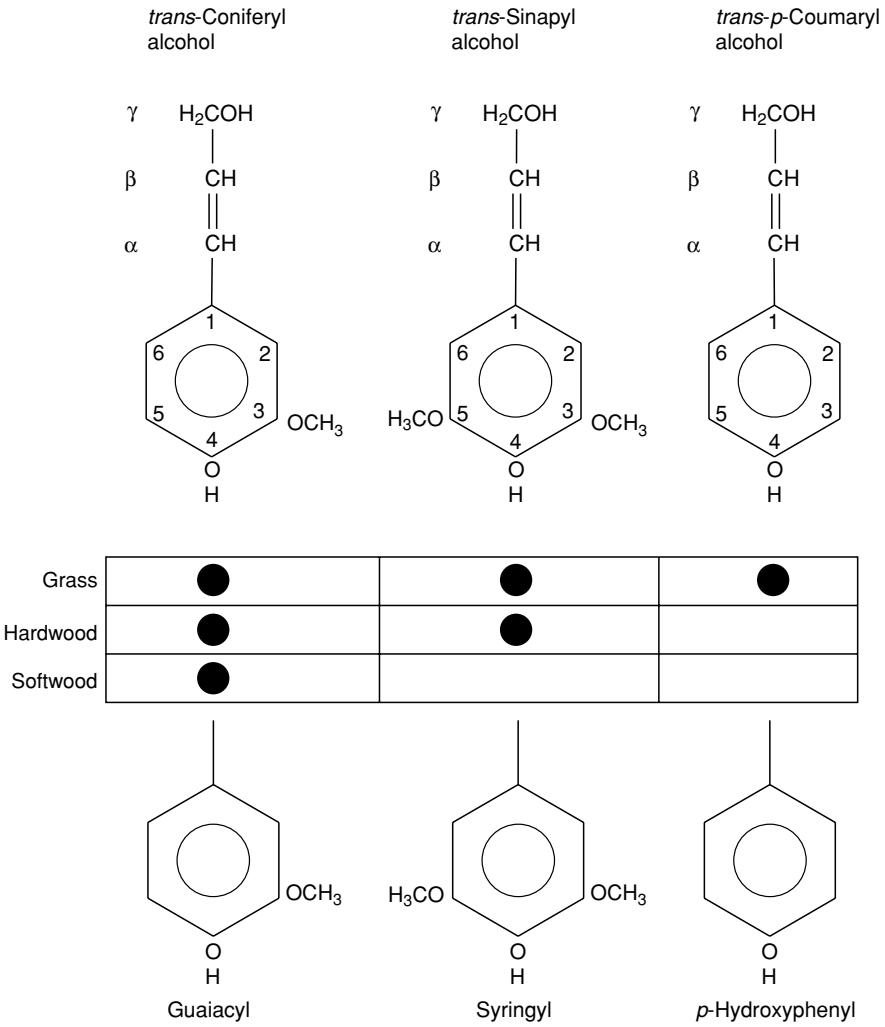

Figure 1 Lignin monomers. Reproduced from Lignin. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

present in significant amounts, whereas grasses have large quantities of all three phenylpropylenes. The guaiacyl, syringyl and *p*-hydroxy-phenyl aromatic groups of the three monomers are also described in Figure 1. The aromatic carbons are numbered 1 through 6, whereas the propylene carbons are lettered α, β, and γ, starting from the phenyl group. Plants produce these phenylpropylene monomers by deaminating tyrosine and phenylalanine, two aromatic amino acids. (*See* **Amino Acids**: Properties and Occurrence.)

Polymer Structure

The phenylpropylene monomers are extremely reactive because they contain two hydroxyl groups and one double bond. Plant enzymes oxidatively dehydrogenate the phenylpropylene, causing it to polymerize randomly into the three-dimensional structure schematically shown in Figure 2. During polymerization, the reactive double bonds are lost, so phenylpropane is the repeating unit. The polymer contains the ether and carbon–carbon linkages shown in Table 1. (Although this structure has been determined for softwood lignin, it is probably representative of other lignins as well.) The β-O-4 ether linkage is the most common, so it is assigned a relative frequency of 1.00, whereas other linkages have a lower relative frequency. Because of the reactive double bond, the α and β carbons are the primary linkage sites between monomers. The γ carbon is rarely linked, except in the circular (or multiple) bonds. About 70% of the phenolic oxygens are involved in ether linkages, whereas the remaining 30% are free. (*See* **Phenolic Compounds**.)

The propane unit contains a variety of functionalities, including hydroxyl groups, ketones, aldehydes, double bonds, and ether linkages. The β carbon is frequently involved in an ether linkage. The adjacent

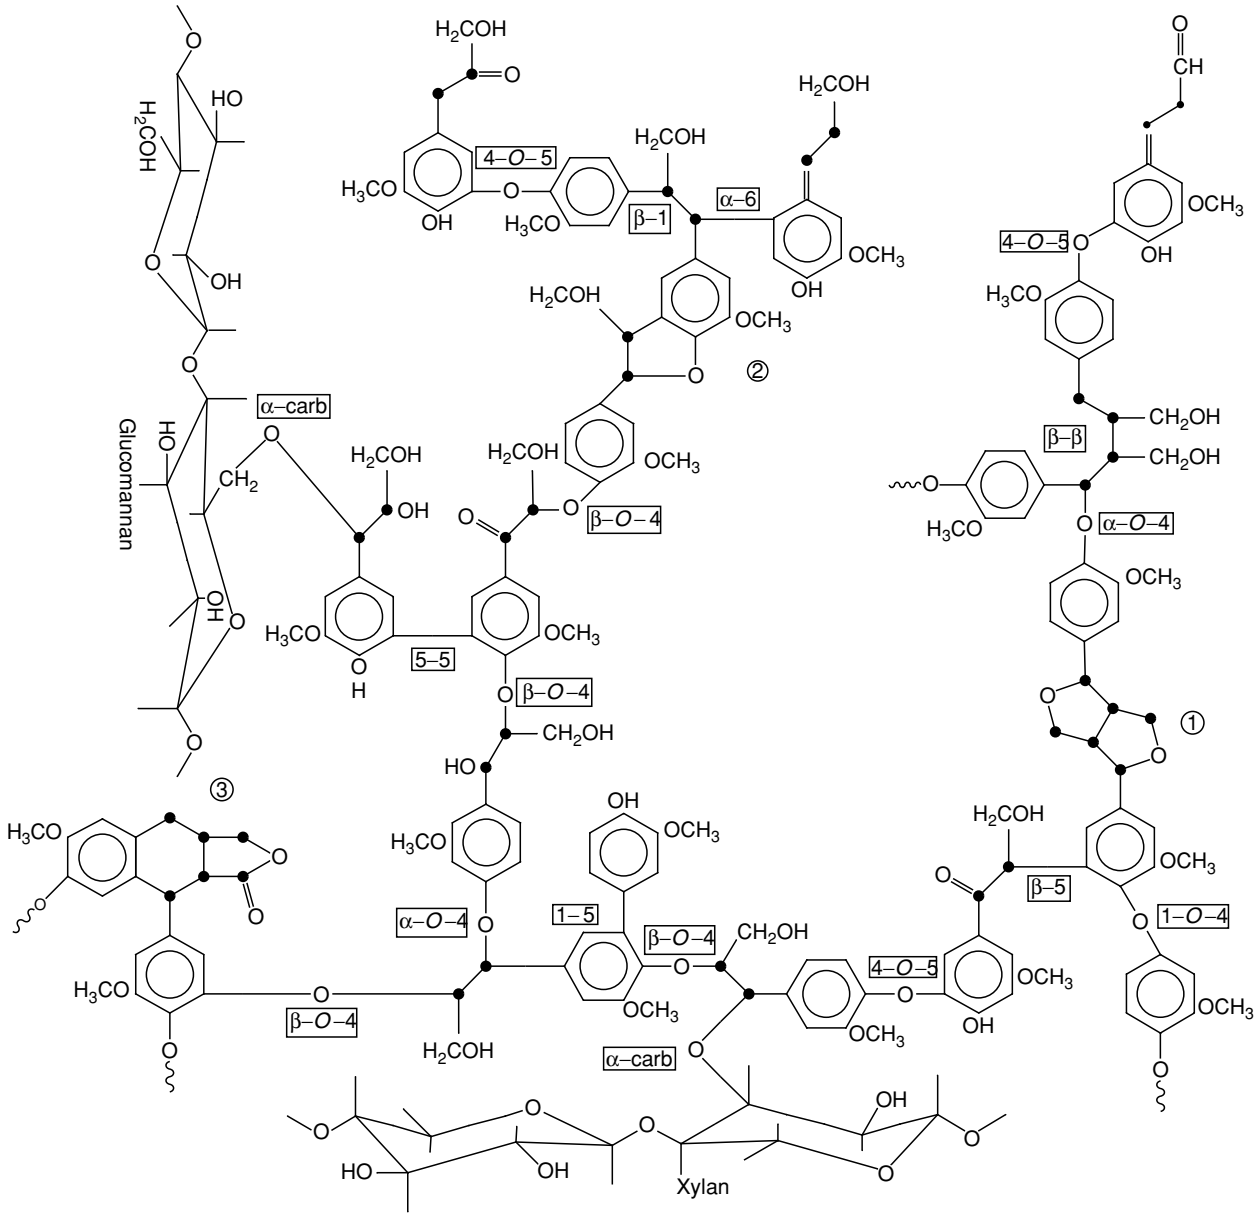

Figure 2 Schematic of softwood lignin structure. Reproduced from Lignin. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Table 1 Lignin bonds

Ether	*Relative frequency*	*Carbon–carbon*	*Relative frequency*	*Circular*	*Relative frequency*
β-O-4	1·00	*β–β*	0·38	① *β–β*, *α-O-γ*, *α-O-γ*	0·29
α-O-4	0·18	*β–1*	0·33	② *α-O-4*, *β–5*	0·22
α-carb	—	*β–5*	0·31	③ α–6, *β–β*, *γ-O-γ*	—
4-*O*-5	—	5–5	*sim*0·27		
1-*O*-4	—	α–6	—		
		1–5	—		

α carbon generally has a hydroxyl group, or another ether linkage. The γ carbon normally retains its hydroxyl functionality, although it is sometimes converted to an aldehyde.

The phenylpropylene monomers not only cross-link with other phenylpropylenes, but also covalently bond to hemicellulose, primarily through the α carbon. The exact nature of the carbohydrate bond

is still being studied. It is thought that carbohydrate linkages infrequently occur as periodic 'spot welds' among the intertwined hemicellulose/lignin matrix.

Softwood lignin has a repeating nine-carbon phenylpropane subunit with an approximate formula of $C_9H_{7.95}O_{2.4}$ $(OCH_3)_{0.92}$ and a molecular weight of about 184. The polymer is believed to have an approximate molecular weight of over 10 000, which corresponds to a degree of polymerization (DP) of 54. It is difficult to know accurately the molecular weight of native lignin because it is impossible to isolate it in an unaltered state.

Hardwood lignin has a repeating nine-carbon phenylpropane subunit with an approximate formula of $C_9H_{7.49}O_{2.53}(OCH_3)_{1.39}$ and a molecular weight of about 200. It has more methoxyl groups than softwood lignin because sinapyl alcohol is a more prevalent monomer in hardwoods. The polymer probably has a molecular weight under 5000 (DP about 25).

Cellular Structure

Plant cell walls are composed of microfibrils deposited in lamellar layers spaced approximately 7–10 nm apart (Figure 3). According to Fengel's model of the microfibril, four 4×4 arrays of elementary fibrils are embedded in a hemicellulose matrix. The elementary fibrils are composed of cellulose which is largely crystalline, except for the paracrystalline edges and amorphous regions interspersed along the length. These rigid cellulose elementary fibrils are primarily responsible for structural load bearing. The hemicellulose is tightly associated with the cellulose, particularly in the paracrystalline and amorphous regions. Hemicellulose is noncrystalline, but is largely oriented in the same direction as the cellulose fibers. The microfibril is encrusted with a lignin layer about 2 nm thick spanned by about two to four phenylpropane units. Although the lignin may be partially oriented, it is mainly amorphous. In effect, the lignin acts as a 'net' holding the fibrous structure together. This net-like form of lignin is dispersed throughout the secondary plant cell wall and accounts for about 20% of its mass.

In mature plant cells, the interstitial space between the cells (i.e., middle lamella) is highly lignified. The lignin layer is about 100 nm thick and forms a completely amorphous three-dimensional array. Although the lignin concentration is very high in the middle lamella, it is very thin and accounts for only about 20% of the total lignin.

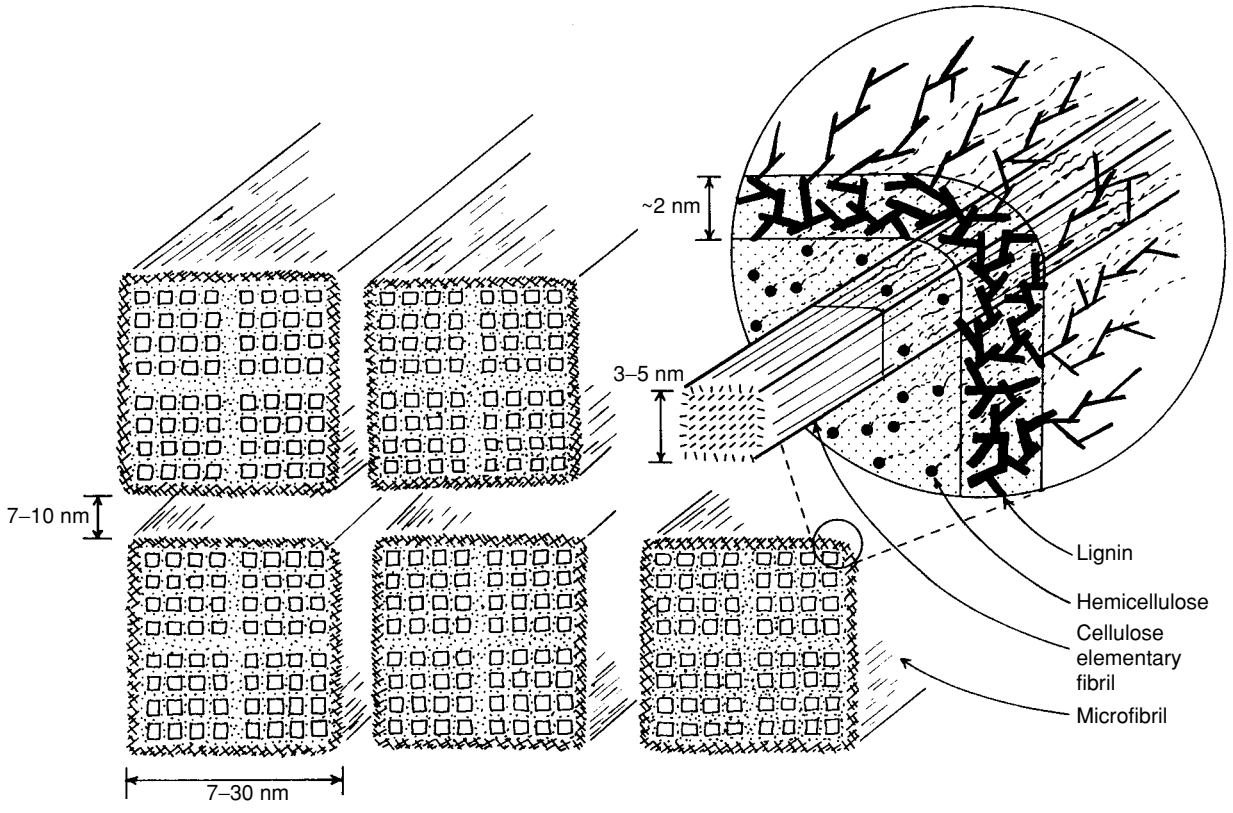

Figure 3 Lignin, cellulose, and hemicellulose composite structure. Reproduced from Lignin. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

The lignification process occurs late in plant cell life after cell growth has ceased. The lignin is first deposited within the primary wall at the cell corners. Then lignification extends along the middle lamella (completely covering the cell exterior) and into the thick secondary wall. In oats, immature plants have a very low lignin content (2% tops, 6% roots) during their first 42 days. Then, they enter a period of rapid lignification for about 20 days in which the lignin content dramatically increases (8% tops, 10% roots). At the end of 112 days, the lignin content reaches its highest level (11% tops, 12% roots).

Properties

Physical

Lignin is a noncrystalline solid with a density of about 1.3–1.4 g cm^{-3} and a refractive index of 1.6. Commercially available lignins, isolated from paper pulp manufacture, are brown powders. The brown color probably comes from degradation reactions because native lignin in some woods is very light in color.

When heated, lignin does not melt, but softens at its glass transition temperature and transforms from a glassy solid to a rubbery plastic. Higher glass transition temperatures (about 193 °C dry; 128 °C moist) occur with high-molecular-weight (85 000) lignin, whereas lower glass transition temperatures (about 127 °C dry; 72 °C moist) occur with low-molecular-weight (4300) lignin. Minor lignin components begin to decompose at about 200 °C, with major decomposition occurring at about 300–400 °C. The heat of combustion is about 29.5 MJ kg^{-1}, which is 67% greater than that of cellulose and hemicellulose. In softwoods, lignin is only about 28% of the mass, but produces approximately 40% of the combustion heat.

No known solvents are capable of dissolving significant amounts of lignin from intact plants as it is so intimately associated with other cell wall components. However, lignin isolated by extensive ball milling is soluble in a number of solvents, including pyridine, acetone, dioxane/water (9:1, v/v), 1,2-dichloroethane/ethanol (2:1, v/v), 50% aqueous sodium thiocyanate, and benzyl alcohol/dimethyl formamide. Lignin which has been subjected to acidic treatment conditions is soluble in aqueous sodium hydroxide.

Chemical

Lignin bonds can be broken by a number of chemical reagents, including acids, bases, halogens, nitrates, oxidants, and reductants.

Acidic conditions are often employed in wood pulping. Even without acid addition, steaming spontaneously generates mild acidic conditions (pH 3.6–4.0), primarily from acetic acid released from hemicellulose acetyl groups. α Ether linkages are more labile than β ether linkages. In acid, not only are bonds broken, allowing the lignin to be solubilized, but new bonds are also formed in undesirable condensation reactions. A classic laboratory method for identifying lignin is to reflux plants with ethanol/hydrochloric acid and assay for the degradation products known as 'Hibbert's ketones.'

Basic conditions are also employed in some pulping reactions. Ether linkages are broken with the simultaneous formation of phenolic hydroxyl groups. In addition, new bonds are again formed in undesirable condensation reactions. Lignin methoxyl groups generally resist alkaline cleavage at temperatures below 200 °C.

Oxidation of lignin readily occurs using peracetic acid, chlorine, nitric acid, chlorine dioxide, sodium hypochlorite, sodium chlorite, hydrogen peroxide, and ozone. These oxidants selectively attack lignin (primarily the aromatic ring) while leaving carbohydrates largely unaffected. Thus, they are useful as bleaching agents in the production of high-quality pulp, or in the laboratory preparation of holocellulose (i.e., cellulose + hemicellulose). Hypochlorite oxidation is thought to be initiated at a free phenolic hydroxyl group and adjacent molecules are then attacked in a 'peeling' reaction analogous to alkaline degradation of cellulose and hemicellulose. Biological enzymatic cleavage of lignin occurs by oxidation. Irradiation at short wavelengths (< 385 nm) photooxidizes lignin, resulting in darkening, a phenomenon readily exhibited when a newspaper is left in the sun.

Reduction of lignin occurs with hydrogen gas using Raney nickel catalyst in a mildly acidic or basic aqueous solvent at 160–170 °C. The product is 'hydrol lignin,' a mixture of low-molecular-weight lignin fragments. The yield of hydrol lignin is higher under alkaline conditions.

Occurrence

The lignin content in vegetables and fruits is low (generally < 5%), in agricultural residues it is medium (7–13%), in hardwoods it is high (16–24%), and in softwood it is extremely high (26–30%). 'Compression wood' (i.e., from the underside of a horizontal branch) is higher in lignin, whereas 'tension wood' (i.e., from the topside) is lower in lignin.

Chemical Pulping

Chemical pulping removes lignin from lignocellulose. The resulting cellulose fibers may be used for paper production, or 'chemical cellulose' for manufacturing

cellulose derivatives such as carboxymethyl cellulose. Pulping conditions tend to be so harsh that hemicellulose is hydrolyzed and removed from the fiber. Softwoods are generally preferred for paper manufacturing because of their long fibers, but hardwoods and agricultural residues (e.g., bagasse) may also be pulped. Pulping necessarily requires that the lignin be cleaved into smaller fragments which may be washed away from the fiber. Because lignin is insoluble in water it must be converted into water-soluble derivatives. Advanced organosolv pulping uses an organic solvent in which the lignin is soluble. Pulping is unable to remove all lignin, so high-quality pulp is subsequently bleached with oxidants to remove residual lignin and color. The two major chemical pulping technologies are the kraft and sulfite processes, with kraft dominating about 96% of the market.

Kraft pulping is an alkaline process wherein lignin is removed by the action of sodium hydroxide and sodium sulfide. The pulping digester operates at about 175 °C for 2–5 h. Kraft pulping has replaced the older soda process, in which sodium hydroxide was the primary pulping chemical. The addition of sodium sulfide in kraft pulping promotes ether cleavage and inhibits undesirable condensation reactions. The simplified chemistry can be represented as shown in eqn (1).

$$R_{lig}-O-R_{lig} + H_2O \xrightarrow[NaOH/Na_2S]{} 2\ R_{lig}-OH$$

$$R_{lig}-OH + NaOH \longrightarrow \underset{\text{Sodium lignate}}{R_{lig}-O^- Na^+} + H_2O \qquad (1)$$

Some sulfur is also incorporated into the sodium lignate. The number-average molecular weight is about 1600 (DP about 8) for softwood sodium lignates and 1050 (DP about 5) for hardwood sodium lignate. The solubilized sodium lignate and spent chemicals are present in aqueous solution as 'black liquor.' The black liquor is concentrated and burned to regenerate the pulping chemicals. Because unrecovered sodium and sulfur are replenished by adding sodium sulfate, the process is often called 'sulfate pulping.' Sulfate is not the active pulping chemical, however, because organic carbon reduces it to sodium sulfide when the black liquor is burned. The kraft process produces high yields of strong fibers, hence the name 'kraft,' meaning strong in German.

Sulfite pulping is an acidic process that produces lower yields than the kraft process, and the fibers are also weaker. Its advantage is that a greater percentage of lignin is removed, making the resulting fibers more suitable for high-quality paper and 'chemical cellulose.' The wood is treated with magnesium bisulfite and excess sulfur dioxide for 6–12 h at about 175 °C. The simplified chemistry can be represented as shown in eqn (2).

$$R_{lig}-O-R_{lig} + Mg(HSO_3)_2 \longrightarrow \underset{\text{Magnesium lignosulfonate}}{2\ R_{lig}SO_3^-\ Mg^{2+}} + H_2O \qquad (2)$$

The magnesium lignosulfonate number-average molecular weight is typically 10 000–40 000 (DP 45–180), although some fractions may be as high as 22 000 000 (DP 100 000). The magnesium lignosulfonate and spent chemicals are dissolved in an aqueous 'weak red liquor' which contains about 2–3% sugar from the degraded hemicellulose. These sugars may be fed to *Candida utilis* (also known as *Torulopsis utilis*) to make single-cell protein. The spent liquor is concentrated and burned to produce magnesium oxide and sulfur dioxide, which are reacted together to remake magnesium bisulfite.

Organosolv pulping heats lignocellulose with water/solvent/catalyst for about 2 h. Many solvents have been tried, including mono- and polyalcohols, aldehydes, ketones, thio compounds, organic acids and bases, and dimethyl sulfoxide. Triethylene glycol is a superior solvent, but its high boiling point (190 °C) makes it difficult to recover. Phenol and butanol are excellent solvents, but ethanol is preferred because of its low cost and low toxicity. Various catalysts have been employed, including hydrochloric acid, sulfuric acid, ferric chloride, ammonia, aluminum salts, and urea. If the temperature is raised above 180 °C, self-generated acids serve as a catalyst. The simplified reaction shown in eqn (3) occurs.

$$R_{lig}-O-R_{lig} + C_2H_5OH \xrightarrow{\text{Catalyst}} R_{lig}=O + HO + R_{lig} + R_{lig}-O-C_2H_5 \qquad (3)$$

Note that some ethanol solvent is incorporated into the solubilized lignin. Double-bonded carbons have also been detected in the propane side chain. The organosolv lignin number-average molecular weight is about 1000 (DP about 5). Of the three pulping technologies, the organosolv process produces lignins most similar to native lignin. Organosolv pulping has been practiced on an industrial scale in Canada.

Uses

In the USA, less than about 2% of the lignin produced by pulping is used for nonfuel applications. Thus, it represents an enormous, underutilized resource. Over 3700 literature references (mostly patents) have explored potential uses, as described in Table 2. The

applications most relevant to food technology are binding agents in animal feed pellets and vanillin production.

Vanillin is one of the most popular food flavors. It is found throughout the plant world, but generally in low concentrations. The orchid vanilla bean has an unusually high concentration (< 5%) and serves as a natural source. Vanillin can also be manufactured from lignosulfonate by alkaline hydrolysis or oxidation. The yields are low (< 10%), so other uses must be found for the unconverted lignin. (*See* **Flavor (Flavour) Compounds**: Production Methods.)

Dietary fiber contains lignin because it is very nondigestible. Lignin adsorbs bile salts and reduces their intestinal uptake, thus possibly lowering blood cholesterol levels.

Lignin Isolation

Milled wood lignin is isolated from plants by breaking the lignin–carbohydrate complex through extensive ball milling or vibratory milling for 2–28 days. The lignin is extracted by dioxane/water (9:1, v/v) with subsequent purifications in solvents. Approximately half the lignin can be isolated by this process. Its properties are very similar to native lignin.

Enzyme lignin is prepared by ball milling the sample for 5–8 h to expose the carbohydrates to enzymatic attack by extracellular enzyme preparations, such as cellulase/hemicellulase isolated from *Trichoderma reesei*. The residue consists primarily of lignin with some unreacted carbohydrates, which can be removed with further ball milling and water extraction. Because the enzymes selectively dissolve polysaccharides, the lignin is similar to native lignin.

Brauns lignin is prepared by extracting finely ground plants with 95% ethanol followed by subsequent solvent purification steps. The chemistry of Brauns lignin is very similar to that of native lignin; however, the molecular weight is lower (generally < 1000). Less than 10% of plant lignin can be isolated by this technique.

Enzymatically liberated lignin results when pure cultures of brown rot fungi selectively digest plant carbohydrates, leaving residual lignin that may be subsequently extracted with 95% ethanol. It is similar to Brauns lignin, but the yields are substantially higher.

Klason lignin is produced when plant matter is contacted with 72% sulfuric acid to dissolve polysaccharides. The residue contains most of the original lignin, so this procedure is often used to quantify lignin. However, the lignin has been highly modified by condensation reactions, making it unsuitable for studying lignin chemistry.

Lignin Analysis

Gravimetric Methods

Two approaches to gravimetric lignin measurement are taken: (1) the polysaccharides are removed and the residual lignin weighed, or (2) the lignin is removed and the residual polysaccharides weighed.

The first approach is used when preparing Klason lignin. Raw plant matter or acid detergent fiber (ADF) is soaked in 72% sulfuric acid, which hydrolyzes the polysaccharides. The residue is primarily lignin which is then filtered, dried, and weighed. Details may be found in the Technical Association of the Pulp and Paper Institute (TAPPI) methods T13 or T222, or the American Society for Testing and Materials (ASTM) method D1106. Approximately 0.2–0.5% of softwood lignin and 3–5% of hardwood lignin is soluble in concentrated acid, so this method (and all other methods) does not indicate 'true' lignin content.

The second approach uses either potassium permanganate or acidified triethylene glycol to remove lignin from ADF or uses chlorine compounds to prepare hollocellulose.

The most popular approaches for determining lignin content are the Klason and permanganate methods mentioned above. These two methods were compared using 75 different materials with lignin contents ranging from 1 to 50%. Although the two measurements were well correlated, the Klason lignin was about 19% less than the permanganate lignin. Sample handling can also affect the measured lignin content because heating may produce 'artifact lignin' by promoting Maillard reactions with proteins and sugars. Thus, it is difficult to measure the 'true' lignin content, so researchers must be satisfied with an operational definition of lignin. Some feel that the permanganate assay is the most accurate. (*See* **Browning:** Nonenzymatic.)

Lignin Indices

Some assays for lignin measurement do not give the lignin content directly, but use arbitrary measures which correlate with lignin. Examples are the κ number (TAPPI standard T236), which measures potassium permanganate depletion, the chlorine number (TAPPI standard T202), which measures chlorine depletion, and the methanol number which measures lignin methoxyl groups.

LIPOPROTEINS

J M Ordovas, Tufts University, Boston, MA, USA

Physiology

In the USA, cardiovascular diseases (CVD) affect about 62 million people. In 1999, almost one million subjects in the USA died as a consequence of CVD, which represents 1 of every 2.5 deaths, placing CVD as the major cause of morbidity and mortality. This is also becoming true at the global level, especially with the recent westernization of lifestyles in developing countries, which has dramatically increased the prevalence of CVD risk factors in those populations. Multiple risk factors and biochemical pathways have been identified with the progression of these diseases. These include tobacco smoke, dyslipidemias, physical inactivity, overweight and obesity, diabetes mellitus, and genetic factors. Several of these risk factors can be ameliorated by adequate nutritional behavior. In this article we concentrate on the physiology of plasma lipoproteins and the impact of nutritional factors on homeostasis and on the prevention of dyslipidemias and of CVD.

Lipids (cholesterol, triacylglycerols, and phospholipids) are transported in blood as part of lipoprotein particles. Lipoproteins are generally spherical particles, with a shell composed of unsterified cholesterol and phospholipid with the fatty acids oriented toward the core of the particle. Included in this shell are specific proteins known as apolipoproteins. The core of the lipoprotein particles is made up of cholesteryl ester and triacylglycerol molecules.

The nomenclature and classification of serum lipoproteins were originally determined by the laboratory technique used for their separation or isolation. These included mainly electrophoretic, ultracentrifuge, and immunological techniques. Accordingly, lipoproteins have been classified based on their electrophoretic mobility, hydrated density, and apolipoprotein composition (Table 1). Here, we present a description of the different lipoprotein particles, their metabolism, and the consequences of the alterations of their homeostasis.

Classification of Lipoproteins

Classification of Serum Lipoproteins According to their Electrophoretic Mobilities

With the development of techniques to separate proteins according to their electrophoretic characteristics, it was shown that most of the lipid present in serum was associated with proteins migrating with α_1- and β-globulin mobilities. This resulted in the first classification of lipoproteins according to their colocalization with other plasma proteins as α_1- and β-lipoproteins. Development of more advanced electrophoretic techniques resulted in further discrimination among the lipoprotein classes into β-, pre-β- and α-lipoproteins. Careful observation of thousands of electropherograms from normal and dyslipidemic subjects provided the basis for the first structured

Table 1 Classification and characteristics of human plasma lipoproteins

Lipoprotein	*Diameter (nm)*	*Density (g ml^{-1})*	*Electrophoretic mobility*	*Major lipids*	*Major apolipoproteins*
Chylomicrons	80–500	< 0.95	Origin	Dietary triacylglycerols and cholesteryl esters	ApoA-I, ApoA-IV, ApoB-48, ApoC-I, ApoC-II, ApoC-III, ApoE
Quilomicron remnants	> 30	< 1.006	Origin	Dietary cholesteryl esters and triacylglycerols	ApoB-48, ApoE, ApoC-III
VLDL	30–80	< 1.006	Pre-beta	Endogenous triacylglycerols	ApoB-100, ApoC-I, ApoC-II, ApoC-III, ApoE
IDL	25–35	1.006–1.019	Pre-beta and beta	Endogenous cholesteryl ester and triacylglycerosls	ApoB-100, ApoE
LDL	18–28	1.019–1.063	Beta	Cholesteryl esters	ApoB-100
Lp(a)				Cholesteryl esters	Apo(a), ApoB-100
HDL2	9–12	1.063–1.125	Alpha	Cholesteryl esters, phospholipids	ApoA-I, ApoA-II
HDL3	5–9	1.125–1.210	Alpha	Cholesteryl esters, phospholipids	ApoA-I, ApoA-II

classification of lipoprotein disorders, which is known as Fredrickson classification (Table 2). This classification played a pivotal role in the clinical aspects of lipoprotein metabolism, genetics, and coronary heart disease (CHD). Recently, a more functional approach to the classification of familial lipoprotein disorders has been made possible thanks to the advances in the elucidation of the specific gene loci responsible for some of these disorders.

Several electrophoresis media have been used for the separation of plasma lipoproteins. These include liquid, paper, cellulose acetate, agarose, and polyacrylamide. These techniques were used well into the 1980s by scientists and clinicians as a relatively quick tool for the assessment of lipoprotein patterns and dyslipidemias. These techniques, especially agarose gel electrophoresis, were used for identifying the presence of what is know as a broad beta band in the diagnosis of type III hyperlipidemia, a rare genetic disorder resulting from the presence of specific mutant forms of apolipoprotein E, primarily Apo E2.

Although, the classification of lipoproteins based on their electrophoretic behavior has been relegated to a historical value, the use of electrophoresis as a separating tool with potential clinical applications has seen a rebirth in recent years resulting from the realization that specific lipoprotein subclasses may be more informative in terms of CHD risk prediction than the traditional plasma lipid measures. At this regard, gradient agarose-polyacrylamide gel electrophoresis under nondenaturing conditions has been an essential tool to analyze the heterogeneity of low-density- (LDL) and high-density lipoprotein (HDL) subclasses. LDL subclasses can be resolved by nondenaturing polyacrylamide gradient gel (2–16%) in up to seven LDL subfractions with densities ranging from 1.020 to 1.063 g ml^{-1} and diameters ranging from 22.0 to 28.5 nm. The individual profiles usually show a major subclass and several minor ones (one to four). A predominance of smaller, denser LDL, versus larger, more buoyant LDL particles in plasma has been associated with increased CHD risk. The presence of specific subclasses in serum is determined by a combination of genetic and nongenetic factors, including age, gender, and diet. A significant correlation has been demonstrated between high triglyceride concentrations and the presence of small LDL subclasses. HDL subclasses have been resolved using similar techniques, with a polyacrylamide gradient ranging from 4 to 30%, into five subclasses (HDL3c, HDL3b, HDL3a, HDL2a, and HDL2b). Improved electrophoresis techniques have allowed the resolution of up to 14 HDL subclasses. The clinical significance of these subfractions needs further clarification. However, the current notion is that the presence of large HDL particles appears to be associated with protection, whereas small HDL particles are either neutral or even atherogenic.

Classification of Serum Lipoproteins According to their Ultracentrifugal Characteristics

The presence of lipids within the lipoprotein particles confers these macromolecular complexes with a lower density compared with other serum proteins. The development of ultracentrifugation in the 1940s allowed their separation from the other proteins based on this flotation property. Initially separated just a single discrete peak, it was not long before it was possible to separate a wide spectrum of particle sizes and densities (d) ranging from 0.92 to 1.21 g ml^{-1}.

Lipoproteins were classically separated into four major subclasses designated as chylomicrons (exogenous triacyglycerol-rich particles of $d < 0.94$ g ml^{-1}), very-low-density lipoproteins (VLDL, endogenous triacylglycerol-rich particles of $d = 0.94$–1.006 g ml^{-1}), LDL (cholesteryl ester-enriched particles of $d = 1.006$–1.063 g ml^{-1}), and HDL particles containing approximately 50% protein of

$d = 1.063–1.21\ g\ ml^{-1}$) (Table 1). Continued improvement of ultracentrifugation equipment and techniques permitted the resolution of these major families into several density subclasses such as HDL2a ($d = 1.10–1.125\ g\ ml^{-1}$), HDL2b ($d = 1.063–1.10\ g\ ml^{-1}$), and HDL3 ($d = 1.125–1.21\ g\ ml^{-1}$) and several LDL and VLDL subfractions.

Ultracentrifugation has been essential for the development of this field; however, this technique is very labor-intensive, thus seriously limiting its clinical and epidemiological applications. Moreover, lipoproteins are subjected during long periods of time to a harsh environment consisting both of high salt concentration and **g** forces. These problems have been mitigated by the development of small vertical and near-vertical rotors, which allow shorter runs, while achieving similar separations.

Classification of Serum Lipoproteins According to their Apolipoprotein Content

The characterization of plasma apolipoproteins (Tables 1 and 3) and the elucidation of their physiological function reinforced the notion that the measurement of the apolipoproteins rather than the lipids in lipoprotein fractions could provide more precise biochemical prediction of CHD risk. However, so far, apolipoprotein measurement has not provided a clear practical advantage over the measurement of more classical risk factors (total cholesterol (TC), HDL cholesterol (HDL-C), and LDL cholesterol (LDL-C)). However, this concept gave a thrust to the development of methods of separation based on apolipoprotein composition, namely those based on immunoaffinity chromatography. By using columns containing antibodies against specific apolipoproteins, several VLDL and HDL subpopulations can be resolved. More effort has been placed on the characterization of the HDL subfractions.

Lipoproteins containing apoA-I can be separated into two major species: those containing both apoA-I and apoA-II, known as LpAI:AII, and those containing apoA-I but not apoA-II (LpAI). It has been hypothesized that the protective role of HDL for CHD is relegated to the LpAI particles, whereas the LpAI:AII fraction may not be protective and could even be atherogenic. Likewise, lipoproteins containing apoB consist of four lipoprotein families. Lipoproteins containing apoB only (LpB) are cholesteryl ester-rich and are found primarily within the LDL density range. Particles containing both apoB and apoC (LpB:C), apoB and apoE (LpB:E), and all three apolipoprotein groups (LpB:E:C) are tryacylglycerol-rich lipoproteins (TRL) and are found within the VLDL and IDL density range.

The power of affinity chromatography has been utilized to separate another lipoprotein fraction known as lipoprotein(a) (Lp(a)). Lp(a) is a lipoprotein containing apoB100 as well as an antigenically unique apolipoprotein (apo(a)). Its separation from other plasma lipoproteins can be readily accomplished

Table 3 Classification and properties of apolipoproteins

Apolipoprotein	*Amino acids*		*Chromosomal localization*	*Main function*
ApoA-I	243	Liver, intestine	11q23	HDL structure, LCAT activator, ligand for HDL binding, reverse cholesterol transport

HDL, high-density lipoprotein; LCAT, lecithin cholesterol acyl transferase; LPL, lipoprotein lipase; HTGL, hepatic triacylglycerol lipase; TRLs triacylglycerol-rich lipoproteins; CETP, cholesterol ester transfer protein; Lp(a), lipoprotein(a); VLDL, very-low-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein.

using immunoaffinity chromatography or alternatively taking advantage of its specific affinity for lectin. The latter has been used to develop a new technique to measure the concentrations of this atherogenic lipoprotein in clinical laboratories.

Measurement of Lipoprotein Subfractions using Nuclear Magnetic Resonance (NMR) Spectroscopy

More recently, NMR spectroscopy is being used to determine the concentrations of VLDL, LDL, and HDL subfractions. NMR distinguishes among the subfractions on the basis of slight differences in the spectral properties of the lipids carried within the particles, which vary according to the diameter of the phospholipid shell. Each profile displays the concentrations of six VLDL, one IDL, three LDL, and five HDL subclasses and the weighted-average particle size of VLDL, LDL, and HDL. The 10 lipoprotein subclass categories used were the following: large VLDL and remnants (80–220 nm), intermediate VLDL (35–80 nm), small VLDL (27–35 nm), large LDL (21.3–27.0 nm), intermediate LDL (19.8–21.2 nm), small LDL (18.3–19.7 nm), large HDL (8.8–13.0 nm), intermediate HDL (7.8–8.8 nm), and small HDL (7.3–7.7 nm). Levels of VLDL subclasses are expressed in units of triglyceride (mg dl^{-1}), and those of LDL and HDL subclasses in units of cholesterol (mg dl^{-1}). LDL and HDL subclasses distributions determined by gradient gel electrophoresis and NMR have also been shown to be closely correlated. The major advantages of NMR spectroscopy to measure lipoprotein subclasses are the low sample requirements, the speed and high throughput of the technique, and the relatively low cost.

Metabolism of Serum Lipoproteins (Figure 1)

Metabolism of Lipoproteins Carrying Exogenous Lipids

Although most of our knowledge about the relation between plasma lipid concentrations and cardiovascular disease comes from studies in the fasting state, we should keep in mind that, in affluent countries, humans are postprandial animals. Considering that the gastrointestinal system is busy with the processing of an ingested meal for at least 6–8 h and the average person takes three meals per day, the conclusion is that for most of the 24 h of a day the intestine is working. The digestive system works efficiently and dynamically with the dietary fat, with virtually no remains of the ingested fat being excreted. This places the gut as a central organ in lipid metabolism, and

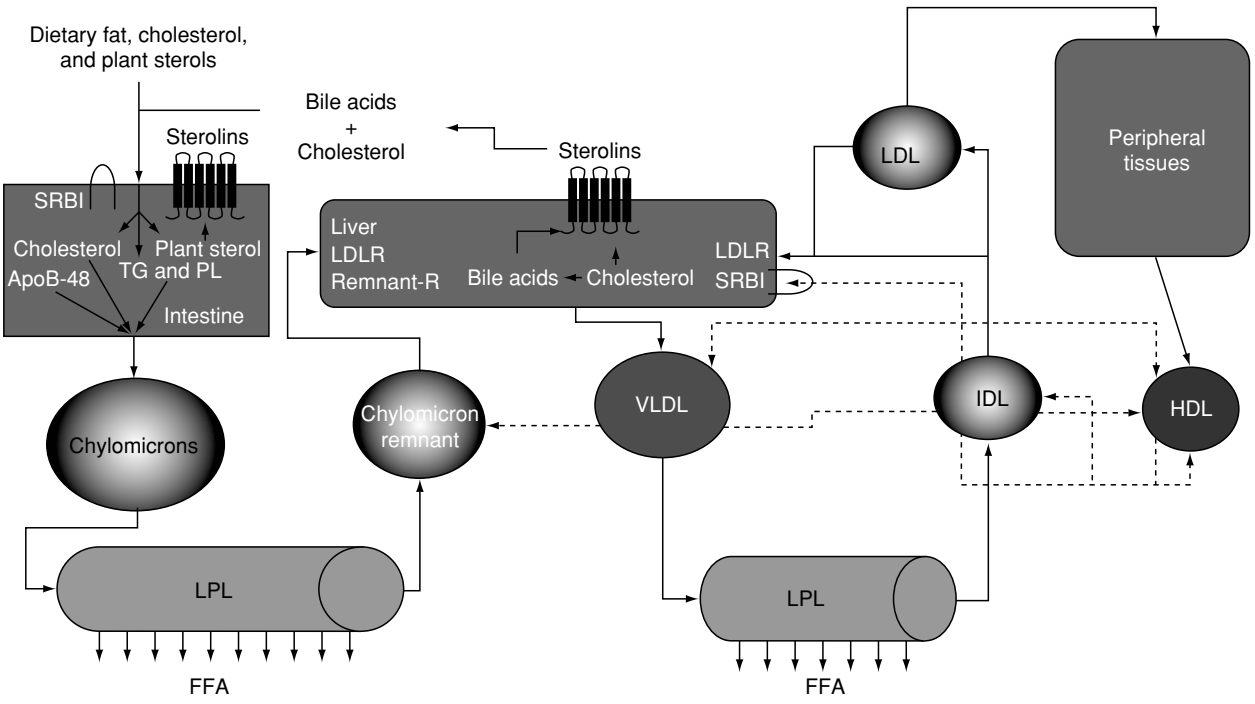

Figure 1 Depiction of the exogenous and endogenous lipoprotein metabolism pathways. underlines the importance of postprandial lipidemia. Postprandial lipid metabolism has received considerable attention since it was shown that postprandial TRL are involved in the development of atherosclerosis. Many studies comparing CHD patients with controls have demonstrated differences in postprandial TG after an oral fat load test and that the postprandial TG concentration is an independent predictor of CHD in multivariate analysis. A delayed clearance of retinyl palmitate (RP), used to study the metabolism of TRL of intestinal origin, discriminates between patients with CHD and controls, even after adjustment for fasting TG or HDL-C in normolipidemic men. The relation of postprandial lipid metabolism to atherosclerosis makes this evaluation a priority in atherosclerosis research. It is no longer possible to ignore its importance and to try to explain the relation between lipids and atherosclerosis exclusively on the basis of the fasting lipid levels. Therefore, it is of paramount importance to gain a better understanding about the mechanisms involved in the metabolism of lipoproteins carrying exogenous (dietary) lipids, primarily triacylglycerols and cholesterol. It is important to emphasize that, whereas the absorption of fat is highly efficient and uniform in most humans, the absorption of cholesterol is highly variable. Therefore, the understanding of this variability could be applied to the generation of new therapeutic targets for the reduction of CHD.

Cholesterol has for decades received a bad press and for most people is just a 'fat' in blood that increases the risk of heart disease. However, cholesterol is essential for the growth and viability of cells in higher organisms. We have about 100 g of cholesterol; of those 100 g, about 7 g is found in the blood circulating as part of lipoproteins, whereas the remaining 93 g is located in the body cells. The physical characteristics of cholesterol, with its insolubility in water and its rigidity, provides cell membranes with their structural integrity and modulates their fluidity, thus maintaining an optimal communication between the cell and its environment, including the transport of nutrients and the proper maintenance of energy resources. Another major use of cholesterol is on the synthesis of bile acids. These are synthesized in the liver from cholesterol and are secreted in the bile. They are essential for the intestinal absorption of fat. Without cholesterol we could not absorb the essential fatty acids and fat-soluble vitamins A, D, E, and K from the food. In lesser amounts, cholesterol is used to synthesize steroid hormones, including the sex hormones estrogen, progesterone, and testosterone as well as the corticosteroids. Cholesterol is also the precursor from which the body synthesizes vitamin D.

Cholesterol homeostasis is crucial for optimal performance of multiple biochemical pathways, and it is maintained by a delicate equilibrium between dietary cholesterol absorption, *de novo* synthesis, and fecal excretion. In terms of the *de novo* synthesis, higher organisms have developed a complex biosynthetic pathway for the synthesis of cholesterol, which has been precisely defined, requiring approximately 30 steps. Conversely, the process of intestinal cholesterol absorption from foods has been an area of controversy. Many believed this to be a process of passive diffusion across the brush-border membrane from the lumen of the gut into the enterocyte. However, evidence exists that points to a highly regulated carrier-mediated process. The scavenger receptor SR-BI and the 'sterolins' have been implicated in this process and various apolipoproteins can affect the rate of cholesterol transfer *in vitro*.

We synthesize approximately 900 mg of cholesterol per day. In addition, we consume on average $\sim$300 mg of cholesterol per day with the diet. Under optimal homeostatic conditions, the same amount (1200 mg day^{-1}) is excreted as fecal sterols. In terms of the intestinal cholesterol absorption, the exogenous cholesterol is hydrolyzed to free cholesterol (FC) by pancreatic lipases secreted into the intestine. Bile acids solubilize dietary and biliary cholesterol in micelles in the proximity of the brush border of enterocytes, where it diffuses through the epithelial membrane to the interior of the cell. Our current knowledge indicates that some of the exogenous cholesterol and most of the plant sterols entering the enterocyte are secreted back to the intestinal lumen via the recently characterized ABC transporter G5 (ABCG5) and ABC transporter G8 (ABCG8), also known as 'sterolins.'

In the smooth endoplasmic reticulum, exogenous cholesterol is converted to cholesteryl ester (CE) by acyl CoA:cholesterol acyltransferase (ACAT), and then used by microsomal triglyceride transfer protein (MTP) to synthesize chylomicrons. These chylomicrons are pumped through the thoracic lymph duct into the blood, where lipoprotein lipase (LPL) hydrolyzes them into chylomicron remnants.

Chylomicrons and their remnants are heterogeneous particles that vary in size, composition, and metabolism. They transport dietary lipids and are considered 'exogenous' lipoproteins, in contrast to 'endogenous' VLDL. Chylomicrons are synthesized continuously, and may increase in size and cholesterol content when dietary fat and cholesterol increase. They have a higher turnover rate than that of LDL particles and may contribute more cholesterol to tissues in a 24-h period. Most chylomicron remnants are rapidly catabolized in the liver after their uptake

by specific receptors. In addition, large chylomicron particles may be metabolized to small remnants (45 nm) that are similar in size to atherogenic LDL remnants and may readily penetrate arterial cells via transcytotic vesicles. Data from animal and human studies strongly support the concept that chylomicron remnants may have a dramatic impact on the risk of atherosclerosis and CHD.

There has been a long and heated debate surrounding the use of low-fat, high-carbohydrate diets as the preferred recommendation to lower CVD risk in the general population. On one hand, these diets have been shown to lower plasma TC and LDL-C; however, on the other hand, in populations leading a westernized lifestyle, these carbohydrate-rich diets can simultaneously raise the levels of the (also atherogenic), TRL and lower HDL-C concentrations. This leads to the concern that, at least in some individuals, the beneficial LDL-lowering effect may be offset by adverse changes in other circulating lipoprotein fractions. This concept is specially relevant following the demonstration of a significant correlation between TG levels and the presence of the highly atherogenic small dense LDL subfraction.

Endogenous Lipoprotein Metabolism

Liver cells can metabolize CE into bile acids or directly secrete it into the bile. Bile acids aid in the formation of micelles, and the secreted cholesterol is excreted via the feces. Hepatic cells also synthesize endogenous cholesterol and release VLDL and LDL-C into the circulation. These molecules are delivered to peripheral organs for either utilization or storage. Therefore, the liver is involved in both the uptake of newly synthesized cholesterol and the export of the metabolized sterol into the feces through either bile acid or neutral sterol formation. Consequently, the liver must respond to variations that occur in both input and output pathways.

Lowering LDL-C by reducing the intake of saturated fat is one of the cornerstones of the current dietary recommendations to reduce CHD risk. In most cases the reduction in saturated fat is accompanied by a parallel reduction in total fat intake. The reduction of LDL-C following a reduction in saturated fat appears to be mediated by increases in LDL receptor activity, resulting in enhanced liver LDL clearance. However, the downside of these recommendations, as previously indicated, lays in the effects on triglyceride levels and possibly on LDL subfractions.

Two major LDL subclasses have been defined: type A and type B. Type A is larger, more buoyant and apparently less atherogenic. Conversely, type B is defined as those particles that are smaller, denser, and more atherogenic. In view of these qualitative differences in CHD risk, it is very important to examine the diet-induced changes on each of those subfractions. The current data support the notion that in asymptomatic subjects carrying the pattern B phenotype, switching from a high-fat to a low-fat diet results in significant LDL-C reduction, which is larger than for those subjects carrying the pattern A phenotype. Moreover, as expected, the LDL-C reduction is primarily due to lowering of the small LDL class and this should result in significant CHD risk reduction. Conversely, in asymptomatic subjects carrying the pattern A phenotype, a change from a high-fat to a low-fat diet results in a shift from buoyant to denser LDL, with very small changes in particle numbers. This shift may not be associated with a reduction in CHD risk and may even increase the atherogenic risk.

Reverse Cholesterol Transport

The recent characterization of SRBI as an HDL receptor and the identification of ABCA1 as the membrane transporter that mediates the efflux of cholesterol from the cells have pushed forward our understanding of HDL metabolism and reverse cholesterol transport.

HDL is synthesized by both the liver and the intestine. Its precursor form is discoidal in shape and matures in circulation as it picks up unesterified cholesterol, and probably phospholipids, from cell membranes by a mechanism mediated by the ABCA1 transporter. Moreover, HDL can also obtain lipids and apolipoproteins from TRL as these particles undergo lipolysis. The cholesterol is esterified by the action of the lecithin cholesterol acyltransferase (LCAT) and the small HDL3 particle becomes a larger HDL2 particle. The esterified cholesterol is either delivered to the liver or to organs synthesizing steroid hormones, such as the adrenals, via SRBI or other receptor-independent mechanisms, or transferred by the action of cholesteryl ester transfer protein (CETP) to other lipoproteins (such as chylomicron, VLDL remnants, or LDL), in exchange for triacylglycerols. This cholesterol may then be taken up by the liver via receptors specific for these lipoproteins (LDLR, VLDLR, remnant receptor), or it can be delivered again to the peripheral tissues. The triacylglycerol received by HDL2 is hydrolyzed by hepatic lipase and the particle is converted back to HDL3, completing the HDL cycle in plasma. In the liver, cholesterol can be excreted directly into bile, converted to bile acids, or reutilized in lipoprotein production.

Diets high in simple carbohydrates reduce HDL cholesterol concentrations. This effect appears to be mediated by increases in the catabolism of apoA-I; however, it has also been proposed that decreases in apoA-I production contribute to this effect.

Disorders of Lipoprotein Metabolism

Many of the major advances in our knowledge of lipoprotein metabolism and physiology have been driven by the study of abnormalities. As indicated above, familial lipoprotein disorders were first classified according to their different electrophoretic profile. This classification was successfully used for decades; however, it had shortcomings. One of them was that it included under the same denomination diseases with different molecular basis. Another one was that some important phenotypes (i.e., familial hypoalphalipoproteinemia) were not part of the original classification. The elucidation of the molecular mechanisms responsible for several of these syndromes has allowed a more functional classification, based on the genetic loci influencing the phenotypes. Below, a brief summary of the most common or relevant familial lipoprotein disorders is presented.

Familial Hypercholesterolemia

Familial hypercholesterolemia (FH), also known as FHC, and according to the original Fredrickson classification as hyperlipoproteinemia type IIa, is an autosomal dominant disorder characterized by dramatic elevations of plasma LDL cholesterol concentrations. The locus responsible for this disorder is the low-density lipoprotein receptor (LDLR) in chromosome 19. The LDLR gene family consists of cell surface proteins involved in receptor-mediated endocytosis of specific ligands. LDL is normally bound at the cell membrane and taken into the cell, ending up in lysosomes where the protein is degraded and the cholesterol is made available for repression of microsomal enzyme 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase, the rate-limiting step in cholesterol synthesis. At the same time, a reciprocal stimulation of cholesterol ester synthesis takes place. Hundreds of mutations have been identified at the LDLR locus, resulting in the FH phenotype. The global frequency of FH is about 1 in 500 in the heterozygous state and 1 in a million in the homozygous state. However, this varies considerably and there are places like the province of Quebec where the frequency of FH is much higher.

The ranges of LDL-C concentrations in the plasma of heterozygous FH are 200–400 mg dl^{-1}, whereas in homozygotes the LDL-C concentrations range between 400 and 1000 mg dl^{-1}. The clinical characteristics observed in heterozygotes include tendinous xanthomas, corneal arcus, and CHD in the 40s and 50s. In homozygotes, there is also the presence of planar xanthomas and the clinical manifestation of the disease is more premature.

Inhibitors of HMG CoA, a key enzyme in the synthesis of cholesterol, are the drugs of choice in the treatment of heterozygotes FH. Most pharmacological therapies are ineffective in the homozygous state. These subjects may be treated with LDL apheresis, liver transplant, and, based on some preliminary results, in the future, these subjects could be excellent candidates for gene therapy. Diet and lifestyle modification are also recommended and in some cases may be highly effective. This is supported by the fact that the phenotypic expression of some of the LDLR mutations is not expressed in populations living a traditional, healthy lifestyle, but it is expressed in those subjects living in societies with a more westernized lifestyle. The impact of modernization on the clinical expression of the disease has also been demonstrated by studying mortality during the last 200 years in a large pedigree with a well-characterized LDLR abnormality. In these subjects the presence of the mutation did not manifest as premature death until the middle of the twentieth century, suggesting that lifestyle could play a relevant role in the clinical expression of this phenotype. Moreover, we are starting to identify some other genetic factors that can modulate the biochemical and clinical manifestation of the phenotype: gene-by-gene interactions.

There are other forms of hypercholesterolemia that are not due to defects on the LDLR. One of them produces similar biochemical phenotypes and it has been named familial defective apoB-100. This disease is also autosomal dominant. The frequency of this disorder has not been well elucidated and it varies considerably depending on the ethnicity of the population studied, as it appears to have a central European origin. The locus responsible for this phenotype is the apolipoprotein B (Apo B) in chromosome 2 and the specific defect is a point mutation that changes the amino acid 3500 of the mature apoB (ARG3500GLN). It has been shown that the arginine-3500 interacts with tryptophan-4369 in the carboxyl tail and facilitates the conformation of ApoB-100, required for normal receptor binding of LDL. Disruption of this conformation prevents the normal binding of LDL to its receptor, resulting in the observed hypercholesterolemia.

The genetic defects associated with the common forms of hypercholesterolemia present in subjects with cholesterol levels between 250 and 300 mg dl^{-1} have not been elucidated. These are, most probably, due to a combination of predisposing alleles (i.e., the

presence of the E4 allele at the Apo E locus) with environmental factors (i.e., diet, physical inactivity, smoking, obesity). This 'garden variety' of mildly severe hypercholesterolemia is also known as polygenic hypercholesterolemia.

Familial Dysbetalipoproteinemia

This disorder is characterized by simultaneous increases in plasma cholesterol and tryglyceride concentrations. The locus responsible for this familial disorders is the Apo E gene in chromosome 19. The most common genetic defect is the presence of the E2 (arg158-to-cys) allele. Other less common mutations include the E2 (lys146-to-gln), E2 (arg145-to-cys) and E2-Christchurch (arg136-to-ser). In most patients, the complete expression of the clinical phenotype needs additional interactions with age, obesity, and diabetes, as well as other genetic loci. In addition to the accumulation in plasma of VLDL and chylomicron remnants, other clinical features of this disorder are tuboeruptive and, in some cases, planar xanthomas. Therapies include diet and hypolipidemic agents such as fibrates, statins, or nicotinic acid. In most cases, diagnosis can be carried out first by lipoprotein electrophoresis, followed by the molecular elucidation of the Apo E defect.

Familial Combined Hyperlipidemia

Familial combined hyperlipidemia (FCHL) was initially described as the combination of hypercholesterolemia and hypertriglyceridemia within the same kindred, and with kindred members having one of these abnormalities or both. Moreover, most subjects with FCHL have HDL-C concentrations below the 10th percentile. In addition, predominance of small dense LDL particles and elevated apolipoprotein B levels is commonly found in members of FCHL families. This disorder has a frequency of approximately 10% in survivors of premature myocardial infarction (less than 60 years of age) and about 14% in kindred with CHD.

Given the high frequency and the clinical implications of this disorder, there has been an intense search for the molecular and genetic defect(s) responsible for this phenoype. It has been reported that affected subjects have overproduction of ApoB-100, and several chromosomal regions have been associated with this defect, including 2p, 11p, 16q, and 19q, as well as mutations at several candidate genes (LPL, ApoA1-ApoC3-ApoA4). The expression of this disorder may be triggered by other factors such as overweight, hypertension, diabetes, and gout. The treatment should include diet and physical activity and, if necessary, statins or fibrates, depending on the major lipid present in excess.

Another common biochemical syndrome associated with increased CHD risk is familial hyperapobetalipoproteinemia, which has been suggested to be a variant of FCHL. Hyperapobetalipoproteinemia is characterized by ApoB values above the 90th percentile in the absence of other lipid abnormalities. Therefore, there will be an increased number of small, dense LDL particles. The gene(s) responsible for this disease has not been elucidated; however, there is evidence showing the Mendelian inheritance and the etiologic heterogeneity of the hyperapoB phenotype.

Familial Hypoalphalipoproteinemia

Severe HDL deficiency, characterized by HDL-C concentrations $< 10\,\mathrm{mg\,dl^{-1}}$, is rare and may be due to Tangier disease (TD), ApoAI, and LCAT deficiencies. The ApoAI deficiency states are due to rare deletions, rearrangements, or point mutations within the ApoA1 locus. Familial hypoalphalipoproteinemia (FHA) is relatively common and is characterized by HDL-C concentrations below the 10th percentile of normal. These subjects have been reported to have either decreased HDL production or increased HDL ApoAI catabolism. This phenotype is present in about 4% of kindred with premature CHD.

A major recent breakthrough in relation to this phenotype has been the identification of ABC1 as the gene for TD and for some cases of FHA. This finding opens enormous opportunities for the lipoprotein field and for CHD therapy. The metabolic pathways determined by the product of the *ABCA1* gene will contribute to our understanding of reverse cholesterol transport and its regulation by dietary fat and cholesterol. It remains to be elucidated whether common mutations at this locus are associated with altered HDL-C levels in the population. This information will determine the full impact of the *ABCA1* gene in controlling cholesterol efflux and HDL metabolism in the general population, beyond those affected by TD or FHA. This information will be applied to the genetic screening of subjects at high risk for CHD and it could provide us with new therapeutic targets, thus increasing our ability to prevent and treat CHD.

Familial Hypertriglyceridemias

Several familial disorders share the phenotype characterized by high TRLs. The initial classification distinguished three distinct categories: type I, IV, and V. The genetic basis has been elucidated only for type I hyperlipidemia, also known as chylomicronemia, familial LPL deficiency, or ApoC-II deficiency. As its name suggests, chylomicronemia is characterized by

greatly elevated concentrations of exogenous triacylglycerols and it is the result of impaired lipolysis of chylomicrons due to a deficiency of LPL of its activator, the ApoC-II. Several genetic mutations at the LPL and *APOC2* genes have been reported. These are autosomal recessive traits. In the heterozygous state, subjects have normal to slightly elevated plasma triglycerides, whereas homozygotes have triacylglycerol levels that may exceed 1000 mg dl^{-1} in the fasting state. The diagnosis of the homozygous state takes place during the first years of life from the presence of recurrent abdominal pain and pancreatitis. Eruptive xanthomas and lipemia retinalis also occur.

The recommended treatment includes a diet low in simple carbohydrates and with a fat content below 20% of total energy. The use of medium-chain triglycerides (MCT) has also been reported to be efficacious. Body weight should be maintained within normal limits and alcohol consumption should be avoided.

Fasting chylomicronemia has not been clearly associated with increased risk for atherosclerosis, but homozygous subjects are at very high risk for pancreatitis. However, there is considerable evidence supporting the atherogenic properties of chylomicron remnants.

Familial type IV and type V hypertriglyceridemias may have some overlapping phenotypes. In type IV or familial endogenous hypertriglyceridemia, triacylglycerol, specifically VLDL concentrations, is increased, even on a regular diet, and HDL is usually decreased. This disorder appears to be autosomal dominant and relatively frequent in populations consuming high-fat diets. The precise molecular defect(s) has not been identified; however, the increase in triacylglycerol is associated with overproduction of triacylglycerol by the liver and often with the subsequent reduced clearance. Precocious atherosclerosis, abnormal glucose tolerance, and atheroeruptive xanthoma may occur. The disorder is undoubtedly heterogeneous and the phenotype is strongly influenced by environmental factors, particularly carbohydrate and ethanol consumption.

Other conditions causing hyperlipoproteinemia IV are uremia, hypopituitarism, contraceptive steroids, and glycogen storage disease I. Diet should be the first step in therapy, followed if necessary by pharmacotherapy using fibrates.

Type V hyperlipidemia is a much rarer disorder associated with increased susceptibility to atherosclerosis. Usually the first signs of this abnormality are abdominal pain or pancreatitis. VLDL concentrations are high and chylomicrons are present in the fasting states. This abnormality has not been linked to any specific molecular defect.

Familial Lipoprotein(a) Excess

Lipoprotein(a) (Lp(a)) is an LDL particle with one molecule of Apo(a) attached to it. Elevated levels of Lp(a) (> 35–40 mg dl^{-1} or 90th percentile) have been associated with premature CHD. This increased risk appears to result from two different mechanisms: cholesterol deposition in the arterial wall and inhibition of fibrinolysis.

Lp(a) concentrations are highly variable; however, they are relatively constant during a person's lifetime. Between 80 and 90% of the variability appears to be of genetic origin, owing, for the most part, to variations at the structural Apo(a) gene locus. Lp(a) concentrations are inversely associated with a size polymorphism of Apo(a). This polymorphism is due to differences in the number of a multiple repeat of a protein domain highly homologous to the kringle 4 domain of plasminogen. Diets and medications used to lower LDL-C do not appear to have a significant effect on Lp(a) concentrations. However, niacin has been reported to decrease Lp(a) concentrations. There is some evidence suggesting that diets high in *trans* fatty acids have a significant raising effect on Lp(a) concentrations, whereas *n*-3 fatty acids and estrogen replacement therapy lower Lp(a) concentrations in the general population and in postmenopausal women, respectively.

Current Guidelines for Dietary Prevention of CHD

The cardiovascular benefit from lowering LDL-C with diet or drug therapies in the general population and in patients with hyperlipidemia or CHD has been shown in many population and clinical studies. In general, dietary therapy includes using diet restricted in total fat, but more specifically saturated fat (< 7% of calories) and cholesterol (< 200 mg day^{-1}) (Table 4). Pharmacological therapies include primarily statins and fibric acid derivatives. Clinical studies have shown that both families of drugs lower CHD and total mortality. However, there is great heterogeneity in the way humans respond to any therapeutic approach, often requiring empirical strategies to find the appropriate diet, behavioral or drug class and dose for each patient. Nutrigenetics and pharmacogenetics provide the experimental basis to understand the current unpredictability in response to diet and drugs as a function of the genetic variability. Some of the evidence for the genetic basis of this phenomenon came from the seminal observations showing differences in drug responses and drug metabolism by subjects from different ethnic groups, suggesting that genetic factors, underlying ethnicity, were responsible for those effects. The formal emergence of pharmacogenetics as a new field of experimental science took

Table 4 Guidelines for the prevention of coronary heart disease

Nutrient	*Recommended intake*	
	American Heart Association recommendations	*International Task Force recommendations*
Saturated fat[a]	Less than 7% of total calories	No more than 7–10% of energy
Polyunsaturated fat	Up to 10% of total calories	No more than 7–8% of energy
Monounsaturated fat	Up to 20% of total calories	No more than 10–15% of energy
Total fat	25–35% of total calories	No more than 30% of energy
Carbohydrate[b]	50–60% of total calories	> 50% of energy
Fiber	20–30 g day^{-1}	More than 25 g dietary fiber per day
Plant stanols/sterols	2 g day^{-1}	
Protein	About 15% of total calories	Less than 300 mg day^{-1}
Cholesterol	Less than 200 mg day^{-1}	
Total calories (energy)[c]	Balance energy intake and expenditure to maintain desirable body weight/prevent weight gain	

[a]*Trans* fatty acids are another low-density lipoprotein-raising fat that should be kept at a low intake.
[b]Carbohydrate should be derived predominantly from foods rich in complex carbohydrates, including grains, especially whole grains, fruits, and vegetables.
[c]Daily energy expenditure should include at least moderate physical activity (contributing approximately 200 kcal day^{-1}).

place during the 1960s and over the past 40 years there has been great progress in understanding the molecular basis of drug action and in elucidating genetic determinants of disease pathogenesis and drug response. More recently, with a better understanding of the human genome and the technical developments in molecular biology as well as in statistics, we are moving towards larger and more complex studies, which may involve multiple genes, gene-by-gene and gene-by-environment interactions. This knowledge should attain the much searched goal of providing each subject at risk with the most effective dietary, behavioral, or pharmacological therapy to reduce the risk of disease.

LIQUEURS

Contents

Composition

M L González-Sanjosé and S Pérez-Magariño,
University of Burgos, Burgos, Spain

Background

Back in the fourth century, ancient alchemists discovered that the medicinal qualities of some of the remedial herbs, spices, fruits, and barks were preserved longer when infused with alcohol.

In the twelfth century, an alchemist located in France wrote of flavored alcohols that had restorative and life-giving powers. He talked of the distillation of wine into 'aqua vitae' and the subsequent flavoring of these spirits with various herbs and spices. It was believed that these beverages were vital and life-restoring. At first, they were used only as alchemy potions but later, around the fourteenth century, were used as a pleasurable drink in the court of 'Catherine de Medici' of France.

Between the fourteenth and seventeenth century, alchemists and monks did most of the production of these liqueurs. Benedictine monks are attributed with the production of Benedictine and Chartreuse, an 'Elixir de longue Vie' (elixir of long life). By the end of the seventeenth century, several distilleries had been set up, which produced commercial quantities of liqueurs.

The word 'liqueur' is derived from the Latin 'liquefacere,' which means 'to melt, or dissolve' and refers to the methods of flavoring the alcohol, forming the base of the liqueur.

Definition

The alcoholic beverages, which have levels of alcohol less than 15–16 ° Alc, are usually named low alcoholic beverages, and their alcohol content is produced by fermentation of their original musts. However, spirits are alcoholic beverages with levels of alcohol over 15–20 ° Alc, from the distillation of a fermenting medium. Liqueurs are, by definition, sweetened spirits that can be both colored and colorless. Most of the older classical liqueurs have their origin in the monasteries and have been produced for several hundred years. Until fairly recently, liqueurs were produced by traditional methods without legal controls. However, nowadays, their classification and legislation are well defined, especially in Europe and USA.

Under European Council Regulations (EEC 1576/1989), a liqueur is defined as:

> a spirit drink having a minimum sugar content of $100\,g\,l^{-1}$ (as invert) produced by flavoring ethyl alcohol of agricultural origin, or a distillate of agricultural origin or one or more spirit drinks, sweetened, and possibly with the addition of products of agricultural origin such as cream, milk, or other milk products, fruit, wine or flavored wine.

Liqueurs are a subclassification of 'spirit drinks', so they must contain at least 15 ° Alc. In practice, they are produced with strengths ranging from 15 to 60 ° Alc, although most of the traditional liqueurs contain 35–45 ° Alc. Owing to consumer demands, many of the newer brands are weaker.

In the USA, the manufacture of liqueurs is controlled by the Bureau of Alcohol, Tobacco, and Firearms, and liqueurs are defined as:

> products obtained by mixing or re-distilling distilled spirits with or over fruits, flowers, plants or pure juices therefrom, or other natural flavoring materials, or with extracts derived from infusions, percolation or maceration of such materials and containing sugar, dextrose or levulose, or a combination thereof in an amount not less than 2.5% by weight of the finished product.

Therefore, the liqueur definitions in Europe and the USA are significantly different, especially in terms of minimum sugar content. In any case, both definitions are not very specific and allow a wide range of liqueur types.

Although liqueurs and spirits are both alcoholic distillates, the terms are not usually interchangeable. The distinction lies in the way in which the various flavors are obtained. Liqueurs are spirit-based drinks to which flavors are added, or extracted from vegetal material by maceration or infusion, and are often enhanced by sweetening.

Sometimes, generic terms such as aquavits, schnapps, eau de vies, or vodkas are used in different countries for both spirits and liqueurs. However, they are in fact two different products, not only in their sugar content but also in their elaboration process. Both are fermented and distilled, but liqueurs are obtained by steeping vegetal materials in an alcohol that has already been fermented and distilled. Some special liqueurs in the British Commonwealth nations, especially the UK and Australia, are called cordials, which are prepared by steeping fruit pulps or juices in sweetened alcohol.

Raw Material and Composition

All liqueurs are produced from a common list of ingredients such as alcohol, sugar, flavoring, colorant or pigment, and water, but some liqueurs may contain other components such as cream, fruit juices, emulsifiers, plant materials, and some additives, which are subject to legislation. The elaboration of a good liqueur implies a good selection of the raw materials and exhaustive control of the substances added to obtain equilibrate and stable beverages.

Alcohol Base

The alcohol base (ethanol) may be originated from any fermentable agricultural material. Synthetic alcohol from petroleum is not allowed for use in alcoholic beverages.

Plants contain simple carbohydrates (sugars) or complex carbohydrates (starch or cellulose), from which it is possible to obtain alcohol by fermentation. This general principle is the basis for the production of the agricultural alcohol for alcoholic beverages. Sugars present in certain vegetable products, simple (most fruits) or complex (cereals) must be extracted, and, if necessary, they must also be hydrolyzed (as starch). Then, the simple sugars can be used as a substrate to obtain alcohol (ethanol) by the action of yeast.

The main steps in this transformation, which may vary slightly depending on the type of material, are as follows:

- Pretreatment of the biomass. This process implies the transformation of the raw material to favor sugar extraction. Raw materials are crushed, milled, grinned, cut, etc., to reduce the particle size and increase the surface of extraction, favoring the extraction of sugars and some other compounds. These processes are needed, especially in the case of cereals, potatoes and other root crops, as well as for other plants such as agaves. Extraction of the juices or dissolution–extraction of the sugars from the solid parts is usually carried out by pressing, boiling, mashing, and extraction by diffusion.
- The next step is the hydrolysis or transformation of the complex carbohydrates into simple sugars in aqueous medium. These sugars are used in fermentation. In the case of alcoholic beverages, this process always takes place by enzymatic activity, generally taking advantage of the activity of the substrates themselves, or resorting to the use of exogenous permitted enzymes.
- Alcoholic fermentation is then carried out, transforming sugars into ethanol by the action of yeasts. Few species of yeast are capable of maintaining themselves in a state of active fermentation once high levels of alcohol have been reached. Several products obtained in this way, with some further modifications, make up the largest group of drinks produced by fermentation with a relatively low alcohol content, such as cider, beer, and wine.
- In order to obtain products with a higher alcohol content, distillation must be carried out. Distillation involves the separation and concentration of ethanol from the fermented medium, to obtain alcoholic distillates of different strengths and sensorial characteristics, depending not only on the original substrate but also on the type of distillation equipment employed. Such products obtained in this way are sometimes called neutral spirits, and they are the base for the manufacture of different spirit beverages such as brandy, whisky, gin, vodka, and liquors, amongst others.

A direct distillation process produces distillates with alcohol strength of no more than 86 ° Alc. To obtain a product with a higher content of alcohol, redistillation is necessary.

The most common process for obtaining high-quality distillates uses a copper still, in which successive distillations are carried out to yield highly flavored products and with an alcoholic strength of about 72 ° Alc. However, the distillation can be also carried out in distillation towers, in which the distillate can achieve higher alcoholic grade, up to 86 ° Alc. In general, these distillates are less flavored than those obtained in stills. Columns can be made of copper or stainless steel.

The distillation process generates several fractions:

1. Heads, which contain the most volatile constituents, are often detrimental to the quality of the spirit. Methanol is one such undesirable product.
2. Heart, which contains the ethanol and other important volatile compounds responsible for the aroma, which evoke the origin of the distillate.

3. Tails, which are rich in alcohols with a high number of carbons and with a high potential to reduce the quality of the spirit. However, this fraction contains some interesting less volatile components that can be important; these can be recirculated to recover these products without spoiling the quality of the spirit.

In order to guarantee the purity of the alcohol, the first fraction (heads) must be correctly rejected, preventing methanol from appearing in the final product, and only the heart is used later to improve the final spirit. The different methods of carrying out the distillation (type of stills, number of successive distillation, recycling of tails, etc.) confer different characteristics to the spirits, and have a direct effect on their quality.

The alcohol base used for liqueurs is usually 'neutral,' i.e., clear and tasteless, so flavor compounds of distillates do not contribute to the final flavor characteristics of liqueurs, which are obtained by adding specific products. However, for special liqueurs, flavored alcohols, rich in odor compounds isolated together with ethanol during distillation, are preferred. For example, in 'juice liqueurs' or 'fruit liqueurs' flavored alcohols obtained from fermentation and distillation of the same juice fruit are used to intensify the flavor of the final product.

Water

Water with a high level of purity is required to avoid any stability problems caused by inorganic ions. The salt content needs to be controlled, especially in calcium, which can produce precipitates. These precipitates produce cloudiness in the liqueurs and, when precipitated, can sweep along with them other components of the liqueurs such as pigment or flavoring.

However, chlorine levels should be controlled, since chlorine imparts undesirable flavors. Thus soft water with a hardness below 8 must be used, and for this purpose, demineralized water can be used.

Sugars

Sugars in liqueurs are a very important material and can be obtained from many sources, depending on the availability, price, legality, and final characteristics required.

The most commonly used sugar is sucrose from sugar cane or beet, although other sweet substances such as liquid glucose syrups, high-fructose corn syrup, honey, or rectified concentrated grape must can also be used. In addition, several other sweet compounds may be used, such as polyalcohols and synthetic sweeteners, which are added in order to increase the sweetness and reduce the levels of sugars added, thus reducing the calorific value of some liqueurs.

The best form in which to add sugars, irrespective of their source, is as a liquid solution. In this way, sugars are already dissolved and can mix better with the hydroalcoholic medium. These solutions are free of impurities (having been eliminated previously during their manufacture), thus reducing the risk of cloudiness or haze. In addition, liquid solutions produce a better taste and mouthfeel probably owing to the inversion of sucrose to glucose and fructose.

Sugars can also be added to liqueurs as a thickening or coloring agent. Starch syrup produces thicker liqueurs, with a higher density, without overly increasing the sweetness. Other carbohydrates may be used as thickening agents also. However, when hydrocolloids are applied, their solubility and stability in hydroalcoholic solutions must be tested beforehand.

Liquid caramels and some syrups obtained by heat treatment of crystalline sucrose or other sugar sources can act as colorants. In such cases, temperature must be carefully controlled during the heat treatment in order to avoid the formation of high quantities of furfural and derivatives, the levels of which are legally limited in liqueurs.

Flavoring and color

Flavoring components can be extracted from natural plants such as herbs (barks, roots, seeds, flowers), fruits, spices, and beans such as coffee and cocoa. These vegetal materials add color, taste, and aroma (flavor) to liqueurs owing to the extraction of different compounds present within them. Also, flavoring compounds can be obtained from essential oils, natural-flavoring extracts, or any combination of these sources with different permitted flavoring and coloring food additives. Usually, synthetic flavors are added in cheaper brands of liqueurs.

The color of liqueurs may result directly from the use of plants such as fruits, seeds, leaves, etc. Plain caramel is often used, as it is the most stable color for spirits and liqueurs. For other colors, synthetic colors can be used, where legislation allows.

Fruits can be used whole or peeled, and they should be employed in the optimum grade of maturation in order to achieve their maximum flavor, color, and sugar contribution.

Generally, a large number of brands use synthetic flavors and colorants to adjust or intensify the 'natural' characteristics of their products. It is important to note that natural extracted pigments are more susceptible to degradation than some synthetic colorant additives, which are very useful to maintain the attractive color of liqueurs.

Different methods to obtain the flavor and color from fruits, herbs, spices, and beans can be used. The methods used most often are as follows:

1. Maceration: This procedure involves steeping the aromatic/flavoring agent, which has usually been bruised in a hydroalcoholic solution for a period of time in order to extract an essence from it. This essence is then added to the base as the flavoring agent. This is the traditional method used in higher-quality liqueurs. The herbs used can be fresh or dry. Their extraction is be carried out using alcohol of different strengths. The fresh herbs can be extracted quickly and with a high yield in high alcoholic solutions between 70 and 96%. However, dry herbs should be extracted with an alcoholic solution of lower ethanol concentration (40–60%), because they must be rehydrated to facilitate the extraction of internal pigments and flavored compounds.
2. Infusion: This is similar to the maceration process in which the flavoring agent is steeped in a base alcohol, but in this case, the alcohol is heated. The heat can be maintained for several days, and the result is a more flavorful and less expensive product.
3. Percolation: This method can be done with either a hot or a cold solution. The alcoholic base is allowed to drip though the raw material (or flavoring agent). The alcoholic base can also be heated, and then the formed steam passed through the agent prior to being collected and recondensed to form the base product (extract).
4. Distillation: Usually, this is steam distillation of the desired flavoring agent, which has previously been extracted by maceration. This is often repeated many times with large amounts of the flavoring agent and reducing the volume to a relatively small amount of liquid. This method produces a very strong essence that can be added to the bulk of the alcohol base.
5. During the 1990s, liquid CO_2 extraction was largely improved, and nowadays, this technique has many applications in the food industry. One such application is the manufacture of essential oil extracts, especially from herbs and species, which are applied in the elaboration of liqueurs. The CO_2 extracts are usually better than extracts obtained by steam distillation in terms of quality, yield, and energy savings.

The choice of method depends on the source from which the flavor is to be extracted and on the particular flavor required from the flavoring agent. Some flavoring will yield different flavors, depending on the type of extraction used.

The final products used to be alcoholic bases, which contain the flavor of the vegetal material. Owing to the fact that potentially toxic substances, present in vegetal material, can be extracted together with pigment and flavoring compounds, these extracts must be analyzed and controlled adequately before they are used in liqueur manufacture. Some of these undesirable compounds include thujones mainly extracted from herbs, cianhydric acid and its derivatives, mainly extracted from almonds and drupes, and methanol, mainly present in extracts from fruits with a high pectin content or when pectinases have been applied in fruit treatment, and so on.

Innovations in liqueur manufacture, mainly in response to consumer demands, have become important in fruit-flavored liqueurs, the development of products with flavors that combine well with mixers, increased sophistication and diversity of flavorings, and greater use of natural flavorings.

Elaboration Processes

There are two main types of processes for producing liqueurs, maceration systems and blending systems, which are usually automated with feedback controls. Both systems yield products with similar characteristics, although the final quality in each case is different.

Maceration Systems

The maceration system is the most traditional procedure, which involves a process very similar to the maceration/infusion processes previously described to extract pigments and flavoring compounds from fruits and plants (Figure 1). After the extraction process, liqueurs acquire their flavor and color characteristics, which evoke the raw material or their origin.

Different studies have been carried out in order to improve the extraction of pigments and flavor compounds during maceration. These include optimization of the strength of hydroalcoholic extracting solutions according to the different vegetal raw material, optimization of the relation between the weight of the raw material and the extracting solution volume, and the contact time or duration of the maceration process. In addition, the use of diverse commercial enzymes, especially clarifying pectolytic and color-extracting preparations, have been described. These types of enzyme preparations can improve the final color of extracts and liqueurs and can prevent haze formation, because they hydrolyze, and reduce the levels of pectins in the final products.

Vegetal materials are usually separated from the liquid extract by decantation or filtration, depending on the type and size of the raw material used (whole fruits, whole or powder herbs, etc.). Different types

of equipment can be used, such as plate and frame filters, leaf filters, or sieve systems. The liquid extract is racked off to a blending tank, where sugars or syrup are added; caramel and other ingredients can also be added. The tanks usually have agitation systems to improve the mixture. If necessary, the alcoholic grade can also be adjusted. In addition, several flavor and colorant substances can be added to adjust the final color and flavor.

The final step is bottling. Prior to bottling, liqueurs are maintained in repose. During this period, different settling processes are developed, which can be improved by cooling. Then, liqueurs are filtered to eliminate any precipitates and to yield a product with a high purity and brightness.

Haze formation after bottling is one of the most undesirable effects, as cloudiness greatly reduces the quality of the final product. This haze formation depends on many factors such as the presence of proteins, polyphenols (mainly ellagic tannins), and pectins, which are present in vegetal materials and extracts. Thus, in recent years, different studies on the use of different clarificants such as polyvinylpyrrolidone and adsorbed resins have been carried out. These products are injected directly into alcoholic extracts or liqueurs, and then, the centrifugation or filtration processes are carried out. However, the effect of the clarification agent on the retention of pigments and flavor compounds must be tested beforehand, in order to prevent any decoloration or undesirable losses of flavor.

Continuous Blending Systems

Continuous blending systems are carried out in steel blending tanks connected to other secondary tanks containing the different components of the liqueur, such as water, alcohol, syrup, liquid starch, solution of colorant, and flavor compounds, etc. (Figure 2). Automated valve systems control the volume of every component of the liqueur pumped to the blending tank. Usually, the blending tank has agitation systems to improve the mixture of the ingredients. Sometimes, the blending is stabilized by the homogenization process. This step is necessary, especially when the final product has a high level of essential oils or other compounds with a low water solubility. In addition, juice liqueurs and other cloudy liqueurs can be homogenized, in order to stabilize their turbidity.

After blending, with the exception of cloudy liqueurs, the final steps are similar to those previously described for traditional methods. Because the initial constituents are liquid solutions that have been

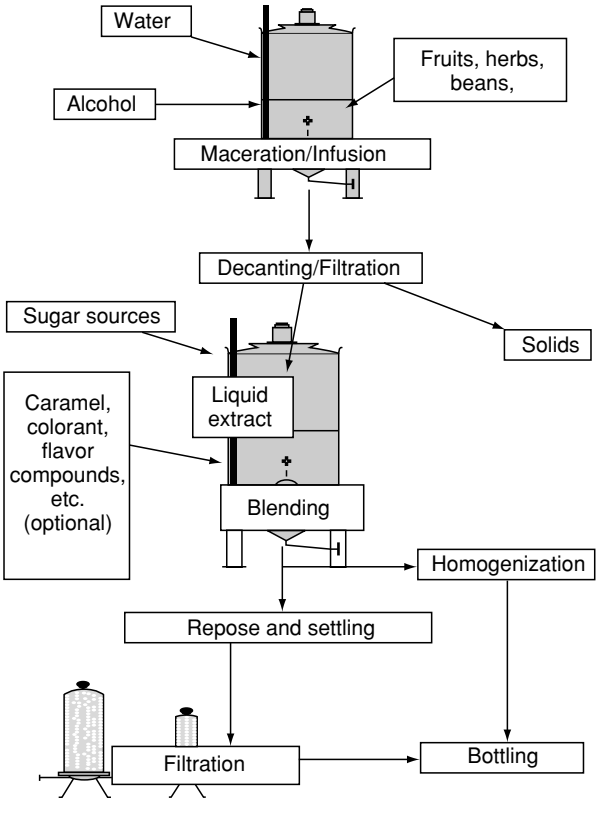

Figure 1 Diagram of traditional (maceration) liqueur-making process.

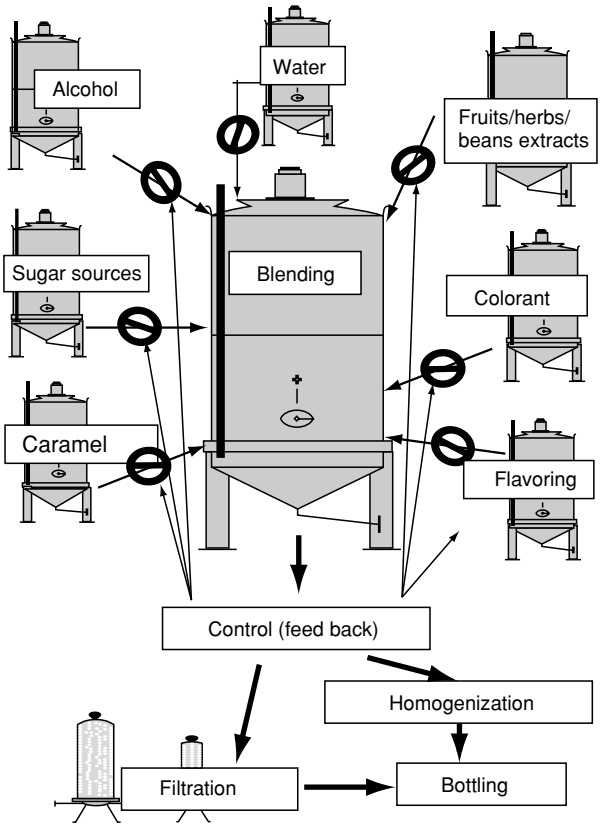

Figure 2 Diagram of continuous blending systems.

adequately treated and filtrated, usually, a few new precipitates are formed during blending. Then, a repose period is optional, and membrane filters are usually employed to increase the brightness of liqueurs.

Modern systems are feedback control systems. From the outlet of the blending tank, an aliquot of the product is sent to the analyzer system, which can be connected directly to the interior of the blending tank (in line control systems). The analysis center confirms whether the product complies with fixed quality parameters such as color, pH, °Brix or sugar content, density, etc. If the product shows any deviation from the allowed limits of any parameter, control systems send a signal to the respective valve to add the component necessary to correct the detected deviation. Only when the liqueur complies with the specifications is the valve of discharge (outlet) of the blending tank opened, and the product is then conveyed to the stabilization process and bottled.

Different software packages, for a wide range of technical calculations in liqueur manufacture, have been developed in the last 5–6 years, and some are used in the aforementioned automatic modern systems.

Types of Liqueurs

The range of liqueurs is enormous; many companies produce a wide range of brands, and different countries produce different national products, probably because of the different raw materials found in different countries. Thus, there are different possibilities to classify liqueurs, such as by strength, sugar content, origin (fruit, beans, or herbs, and type), color (color and colorless), appearance (clear or cloudy), manufacturing process (maceration or blending), etc. It is useful at this point to note the differences between similar products such as 'Cream' and 'Crème' liqueur.

'Cream liqueurs' are thick liqueurs made with cream, milk, or some other dairy product, and their strength is usually lower than that of other liqueurs. Owing to their 'special' composition, their shelf-life is shorter than that of other liqueurs, and after they have been opened, they should be kept refrigerated. 'Crème' (pronounced 'Krem') is a term that is followed by the name of a specific fruit or other vegetal material and is reserved only for liqueurs with a minimum sugar content of 250 g l^{-1}. These liqueurs contain enough sugar to become thick and creamy in texture, but there is no actual cream in them.

According to European legislation, liqueurs that specify fruits or plant materials (including pictorial representation) must contain at least 90% of the cited materials, and only 100% natural products can be used in their elaboration. If the term 'natural' source of flavor is not specified in the label, artificial (synthetic) flavorings may be used. However, USA legislation allows the use of the term 'boosted natural' flavors, which may contain up to 0.1% of artificial flavor components. Some regulations of other countries may also specify different specifications, e.g., Spanish legislation determines that 'juice liqueurs' must contain at least 20% natural juice from the cited fruit.

Recently, 'gelled liqueurs' and 'alcopops' have appeared on the market. 'Gelled liqueurs' are characterized by their gel texture, and an alcohol-free beverage base is mixed with hydrocolloids (e.g., gellan and gelatin) at high temperature, followed by turbulent mixing with an alcohol/water mixture and homogenization to produce a solid gel. This gel is stable at ambient temperature and may be used for direct consumption or as a filling in wafers, chocolates, and other foods. The mouthfeel of the gelled product depends on the composition of the alcoholic beverages and the gelling agents used.

'Alcopops' are liqueurs, usually fruit liqueurs, of low alcoholic content, and have recently appeared on the UK market, being marketed primarily at young people.

Owing to the specific characteristics of certain liqueurs or their manufacturing processes, some liqueurs are protected under specific quality denominations, similar to spirits such as whiskies, brandies, and gins. The most common indication, especially for products elaborated in European countries, is PDO (Protected Designation of Origin).

However, because liqueurs are not a static medium, their composition and characteristics do not remain constant. Their minor constituents, especially pigments and flavoring, undergo a large number of changes, not only during manufacture but also during storage. These are mainly degradation reactions catalyzed by aqueous acidic medium, high temperature, and light (UV irradiation).

Such changes make it difficult to determine the authenticity of these products, and so, in the last decade, many papers on the determination of authentication parameters of different liqueurs have been published. In general, aroma compounds have been studied and described as useful parameters to determine the authentication of liqueurs. Isomers and isotopes studies are very useful, because their presence and relative amounts in natural flavor extracts and synthetic preparations are usually different.

Phenolic compounds and other pigments such as carotenoids have also been evaluated as characteristic parameters of natural liqueurs.

Cream Liqueurs

B T O'Kennedy and W J Donnelly, National Dairy Products Research Centre, County Cork, Ireland,

Definition of Product

Cream liqueur is an alcoholic beverage containing emulsified milk fat. The first of the new generation of cream liqueurs which now dominate that market is manufactured in Ireland and marketed under the name Bailey's Irish Cream. Similar products are now manufactured in several countries. A standard definition of cream liqueur does not exist internationally and since there can be wide variations in the composition of liqueurs from different manufacturers only the broadest technical definition is possible. For marketing and regulatory purposes more precise definitions exist or are contemplated in several countries. An example is the proposed standard for Irish cream liqueur currently under discussion among manufacturers in Ireland, which specifies among other things that the product must contain 12% (w/v) minimum butterfat, 15% v/v minimum alcohol, $100\,g\,l^{-1}$ minimum sugar, and have an 18 months' shelf-life.

Table 1 Composition of a typical cream liqueur

Ingredient	*Percent*
Milk fat	16%
Sugar	20%
Sodium caseinate	3%
Nonfat milk solids	1%
Total solids	40%
Ethanol	14%
Trisodium citrate	$10\,mmol\,l^{-1}$
Water	46%

Percentage values are on a w/w basis.

A typical cream liqueur composition is shown in **Table 1**. Most of the major liqueurs approximate the typical composition.

Basis of Formulation

High-quality cream is a prerequisite for the production of consistent quality and stability. For the most part, the fat in the cream acts as an inert diluent, imparting a creamy texture, the absence of which can be quite noticeable when the fat is reduced. Homogenization reduces fat globule size such that creaming is prevented on storage. Most commercial cream liqueurs incorporate sodium caseinate with the purpose of stabilizing the newly formed fat emulsion. The use of small amounts of low-molecular-weight surfactants such as glycerol monostearate (GMS) is also widespread in commercial practice. While sodium caseinate would be recognized as the prime emulsifier, the effect of GMS can be significant in the subsequent behavior of the product. The presence of 14% by weight of ethanol has a marked effect on sensory properties and is an effective control on microbial spoilage. The presence of large quantities of sucrose in the formulation is central to the taste and organoleptic properties of the product. Besides its obvious importance to the sensory characteristics of the product, sucrose can also have direct effects on the behavior of the other components and on such physical properties as refractive index or viscosity of the aqueous phase. (*See* **Casein and Caseinates**: Uses

in the Food Industry; **Emulsifiers**: Uses in Processed Foods; **Sucrose**: Properties and Determination.)

During the production of cream liqueurs, the concentration of some of the components in the system may exist at a much higher level than is apparent in the final product. This is due to the order of addition and the water or alcohol content at various stages during formulation. Because multicomponent interactions are seen as the basis for consistency of product, regulation of the water activity at any given step in the production process, within the constraints of practicality, can be a means of altering final product characteristics.

Manufacturing Protocol

A typical manufacturing process for cream liqueur is shown in Figure 1. This involves the blending of sodium caseinate solution with a cream/sugar solution, followed by homogenization and alcohol addition. Considerable variation is likely in the sequence of different steps and additions and in the precise composition of the final mixture. Some of these variations may influence the characteristics of the final product. Use of citrate as stabilizer has a dramatic effect on shelf-life and is to be recommended. Use of an emulsifier is optional since adequate emulsion stability can be provided by caseinate alone, provided sufficiently high pressures are used in the emulsification step. In practice, moderate pressures are preferred and hence emulsifiers are desirable. The homogenization step may be carried out before or after alcohol addition. Homogenization with alcohol present gives more efficient emulsification, but also imparts a different mouth feel. Depending on the homogenization conditions, the stage of emulsifier addition may also be critical. (*See* **Stabilizers**: Types and Function.)

Characteristics Expected in End Products

Following the manufacturing processes outlined, it is expected that the cream liqueur will be stable to excess creaming, gelation, or deposit formation for a period in excess of 18 months. However, most exporters will take precautions to insure that the product is not subjected to extremes in temperature. Exposure to temperatures in excess of 40 °C for any period of time may result in a dramatic thickening of the product. The viscosity of the product following manufacture is one of the main textural characteristics of the product, typically being in the region of 30 mPa at moderate shear rates and 20 °C. Cream liqueur is very subject to shear thinning, having a high viscosity at very low shear rates but becoming instantly pourable on disturbance. It may therefore be regarded as having the structure of a weak particle gel.

The mouth feel and textural parameters of the product are modified by fat globule distribution. Different products generally show a difference in size

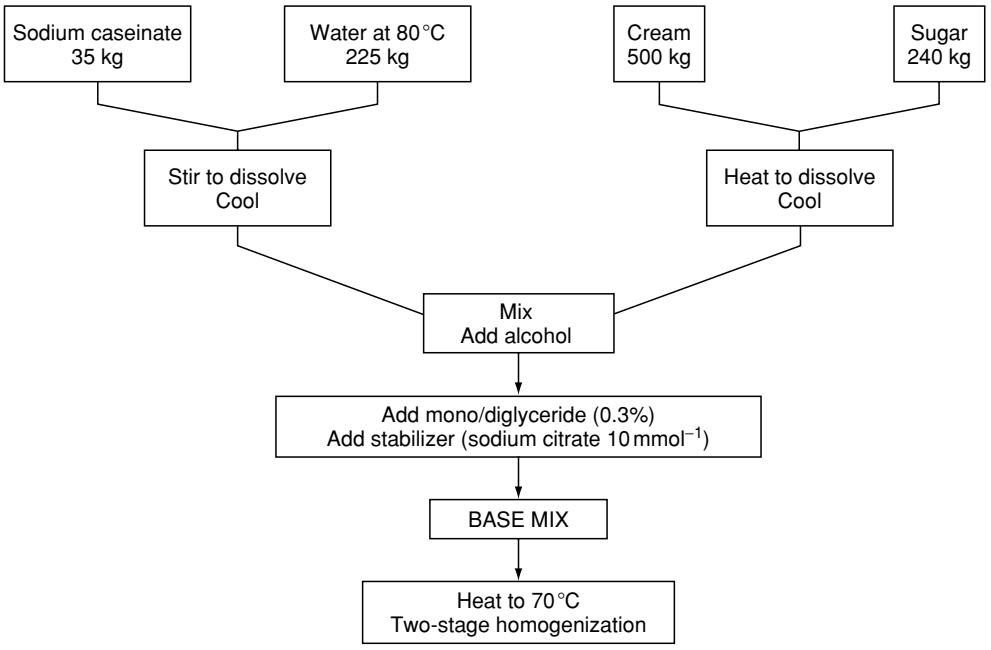

Figure 1 A flow diagram for a typical cream liqueur manufacturing process. Reproduced from Liqueurs: Cream Liqueurs, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

distribution, most probably due to differences in processing and homogenization regimes. The opacity and glass-holding ability are also directly related to fat globule size distribution; the smaller the fat globules, the more translucent or less opaque the product can become.

A characteristic of cream liqueurs to a greater or lesser extent, which is very noticeable to the consumer, is the dramatic whitening effect that occurs on dilution with neutral mixers, or on addition of ice. This is due to a change in the refractive index of the aqueous phase, emphasizing the light-scattering properties of the fat globules. The choice of sodium caseinate as the proteinaceous emulsifier makes the liqueur unstable to acid. This characteristic is of some importance as the addition of acid mixers to the system may lead to coagulation and consumer rejection. This can be overcome by omitting the caseinate and relying on low-molecular-weight surfactants as a means of stabilizing the emulsion. However, a loss in product quality is probable.

Storage/Stability Problems

There are two main problems of instability associated with cream liqueurs. These are creaming and age thickening. Creaming arises because of inadequate fat dispersion and is controlled by varying homogenization conditions during manufacture. The important variables are homogenization pressure, temperature, and number of homogenization stages. Normally, manufacturers employ a two-stage process, the first stage being at intermediate pressure (about 20 MPa) and the second stage at low pressure (about 40 MPa). Alternatively, multiple-stage high-pressure (about 30 MPa) homogenization may be employed. When homogenization is carried out after alcohol addition, fat dispersion is improved. Since there is a relationship between homogenization conditions and liqueur characteristics such as mouth feel, opacity, and glass adhesion, the precise conditions used will represent a balance between stability and sensory requirements.

A much more complex instability problem is age thickening. This is generally accompanied by phase separation and emulsion breakdown. Age thickening is best viewed as protein aggregation, involving complex interactions between casein in the continuous phase and at the fat/water interphase (recombined fat globule membrane). Aggregation is promoted by ionic calcium and by alcohol. An important additional destabilizing factor is the process of homogenization itself, which, in some manner not yet understood, enhances the susceptibility of casein to aggregation. The severity of the homogenization effect increases with fat content, and liqueurs with lower than normal fat are less likely to show instability problems. The simplest remedy for problems of protein instability is addition of a calcium complexing agent such as sodium citrate. Liqueur pH may also be a determining factor and small pH adjustments may prove beneficial for individual manufacturers.

Recently, it has been shown that the apparent viscosity of cream liqueurs on storage at 45 °C was dependent on the sodium caseinate source and suggested that electrostatic and sulfhydryl interactions were involved. This was further substantiated by information indicating that certain fractions of the sodium caseinate ingredient were far more susceptible to alcohol-induced aggregation reactions. The alcohol-susceptible fraction contained sulfhydryl groups.

Other stability problems encountered from time to time are deposit formation, lactose crystallization, or citrate precipitation. These are formulation-dependent and in most instances the remedy is slight adjustment of the concentrations of individual components.

LISTERIA

Contents

Properties and Occurrence

M W Griffiths, Canadian Research Institute for Food Safety, University of Guelph, Guelph, ON, Canada

Introduction

Although an organism, later to be identified as *Listeria monocytogenes*, was isolated from cerebrospinal fluid as early as 1918, characterization of the bacterium which we now know as *L. monocytogenes* did not take place until 1926. It is only since the 1980s that the importance of food in the transmission of listeriosis has been acknowledged. There was a suspicion that the fecal–oral route was involved in the spread of listeriosis as an enlightened Russian scientist had written as early as 1953 that 'The most important way of the infection of people is the food-borne one.' Nevertheless, as late as 1976, *L. monocytogenes* was not listed among bacteria that could cause foodborne disease by a World Health Organization/Food and Agriculture Organization expert committee.

Listeria species are short, Gram-positive, nonspore-forming, facultatively anaerobic rods. *L. monocytogenes* is motile at 20–25 °C but nonmotile at 37 °C because the gene encoding flagellin is not transcribed at this higher temperature. It can grow over a wide range of temperatures, at low pH and at low oxygen tensions. Thus, it is able to grow in many environments.

The genus *Listeria* contains six species (*L. monocytogenes, L. innocua, L. ivanovii, L. seeligeri, L. welshimeri*, and *L. grayi*), of which only *L. monocytogenes* can cause infections in humans. Analysis of the genome of *L. monocytogenes* indicates that the bacterium exists in at least three evolutionary lines which are strongly conserved. However, most isolates are distributed between two of these lineages.

Occurrence in Foods and the Environment

Environmental Isolation of *Listeria* spp.

L. monocytogenes is widely distributed in the environment. It has been commonly isolated from surface waters, decaying vegetation, soils, sewage, and silage. It has been found on all continents except Antarctica.

Listeria can grow in sterile soil samples, but does not compete well in the presence of natural soil microflora. In several instances it has been demonstrated that *Listeria* spp. can survive in soil for several years. It is likely that the principal source of the bacterium in soil is from animal feces. Listeriosis is recognized most frequently in ruminants, but *L. monocytogenes* has been isolated from more than 37 species of mammals and 17 species of birds. The occurrence of the disease in ruminants has been strongly associated with silage feeding as the organism is rarely detected on growing grass and vegetables. The incidence of *L. monocytogenes* in silage increases with the use of 'big bale' silage production and in silage contaminated with mold. It has also been postulated that birds are a possible source of listerial contamination of silage. Fecal samples from gulls feeding at sewage sites were reported to have a higher carriage rate for *Listeria* spp. than those from birds feeding elsewhere.

The excretion of *L. monocytogenes* by farm animals is linked to their diet. Animals fed entirely on hay or manufactured diets do not excrete detectable levels of *Listeria*, but animals fed on silage commonly excrete the organism.

The practice of applying sewage to agricultural land may also create a risk of listerial contamination. It has been calculated that 40% of the total sludge produced at sewage works in England and Wales may be applied to agricultural land. Sewage sludge can contain large numbers of *L. monocytogenes*, with counts ranging from 800 to $>18\,000\,l^{-1}$. The numbers of the bacterium showed no detectable decrease 8 weeks after spraying. Isolation of *Listeria* spp. from nonagricultural, residential, suburban communities indicates that the organism could be associated with areas other than those involved in agriculture.

L. monocytogenes has been isolated from effluent, not only from sewage treatment plants, but also those of poultry-packing factories, abattoirs, and cattle markets. Surface waters receiving these discharges

may be a good route for recycling these bacteria. *L. monocytogenes* was isolated from 62% of fresh or low-salinity waters in tributaries draining into an estuary impacted by humans and domesticated and wild animals. One *L. monocytogenes* serogroup appeared to predominate in fresh water when domesticated animals were nearby, but a greater variety of strains with no predominance by a single serogroup was observed in areas with no direct animal influence. The majority of strains found on decaying plants are not animal pathogens and this suggests that the predominance of certain serotypes of *L. monocytogenes* may depend on environmental factors.

Presence in Food

L. monocytogenes has been isolated from a wide variety of foods of animal and plant origin (Table 1). The incidence of the bacterium in foods will be described on a commodity basis.

Occurrence in Milk and Dairy Products

Because of the well-documented foodborne outbreaks of listeriosis associated with the consumption of dairy products, these foodstuffs have attracted the attention of many researchers. Several studies have been carried out across the world to assess the incidence of *L. monocytogenes* in raw milk. Five large studies were carried out in Pennsylvania, USA (2511 samples), England and Wales (2009 samples), Ontario, Canada (1720 samples), France (1409 samples), and Transvaal, South Africa (961 samples). These studies revealed the incidence of *L. monocytogenes* to be 3.1, 5.1, 2.7, 6.0, and 5.2%, respectively. Collectively these investigations found that 363 of 8610 samples or 4.2% of raw milks were positive for *L. monocytogenes*. The level of the organism in raw milk is usually less than 1 cfu ml^{-1} but counts may reach 64 cfu ml^{-1}. The source of *L. monocytogenes* in the milk supply is still in some doubt. *L. monocytogenes* is a causative agent of mastitis, albeit only rarely. The organism has been recovered from milk of mastitic cows at counts ranging from 10^3 to 10^4 cfu ml^{-1}. Prolonged excretion of *L. monocytogenes* in milk and feces of infected animals and asymptomatic carriers has been described. This would lead to the build-up of an endogenous pool of *Listeria* in the environment which could be augmented from other sources such as the use of poor-quality silage and feces of feral animals and birds. In a large case-control study involving 128 dairy farms in France, poor-quality silage (pH > 4), inadequate frequency of cleaning the exercise area, poor cow cleanliness, insufficient lighting of milking barns and parlors, and incorrect disinfection of towels between milkings were associated with contamination of milk by *L. monocytogenes*.

Numerous other dairy products have been found to contain *L. monocytogenes*. The bacterium has been found in pasteurized milk and an outbreak of listeriosis in Massachusetts in 1983 was associated with the consumption of this product. One report from Spain suggested that 21% of pasteurized milk samples tested

were positive for the organism. However, these milks showed evidence of gross contamination with other bacteria, indicative of poor hygiene conditions in the processing plant and of postpasteurization contamination, e.g., at bottling/packing. More reliable estimates put the level of contamination of pasteurized milk with *L. monocytogenes* at <1%. Other fluid milk products, such as chocolate milk, can have *L. monocytogenes* present. The isolation of *L. monocytogenes* from pasteurized milk prompted investigators to suggest that, because of its intracellular location, it was able to survive pasteurization. However, many studies have now confirmed that this is not the case (**Figure 1**).

Dairy products most at risk of contamination with *L. monocytogenes* are soft cheeses such as Camembert and Brie. Again, numerous surveys have been carried out worldwide to determine the incidence of listerial contamination of these products. These studies have revealed a widespread distribution of the organism with *L. monocytogenes* counts in the range 1×10^2 to $1 \times 10^6\,g^{-1}$. In a study carried out in the Netherlands, all positive cheeses were manufactured from raw milk, but other work has shown no difference in the incidence of *L. monocytogenes* in cheese produced from raw or pasteurized milk. The contamination of Swiss cheese with *L. monocytogenes* was primarily due to the presence of the organism on shelves used for maturation of the cheeses. On rare occasions, hard cheeses, including Cheddar, have become contaminated with the bacterium.

Among other dairy products shown to harbor *L. monocytogenes* are icecream and butter, although there have been no documented cases of listeriosis where icecream was the vehicle of infection.

Since the recognition of the link between listeriosis and consumption of contaminated milk products, research has focused on the source of this contamination. In one such study the incidence of *Listeria* contamination of processing equipment was compared with that of the general dairy-processing environment. Positive equipment samples were obtained from six of the 21 (28.6%) plants, whereas 19 of the 21 (90.5%) plants had positive environmental sites. *L. monocytogenes* was isolated from 11 of the 215 (5.1%) samples taken from equipment, and these included three holding tanks, two table tops, three conveyor-chain systems, a pasta filata wheel, a pint milk filler and a brine prefilter machine. Twenty-four of the 163 (14.7%) samples from environmental sites were positive for *L. monocytogenes*. These results suggest that environmental contamination with *Listeria* does not necessarily translate into contamination of equipment within the same dairy plant. Sites that are typically positive for *L. monocytogenes* include drains, conveyor belts, floor mats and foot baths, coolers, freezers, areas underneath equipment, areas associated with case washers, areas where raw milk is handled, cheese-ripening rooms, and cheese-washing brushes.

In addition, the processing environments of 30 dairies were surveyed for the presence of *Listeria* spp. Nine of these dairies had a dairy farm in close proximity to the processing facilities, and these plants were more likely to be contaminated (9/9) than the plants without on-site dairy farms (17/21). Plants producing dairy ingredients, frozen dairy products, or fluid milk had significantly higher incidence rates than expected, whereas plants producing fermented dairy products, or a combination of fermented dairy products and fluid milk, had significantly lower incidence rates than expected. There was no significant difference in contamination rates between areas within the plants.

Occurrence in Meat and Meat Products

L. monocytogenes has been isolated from beef, lamb, pork, turkey, and chicken with high frequency (Table 1). There is considerable evidence that the contamination of meat arises from environmental sources which can occur at all points along the processing and retail chains. Common sources of contamination are the environment of the chilling and cutting rooms, hands, and equipment. Cross-contamination may also occur between raw and cooked product, and from contact of cooked products with soiled surfaces due to inadequate cleaning and disinfection.

The source of contamination can vary depending on meat species. For beef and lamb, the hide seems to be a more important source of carcass contamination by the bacterium than feces, but for pork, fecal contamination is more important. Poultry carcasses can become contaminated from the environment of processing plants or due to carriage of the organism in the gut of healthy birds. *L. monocytogenes* can contaminate poultry at several points during production, including at evisceration due to spillage of gut contents, from handling, from equipment such as the rubber fingers used for plucking, and from the scald tank water. *L. monocytogenes* can persist in the environment of poultry-processing plants for up to 1 year.

Levels of *L. monocytogenes* found in cooked poultry products can be high ($>10^4$ cfu g^{-1}) and this may be the result of inadequate cooking or growth of the bacterium arising from contamination after the cooking step. However, most studies have shown that when *Listeria* is present in meats it is usually found in low numbers. The level of contamination is generally

higher for poultry than pork, which, in turn, is higher than in beef. There is evidence that *L. monocytogenes* apparent numbers are affected by the microbiological methods applied, especially where cells might be injured.

L. monocytogenes is widely distributed in meat-processing plants and the conditions present in these locations are ideal to promote the growth of the organism. This makes it difficult, but not impossible, to control contamination of the meat.

Occurrence in Fish and Seafood

Because of the many routes by which *Listeria* can contaminate water, it is not surprising that *L. monocytogenes* has been isolated from fish and seafood at high prevalence rates. The organism can become widely disseminated throughout smokehouses during production of smoked salmon and *L. monocytogenes* can be isolated from many sites in a raw-shrimp-processing plant. These include processing water, equipment, food handlers, doors, walls, floors, and drains. Thus, it is essential to institute a regular cleaning and disinfection program within these operations.

A study in the UK which examined 4435 seafood samples found that *L. monocytogenes* could be isolated from 128 (3%) of these samples. The organism was most frequently isolated from smoked fish and fish pâté. The extent of contamination was generally low, but in eight samples *L. monocytogenes* counts exceeded 10^2 cfu g^{-1}.

Occurrence in vegetables

As has been previously stated, *L. monocytogenes* is found in many habitats, including soil, water, manure, decaying vegetation, and sewage effluents. This provides many opportunities for the contamination of vegetables by this bacterium. Despite this potential for contamination, surprisingly few types of vegetables are consistently found to contain *L. monocytogenes*. These are mainly potatoes and radishes. The incidence of the organism on fresh-cut vegetables varies between 0 and 19%, and when *L. monocytogenes* is detected it is present in low numbers ($< 2 \times 10^2$ cfu g^{-1}).

Occurrence in Processing Plants and Kitchens

Listeria spp. are widely distributed in the environment of food-processing plants (Table 2). Common sources of these bacteria include drains, floors, standing water, and food residues. The absence of *Listeria* spp. from dry culinary food units prompted one group of researchers to conclude that dry conditions and the absence of food residues contribute to the control of *L. monocytogenes*. Codes of practice for the food industry have been set out to help eliminate problems caused by *L. monocytogenes*. These entail a rigid program encompassing personal hygiene, separation of raw material and product, and effective clean-up and disinfection procedures. These, coupled with the adoption of a hazard analysis critical control point (HACCP) management system operated by trained and knowledgeable staff, should help to insure the microbiological safety of foods.

Even when the product entering the home is free from contamination, there is considerable scope for mishandling foods in domestic kitchens. One survey has reported that 20% of domestic environments are contaminated with *Listeria* spp., with dishcloths being the main culprits. *L. monocytogenes* was also isolated from a domestic refrigerator.

Table 2 Occurrence of *Listeria* spp. and *L. monocytogenes* in environmental samples taken from food-processing plants[a]

Fate During Processing

Temperature

The identification of pasteurized milk as a vehicle in the transmission of listeriosis led to the assumption that *L. monocytogenes* was unusually heat-resistant. It was thought that this resistance was mediated by its intracellular location within the leukocytes found in milk. This provoked much interest in the thermostability of the organism. It is now commonly accepted by most researchers that it is unlikely that *L. monocytogenes* can survive commercial pasteurization conditions in appreciable numbers and there is little difference in the heat resistance of free and intracellularly located cells.

Results of several researchers who examined the effect of heat on *L. monocytogenes* have been analyzed and, in general, the heat stability of *L. monocytogenes* can be described by the equation:

$$\log D = 13.64 - 0.19\ T \qquad (1)$$

where D is the time in seconds to achieve a 10-fold reduction in bacterial number, and T is the heating temperature in degrees Celsius. Representative D-values at a variety of temperatures and in different foods are given in Table 3.

The heat resistance of this bacterium is increased after sublethal heat shock. This increase in resistance due to sublethal injury can also be triggered by prior exposure to other stressors, such as low pH. As well, the heat resistance of *L. monocytogenes* may be increased severalfold on cured meats, and this increase may not be entirely due to changes in water activity (a_w) in the presence of curing salts.

The method used to recover heat-stressed cells can also have an impact on the apparent heat-resistance of the bacterium. For example, the use of anaerobic conditions leads to greater recovery of heat-stressed cells than culture in the presence of oxygen.

Table 3 Heat resistance of *Listeria monocytogenes* in various products

The organism is resistant to freezing. The viable populations of four strains of *L. monocytogenes* decreased by only 3–6% after 14 days' storage at −18 °C. In another study, the effects of freezing and subsequent frozen storage at −18 °C on the viability of a mixed inoculum of seven *L. monocytogenes* strains in ground beef, ground turkey, frankfurters, canned corn, icecream mix, and tomato soup was determined. *Listeria* responses were related to the pH of the food. Where the pH of the food was >5.8, *L. monocytogenes* survived freezing and storage well. However, in tomato soup, where the pH was 4.74, the organism showed a decline in viability during prolonged storage and could not be quantitatively recovered on selective media. *L. monocytogenes* can also survive in seafood during storage at −20 °C for 3 months. Under these conditions populations on the frozen products decreased by less than 1 log after 3 months.

Sanitizers

A number of approved sanitizers, including acid anionic detergents, quaternary ammonium compounds, carrier-bound iodine, and chlorine, all reduced *L. monocytogenes* populations by a minimum of 99.999% at the recommended doses. Products showing a high efficacy contained iodine, peroxide, or quaternary ammonium as the active agent. However, the efficiency of sanitizers can be reduced in the presence of organic material. There is also evidence that repeated exposure to quaternary ammonium compounds can result in the acquisition of resistance to the sanitizer. The mechanism of action appears to be by the use of efflux pumps which can reduce intracellular concentrations of the sanitizer.

In addition, *Listeria* spp. can attach to processing surfaces where they may form biofilms. Cells present in biofilms have increased resistance to desiccation and the effects of disinfectants. Resistance of adherent cells to sanitizers is dependent upon the surface to which they are attached. Complete biofilm removal and/or inactivation was obtained in many cases where the surface was first cleaned prior to exposure to sanitizer.

Survival in Foods

L. monocytogenes has the ability to survive in a wide variety of foodstuffs (Table 4). The main factors affecting survival appear to be pH, salt concentration, and a_w, although the resistance of the organism to drying is also affected by temperature and relative humidity, as well as the nature of the suspending menstruum. Survival times are generally longer at lower temperatures. The organism can survive pH

[c]NS; no survival.

values of 3.6 for up to 25 days if kept at refrigeration temperatures. However, survival is dependent on the acidulant used. There are also reports indicating that some strains of *L monocytogenes* can survive salt concentrations as high as 25.5% for at least 32 days when stored at 4 °C.

Because it is essential to minimize recontamination of processed foods from the environment, processors must be aware that once *L. monocytogenes* is present in a food-processing plant it can persist for long periods of time (> 136 days), especially if the temperature is low and the bacterial cells are protected by residual food components.

Irradiation

In studies carried out using chicken breast meat, *L. monocytogenes* was found to be the most resistant to irradiation when compared to six other common foodborne pathogens. However, no significant differences were observed in the radiation resistance of *L. monocytogenes* in different meats. The D_{10} value at 5 °C was approximately 0.5 kGy for all the meats tested. Results obtained for *L. monocytogenes* were the same regardless of whether irradiation was delivered by electron beam or by gamma-rays from a ^{60}Co source. It is generally accepted that the irradiation dose currently approved by the Food and Drug Administration for use in meats is sufficient to control *L. monocytogenes*.

Other Nonthermal Processing Techniques

In an effort to provide consumers with minimally processed foods that have retained their nutritional status, a variety of nonthermal processing techniques are in various stages of development. These include high-pressure, pulsed electric fields, oscillating magnetic waves, high-intensity light, and others. The effects of a number of these on *L. monocytogenes* have been investigated. The ability of the organism to survive high-pressure processing of a variety of foods, including milk, cheese, beef, pork, and icecream mix, has been evaluated. In one study, early-stationary-phase cells in 1% peptone solution were pressurized at 345 MPa for 5 min at 25 °C or for 5, 10, or 15 min at 50 °C. Viability losses (in decimal reductions) following pressurization at 25 °C ranged from 0.9 to 3.5 among nine *L. monocytogenes* strains. When two strains showing the greatest difference in pressure resistance were treated at 345 MPa and 50 °C, both strains were reduced by greater than eight decimal reductions within 5 min.

In raw milk, pressures greater than 350 MPa did not permit enumeration of survivors of *L. monocytogenes* Scott A, due to the rapid fall in numbers. Although *L. monocytogenes* had a higher instantaneous pressure kill value, it was more resistant during holding under pressure than natural microflora.

Effects of high hydrostatic pressure on two *Listeria monocytogenes* strains (NCTC 11994 and a poultry strain) were examined in different foods at approximately 18 °C. Samples of ultra heat-treated (UHT) milk, raw and cooked chicken mince, and raw and cooked beef mince were inoculated with *L. monocytogenes* and exposed to a pressure of 375 MPa. Generally, for both strains, increasing the time of exposure led to a decrease in the number of survivors; however, resistance did vary depending on the nature of the food substrate. Survival was significantly greater ($P < 0.01$) in UHT milk compared to that in meat, and survival of both strains was higher in cooked meats compared to raw meats. Complete inactivation of strain NCTC 11994 occurred in milk treated with a pressure of 375 MPa for 15 min at 45 °C.

In order to investigate the effect of pulsed electric field (PEF), pasteurized whole, 2% and skim milk were inoculated with *L. monocytogenes* Scott A and the effects of milk composition (fat content) and PEF parameters (electric field strength, treatment time, and treatment temperature) on the inactivation of the bacterium were studied. No significant differences were observed in the inactivation of *L. monocytogenes* Scott A in the three types of milk by PEF treatment. However, the lethal effect of PEF was a function of field strength and treatment time, with higher field strength or longer treatment time resulting in a greater reduction of viable cells. A 4-log reduction of the bacterium was obtained by increasing the treatment temperature to 50 °C. The use of PEF is a promising technology for inactivation of *L. monocytogenes*, especially when combined with the addition of nisin.

Factors Affecting Growth

Many factors affect the growth of *L. monocytogenes* and, because they interact, they should not be considered in isolation. Many mathematical models have been developed that predict the response of the organism when grown under a variety of conditions. Some of the important variables governing the growth of this bacterium are discussed below and limiting parameters for growth are shown in Table 5.

Temperature

One of the major reasons why *L. monocytogenes* has posed such a threat to the food industry is its ability to grow at refrigeration temperatures. Some strains of the organism are capable of growth at −0.1 to −0.4 °C in UHT milk and chicken broth, but a study of 100 strains of *L. monocytogenes* found a mean minimum growth temperature of −1.1 °C. At refrigeration temperatures (4–5 °C) the generation time for *L. monocytogenes* varies between about 20 and 60 h, depending on the food in which it is present. At abusive temperatures (10 °C) the organism will grow with doubling times of 10–15 h.

The previous growth temperature of the inoculum can have a marked effect on both rate and extent of growth at low temperatures. Prior acclimatization of the bacterium at low temperatures reduces the lag time for growth.

There is evidence that virulence of *L. monocytogenes* is enhanced by growth at low temperatures.

Table 5 Limiting growth conditions for *Listeria monocytogenes*[a]

Factor	*Minimum*	*Optimum*	*Maximum*
Temperature (°C)	−0.4–0.1	37	44
pH	4.3–5.7	7	8
Water activity	0.9–0.96	–	–

[a]Values vary depending on strain, medium, humectant, acidulant, and interactive effects between growth conditions.

pH

Listeria spp. grow at a wide range of pH (5–9.5) which encompasses the pH of most foods. The minimum pH at which growth occurs is inversely proportional to the growth temperature and growth at pH values below 5 has been observed at temperatures near the optimum for growth (30 °C). The nature of the acidulant also affects growth. In terms of concentration of undissociated acid required to inhibit growth, lactic and citric acids are the most effective inhibitors of the organism.

Other factors, such as a_w, alter the response of *Listeria* spp. to pH changes. The inhibitory effects of salt and pH appear to be additive.

Water Activity and Osmotic Pressure

Growth of *L. monocytogenes* is inhibited in media with an a_w of less than 0.942 (achieved by the addition of sucrose or sodium chloride) or 0.932 (by the addition of glycol). In one study involving the addition of sucrose to broth, growth of *L. monocytogenes* was observed at an a_w of 0.92. Proliferation of the organism was observed in 12% sodium chloride at pH 7 and 30 °C, but the concentration of sodium chloride supporting growth increased with a decrease in temperature.

L. monocytogenes can grow in high-osmotic-strength environments. A number of compounds, including glycine betaine, and carnitine, act as osmoprotectants, and their addition to defined medium causing osmotic stress resulted in an increase in growth rate of *L. monocytogenes* 10403S and Scott A. These same compounds also act as cryoprotectants, as, when added to media, they increased the growth rate of *L. monocytogenes* at 5 °C.

Substrate

The rate of growth of *L. monocytogenes* is remarkably similar in a variety of foodstuffs (Table 6). This may be expected, considering the pH and a_w values for these foods are similar. When slices of cooked beef, pork, chicken, or turkey were inoculated with *L. monocytogenes* strain Murray B, vacuum-packaged, and stored at 5 °C, decreases in pH (6.9 to 5.9) and a_w (0.993 to 0.960; adjusted with NaCl) of the cooked meats increased the lag time and reduced the growth rate of the bacterium, but the type of meat had no effect on the growth of the organism after allowance was made for pH. Thus, slower

Table 6 Typical generation times for *Listeria monocytogenes* growing in various foods at 7 °C

Food	*Generation time (h)*
Raw milk	
Naturally infected	16
Experimentally infected	19

Eggs, pasteurized whole	17
Crabmeat	12
Shrimp	14
Surimi	12
White fish	15
Tryptic soy broth	13

growth could be expected in fermented foods, although other factors may also contribute to the rate of *Listeria* replication in foods. For example, when growth of *L. monocytogenes* on raw and cooked beef, chicken meat, catfish, and shrimp at 4 °C was compared, *L. monocytogenes* grew faster and reached a higher population on raw and cooked catfish and shrimp than on beef or chicken. Some difference in growth rate was due to inherent pH differences of fresh tissues, but on cooked tissues, growth rate on acidified shrimp was the same as that on shrimp with the normal pH of 7.6. Growth rates of *Listeria* on cooked beef at either pH were similar to those noted on uncooked tissue. This indicates that additional factors in shrimp exert inhibitory effects at reduced pH levels, and that these may be heat-related.

The fat content of milk may dictate growth rates and population levels for *L. monocytogenes* strains of serotype 4b. However, other work failed to confirm this enhanced growth with increasing fat levels. Better growth of *L. monocytogenes* on fatty meat rather than lean tissue has also been found, and this was reportedly due to a shorter lag phase of growth on the fat.

L. monocytogenes was able to grow to greater cell numbers in chocolate milk than in skim or whole milk. The growth of the organism in milk was also enhanced by the addition of sugar, cocoa, and carrageenan stabilizer. The major substrate supporting the growth of *L. monocytogenes* in milk appears to be glucose.

The characteristics of *L. monocytogenes* isolated from different foods appear to be different.

Modified Atmospheres

In a study on cooked chicken loaf stored under a modified atmosphere containing 50% carbon dioxide and 10% oxygen, growth of *L. monocytogenes* was retarded at 3 and 7 °C but not at 11 °C. Modification to obtain an atmosphere of 80% carbon dioxide and 0% oxygen resulted in decreased growth at all three storage temperatures. Similar results have been reported for beef, pork, lamb, and turkey packed under carbon dioxide when growth was observed at 10 °C, but was inhibited at temperatures between 0 and 5 °C. In general, for *L. monocytogenes* present in modified-atmosphere-packaged raw meats, growth is decreased with increasing carbon dioxide concentrations and decreasing temperature. Growth of *L. monocytogenes* occurs in beef and cooked chicken packaged under vacuum and in oxygen-permeable or -impermeable films.

To investigate the effect of modified-atmosphere packaging on processed meats, samples of sliced frankfurters were inoculated with *L. monocytogenes* and packaged under atmospheres containing between 20 and 80% carbon dioxide (the remainder being nitrogen). Only the 80% carbon dioxide atmosphere fully inhibited *L. monocytogenes* at 4, 7, and 10 °C, but this carbon dioxide concentration caused unacceptable souring of the sample.

Modified-atmosphere packaging also has little effect on the ability of *L. monocytogenes* to grow in fish and seafood or in fresh-cut vegetables such as lettuce. However, there is evidence to suggest that bacteriocin-forming lactic acid bacteria or bacteriocin isolates may be useful as biopreservatives for modified-atmosphere-packaged vegetables.

Inhibitors

A number of naturally occurring compounds and food additives are inhibitory to *L. monocytogenes*. These include the enzymes lactoperoxidase (found in milk) and lysozyme (milk and egg white). Lactoperoxidase enhances thermal destruction of the bacterium. Milk lactoferrins also inhibit the organism and it is speculated that an animal tissue bacteriostatic agent active against *L. monocytogenes* exists.

Fatty acids, naturally occurring in milk from several mammalian species, are inhibitory for *L. monocytogenes*, with lauric (C12:0), linoleic (C18:2), and linolenic (C18:3) acids exerting the strongest bactericidal activity. These fatty acids also decreased the ability of *L. monocytogenes* to invade mammalian cells.

Antibiotic compounds, bacteriocins, produced by lactic acid bacteria are effective against *Listeria* spp. Among these are nisin produced by *Lactococcus*

lactis, pediocins of *Pediococcus acidilacti* and *P. pentosaceus*, as well as several other compounds secreted by other lactic acid bacteria.

Some preservatives commonly used in the food industry inhibit and/or inactivate *L. monocytogenes*. These include sorbic acid, sodium benzoate, and sodium propionate. The levels of nitrite (120 p.p.m.) and salt (3%) used in the meat industry reduced numbers of the organism during production of sausage lasting 21 days, but surviving cells were detectable. Populations of *L. monocytogenes* can be reduced to below detection limits by a variety of liquid smoke products.

Among other compounds that inhibit this bacterium are lauric (C12:0), linoleic (C18:2), and linolenic (C18:3) acids, monolaurin, organic acids, and high-molecular-weight sodium polyphosphates. Extracts of numerous herbs and spices also have the ability to inhibit growth of *L. monocytogenes*, including rosemary extract and cinnamon extract.

It is noteworthy that the efficacy of these antilisterial compounds in food is dependent on many factors, such as the food matrix, pH, and a_w.

Interaction with Other Microorganisms

Growth of *L. monocytogenes* is inhibited in the presence of lactic acid bacteria, including *Lactococcus lactis, L. cremoris, Leuconostoc gelidum*, and *Lactobacillus bulgaricus*. The inhibition is partly due to production of bacteriocins by the lactic acid bacteria but there is also a substantial pH effect. In most instances growth of the pathogen is completely inhibited when the pH drops below 4.75.

Interactions between *Listeria monocytogenes* and other organisms have been described. Coinoculation of milk or broth with *L. monocytogenes* and *Pseudomonas* spp. resulted in either slight retardation of growth of the pathogen or no effect, depending on strains and temperature of incubation. However, a significant stimulation of growth of *L. monocytogenes* in milks that had previously supported growth of *Pseudomonas* spp. has been reported. This effect on growth is due to the production of proteases by the pseudomonads. Accelerated growth of *L. monocytogenes* in whey cultured with *Penicillium camembertii* compared with uncultured whey has been reported.

Foodborne Outbreaks of Listeriosis

Several major outbreaks of listeriosis have been described where food was shown to be, or was strongly implicated as, the source of infection (Table 7). Several other sporadic outbreaks have occurred where food has been the suspected vehicle for infection. In most foodborne cases, the foodstuff was either unprocessed or inadequately processed. Some of the major foodborne outbreaks of listeriosis are discussed.

Table 7 Notable outbreaks of listeriosis associated with foods

Year	*Location/country*	*Approximate no. of cases (deaths)*	*Possible vehicle for transmission*	Listeria monocytogenes *serotype*
1979	Boston, USA	20 (5)	Raw celery, tomatoes, lettuce	4b
1980	New Zealand	29 (9)	Shellfish, raw fish	1/2b
1981	Maritime Provinces, Canada	41 (17)	Coleslaw	4b
1983	Massachusetts, USA	49 (14)	Pasteurized milk	4b
1985	California, USA	142 (48)	Jalisco cheese	4b
1983–87	Switzerland	122 (31)	Raw milk cheese	4b
1986–87	Philadelphia, USA	36 (16)	Icecream, salami	Several
1989	Connecticut, USA	9 (1)	Shrimp	4b
1987–89	UK	355 (94)	Pâté	4b
1990	West Australia	11 (6)	Pâté	1/2a
1991	Tasmania, Australia	4 (0)	Smoked mussels	1/2
1992	New Zealand	4 (2)	Smoked mussels	1/2
1992	France	279 (83)	Pork tongue in jelly	4b
1993	France	39 (12)	Pork rillettes (pâté)	4b
1993	Italy	23 (0)	Rice salad	1/2b
1993–94	Texas, USA	8 (1)	Frozen mixed vegetables	4b
1994	USA	45 (0)	Chocolate milk	1/2b
1994–95	Sweden	6 (1)	Cold-smoked rainbow trout	4b
1995	France	20 (4)	Raw milk soft cheese	4b
1998–99	USA	100 (21)	Hot dog sausages	4b
1999–2000	France	6 (2)	Rillettes, langoustines	4b
1999–2000	France	32 (10)	Pork tongue in jelly	4b
2000	USA	29 (4)	Processed turkey	?

Maritime Provinces, Canada, 1981

This outbreak was traced to contaminated coleslaw. *L. monocytogenes* of the same serotypes were isolated from patients, coleslaw from the refrigerator of an infected person, and unopened packs of the product from the same manufacturer. The coleslaw had been made from cabbages grown on land fertilized by sheep manure from a flock known to be infected with listeriosis.

An outbreak of the illness at a hospital in Boston in 1979 may also have been due to the consumption of contaminated raw vegetables.

Massachusetts, 1983

A case-control study showed that this outbreak was strongly associated with the consumption of pasteurized milk. The organism was not isolated from the implicated milk, but cases of bovine listeriosis had occurred in herds supplying milk to the creamery involved. This led to the suggestion that *L. monocytogenes* could survive pasteurization due to its intracellular location in somatic cells. Plant inspection revealed no obvious faults that would have resulted in inadequate heat treatment or postpasteurization contamination. However, the fact that the pasteurizer was not located adjacent to the packaging room could have been a contributing factor in the contamination. A few facts are difficult to explain. For instance, the strain isolated from the raw milk was a different phage type from the epidemic isolate. Also, only consumption of 2% fat and whole milk was associated with infection and not skim milk, which was processed on the same day, with the same equipment and milk supply.

California, 1985

An outbreak of listeriosis in California between January and August 1985 resulted in 48 deaths. The most likely source of infection was Mexican-style cheese from one manufacturer. *L. monocytogenes* serotype 4b was isolated from the cheese and processing plant. Phosphatase tests on the cheese showed that pasteurization was inadequate or the product was contaminated with raw milk. Inspection of the plant revealed several defects. There were holes in the pasteurizer plates, a cleaning-in-place line connected raw milk supply to the cheese vat, and the capacity of the pasteurizer was exceeded. This led to the conclusion that raw milk was the cause of the outbreak.

Vaud, Switzerland, 1983–87

Only sporadic cases of listeriosis had been encountered in the Swiss canton of Vaud prior to 1983. The number of cases increased dramatically in the winter of that year. In the following years a similar seasonal peak in cases was recorded. Cheeses were found to harbor *L. monocytogenes*, including a particular type of soft cheese exclusively produced in the winter and mainly eaten in the region of the listeriosis outbreak. The sero- and phage type of the strains isolated from this cheese, Vacherin Mont d'Or, were the same as the epidemic isolates. The cheese was made from raw milk, although *L. monocytogenes* was rarely isolated from the milk supply (< 1% of samples positive). In 1987 the product was recalled and production stopped. After introduction of these measures. no cases of listeriosis were recorded in the area in 1988.

France, 1992

An outbreak of listeriosis in France in 1992 was reported to be responsible for 279 cases, including 22 abortions and 63 deaths. It was attributed to the consumption of pork tongue in aspic, but some other cases may have been caused by other delicatessen products that had become cross-contaminated. The epidemic strain was isolated from 220 food products at 30 retail stores where the pork tongue was sold.

France, 1995

An outbreak of listeriosis in France in 1995 was traced to the consumption of Brie de Meaux cheese made from unpasteurized milk. The outbreak involved 20 cases and four deaths. Further cases were prevented by instigating disinfection and other control measures at the cheese plant.

USA 1998–2000

Between 2 August 1998 and 8 February 1999, the Centers for Disease Control and Prevention (CDC) reported an outbreak of listeriosis involving a rare strain of *L. monocytogenes*, serotype 4b, involving approximately 100 illnesses in 22 states covering almost every region of the contiguous USA. This outbreak was responsible for 21 deaths (15 adults and six miscarriages/stillbirths). CDC and state and local health departments identified the vehicle for transmission as hot dogs and possibly deli meats produced under many brand names by one manufacturer, Bil Mar Foods. On 22 December 1998, the manufacturer issued a voluntarily recall of specific production lots of hot dogs and deli meats that might be contaminated and the number of illnesses caused by the outbreak strain decreased dramatically following the recall. The direct cost of recalling the meats was $76 million, but that did not include the resulting loss of sales. Meat sales dropped about $200 million in the 6 months after the recall. The outbreak strain of *L. monocytogenes* was isolated from an opened and

previously unopened package of hot dogs manufactured at the company's plant in Zeeland, Michigan.

In 1997, the plant was shut down for several days for violating standard sanitation procedures, and in July 1998 evidence of *Listeria* was found in the plant, but not along the food production line. The plant was supposedly aggressively sanitized and cleaned after the July testing. Federal investigators suspect dust kicked up during a summer maintenance project at the meat-processing plant may have been the source of the outbreak. The US Department of Agriculture, which regulates the quality, sanitation, and safety of meat products in the USA, found a dramatic increase in the amount of *Listeria* levels on floors and equipment in the plant in the 6 weeks after the construction work, during which time the isolation rate for '*Listeria*-like indicator organisms' on production equipment rose from 25 to 92%. Maintenance on the air-conditioning system performed in one of the rooms at the plant could have caused widespread contamination of meat products throughout the plant.

In another outbreak involving processed meats, 29 illnesses caused by a strain of *L. monocytogenes* were identified in 10 states between May and November 2000. The isolates from these cases were indistinguishable when subjected to genotyping by pulsed-field gel electrophoresis and ribotyping. The outbreak was linked to the consumption of contaminated turkey and chicken deli meats produced at two establishments; one of these establishments produced turkey meat for the second establishment.

Sporadic Cases

Sporadic cases of listeriosis have arisen from the consumption of meat and poultry products, dairy products, vegetable products, and seafood. *L. monocytogenes* counts of $3–5 \times 10^7$ were found on analyzing samples of goats' milk cheese implicated in one case, and subsequent investigations suggested that counts may have increased to these levels during storage in the display cabinet of the retailer. This led one researcher to propose that the increase in consumption of relatively young soft cheese, coupled with extended refrigeration of foods as family shopping is carried out at weekly, or even monthly, intervals, may be important factors contributing to listeriosis cases reported in the UK.

Detection

M W Griffiths, Canadian Research Institute for Food Safety, University of Guelph, Guelph, Ontario, Canada

Background

One of the primary goals of a food microbiologist is to detect the presence of specific pathogens in foods in the shortest possible time. This is not an easy task as often, the organism of concern is present in low numbers, and more often than not, it is found in foods in the presence of large populations of other bacteria. Detection of pathogens is primarily achieved using a cultural approach involving essentially three steps: (1) a nonselective and/or selective enrichment procedure to increase the numbers of the target organism to detectable levels and provide an opportunity for injured cells to recover, (2) a selective step when the organism is presumptively identified and (3) confirmation of the identity of the isolates obtained by the first two phases.

Detection

The type of food being analyzed is an important factor to consider when evaluating methods for recovery and enumeration of specific bacteria, and *L. monocytogenes* is no exception. The physical nature of the food may affect distribution of the inoculum on the medium or mask color reactions important for colony differentiation. More importantly, foods differ with respect to

their indigenous microflora. Thus, a medium selective for *Listeria* may successfully inhibit contaminants from one type of foodstuff, but not from another. For this reason, there is no one universally acceptable method for the isolation of *L. monocytogenes* from foods, and each regulatory jurisdiction has its own preferred method.

Enrichment

One of the most useful methods for enrichment of *L. monocytogenes* involves incubation of samples at 4 °C for up to 12 weeks in a nonselective medium. Unfortunately, the length of this procedure precludes its general use in the food industry.

Experiments performed to optimize basal broth medium for the growth of *L. monocytogenes* gave rise to the formulation of an enrichment broth containing proteose peptone (0.5%), phytone peptone (0.5%), sodium chloride (0.5%), dextrose (0.1%), yeast extract (0.1%), sodium pyruvate (0.1%), and disodium phosphate (0.25%). Under optimum conditions, the generation time of *L. monocytogenes* was at least 6 min shorter in this broth than in tryptose broth.

A number of selective agents have been incorporated into enrichment broth. Most enrichment broths for *L. monocytogenes* have contained nalidixic acid to prevent growth of Gram-negative bacteria and acriflavin to provide additional selectivity with regard to Gram-positive organisms. A commonly used enrichment broth, developed by the US Food and Drug Administration, contains acriflavin, nalidixic acid, and cycloheximide. Formulations based on these inhibitors may not be entirely satisfactory due to the growth of interfering species. Of special concern are highly resistant strains of *Enterococcus faecalis* and other enterococci. Reports of resistant strains of *Staphylococcus aureus* and *Kurthia* spp. have also appeared in the literature. An improved enrichment formulation has been described by researchers at the US Department of Agriculture (USDA). They claim that buffered tryptose phosphate broth containing acriflavin and claforan may be an effective enrichment system, but still expressed some reservations about its ability to control the growth of all enterococci.

It has been claimed that two-stage enrichment procedures are more effective for amplifying the growth of *L. monocytogenes* from food samples. In one such procedure, UVM *Listeria* enrichment broth (containing acriflavin and nalidixic acid) was used initially. After 24 h, samples were transferred to a modified broth containing lithium chloride to inhibit enterococcal growth. The second enrichment broth also contained esculin and ferric ammonium citrate so that presumptive growth of *L. monocytogenes* could be detected by the appearance of a black precipitate due to the formation of iron phenolic compounds resulting from esculin hydrolysis. No false negatives were found when this technique was used on a variety of dairy and environmental samples. Unfortunately, a high rate of false positives was detected, which was again primarily due to growth of enterococci. The strongly buffered UVM broth has advantages when isolating *L. monocytogenes* from soft cheese as it combats the rapid drop in pH that results when sampling this product.

Where there is likely to be heavy contamination with interfering organisms, the more selective enrichment broth, L-PALCAMY, may give better results. However, the use of highly selective media may be problematic as the high concentration of inhibitors in the media can slow the growth of sublethally injured or sensitive strains of *Listeria*. To overcome problems associated with the recovery of sublethally injured cells, a nonselective medium, such as buffered peptone water, has been used as the primary enrichment broth followed by secondary enrichment in a more selective medium. A nonselective universal enrichment broth has been described for the combined enrichment of *Listeria* and *Salmonella*. It has also been shown that strict anaerobic incubation aids in the recovery of injured *L. monocytogenes*.

A two-stage enrichment of particular value for meats involves primary enrichment for 24 h at 35 °C in proteose peptone–yeast extract broth followed by a secondary enrichment under the same conditions in the same broth, but this time modified to contain the selective agents lithium chloride, glycine anhydride, acriflavin, Tween 80, polymyxin B, ceftazidime, phosphomycin, and nalidixic acid.

The resuscitation of *L. monocytogenes* depends on the media, incubation conditions, and sample matrix. For example, the recovery of *L. monocytogenes* from cheese was affected by the method of homogenization of the sample, the type of diluent used, and the temperature of the diluent. The best results were obtained when cheese samples were homogenized in a Waring blender for 2 min and diluted in trisodium citrate (2% w/v) pretempered to 40 °C. However, due to safety concerns, the authors recommended that blending be replaced by stomaching for 3 min. When enrichment was performed at 30 °C, there was generally no advantage in prolonging the incubation time from 24 to 48 h. Optimum growth of *L. monocytogenes* during enrichment is obtained if the initial pH of the broth was between 6.8 and 7. Improved isolation of *L. monocytogenes* was reported when the enrichment was carried out under microaerophilic conditions

(5% oxygen; 10% carbon dioxide; 85% nitrogen). There was a decreased lag period noted for growth of *L. monocytogenes* under microaerophilic conditions with increased carbon dioxide concentrations. Dilution of the sample after enrichment with potassium hydroxide is often recommended in protocols but is of limited value, having no effect on the number of recoveries or the background microflora. Enrichment broths used for the detection of *Listeria* are shown in Table 1.

Selection

After amplification of the number of *L. monocytogenes* cells by enrichment, a presumptive isolation is carried out. This usually entails plating on to selective or differential media. Several such plating media for detection of *L. monocytogenes* have been described (Table 2).

One formulation that has been used widely is McBride's *Listeria* agar. Phenylethanol, lithium chloride, and glycine serve as the selective agents, and blood is incorporated into the medium to identify hemolytic strains. Overgrowth of plates with resistant staphylococci and streptoccoci can occur with this medium. Modifications to this medium include the incorporation of cycloheximide to prevent the growth of yeasts and molds, and substitution of glycine with glycine anhydride (a more effective selective agent). Cephalosporin antibiotics such as moxalactam have also been added to McBride's agar to produce a highly selective medium, although periodic problems due to growth of resistant isolates of enterococci, *Staphylococcus* spp. and *Kurthia* spp. can arise. Another cephalosporin, ceftazidime, may be more effective than moxalactam. A medium containing ceftazidime and acriflavine as selective agents inhibited all organisms, other than *L. monocytogenes*

Table 1 Composition of enrichment broths used for the detection of *Listeria*

Stage of enrichment/enrichment broth	*Acriflavine (mg l^{-1})*	*Nalidixic acid (mg l^{-1})*	*NaCl (g l^{-1})*	*Buffer*	*Other additions*
Primary enrichment					
Buffered peptone water	0	0	5	Phosphate	None

PALCAM	5	10 (P)	10	Ceftazidime (30)

with the exception of a few enterococci, members of the Enterobacteriaceae, yeasts, and molds.

Differentiation of *Listeria* colonies on many media is achieved by their characteristic blue to blue–gray color when the plates are illuminated with obliquely reflected light (Henry illumination). This technique has been criticized because it is often difficult to perform effectively, is subjective, and is not easily quantifiable. Therefore, research has been concentrated on the development of media that rely on other means of differentiation.

A series of differential selective media have been developed by researchers in The Netherlands. The first, RAPAMY agar, used a Columbia blood agar base with the addition of ferric ammonium citrate and egg yolk emulsion. Selectivity was provided by nalidixic acid, acriflavine, phenylethanol, and incubation under microaerobic conditions. The presence of esculin and ferric ammonium citrate together with D-mannitol and Phenol Red results in presumptive positive colonies that are dark gray with a black center surrounded by a dense black halo (due to esculin hydrolysis) against a cherry red background (caused by the inability of *Listeria* to ferment mannitol). However, RAPAMY medium failed to isolate *Listeria* from food in which *Enterococcus* spp. exceeded *Listeria* by a factor of about 10^3. A modification of the medium to replace nalidixic acid with lithium chloride to prevent growth of enterococci gave encouraging results with a variety of foods, including raw chicken, raw milk, raw vegetables and raw milk soft cheeses. *Enterococcus* spp. and *Staphylococcus* spp. that were able to grow on this medium (ALPAMY) could be differentiated from *Listeria* spp. on the basis of their colony morphology. However, sublethally injured cells of *L. monocytogenes* could not be recovered reliably on ALPAMY. Further modification of the medium resulted after addition of polymyxin B and ceftazidime and supplementation of the Columbia agar base with glucose. The modified medium (PALCAM agar) recovered strains of *L. monocytogenes* and other *Listeria* spp. quantitatively and suppressed growth of most other bacteria commonly found in food. The occasional *Enterococcus* or *Staphylococcus* isolates that developed on the medium gave gray colonies with a brown–green halo or yellow colonies with a yellow halo.

Another differential agar that has found widespread use is Oxford agar. Again, Columbia agar forms the basis of this medium, but the selective agents used consist of lithium chloride, acriflavine, colistin, cycloheximide, cefotetan, and fosfomycin. Differentiation of *Listeria* spp. is obtained by the incorporation of esculin and a ferric salt, resulting in black zones around suspect colonies. Good inhibition of interfering organisms, including enterococci, has been reported using this medium.

Good results have been obtained for the isolation of *Listeria* spp. from meats, poultry, and seafood using a modified Vogel Johnson agar. The medium includes glycine, elevated levels of lithium chloride, nalidixic acid, bacitracin, and moxalactam as selective agents. The medium also includes mannitol as a differential agent and potassium tellurite as both a differential and selective agent. On this medium, *Listeria* spp. are entirely black on a red background, whereas resistant strains of enterococci and staphylococci are surrounded by a yellow zone due to mannitol fermentation. The medium surrounding resistant *Kurthia* strains turns maroon due to their strong alkaline reaction.

Media for the presumptive identification of *L. monocytogenes* based on the formation of the enzyme phosphatidylinositol-specific phospholipase C have been described. CHROMagar *Listeria* helps to easily differentiate *Listeria monocytogenes* from other *Listeria* directly at the isolation step. *Listeria monocytogenes* colonies are blue and are surrounded by a white halo due to a specific phospholipase activity. Formation of an opaque halo surrounding *L. monocytogenes* colonies on Otaviani & Agosti Listeria Agar (ALOA) permits identification of *L. monocytogenes* even in mixed bacterial populations. When ALOA was compared with Oxford medium for the detection of *L. monocytogenes* in a variety of foods, including meat, meat products, sea foods, egg products, dairy products and foods of plant origin, the proportion positive for *Listeria* spp. was 34.1% for ALOA compared with 30.4% for Oxford medium. The proportion positive for *L. monocytogenes* was 18.3% on ALOA and 3.6% on Oxford medium. The chromogenic (5-bromo-4-chloro-3-indoxyl-myo-inositol-1-phosphate) or fluorogenic (4-methylumbelliferyl-myo-inositol-1-phosphate) substrates have been added to media in order to identify the presence of the phospholipase.

The temperature at which the selective medium is incubated may be important as the minimal inhibitory concentration of *Listeria* spp. to four antibiotics commonly used in selective plating media decreased with increasing temperature. Strains tended to be more susceptible to inhibition by the antibiotics at 37 °C rather than at 30 °C.

It is unlikely that one medium will prove suitable for the isolation of *L. monocytogenes* from all types of food. In studies on direct plating of *L. monocytogenes* from foods, noncultured dairy products such as pasteurized milk and chocolate icecream mix presented the fewest problems. However, Brie cheese

and raw cabbage contained high levels of contaminants that grew on isolation media. The main contaminants associated with Brie were molds, yeasts, and Gram-positive cocci. High levels of Gram-positive, rod-shaped contaminants were isolated with *Listeria* spp. from cabbage, although Gram-negative rods could often be detected on isolation media. Meats also contained high populations of contaminating microorganisms, principally Gram-positive cocci. Of the food examined, raw oysters posed the biggest problem because of the high numbers of indigenous Gram-positive, rod-shaped bacteria present. In addition, pseudomonads were often recovered from test media plated with raw oysters.

Confirmation

Confirmation of the identity of presumptive isolates on selective agar is usually achieved by a study of morphological and biochemical characteristics.

L. monocytogenes is a Gram-positive, small, short rod-shaped organism. These bacteria are flagellated and exhibit a characteristic tumbling motility at 20 °C. At higher temperatures (30–37 °C), production of flagella is suppressed with a concomitant loss in motility. On solid medium, *L. monocytogenes* colonies are translucent but take on a blue–green coloration when viewed by transmitted light. On blood agar, colonies produce a narrow zone of β-hemolysis.

Listeriae are aerobic to microaerophilic, and growth is enhanced in atmospheres with reduced oxygen and 5–10% carbon dioxide. They possess a heme-containing catalase and are oxidase-negative. *L. monocytogenes* is positive for the Voges–Proskauer and tellurite tests. The bacterium ferments glucose with the production of mainly L(+)-lactic acid, but no gas. All members of the genus hydrolyze esculin and maltose. Rhamnose and xylose reactions are important in differentiating *Listeria* spp. The CAMP test is also used to differentiate *L. monocytogenes* from other members of the genus. Both *L. seeligeri* and *L. monocytogenes* may not produce enough hemolysin to be noticeably hemolytic. However, when grown in an area of *Staphylococcus aureus* growth, the hemolytic reaction of these *Listeria* spp. is enhanced. The hemolysis is unreactive to metabolites of *Rhodococcus equi*. Reactions used for differentiation of *Listeria* spp. are summarized in Table 3.

Confirmation by biochemical tests can be made simpler by the use of ready-to-use test strips and automated identification systems such as the Vitek Junior. The Vitek Gram-positive identification card correctly identified 229 of 236 *Listeria*-positive isolates, and 95% of these were confirmed within 6–8 h. Other miniaturized test kits for the identification of *L. monocytogenes* based on phenotypical biochemical reactions include an arylimidase test on paper disks, API *Listeria* miniaturized test kit, Biolog Micro-ID *Listeria* and Biolog Phenotype microarrays for *Listeria*, and the Rosco system. When the Micro-ID *Listeria* System, API *Listeria*, and the Rosco system were compared with conventional identification tests, all these rapid biochemical test kits gave fast, reliable identification of *Listeria* species when compared with classical techniques. However, the API *Listeria* system identified the test strains without a complementary CAMP test.

Detection in Processed Foods

The main difference between the detection of *L. monocytogenes* in raw and processed foods is that the latter may have been subjected to conditions that sublethally stress the organisms of concern as well as reducing their numbers. It is known that *L. monocytogenes* can be sublethally stressed by heat, acidulants, and, to a lesser extent, freezing. Injured organisms need a period of recovery to repair cellular damage. The resistance of sublethally injured cells to selective agents used in their detection may be substantially reduced. In general, the greater the selectivity of the medium, the less likely it will be that stressed cells will grow.

Injured *Listeria* cells are unable to grow in the presence of 2% sodium chloride, and the proportion of stressed cells may be determined by comparing

Table 3 Biochemical tests for the differentiation of *Listeria* spp

Test	*Listeria spp.*

Xylose	−	−	+	+	+
Rhamnose	+	V[a]	−	−	V

[a]Variable reaction.

counts on media with and without sodium chloride addition. Using this technique, the effect of various agents on the recovery of sublethally injured *L. monocytogenes* has been determined. Selective agar used for isolation of *Listeria* spp. generally did not allow resuscitation of heat- or acid-injured cells. However, freezing did not appreciably affect the ability of test strains to grow on selective agar. The inability of a medium to support colony formation by thermally injured *L. monocytogenes* could be correlated with the inclusion of phenylethanol, tellurite, polymyxin B, sodium thiosulfate and oxgall, as well as sodium chloride. The addition of Tween 80, bovine fetal serum or egg yolk emulsion to modified Vogel–Johnson medium increased the ability to detect heat injured cells of the organism 100-fold without any loss of selectivity of the medium.

The universal response of cells undergoing injury appears to be the accumulation of hydrogen peroxide, and injured cells have an increased sensitivity to the toxic effects of hydrogen peroxide. Removal of hydrogen peroxide by the addition of catalase, or the nonenzymatic peroxide decomposer sodium pyruvate, has a beneficial effect on the recovery of injured cells of several microorganisms, including *Staphylococcus aureus* and *Salmonella typhimurium*. Effective repair of stressed *L. monocytogenes* cells on solid medium containing catalase has been described. Also, pyruvate addition to modified McBride agar enhanced recovery of heat-injured *L. monocytogenes*, but it was necessary to incubate plates at 22–25 °C for 7 days in order to achieve beneficial effects. However, the situation is confused as another study failed to show enhanced recovery of *L. monocytogenes* Scott A strain after addition of pyruvate to modified McBride agar. The addition of reducing agents to the medium has been shown to have a mixed effect on the recovery of heat-injured cells of *L. monocytogenes*, but recovery is increased if cells are incubated anaerobically. Enrichment in broth containing oxygen scavengers, such as oxyrase, enabled recovery of heat-injured listeriae within 6 h.

When the effects of incubation temperature, oxygen availability and supplementing the culture medium with magnesium chloride, magnesium sulphate, D-glucose, L-cysteine, catalase, or lithium chloride on the recovery of salt- or acid-damaged *Listeria monocytogenes* serovar 1/2c was studied on a solid repair medium, results showed that conditions promoting resuscitation of acid- or salt-injured cells are stress-specific, and differ in part from those described for heat-stressed *Listeria*.

It is strongly recommended that a nonselective enrichment is included when processed foods are analyzed for *L. monocytogenes*. An incubation time of 6–9 h at temperatures in the range of 20–40 °C is required for complete recovery of injured cells. The temperature optimum appears to be 25 °C. The organism does not appear to be able to repair at low temperatures. Prevention of large pH changes during the enrichment by buffering of the medium also promotes recovery of heat-stressed cells.

Detection in Suspected Food Poisoning

Confirmation of the involvement of *L. monocytogenes* in a case of illness suspected to be of food origin relies on isolation of identical strains of the organism from the patient and the suspected food. In practice, this is not feasible in the majority of cases, and epidemiological case-control studies have proved crucial in implicating a specific food product in an outbreak. The epidemiological surveillance of listeriosis has been hampered by the lack of adequate typing schemes. A serotyping system is available, but is of limited value as a high proportion of strains causing disease belong to only a small number of serovars. Of all *L. monocytogenes* strains isolated in Britain from human cases of listeriosis, 91% comprised only three serovars: 4b (59%), 1/2a (18%), and 1/2b (14%). A phage-typing scheme is also used, but a high proportion of strains (about 36% in Britain) are not typable by this system. An international multicenter typing study of *L. monocytogenes* was initiated by the WHO (Food Safety Unit, Geneva) in order to evaluate the usefulness of various phenotypic and genotypic typing methods for *L. monocytogenes* and to select and standardize the most appropriate methods. Several genotyping methods were compared, including pulsed field gel electrophoresis (PFGE) coupled with the use of the restriction enzymes, *Apa*I and *Sma*I, random amplification of polymorphic DNA (RAPD), high frequency restriction endonuclease analysis (REA), and restriction-fragment length polymorphism (RFLP). In general, this study reconfirmed that PFGE is a very accurate and reproducible method for fine structure comparison and molecular typing of *L. monocytogenes*. An automated genotyping system, the RiboPrinter, has proved useful for the analysis of *L. monocytogenes* and was used successfully to determine the source of the outbreak linked to hot dogs produced at the Bil Mar plant of Sara Lee. *L. monocytogenes* has been classified into three genetic lineages using ribotyping and PCR-RFLP typing of *hlyA* and *octA* genes. A higher proportion of human isolates (69.1%) than industrial isolates (36.8%) were classified as lineage I, which contains human sporadic isolates and all epidemic isolates. All other industrial isolates (63.2%) were classified as lineage II, which contains only human sporadic isolates.

Other Methods of Detection

As well as the classical cultural approach to the detection of *Listeria* spp., more sophisticated techniques are available commercially. These have advantages in their ease of use and in rapidity.

Impedance Monitoring

When microorganisms grow in a medium, large-molecular-weight substrates are catabolized to more highly charged, low-molecular-weight end products. These modify the electrical properties of the medium, and the changes can be detected as changes in conductance or capacitance. A selective medium has been described that contains acriflavin, ceftazidime, and nalidixic acid for use with impedance monitors such as Bactometer, Malthus, and RABIT. The medium also contains esculin and a ferric salt. The presence of *Listeria* spp. is confirmed by detection of growth and black coloration of the medium. In addition, growth of *Listeria* spp. gives a characteristic response curve when the capacitance signal is monitored. The medium gave good results with fermented dairy products, but there appears to be a high rate of false positives when soft cheeses are analyzed. A medium (LED medium) based on the selective agents used in Oxford agar has also been described for the electrical detection of *Listeria* spp. The medium relied upon the ability of *Listeria* spp. to induce a greater than 30% change in capacitance within 30 h. When compared with a traditional Fraser broth enrichment, the method gave far fewer false-positive results when used to analyze environmental swabs and products, such as meat, cream cakes, cheeses, and milks.

An indirect conductimetric assay that detects carbon dioxide evolved during growth of microorganisms is available. Such methods allow the incorporation of high concentrations of salts, such as lithium chloride, into media to aid selective growth of *Listeria* spp.

Immunological Methods

Monoclonal antibodies specific for *Listeria* spp. have been produced in a number of laboratories. There are several commercially available immunoassays for *Listeria* and *L. monocytogenes* (Table 4). A commercially available system applicable to foods involves the use of two monoclonal antibodies with an enzyme-linked immunosorbent assay (ELISA). Following enrichment in broth for 40–48 h at 30 °C, the ELISA procedure is performed. One antibody is used for antigen capture, and one for enzyme conjugation with horseradish peroxidase. For the ELISA to be effective, the enrichment broth must contain at least 10^6 *Listeria* cells per milliliter. The method was able to identify all milk samples containing *L. monocytogenes*. However, the detection rate with raw vegetable samples was only 68%. This was probably due to inadequacies in the enrichment procedure caused by low levels of *Listeria* spp. in the presence of mixed microflora. The method lacks species specificity within the genus *Listeria*. A monoclonal antibody specific for strains of *L. monocytogenes*, *L. innocua*, and *L. welshimeri* has been isolated.

A direct immunofluorescence test has been used to detect successfully *L. monocytogenes* in naturally contaminated soft cheese samples when numbers exceeded 10^2 per gram. The test could be carried out in 2 h. An immunomagnetic capture assay has been developed that is capable of detecting less than 2×10^2 *Listeria* cells per milliliter in enriched foods.

An automated instrument, Vidas, has been developed consisting of a solid phase receptacle (SPR) and pipetting device. The SPR is coated with antibodies against the target antigen, and the necessary reagents to perform an enzyme-linked fluorescent assay are contained in a ready-to-use reagent strip. The fluorescence measured is directly proportional to the quantity of antigen present in the sample. Two tests are available: the VIDAS LIS method detects *Listeria* spp., and the VIDAS LMO method is claimed to be specific for *L. monocytogenes*. The VIDAS LIS method was compared with two conventional culture methods for detection of *Listeria* spp. in naturally contaminated or inoculated ice cream, cheese, green beans, fish, roast beef, and turkey mince. The agreement between the VIDAS LIS and culture methods for all samples tested was 86%. The VIDAS LIS method has been approved by AOAC International for detection of *Listeria* in foods. When used to detect *L. monocytogenes* in cheese, the Vidas assay gave positive results in 97.5% of all contaminated cheeses after 48 h of enrichment. The detection limit was 6.3×10^5 to 2.0×10^6 cfu ml^{-1}.

A comparison of commercially available immunological kits for detection of *Listeria* spp. (Listeria Rapid Test Clearview, Pathalert Listeria, VIDAS Listeria LIS, VIP Listeria) and *Listeria monocytogenes* (Pathalert *Listeria monocytogenes*, VIDAS *Listeria monocytogenes* LMO) in food showed that there were no significant differences between the tests, but all methods had difficulties with the detection of *L. monocytogenes*.

Gene Probes and Related Techniques

A nonisotopic, colorimetric nucleic acid hybridization assay based on 16S rRNA sequences for the detection of *Listeria* spp. in dairy and environmental samples has been described. After a two-stage

Table 4 Commercial immunoassays for *Listeria* spp. and *L. monocytogenes*

Company	*Test name*	*Specificity*	*Time to perform*	*Principle*
BioMérieux, Inc.	Vidas Lis	*Listeria* spp.	45 min (excluding enrichment)	Automated enzyme-linked fluorescent assay
	Vidas LMO	*L. monocytogenes*	45 min (excluding enrichment)	
TECRA International Pty Ltd	*Listeria* Via	*Listeria* spp.	48 h (including enrichment)	Visual immunoassay
	Listeria Unique	*Listeria* spp.	32 h (including enrichment)	Antibody-coated dipstick
BioControl	VIP for *Listeria*	*Listeria* spp.		Single-use, visual immunoprecipitate assay
	Assurance *Listeria*	*L. monocytogenes* and related species	30 min (excluding enrichment)	Polyclonal enzyme immunoassay, microplate with breakaway wells
Neogen	Reveal for *Listeria*	Five of six *Listeria* spp. including *L. monocytogenes*	43 h (including enrichment)	Antibody against specific flagellar antigen; ELISA sandwich immunoassay combined with chromatography in a single-use device
Hardy Diagnostics	Listeria Rapid Test kit			
Vicam	Listertest	*Listeria* spp.	24 h	Immunomagnetic beads coupled with selective media and confirmation with membrane lift immunoassay
Diffchamb	Transia Plate *Listeria*	*Listeria* spp.	24–48 h	Based on a sandwich-type, immunoenzymatic reaction using a mixture of antibodies
	Transia Plate *Listeria monocytogenes*	*Listeria monocytogenes*		Based on three-step, sandwich-type, immunoenzymatic reaction; solid support of the reaction is a microtiter plate coated with antibodies specific for the extracellular P60 protein excreted by *Listeria monocytogenes*

enrichment procedure, the hybridization assay is performed, permitting detection of the organism in about 60 h. The procedure was able to identify 98% of *Listeria*-positive milk samples but only 45% of positive raw vegetable samples. The latter results were thought to be due to inadequate growth of the organism in the enrichment broth used.

A DNA probe specific for β-hemolytic *L. monocytogenes* has been applied to colonies obtained on selective media inoculated with food samples. The method was rapid and accurate for detecting the pathogen in raw milk, semisoft cheese, and ricotta cheese. The method was quantitative, provided that the contamination level in the food was greater than 10 cells per gram. Enrichment was necessary if numbers of *L. monocytogenes* were below this level. A probe, specific for *L. monocytogenes* has been obtained from two DNA fragments encoding part of the listeriolysin O molecule.

Two DNA hybridization assays for *L. monocytogenes* have been commercialized (Table 5). One, the Gene-Trak *Listeria monocytogenes* Assay, has been compared with the IDF Standard 143A:1995 using 107 cheese, fish, and meat samples naturally contaminated with *Listeria*. The Gene-Trak assay gave a significantly higher number of positive results. Examination of a further 75 cheese and meat samples with both methods and, additionally, with three immunological tests (Listeria Rapid Test Clearview, VIDAS Listeria LIS, and a noncommercial ELISA) again confirmed that the Gene-Trak assay gave a greater number of positive samples than all the other methods. The differences, however, were not significant. Another commercially available gene probe

Table 5 Commercial nucleic-acid based kits for the detection of *Listeria* and *L. monocytogenes*

Company	*Test name*	*Specificity*	*Time to perform*	*Principle*
Gen-Probe, Inc.	Accuprobe *L. monocytogenes*	*L. monocytogenes*	45 min (from culture)	Probe method
Neogen	Gene-Trak *Listeria* and *Listeria* DLP assays	*Listeria* spp.	27–48 h (including enrichment)	Probe to 16S rRNA sequence; capture probe on dipstick; colorimetric reaction; sensitivity of 10^6 cells per milliliter
DuPont Qualicon	Genus *Listeria* Automated Bax system	*Listeria* spp	< 4 h (excluding enrichment)	Amplification of rDNA spacer polymorphisms; tableted PCR reagents; the automated BAX system allows detection of multiple targets in the same run; up to 96 samples per batch
	Listeria monocytogenes Automated Bax system	*L. monocytogenes*	< 4 h (excluding enrichment)	
Bio-Rad Laboratories	Probelia *Listeria monocytogenes*	*L. monocytogenes*	30 h (including enrichment)	PCR amplification; unique lysis reagent for DNA extraction; single-pipette dose and single test tube; ready-to-use amplification buffer that contains an enzymatic decontamination system; semiautomatic; colorimetric detection of amplified products on microplates

assay for *L. monocytogenes* (AccuProbe) correctly identified samples containing the organism. However, it has been determined that some enrichment media (University of Vermont broth and Fraser broth) interfered with the AccuProbe test, due to prevention of cell lysis by the high salt concentration in these media. The detection limit of the AccuProbe test was also affected by enrichment and selective broths.

The polymerase chain reaction (PCR), using thermostable DNA polymerase, permits the rapid amplification of specific DNA sequences by a factor of up to 10^7. The portion of DNA amplified is determined by oligonucleotide sequences (primers). Primers have been synthesized that result in PCR products specific for *L. monocytogenes*. PCR protocols based on amplification of the listeriolysin O gene (*hlyA*), the internalin gene (*inlA*), a gene encoding a metalloproteinase (*mpl*), and the gene encoding an invasive-associated protein (*iap*) are among those that have been developed. The products can be detected by agarose gel electrophoresis, but more recently, real-time PCR methods have been developed that allow the detection of amplified products using fluorescence.

To overcome problems due to inhibition of the PCR by components of food, several methods have been investigated such as the use of filters to entrap and lyse bacterial cells, the use of immunomagnetic separation, and magnetic capture hybridization.

Commercial kits to detect *L. monocytogenes* based on PCR have become available (Table 5). The Bax system has been semiautomated and has been shown to be an effective method of screening for *L. monocytogenes* in smoked fish and many different types of fresh produce.

Undoubtedly, with the further development of real-time PCR methods and the advent of DNA array technology, molecular methods will be increasingly used for routine testing of foods for *L. monocytogenes*.

Listeriosis

F J Pagotto and J M Farber, Bureau of Microbial Hazards, Ottawa, Ontario, Canada

Background

The bacterium *Listeria monocytogenes* was identified in 1940. However, it can be dated back further in time, as a bacterial sample from a meningitis case dating to 1921 was the source of the bacterium described by Murray and colleagues as *Bacterium monocytogenes*. *B. monocytogenes* was so named because it caused mononuclear leucocytosis in rabbits. In 1940, Pirie isolated an organism, which he named *Listerella hepatolytica*, in honour of Lister. Listerellosis was thus used to describe the disease caused by this bacterium. Over time, it was discovered that *B. monocytogenes* and *L. hepatolytica* were in fact the same organism. Because *Listerella* was already chosen to describe a group of slime molds, Pirie proposed that the organism be called *Listeria monocytogenes*.

Listeriosis, an infection caused by *L. monocytogenes*, is now considered an important emerging foodborne infection. The importance of this organism can be seen not only from a human disease point of view but also from an economic perspective. Listeriosis is addressed here from a number of aspects: food and clinical diagnosis, antimicrobial chemotherapy, prevention from infection, and mechanisms of pathogenesis.

Listeriosis

Listeriosis is a serious infection caused by the bacterium *L. monocytogenes*. Listeriosis can affect all individuals, but pregnant women, the elderly, and immunocompromised individuals are especially at risk. Although expectant mothers may only present mild flu-like clinical symptoms, they can suffer from more serious complications such as premature delivery and infection of the newborn. In some instances, stillbirth may occur. Because *L. monocytogenes* is able to cross the three protective barriers (gastrointestinal, blood–brain, and placental), the symptoms of listeriosis are diverse, ranging from minor aches to death (**Table 1**).

In nonpregnant adults, *L. monocytogenes* has been shown to cause meningitis, encephalitis, and septicemia. In rare cases, contact with infected animals has caused focal infections in veterinarians. Although skin lesions are the major symptoms usually observed, endocarditis, arthritis, osteomyelitis, intra-abdominal abscess, and pleuropulmonary infections have also been described, albeit on rare occasions.

Listeriosis can be sporadic or epidemic, with food being the primary vehicle of transmission. While the reported incidence of listeriosis ranges from 0.2 to 8.3 cases per million population in industrialized countries, it is widely accepted that the true rate of the human disease is underestimated. Interestingly, the incubation period of listeriosis can range from 24 h to 91 days. The reason for this is not fully understood, but factors such as immune status, bacterial load, genetic predisposition, and other reasons may play a role. Another unresolved issue is the tropism of *L. monocytogenes* for the central nervous system.

Human listeriosis can be caused by all serotypes of *L. monocytogenes*. However, the majority of

Table 1 Symptoms ascribed to infections from *Listeria monocytogenes*

Category	*Symptoms*
Foodborne	Abdominal pain
	Chills
	Diarrhea
	Febrile gastroenteritis
	Fever
	Myalgia
	Nausea
	Vomiting
Pregnancy-related	Bacteremia
	Flu-like symptoms
	Intrauterine or cervical infections
	Neonatal meningitis
Other reported clinical manifestations	Cutaneous listeriosis

	Convulsions
	Hepatitis
	Meningoencephalitis
	Native/prosthetic valve endocarditis
	Osteomyelitis
	Rhomboencephalitis
	Spontaneous bacterial peritonitis
	Upper respiratory tract symptoms

listeriosis cases have been shown to be caused by serotypes 1/2a, 1/2b, and 4b. Further analyses has revealed that serotype 4b is prevalent in many European countries. In North America, serotypes 1/2a (Canada) and 4b (USA) are most often recovered in cases of listeriosis. Again, the reason for the differences observed in serotype and geographical distribution is unclear. Equally, it is not known at present why only three serotypes cause most of the illness.

Food and Clinical Diagnosis

The food microbiologist has the task of analyzing a food product for the presence of *L. monocytogenes*. They must be able to achieve this goal as rapidly as possible, as the food implicated may have already been consumed prior to the identification protocol being completed. Because listeriae are found throughout nature and in a wide variety of foods, there is no universal protocol at the moment. The majority of identification methods for the detection and enumeration of *L. monocytogenes* are cultural in nature. Other methods include the use of DNA probes, amplification-based methods, antibody-based technologies, and other rapid methods.

In Canada, the Bureau of Microbial Hazards (part of the Health Products and Food Branch) uses a detection method developed for all food and environmental samples (Figure 1). Presumptive colonies are then subjected to biochemical testing, using the criteria listed in Table 2 to differentiate

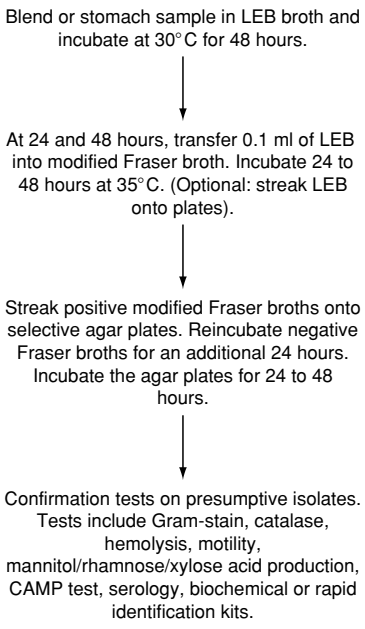

Figure 1 Flow chart for the isolation of *L. monocytogenes* from environmental and food samples.

L. monocytogenes from other species. Enumeration would involve macerating the sample with peptone water and plating on to any of two LPM, Oxford, MOX, or Palcam agar plates, followed by incubation at 30 °C (LPM) or 35 °C (Oxford, MOX, Palcam).

The cultural method utilizes selective agents with the hope of allowing cells of *L. monocytogenes* to grow and competing flora to be inhibited. LEB, also known as University of Vermont broth, contains nalidixic acid and acriflavin as selective agents. LPM medium contains the Gram-positive and Gram-negative inhibitory compounds, lithium chloride, phenylethanol, and moxalactam. Fraser broth contains lithium chloride, nalidixic acid, and acriflavin. The addition of esculin and ferric ammonium citrate causes a darkening of the broth or agar in the presence of *Listeria* species (*Listeria* species have the ability to hydrolyze esculin, and hydrolysis of esculin turns the medium black, denoting a presumptive positive test). Oxford agar contains lithium chloride, cycloheximide, colistin, acriflavin, fosfomycin, and cefotetan as selective agents, in addition to esculin and ferric ammonium citrate. Palcam agar and broth contain, in addition to esculin and ferric ammonium citrate, lithium chloride, polymixin-B-sulfate, ceftazidime, and acriflavin. Interestingly, it would appear that Palcam is preferred in Europe, while LPM, Oxford, and modified Oxford are used predominantly in North America. Many laboratories across the world are currently working on novel formulations that one day may be superior to currently used media.

Other methods have been reported in the literature for the detection and enumeration of *L. monocytogenes* in foods. The first report of a monoclonal antibody specific for the genus *Listeria* was reported in 1987. Since then, antibody-based detection methods have been described. These are based on the enzyme-linked immunosorbent assay. Many companies offer commercially available kits that use the antibody–antigen–antibody sandwich technique as the basis for detection. Antibodies have also been used in conjunction with magnetic beads. The beads are covered with *Listeria*-specific antibodies and mixed with the sample to be tested. A magnetic field is applied to separate the magnetic beads on which the *Listeria* cells are bound. After a washing step, other methods (for example, cultural methods) may be applied. Monoclonal antibodies have been used to serotype the genus *Listeria*, supplemented by hemolysis of blood and *in vivo* mouse assays (Table 3).

There are many protocols described that have, as their basis, hybridization of genetic material (DNA). Many probes have been described and used in colony hybridization methods, as have polymerase chain

reaction protocols. These methods offer the advantage of reducing the time required to obtain a positive results. However, a possible disadvantage of these methods is that isolation of *L. monocytogenes* is not required. A consequence of this would be the lack of pure isolates to do molecular typing and build on currently existing databases. Some of the existing alternative methods are summarized in Table 4.

In the clinical setting, the diagnosis of listeriosis is dependent on the isolation of the organism from normally sterile sites. These include the blood, placenta, amniotic, or cerebrospinal fluid (CSF). A positive diagnosis may also be ascertained through analysis of stool samples. Samples obtained from normally sterile environments are streaked on to blood agar. On sheep blood agar, narrow zones of β-hemolysis

[a]This is a partial list only and not meant as an endorsement by the authors.

can be seen. *L. seeligeri* has a similar appearance to *L. monocytogenes*, except that a weaker zone of hemolysis is observed. A wider zone of hemolysis has been noted with *L. ivanovii*. As all strains of *Listeria* are motile, tumbling motility (hanging drop preparations from primary cultures isolated) can be used to distinguish them from *Erysipelothrix* and *Corynebacterium* species. One must remember that *Listeria* is motile at room temperature (25 °C), and much less so or not at all at 37 °C.

It is difficult to diagnose listeriosis infections in the absence of culture isolation. While there are many monoclonal antibodies available for the genus *Listeria*, clinical use of these has been hampered owing to their cross-reactivity with other bacteria. Serological studies have shown that cross-reactivity to staphylococci, enterococci, and corynebacteria can occur. Newer antibodies, targeting the virulence factors, for example, may be more useful in the clinical setting. Stool sample carriage rates can range from 1 to 5%. As such, isolation of *L. monocytogenes* from the stool may be helpful in identifying *Listeria* gastroenteritis.

Culture of *L. monocytogenes* from blood or CSF does not require selective media, thus explaining why blood agar plates are the medium of choice. However, the isolation of specimens from food or environmental sources, stools, and vaginal secretions requires selective media (as described in Figure 1). (*See* **Microbiology**: Detection of Foodborne Pathogens and their Toxins.)

Antimicrobial Chemotherapy

Because *Listeria* infections are often associated with high mortality rates, it is imperative that effective antibiotics be used for treatment. The current treatment for listeriosis involves a combination of ampicillin and gentamicin. Therapy for 2–3 weeks appears to be sufficient to prevent relapses. Most β-lactam antibiotics may be used. However, cephalosporins are not effective against *L. monocytogenes* and should not be used to treat serious infections such as neonatal meningitis. Other chemotherapeutic agents, considered secondary treatments, include erythromycin, fluoroquinolones, and vancomycin.

There have been reports of plasmid-encoded resistance to antibiotics such as chloramphenicol, erythromycin, streptomycin, and tetracycline. Tetracycline resistance has been reported in 2–5% of strains of *L. monocytogenes*. These resistant strains have been shown to contain the *tetM* chromosomal determinant (within a transposon). The *tetM* gene has also been reported in *L. innocua*. Plasmid-mediated resistance to tetracycline is due to a *tetL* (minocycline sensitive) or *tetS* (minocycline resistant) gene. Interestingly, the *tetS* gene, while first noted in the genus *Listeria*, has been detected in *Enterobacter faecalis*.

Prevention from Infection

There have been many outbreaks of listeriosis involving a wide variety of foods. Coleslaw, cold-smoked salmon, delicatessen meats, hot dogs, pâtés, soft cheese, and even pasteurized milk have been implicated in major outbreaks. In addition, because *L. monocytogenes* is ubiquitous in nature, it may not be possible to eliminate it completely from the food chain.

Many initiatives have been introduced by government agencies in an attempt to ensure that foods are safe. Newer technologies are also currently being investigated as means of preventing the growth of *L. monocytogenes* in foods. Irradiation is one

example that has been approved for certain foods, including meats, fruits, vegetables, and spices. (*See* **Irradiation of Foods: Basic Principles; Applications.**)

Numerous recommendations have been put forth by many scientists and government agencies regarding ways to reduce the exposure to *L. monocytogenes* and the risk of foodborne listeriosis. These are summarized in Table 5. The incidence of *L. monocytogenes* in ready-to-eat foods ranges from 1 to 10%. It is certain, therefore, that most healthy people around the world consume foods containing low levels of this organism, without getting sick. Although the minimum infectious dose (MID) for *L. monocytogenes* is still unknown, if it were low, one would expect many more cases of listeriosis to be reported than are currently observed. Most countries do not have active human listeriosis surveillance programs in place. It appears that the incidence of human listeriosis is similar in countries with and without a "zero tolerance" policy in place.

Mechanisms of Pathogenesis

It is presumed that most infections of *L. monocytogenes* occur in the gastrointestinal (GI) tract, where invasion is thought to occur. While it is believed to be a resident of the GI tract for a short period of time, there have been reports describing patients with a long incubation time (up to 90 days) after eating contaminated food. In this instance, the ability to remain associated with the GI tract for extended periods is still not clear or defined and is currently an area of active research.

There is much speculation on why most clinical isolates belong to serovars 1/2a, 1/2b, and 4b; however, factual data in the form of animal studies or cell-culture experiments are lacking. In 1979, Seeliger and Hohne described a serotyping scheme for the genus *Listeria*. According to this designation, the letters a, b, c, etc. refer to the flagellar antigens. The numerical aspect (i.e., 1/2, 3, 4, etc.) describes the somatic antigens, being mostly techoic acid-associated (Table 3). While much work has been done in the area of pathogenesis, it is important to remember that these studies have utilized the serotype 1/2a (e.g., strains 10403S, EGD, NCTC7973, and Mack) or those belonging to serotype 1/2c (LO28). Since serotype 4b is responsible for a large number of reported outbreaks, it is quite probable that significant differences exist when compared to those serotypes currently being studied. For example, several multilocus gel electrophoresis-based studies have classified *L. monocytogenes* into two genetic groups: one that includes 'a' and 'c' serotypes (1/2a, 1/2c, 3a, and 3c) and another including the 'b' serotypes (1/2b, 3b, and 4b). Thus, while currently known virulence factors seem to be a common denominator in the pathogenesis of *L. monocytogenes*, certain class-specific host–pathogen interactions may explain the tropisms observed related to serotype.

L. monocytogenes has proved to be an extremely useful tool for examining protective immunity and immune responses during systemic infections. Upon ingestion of food contaminated with *L. monocytogenes*, the organism is believed to invade the intestinal epithelium and/or Peyer's patches. From here, the bacteria enter the draining lymph node and disseminate via the bloodstream to the liver and spleen. In most cases, infections of *L. moncytogenes* are limited, with clinical symptoms appearing in the immunocompromised, pregnant women, and neonates. However, it is equally important to note that listeriosis has one of the highest case fatality rates of all foodborne bacterial infections.

Upon injection of the organism into the bloodstream of mice, *L. monocytogenes* is usually cleared. Studies have shown that over 60% of organisms are taken up by the liver within 10 min of intravenus inoculation, with hepatocytes being the major site of replication in the liver. Hepatocytes contain over 90% of the organism after 6 h of infection.

Table 5 How to lower the risk of acquiring foodborne listeriosis

Group of interest	*Food item*	*Recommendations*
'Normal' individuals	Meat, fish, poultry	Cook all food of animal origin thoroughly
	All foods	Separate uncooked from cooked
	Milk and milk products	Avoid unpasteurized milk
	Nonfood items	Properly wash hands, knives, and kitchen utensils
	Fruits and vegetables	Wash all fruits and raw vegetables prior to consumption
High-risk (elderly, pregnant, or immunocompromised) individuals	Dairy products	Do not consume soft cheeses such as Brie, Camembert or feta (hard cheese, cottage, processed and yogurt are OK)
	Leftovers	Heat thoroughly to 70°C for a minimum of 2 minutes
	Hot dogs/wieners	Heat to 70°C for a minimum of 2 minutes
	Deli meats	Avoid unless thoroughly heated
	Pâté	Should be avoided

The innate component of the immune system is responsible for controlling the replication of the organism during the first 3 days of infection, based on studies performed in mice. This response will either eliminate the organism or prevent sepsis. The T-cells, part of the cell-mediated immune system, mediate a protective primary as well as a memory response to *L. monocytogenes*. Within the liver, macrophages known as Kupffer cells are believed to trap the majority of *Listeria* that enter. However, it has been shown that over 90% of liver bacteria are associated with hepatocytes, and not Kupffer cells. Currently, it is believed that there is a physical interaction between the Kupffer cells and neutrophils that is mediated via intercellular adhesion molecule-1, thereby promoting resistance against *L. monocytogenes*. Chemokines and other adhesion molecules cause the efflux of neutrophils and monocytes from the bone marrow to the peripheral blood, probably via interleukin-6 and macrophage colony-stimulating factor stimulation, respectively.

L. monocytogenes is considered an intracellular pathogen because it is able to enter a host cell, move across the cell cytoplasm, and enter neighboring cells without ever becoming extracellular (Figure 2). The infection process begins with the internalization of the organism into cells that may or may not be phagocytic. In the case of phagocytes such as macrophages, the phagocytosis process itself causes the organism to be taken within. For nonphagocytic cells, induced phagocytosis (known as invasion) occurs. The plasma membrane envelops the bacteria upon contact. The bacteria reside within membrane-bound vacuoles prior to lysing of the vacuolar membrane. Once free within the cell cytoplasm, *Listeria* are able to replicate and become covered with host actin filaments. The host actin filaments are rearranged to a polar tail, consisting of short actin filaments and other host proteins. The formation of the actin 'tail' at one end of the organism 'propels' it to move through the cytoplasm. As the organism nears the cell membrane, it protrudes and neighboring cells internalize them upon contact. In this manner, *L. monocytogenes* is able to move from one cell into another without being exposed to the 'outside' environment. Once in a neighboring cell, the bacterium is contained in a double plasma membrane, one from the previous cell (while protruding outward from the membrane) and one from the new cell (as it takes in the organism via phagocytosis).

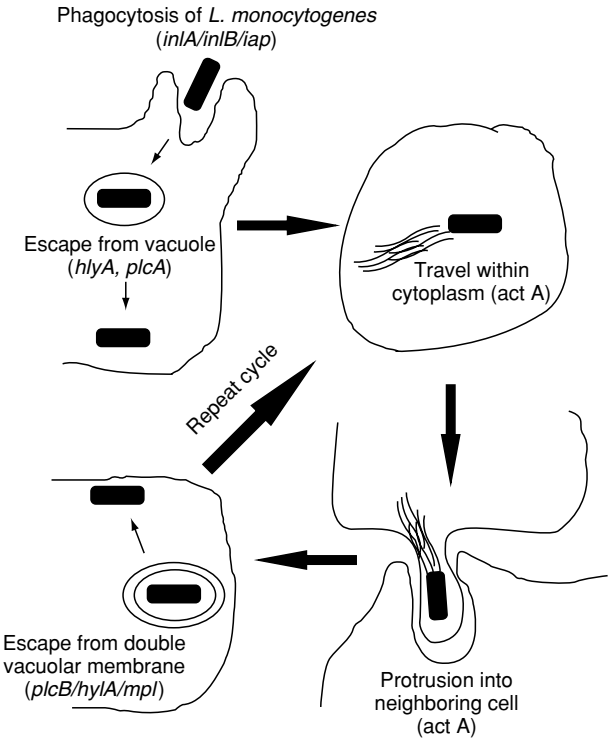

Figure 2 Proposed mechanism of entry into mammalian cells by *L. monocytogenes*. The genes implicated are listed.

The bacterium is able to internalize itself through the action of at least two proteins, internalin A (InlA) and internalin B (InlB). Currently, two pathways have been proposed for entry into mammalian cells. The first is the internalin-E-cadherin pathway, in which the invasin from *L. monocytogenes* interacts with the β-1-integrin adhesion molecule thought to be connected to the cytoskeleton. The second pathway is InlB-dependent, sharing similarities with the growth-factor-mediated signaling pathways. InlB has recently been shown to bind the extracellular domain of MET (also known as the hepatocyte growth factor (HGF)), a receptor tyrosine kinase. Upon binding to MET, InlB is proposed to cause a 'scattering' of epithelial cells. The protein p60, encoded by the gene *iap*, has been shown in experiments to be essential in the invasion process. Deletion of the *iap* gene is lethal. Believed to be a mureine hydrolase, its role is still unclear. What is known, however, is that cells producing reduced levels of p60 show a 'rough' morphology and exhibit reduced adherence, invasiveness, and virulence.

The bacterium is able to escape the vacuolar membrane through the action of listeriolysin O, a pore-forming toxin encoded by the gene *hylA*. Phosphatidylinositol-phospholipase C, a member of the pore-forming family of thiol-activated cytolysins, also contributes to the organism's ability to escape the vacuole. ActA is a surface protein with a membrane anchor at its carboxyl-terminal end. Its amino-terminal has been shown to be essential for actin

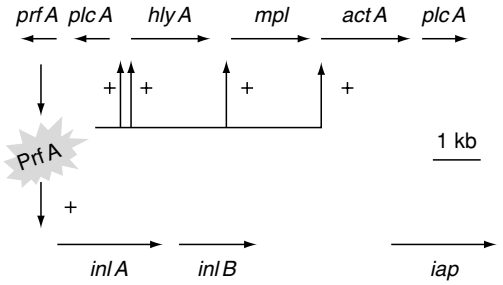

Figure 3 PrfA, the master regulator of most virulence genes found on the chromosome of *L. monocytogenes*.

assembly. ActA is responsible for the intracellular actin-based motility. It is believed that ActA is able to recruit the host actin filaments and make them assemble at one pole of the bacterium. This actin tail formation would then be the driving force in the intracellular movement observed using microscopy technology. The lecithinase PlcB acts on the double-membrane vacuole that the bacteria faces when it reaches its neighboring cell. PlcB is synthesized as a precursor and is cleaved by a zinc metalloprotease, shown to be encoded by the *mpl* gene. Listeriolysin is also implicated in escape from the second vacuole.

Regulation of the virulence genes that allow for intracellular movement, and thus escape from the immune surveillance system, all fall under the pleiotropic activator, PrfA (Figure 3). Encoded by the gene *prfA*, PrfA is able to regulate the expression of many of the virulence genes described, including *plcA*, *hlyA*, *mpl*, *actA*, and *inlAB*. A 27-kDa protein, PrfA, has been shown to activate the transcription of these genes and has been shown to be a DNA-binding protein (Figure 3).

The regulation of *prfA* itself is complex. It has been shown that at temperatures below 30 °C, PrfA-dependent genes are not transcribed, since there is a lack of *prfA* transcription. Shifting the temperature to 37 °C causes expression (transcription, translation) of the *prfA* gene, which in turn activates the virulence gene cluster. Addition of activated charcoal to a culture medium also has the same effect. Presumably, the charcoal somehow sequesters a signal molecule, which permits the transcription of *prfA* and, thus, the virulence genes. Increasing glucose concentrations in the medium turn off virulence gene expression, by directly influencing the expression of *prfA*. While the *prfA* gene product appears to auoregulate its own expression and synthesis, there is certainly more to the complexity of regulation of virulence genes and their prime activator, PrfA. A member of the cyclic AMP (cAMP) receptor protein (CRP)/FNR (regulator of fumarate and nitrate reduction) family of bacterial regulators, it is currently believed that PrfA is a regulatory protein that binds its symmetric target sequence and enhances (or, alternatively, inhibits) the binding of RNA polymerase, thereby influencing transcription. The Crp (or catabolite activator protein) is a regulatory protein that modulates the expression of genes involved with catabolite repession, whereas the Fnr family has been shown to regulate the cellular response to anaerobic growth.

LITHIUM

M Anke, U Schäfer and W Arnhold, Friedrich-Schiller-Universitat, Jena, Germany

History, Nature, and Function

Lithium (Li) is the lightest alkali metal (atomic weight 6.94). It shows physicochemical anomalies which result from the unexpectedly great difference between the electronegativity of this element and that of sodium, potassium, and rubidium. These differences are seen in both the properties and the reactions of this silvery white metal which was discovered by Arfvedson (1818) in Berzelius's laboratories. The new alkali element was detected when a fossil known as petalit was analyzed. It was called lithion (stone) because it was first found in the mineral kingdom.

The Earth's crust contains 50–65 mg lithium kg^{-1}. The geological origin of the soil is reflected in its lithium content. The plants of slate, keuper, and gneiss weathering soils are richer in lithium than those of diluvial and alluvial formations (Table 1).

Therapy and Toxicity

In 1843, lithium carbonate was introduced into the materia medica as a new solvent for stones in the bladder by the surgeon Ure. In 1859, the internist Garrod recommended a therapy with lithium salts for a wide range of diseases and complaints, especially gout, urinary calculi, rheumatism, mania, depression, and headache. All of them were grouped under the general heading of the uric acid diathesis which became a major unifying medical principle for almost a century. In 1941, however, this hypothesis was declared to be ill-founded.

The fascinating discovery of the specific antimanic effect of the lithium cation by the psychiatrist Cade in 1949 initiated the career of this chemically simple drug as a very potent substance against symptoms of manic-depressive illness. After numerous hindrances due to the lack of knowledge of its biochemical and pharmacokinetic properties had been overcome, lithium developed into a safely used psychopharmacological agent. Improvements in its monitoring, especially by the introduction of the lithium ion-selective electrode, as well as in patient compliance with medication, were also decisive. It was possible to extend the classical antimanic, antidepressive and recurrent-prophylactic action profile of lithium by an antipsychotic, antiaggressive, antisuicidal, and anti-neurotic component. Recently, topical lithium has found employment in dermatological disorders, e.g., seborrheic dermatitis and herpesvirus infections. It is promising that further applications of lithium as an antiinflammatory, antiviral, antifungal, antitumor, and immunomodulating agent, e.g., in the treatment of acquired immune deficiency syndrome (AIDS) and cancer, may become established in the future. The characteristic pharmacologically rare properties of the drug lithium are that it does not lose efficacy and does not induce addiction and dependence. Thus, a 'mechanical switch-on and -off function' in its biochemical mechanism is discussed.

However, lithium therapy (lithium exposure) also induces side-effects in the form of thyroid changes, nephrogenic diabetes insipidus, cardiovascular disturbance, epithelial damage, changes in carbohydrate metabolism, and skeletal damage in the form of bone mineralization. Patients treated with lithium usually tend to gain weight. It must be emphasized that the lithium dosage of 24–48 mmol or 167–333 mg day^{-1} (0.5–1.5 mg day^{-1} serum lithium) now used in humans is relatively high compared with the effects registered in animals. In rats, chickens, hens, pigs, and bulls, 50–100 mg lithium kg^{-1} ration dry matter reduced the feed consumption significantly. All lithium-exposed pigs took in considerably more water than control animals. The same is apparently true for humans treated with lithium, who meet these high fluid requirements with high-caloric beverages and thus consume more energy.

Table 1 The site-specific lithium content of indicator plants as a percentage of the site richest in lithium

Site	*Relative number*
Sandstone weathering soils of chalk formation	100
Slate	94
Keuper	94
Gneiss	92
Muschelkalk	83
New red sandstone (Bunte)	83
Lower strata of new red sandstone (Rot-bigende)	70
Diluvial sands	72
Granite	72
Loess	71
Syenite	68
Phyllite	65
Moor, peat	58
Boulder clay	54
Alluvial riverside soils	51

All species with >100 mg lithium kg^{-1} feed dry matter reduced life weight gain and egg production. Ruminants seem to be equally sensitive to lithium exposure. Lithium applications from 10 mg kg^{-1} feed dry matter upwards led to a significantly higher suet content.

The lower sexual aggressiveness of bulls receiving 100 and 200 mg lithium kg^{-1} ration should also be mentioned. Rats with lithium-rich ration gave birth to lighter offspring which developed more slowly.

All pigs receiving 1000 mg lithium kg^{-1} feed dry matter died within 92 days. Cases of death also occurred in animals on 500 mg lithium kg^{-1} feed dry matter.

Essentiality

Plants There are considerable differences in the tolerance of various plant species to lithium and in their ability to take up this element. Solanaceae are known to have the highest tolerance to lithium. Some members of this family accumulate more than 1000 p.p.m. lithium. On the other hand, citrus trees are the most susceptible to injury by an excess of lithium, which is reported to be toxic at a concentration of 140–220 p.p.m. in the leaves. In Russia, the beneficial effects of lithium are still used in agriculture. Lithium-containing fertilizers lead to increased starch levels and biomass in potatoes. The observed lithium-induced growth stimulation seems to allow the evaluation of lithium as an agrochemical. However, it is still not proven that lithium is an essential nutrient or an active substance for plants because they can complete their life cycle without this element. Lithium must rather be considered a toxic substance, with marked species-dependent differences in sensitivity. There is no proof yet that lithium is essential for plants. Lithium must rather be regarded as potentially phytotoxic.

Animals

Whether lithium is essential for fauna has been investigated systematically since 1976 in goats, sheeps, and rats in Germany, in Hungary, in the USA, and in Japan. The influence of a lithium-poor ration on the pre- and postnatal growth of goats was tested in 13 experiments over 13 years. It was shown that the kids of lithium-deficient goats had a 9% lower birth weight than those of control goats. In lithium-deficient rats the litter was 20–30% smaller in comparison to control animals. Moreover, the lithium-poor nutrition caused reproductive disorders in goats and rats. Lithium-poor rations of female goats did not have an effect on the intensity of estrus behavior. The first mating, however, produced a significantly worse rate of conception in these animals. Repeated services at the following ovulations improved the conception rate of lithium-deficient goats. The difference between the groups remained significant.

The increased abortion rate of lithium-deficient goats is also important. Miscarriages occurred at a rate of 14% between the third and fifth month of gravidity. The effect of lithium deficiency on sex ratio was most surprising. As a rule, hornless goats give birth to more male than female kids. Lithium-deficient goats, however, gave birth to significantly more female kids. The 5-year average showed that lithium-deficient goats produced 20% less milk than control animals.

Long-term lithium deficiency experiments with female goats allowed the analysis of the influence of the lithium-poor nutrition on the life expectancy of the animals. The investigations showed that 41% of lithium-deficient goats and 7% of control animals died during the first year of the experiments. Skin lesions occurred in individual animals with lithium-poor rations. In the meantime, it was shown, that lithium was also effective in the treatment of herpesvirus infections and of seborrheic dermatitis in humans.

Lithium deficiency did not affect the biochemical blood profile, but it changed the activity of several serum enzymes. As a rule, lithium deficiency reduced the serum enzyme activity, mainly the enzymes of the citrate cycle (ICDH, isocitric acid dehydrogenase; MDH, malate dehydrogenase), of glycolysis (ALD), and of nitrogen metabolism (GLDH, glutamine dehydrogenase), for which significant differences between control and lithium-deficient goats occurred. Only creatine kinase, a stress indicator enzyme, was significantly increased in lithium-deficient goats.

Owing to the particular role of monoamine oxidase (MAO) in manic-depressive diseases, chronic schizophrenia, and unipolar depression, this enzyme was also investigated in the liver of control and lithium-deficient goats. MAO activity in the hepatic tissue of the latter group was reduced by 28%.

Abnormal behavior was observed in lithium-deficient rats, and this disappeared after lithium supplementation. This assessment is interesting in so far as the MAO hypothesis is discussed as a biochemical mechanism of lithium effect in humans. In brief, the results of a lifelong lithium-poor nutrition over >10 generations of goats show that lithium may be essential to fauna, and thus, to humans as well.

Lithium in the Diet

The lithium intake of adult humans with mixed diets was systematically investigated in 10 test populations

of 7 women and 7 men, each from different regions of Germany and aged between 20 and 69 years (Table 2).

Men and women consumed the same amount of lithium-rich and lithium-poor foods and beverages. The lithium intake of both sexes doubled after the reunification of Germany and worldwide trade. Since men consume 24% more dry matter than women, they take in more lithium than women. The distribution of the individual lithium intake does not follow the Gaussian curve but it is shifted to the left (Figure 1). The lithium consumption was characterized by an extreme variation range, which may be caused by water and beverages.

Adults of both sexes with mixed diets consumed significantly more lithium with increasing age. On average, elderly test persons consumed 30–46% more lithium. They clearly preferred lithium-rich foodstuffs. The lithium intake per day on individual sites varies between 200 and 2400 μg day^{-1} on average. The postulated potential lithium requirement of 100 μg day^{-1} is met on the average of the population. Ten percent of the men tested consumed < 100 μg lithium day^{-1} as a weekly average. Worldwide, a lithium intake for adults between 660 and 3420 μg day^{-1} is calculated.

The Lithium Content of Foodstuffs and Beverages

The lithium content of water seems most likely as an explanation for the different lithium intake. Water from swamp and peat sites contained eight times more lithium than that from diluvial sands (Table 3). In addition, a relationship between high lithium contents in drinking water on the one hand and low rates of crimes, suicides, and arrests on the other was controversially discussed.

In line with the low lithium content of cereals, flour and other cereal products contained little lithium. Honey and sugar are also extremely poor in lithium. Ready-to-serve soups with meat and eggs were richer in lithium, whereas various puddings, macaroni, and vermicelli usually contained < 1 mg lithium kg^{-1} dry matter (Table 4).

Bread, cake, and pastries are usually poor sources of lithium. On average, they contained less lithium than wheat flour. The addition of sugar apparently leads to a further reduction of the lithium content in bread, cake, and pastries.

All vegetables and potatoes contain > 1.0 mg lithium kg^{-1} dry matter. Peeling potatoes decreases their lithium content, as potato peel stores more lithium

Table 2 Lithium intake of German adults with mixed diets depending on time (μg day^{-1})

Year (n;n)	*Women*		*Men*		*Fp*	*%*[a]
	SD	*x*	*x*	SD		
1988 (196; 196)	444	374	419	432	< 0.01	112
1992 (294; 294)	724	713	990	1069		139

Figure 1 The mean weekly lithium intake of men in μg day^{-1}.

Table 4 The lithium content of several groups of foodstuffs

Group of foodstuffs	*μg/kg resp. μg/l*	*Variation*
Beverages	192	18–329
Sugar, honey	363	199–527
Bread, cake	612	317–935
Cereal products	888	538–1391
Luxuries	1678	372–3737
Spices	1850	1046–2316
Fruits	2846	383–6707
Meat	3217	2379–3844
Milk, dairy products	3626	1070–7533
Eggs	7373	SD 6500

than the inner part of the potato that is commonly eaten.

As a rule, fruits contain less lithium than vegetative parts of plants (vegetables). Lemons and apples contained significantly more lithium, with about 1.4 mg kg^{-1} dry matter, than peas and beans, which, like the different kinds of cereals grains, are extremely lithium-poor as seeds.

Owing to the small amounts used in their application, spices do not contribute much lithium to the diet. It is surprising that mustard is relatively lithium-rich, with 3.4 mg kg^{-1} dry matter, whereas mustard seed contains extremely little lithium.

Various semiluxury foods usually provide only modest amounts of lithium. The total amount in tea and coffee, not their water-soluble fraction in the beverage, was registered. Their low lithium content indicates that insignificant amounts of lithium enter the diet via these beverages. The lithium content of chocolates, chocolate candies, and sweets amounted to about 0.5 mg kg^{-1} dry matter. Cocoa is somewhat richer in lithium. The addition of sugar in chocolates reduces their lithium content.

On average, eggs, meat, sausage, and fish deliver significantly more lithium per kg of dry matter than most cereal foodstuffs. Eggs, liver, and kidneys of cattle had a mean lithium content of 5 mg kg^{-1}. Beef and mutton contain more lithium than poultry meat. Green fodder and silage consumed by cattle and sheep are much richer in lithium than the cereals largely fed to poultry. Sausage and fish contain similar amounts of lithium to meat. There were significant differences between the lithium content of milk: milk contains a high lithium concentration of 10 mg kg^{-1} dry matter.

In contrast to milk, curd cheese and other cheeses only retain 20–55% of lithium in the original material available for human nutrition. The main fraction of lithium certainly leaves cheese and curd cheese via the whey. Like margarine made of plant fat, butter is also lithium-poor, with 1.2 mg kg^{-1} dry matter.

The fact that lithium is easily soluble may also be the reason for the high lithium content of beverages. Cola and beer deliver considerable amounts of lithium for humans, and this must be taken into consideration when calculating the lithium balance of humans.

Identification of Lithium Status

As already demonstrated in the literature, blood serum best reflected lithium status, followed by hair. Milk reflects the lithium status well. Lungs, spleen, and carpal bones also reflected the different lithium supply. Other parts of the body indicated the lithium status only insignificantly and the cardiac muscle not at all.

Determination of Lithium

Lithium may be determined in foods and biological samples with the same techniques employed for sodium and potassium. However, the much lower levels of lithium compared with these other alkali metals, mean that techniques such as flame photometry often do not show adequate sensitivity. Flame (standard addition procedure) or electrothermal atomic absorption spectrophotometry are the most widely used techniques after wet or dry ashing of the sample. Corrections may have to be made for background/matrix interferences. Inductively coupled plasma atomic emission spectrometry is not very sensitive for this very low-atomic-weight element.

LIVER

Contents

Structure and Function

D G Cramp, South Wonston, Winchester, UK

Gross Structure

The liver is the largest solid organ in the body, weighing between 1200 and 1500 g. It lies in the right hypochondrium and is roughly wedge-shaped, with its apex to the left side and base to the right. Grossly, it appears to be divided into a larger right and a smaller left lobe by the falciform ligament. However, this has no apparent functional significance, as the blood supply to the two lobes is almost equal. This blood supply is derived from two sources: the hepatic artery, usually a branch of the coeliac axis, and the portal vein, formed from the mesenteric vein and the splenic vein.

The total hepatic blood flow is some 1300 ml min^{-1}, approximately 25% of the resting cardiac output, with the hepatic artery supplying about 25–30% of blood by volume and the low-pressure portal vein the remainder. Both of these vessels run in the free edge of the lesser omentum to the liver hilum before dividing into major right and left branches. Blood leaves the liver through several hepatic veins that drain directly into the inferior vena cava, which runs in a groove between the two lobes. Three such hepatic veins enter just below the diaphragm, with a number of smaller veins draining the posterior aspect of the right lobe directly into the inferior vena cava.

The biliary system collects, stores, and concentrates bile in the gall bladder, prior to its delivery to the duodenum as required. The main right and left hepatic ducts join in the liver hilum to form the common hepatic duct. The gall bladder itself lies on the underside of the right lobe of the liver, with the cystic duct running backwards and upwards in order to join the hepatic duct; the resulting common bile duct runs with the hepatic artery and portal vein and then passes behind the first part of the duodenum

and the head of the pancreas before it enters the duodenum.

Fine Structure

At the tissue level, the liver is comprised of a large series of channels lined with endothelial cells, the sinusoids, which run between layers or plates of hepatocytes. The endothelial cells possess fenestrations, which allow access of circulating blood to the sinusoidal surface of the hepatocytes. Some of the cells lining the sinusoids, Kuppfer cells, possess phagocytic activity. The space of Disse, i.e., the space between the endothelial cells and the hepatocytes, contains interstitial fluid. The membrane transport of nutrients and waste material between the space of Disse and the parenchymal cells is facilitated by the numerous microvilli, which extend the sinusoidal surface of these cells. From and around the liver branches of the hepatic artery, portal vein and bile duct are carried portal tracts, the smallest of which contain terminal branches supplying groups of sinusoids that form a functional unit, the acinus. Blood from each acinus passes into a number of efferent veins. It is the radially orientated sinusoids centered on these efferent veins that give the liver its classical lobular architecture.

Histochemical studies have demonstrated a marked heterogeneity of hepatocytes, with cells at different locations differing both structurally and functionally. This differentiation probably reflects the many specific metabolic functions that the liver has to meet. The overall functional capacity of the liver (liver functional mass) is highly dependent on the number and activity of these hepatocytes and their contact with circulating blood (effective liver perfusion).

Functions of the Liver

The anatomical site and cellular architecture of the liver enable it to perform many diverse metabolic functions that are essential to the body. Its position, between the digestive tract and the general circulation, ensures that substances ingested orally and absorbed by the intestine must normally pass to the liver. As a result, the liver has developed the ability not only to receive, process, and store these substances but also to release them or their metabolites in a highly regulated fashion by monitoring demand and responding to multiple hormonal and neural stimuli.

A cardinal role of the liver is to regulate the supply and utilization of energy-containing substrates through its participation in the integrated control of carbohydrate, protein, and lipid metabolism. In the body, there is a fine balance between anabolic and catabolic processes, between supply and demand. This state of metabolic homeostasis is essential for the maintenance of an adequate and continual supply of fuel to the tissues, especially cerebral tissue, as the body adapts to periods of relative plenty alternating with periods of fasting. This is facilitated by three processes: providing fuel from ingested food to meet immediate energy demands; storing fuel reserve as glycogen in the liver and muscle, at the same time replenishing tissue protein lost since the last meal; diverting excess energy-rich substrate into triglyceride for transport to adipose tissue for storage. As for any tissue, these metabolic processes in the liver are dependent on several factors, including the circulating concentration of substrate, blood flow to tissue, cell permeability, the mechanism of entry to the metabolic pathways and their hormonal regulation. (*See* **Amino Acids**: Metabolism; **Carbohydrates**: Digestion, Absorption and Metabolism; **Fatty Acids**: Metabolism; **Glycogen**.)

The liver is the major site of plasma protein synthesis, including albumin, the α- and β-globulins, clotting factors, and transport proteins. These proteins have important roles in body homeostasis: regulation of blood coagulation and hemostasis; the transport and optimization of circulating concentrations of calcium and magnesium ions, bilirubin, fatty acids, and hormones. Also, albumin contributes to the maintenance of the plasma colloidal oncotic pressure and hence the control of body fluid distribution. There is a close relationship between the liver, gut, and muscles with respect to amino acid metabolism. The average adult turns over about 2% of total body protein, approximately 250 g per day, with muscle the major source, contributing 140 g, and dietary intake accounting for 90 g. After a meal, approximately 25% of the amino acid nitrogen absorbed into the portal bloodstream reaches peripheral tissues because the liver has the ability to regulate the rate of gluconeogenesis and transamination, thereby modifying the circulating plasma amino acid composition. The aromatic amino acids phenyalanine, tyrosine, and methionine are preferentially metabolized to urea, while the branched-chain amino acids valine, leucine, and isoleucine are selectively able to reach peripheral muscle for reincorporation into protein. A major synthetic function of the liver is the formation of bile acids from cholesterol and their secretion into the intestine, thereby generating bile flow and facilitating dietary fat emulsification and absorption. (*See* **Bile**.)

Substances circulating in the systemic bloodstream have access to the liver by way of the hepatic artery and the mesenteric artery. The liver is the main site of metabolic transformation and detoxification of

endogenous compounds, including bilirubin, ammonia, and thyroid, steroid, and other hormones, as well as exogenous foreign compounds.

Role of Liver in Postabsorptive Events

Over a 24-h period, a subject of average body mass utilizes about 7560–8400 kJ (1800–2000 kcal), derived from 75 g of protein (mainly muscle) and some 160 g of triglyceride from adipose tissue. During that time, the liver releases about 180 g of glucose, 80% of which is totally oxidized by nervous tissue, mainly the brain. The rest is metabolized by those tissues for which glucose is the preferred energy substrate, namely red blood cells, hemopoietic tissue, and the renal medulla. The endproducts of this glycolysis, pyruvate and lactate, are recycled to the liver and converted to glucose. This carbon shuttle, the Cori cycle, provides a means of sparing gluconeogenesis from protein. (*See* **Glucose**: Function and Metabolism; Maintenance of Blood Glucose Level.)

Following a large meal with significant carbohydrate content, the liver takes up glucose in response to increased insulin secretion and suppression of glucagon. This glucose is converted into glycogen and stored. If the meal has a relatively low carbohydrate content, the liver will continue to produce glucose in response to raised glucagon levels, notwithstanding a normal insulin response to food. Insulin and glucagon regulate the intracellular concentration of cyclic adenosine monophosphate (cAMP), which in turn initiates complex enzyme changes that modulate glycogen synthesis and breakdown as well as gluconeogenesis. In a normal subject, following the ingestion of a 100-g glucose load, the liver retains approximately 60–80%, the rest escaping into the systemic circulation. The liver contains about 10% by weight of glycogen (approximately 150 g), less than the daily body glucose requirement of some 180–200 g; thus, it is only able to meet short-term requirements.

The conventional model suggests that glycogenolysis is able to maintain glucose homeostasis for some 18 h into a fast and is then superseded by gluconeogenesis. The switch to gluconeogenesis is initiated by two processes: a raised glucagon: insulin ratio, which increases the hepatic cAMP concentration, and increased peripheral tissue lipolysis, leading to a higher intrahepatic concentration of free fatty acids, the oxidation of which yields an increase of gluconeogenic precursors such as acetylcoenzyme A (acetyl-CoA).

It is the action of insulin and its counter-regulatory hormones that integrate intermediary metabolism in both the liver and peripheral tissues. The systemic regulation of protein and lipid metabolism, through a variety of actions that affect the flux of protein and lipid substrates to the liver, complements glucose regulatory mechanisms.

The hepatic actions of insulin lead to fuel conservation, by optimizing glucose availability, reducing fatty acid oxidation – and thus ketone body production – and diverting the fatty acids into triglyceride for transport to peripheral tissues where they are stored.

In the fasting state, insulin modulates hepatic glucose production by restraining glycogenolysis and increasing gluconeogenesis. In the fed state, insulin levels rise, and there is virtually total inhibition of both these processes so that hepatic glucose production drops to zero. This is achieved by inhibition of phosphorylase and the key gluconeogenic enzymes pyruvate carboxylase, phosphoenolpyruvate carboxykinase and fructose 1,6-diphosphate, probably through inhibition of cAMP-dependent protein kinases. Insulin is also essential to the disposition of incoming glucose through its enhancement of glucokinase activity and glucose phosphorylation. The glucose 6-phosphate formed can follow several alternative metabolic routes:

1. Glycogen formation following the activation of glycogen synthase: this step is subject to the limitations on the capacity of hepatocytes to store glycogen. Excess glucose 6-phosphate is converted to pyruvate, which, through activation of pyruvate dehydrogenase and acetyl-CoA carboxylase, is diverted into fatty acid synthesis.
2. Increased flux of glucose 6-phosphate into the pentose phosphate shunt increases the availability of the reduced form of nicotinamide adenine dinucleotide phosphate for fatty acid synthesis. The fatty acids are esterified with glycerol 3-phosphate also formed during glycolysis. The resulting triglycerides are incorporated into very-low-density lipoproteins (VLDLs) and secreted by the liver to extrahepatic sites for storage. (*See* **Lipoproteins**.)
3. As fatty acid synthesis is accelerated, fatty acid oxidation and ketogenesis are inhibited. The first committed step of fatty acid synthesis is malonyl-CoA formation. Increased levels inhibit the enzyme carnitine acyltransferase I, which facilitates the transport of fatty acids, as fatty acyl-CoA, into mitochondria for oxidation. If fatty acids cannot be oxidized, they become available for esterification; furthermore, the blocking of fatty acid oxidation also prevents ketogenesis, owing to the lack of precursor acetyl-CoA.

Glucose Homeostasis

During a brief fast, a precipitate fall in the blood glucose concentration is avoided by drawing upon

hepatic glycogen stores. During long-term fasting, i.e., starvation, gluconeogenesis plays the most significant role in maintaining blood glucose concentrations. If the pathways activated during a brief fast persisted through a period of prolonged food deprivation, the loss of body protein to provide glucose would be extremely rapid. However, with prolonged starvation the brain is progressively able to adapt to utilizing lipid-derived ketone bodies as a substitute for glucose. The reduction in protein breakdown, as reflected by a fall in urinary nitrogen, and the concomitant decreased gluconeogenesis result from the increased utilization of ketone bodies. They not only decrease the requirement of the brain for glucose derived from protein but also have a direct effect on reducing peripheral tissue glucose utilization and the flux of alanine from muscle.

Cholesterol and Bile Acid Metabolism

The liver has a primary role in cholesterol metabolism within the body because it is the site of most of the endogenous cholesterol synthesis, it handles exogenous cholesterol from the diet and extrahepatic tissues received by way of plasma lipoproteins, and it is the only organ with the capacity to excrete cholesterol from the body.

Hepatocytes have the capacity both to synthesize and to take up cholesterol from lipoprotein remnants. Negative feedback control of the cholesterol synthesis pathway and control of the cell surface receptor population ensure that intracellular accumulation of cholesterol does not occur. Some cholesterol may be secreted from hepatic cells in VLDL, the vehicle for triglyceride transport to adipose tissue. On removal of triglyceride, the lipoproteins become smaller, cholesterol-rich particles, low-density lipoproteins (LDLs), which are recognized by LDL receptors on hepatocytes. Following internalization, cholesterol is released from the disrupted lipoprotein.

The dietary cholesterol intake is about 600–800 mg daily and is mainly derived from dairy products, eggs, and meat. Cholesterol derived from dietary fat, together with that from the bile, is taken up by mucosal cells of the intestinal wall with about 30–60% of the total presented being absorbed or reabsorbed. The efficiency of absorption increases with the saturated fat content of the diet. Absorbed cholesterol reaches the liver in chylomicron remnants and is taken up by chylomicron receptors.

The primary bile acids, cholic and chenodeoxycholic acid, are synthesized in the liver from cholesterol, conjugated with the amino acids taurine or glycine to form bile salts, and then excreted by an active transport mechanism into the bile canaliculi and, eventually, into the duodenum. In the distal ileum, there is an active reverse transport mechanism, whereby bile salts are conserved by reabsorption after fulfilling their digestive function. The enterohepatic circulation is extremely efficient: the entire body pool of bile salts is cycled through the gut roughly twice during the course of a meal, with so little being lost that only about 5% needs replacement by *de-novo* synthesis. The small amount that reaches the stools (about 4%) is acted upon by bacteria in the gut lumen to yield, by 7-α hydroxylation, the secondary bile acids deoxycholic and lithocholic acids. All bile salts are powerful detergents, solubilizing lipids by enclosing them in bile salt aggregates to form micelles. These are structured so that hydrophobic groups are orientated towards the lipid-rich interior of the micelle, while the hydrophilic hydroxyl (OH) and carboxyl (COOH) groups are on the outside.

Cholesterol and lecithin are excreted into the bile, but if their concentration is too high, relative to that of bile salts, the bile becomes supersaturated, and precipitation of cholesterol occurs, particularly if a nidus for crystal formation is present. This is the pathophysiological basis of gallstone formation. The active transport of bile salts is the main driver of bile formation and secretion. Failure leads to intrahepatic cholestasis. A bile-salt-independent contribution to bile secretion is the result of active sodium transport in the distal canaliculus, with bicarbonate being secreted into the small bile ductules under the stimulus of the hormone secretin. Cholecystokinin stimulates gall bladder contraction.

Enterohepatic Circulation

A Lanzini, University of Brescia, Brescia, Italy

Definition

The enterohepatic circulation is an anatomical and physiological entity, only part of which is vascular. It involves passage of substances that have been absorbed from the intestine via the portal vein to the liver, and their subsequent passage via the biliary system back into the intestine. Bile acid molecules are unique in that they are restricted to the enterohepatic circulation (Figure 1). They are secreted in bile as glycine and taurine conjugates, and are mainly absorbed by active transport in the distal ileum. Many other endogenous and exogenous compounds undergo some degree of enterohepatic circulation, but this usually represents a minor component of their tissue distribution. By contrast with bile acids, these substances are excreted in bile as glucuronate or sulfate conjugates, and deconjugation by colonic bacteria is essential for these molecules to reenter the enterohepatic circulation by passive colonic absorption following biliary excretion.

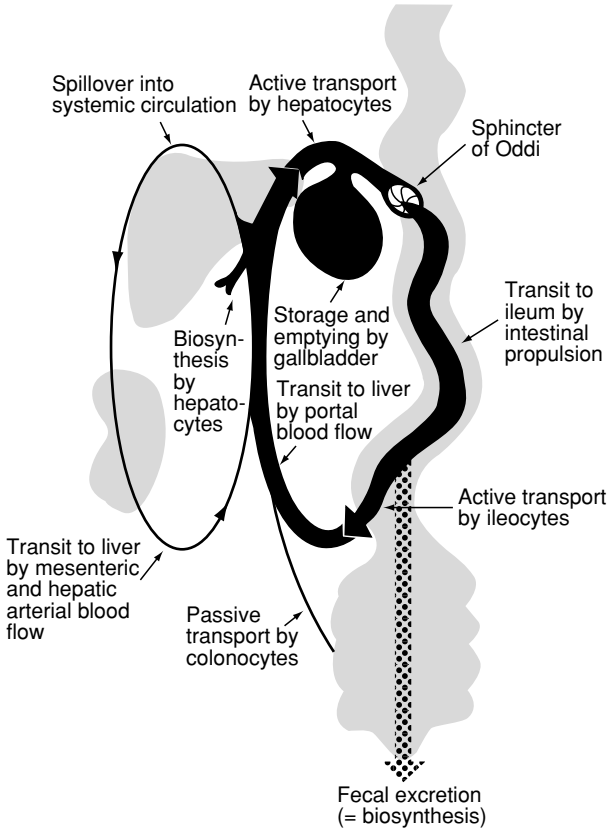

Figure 1 Schematic representation of the enterohepatic circulation of bile acids: see text for details. Reproduced from Hofmann AF (1992) Bile acids in liver and biliary disease. In: Millward-Sadler GH, Wright R, and Arthur MJP (eds) *Wright's Liver and Biliary Disease*, 3rd edn, pp. 289–316. London, UK: WB Saunders, with permission.

Bile Acids

The driving force for the enterohepatic circulation of bile acids comprises chemical and mechanical pumps, both affecting bile acid kinetics to a different extent.

Kinetics

All aspects of bile acid kinetics are measurable under physiological conditions in humans using the isotope dilution technique developed by Lindstedt. According to this technique, bile acid pool size is the mass of bile acid that dilutes a trace amount of an isotopically labeled bile acid. The fractional turnover rate is the fraction of the pool lost from the enterohepatic circulation and replaced by *de novo* bile acid synthesis each day. Chenodeoxycholic acid and cholic acid are the only two bile acids synthesized by the human liver, and are thus called 'primary' bile acids (*See* **Bile.**) These two bile acids are biotransformed in the intestine to form 'secondary' bile acids, lithocholic and deoxycholic acid. Further intestinal and hepatic biotransformation of primary bile acids results in the formation of 'tertiary' bile acids (ursodeoxycholic acid and ursocholic acid). Input rate is the amount of bile acid entering the pool each day, and represents synthesis in the case of the primary bile acids.

According to the Lindstedt's technique, the specific activity (SA = disintegrations per minute/bile acid mass) of the radiolabeled bile acid injected intravenously is measured in gallbladder bile samples collected on 4–5 successive days by nasoduodenal intubation during intravenous infusion of cholecystokinin to contract the gallbladder. The reduction of the SA over time is exponential (Figure 2) because a constant fraction rather than a constant amount of the pool is lost each day (first-order kinetics). This exponential decrease of SA is described by the following equation:

$$SA_t = SA_0\, e^{-Kt}$$

were SA_t and SA_0 are the SAs at times t and zero respectively. The extrapolated value for SA_0 on logarithmic scale gives the specific activity of the pool assuming instantaneous mixing of the injected tracer with the pool, and the slope of the line ($-K$) gives the turnover rate. Total bile acid pool size is derived by the following formula:

$$\text{Bile acid pool} = SA_{inj}/SA_0$$

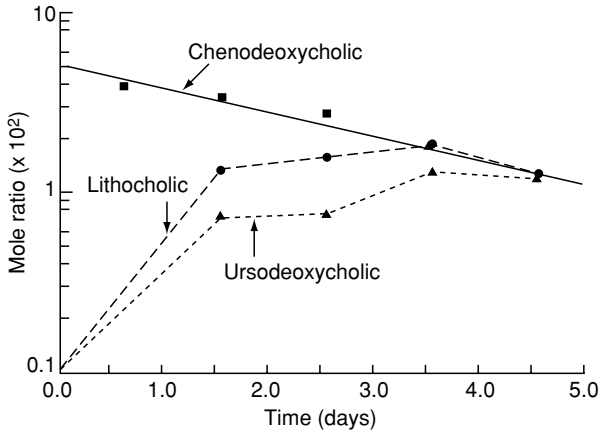

Figure 2 Decline of specific activity of a 'primary' bile acid (chenodeoxycholic) and input of 'secondary' (lithocholic acid) and 'tertiary' (ursodeoxycholic acid) bile acids in gallbladder bile samples collected over a 5-day period. Reproduced from Hofmann AF (1989) Enterohepatic circulation of bile acids. In: *Handbook of Physiology*, section 6, vol. III, pp. 567–596. American Physiological Society, with permission.

Table 1 Kinetics of individual bile acids in humans

Bile acids	*Pool size (g)*	*FTR (days^{-1})*	*Synthesis (g)*	*Input (g)*
Cholic	0.5–1.5	0.2–0.5	0.2–0.4	
Deoxycholic	0.2–1.0	0.2–0.3		0.04–0.2
Chenodeoxycholic	0.5–1.4	0.2–0.3	0.1–0.25	
Lithocholic	0.05–0.1	1.0		0.04–1.0
Total	1.3–4.0		0.28–0.61	0.08–0.3

FTR, fractional turnover rate.
From Carey MC and Duane WC (1994) Enterohepatic circulation. In: Arias IM, Boyer JL, Fausto N, Jakoby WB, Schachter D and Shafritz DA (eds) *The Liver: Biology and Pathobiology*, 3rd edn, pp. 769–786. New York: Raven Press, with permission.

where SA_{inj} is the specific activity of the injected tracer. Daily synthesis rate is derived by the following formula:

$$\text{Synthesis rate} = \text{pool size} \times -K$$

If bile acid secretion rate is measured by means of duodenal perfusion techniques simultaneously with bile acid pool size, the recycling frequency of the pool can be derived from the following formula:

$$\text{Recycling frequency} = \text{24-h bile acid secretion/bile acid pool size}$$

The kinetics of the enterohepatic circulation vary for individual bile acids, and values for each individual bile acid are reported in Table 1. Given a secretion rate of 11–40 g day^{-1} and a pool size of 1.3–4.0 g, the recycling frequency of the pool varies between 4 and 15 per day in humans.

Chemical Pumps

Intestinal absorption Two chemical pumps are involved in the enterohepatic circulation, intestinal absorption and hepatic uptake. The mechanisms involved in intestinal bile acid absorption vary with the anatomical site and consist of passive nonionic diffusion in the whole intestine, and of active absorption in the distal ileum.

The ileal transport system satisfies the criteria for active and saturable transport, and the rate of active ileal bile acid transport is described in terms of maximal transport velocity (V_{max}) and Michaelis–Menten constant (K_m). In humans, V_{max} is higher for taurocholic acid than for chenodeoxycholic and glycochenodeoxycholic acid by a factor of 4:2:1 respectively. Values for K_m are similar for conjugated and unconjugated bile acids. It appears, therefore, that active ileal transport is best suited for taurine-conjugated bile acids, i.e., for bile acids with negligible passive absorption in the proximal small intestine.

The active uptake of bile acid on the enterocyte apical membrane is mediated by the ileal Na^+-taurocholate cotransporter (iNTCP), a glycoprotein containing 348 aminoacids with predicted molecular mass of 38 kDa. This glycoprotein presumably contains seven transmembrane domains and belongs to a superfamily of Na^+-solute transporters. The expression of the sodium-bile acid cotransporter is inducible by taurocholate, suggesting that this mechanism may protect against ileal bile acid loss and subsequent formation of excess secondary bile acids in the colon. This uptake mechanism is absent in the duodenum and jejunum.

During transmembrane transport, bile acid orientation is though to be 'head ahead,' i.e., with the steroid nucleus 'head' crossing first the apical membrane followed by the side-chain 'tail.' Bile acid molecules are transported within the ileocyte by a cytosolic bile acid-binding protein constituted of 128 amino acids and with putative molecular weight of 14 kDa. Following intracellular translocation, bile acids leaves the ileocyte by a sodium-independent anion exchange mechanism. The overall efficiency of the ileal transport system in humans is very high, in the region of 90% per meal, or 70–80% per day.

By contrast with the distal ileum, bile acid absorption in the jejunum and in the colon occurs by passive nonionic diffusion alone. At the physiological pH of the upper small intestinal content (pH 5.5–6.5), about 50% of unconjugated bile acids is undissociated by comparison with only about 25% of glycine conjugates. At this pH no taurine-conjugated bile acid is protonated. These observations suggest that, on a purely physicochemical basis, passive diffusion

in the proximal small intestine is best suited for glycine-conjugated bile acids, i.e., for bile acids less efficiently absorbed by the active ileal transport system. At the slightly acidic pH of colonic content unconjugated bile acids resulting from bacterial deconjugation of bile acids escaping ileal absorption are also absorbed by passive nonionic diffusion.

Hepatic uptake Following absorption, bile acids are transported to the liver in the portal blood, and to a negligible extent in the lymph. In blood, bile acids are strongly bound to albumin, a phenomenon preventing dispersion of bile acids outside the enterohepatic circulation. The binding affinity of bile acids for serum albumin is greater for unconjugated than for conjugated bile acids, and for mono- than for di- and trihydroxylated bile acids.

Given a portal blood flow of $500\,ml\,min^{-1}$ and a bile acid concentration of $20\,\mu mol\,l^{-1}$, about $600\,\mu mol\,h^{-1}$ bile acid reaches the liver by the portal system. The process of hepatic uptake is extremely efficient, and consists of a saturable carrier-mediated process involving a 54-kDa carrier protein. Hepatic first-pass clearance of bile acids depends upon both portal blood flow and hepatic first-pass extraction of bile acids. This latter is relatively independent of flow within the physiological range of portal flows, and is mainly influenced by bile acid structure. First-pass extraction of total (conjugated plus unconjugated) bile acids ranges between 80% and 90% for cholic acid, and is about 70% for both chenodeoxycholic and deoxycholic acid.

The transport system responsible for hepatic bile acid uptake is located on the sinusoidal membrane of the hepatocyte and consists of the liver NTCP (Figure 3), a glycoprotein with 40% structural identity to the ileal iNTCP described above. Other transport systems for bile acids have been described in addition to NTCP. In particular an organic anion-transporting polypetide has been cloned from rat (oatp) and human (OATP) liver. OATP is a polyspecific Na^+-independent transport system involved in the hepatic uptake of a large number of structurally unrelated anphipatic compounds, including bromosulfophthalein, bile acids, and steroids (*See* **Bile**.)

Portal bile acids escaping first-pass hepatic extraction account for the $1–5\,\mu mol\,l^{-1}$ bile acid concentration in peripheral blood. Intravenous administration of radiolabeled bile acids is followed within a few minutes by clearance of radioactivity from plasma, suggesting that bile acids in peripheral blood are rapidly taken up by the liver, thus reentering the enterohepatic circulation.

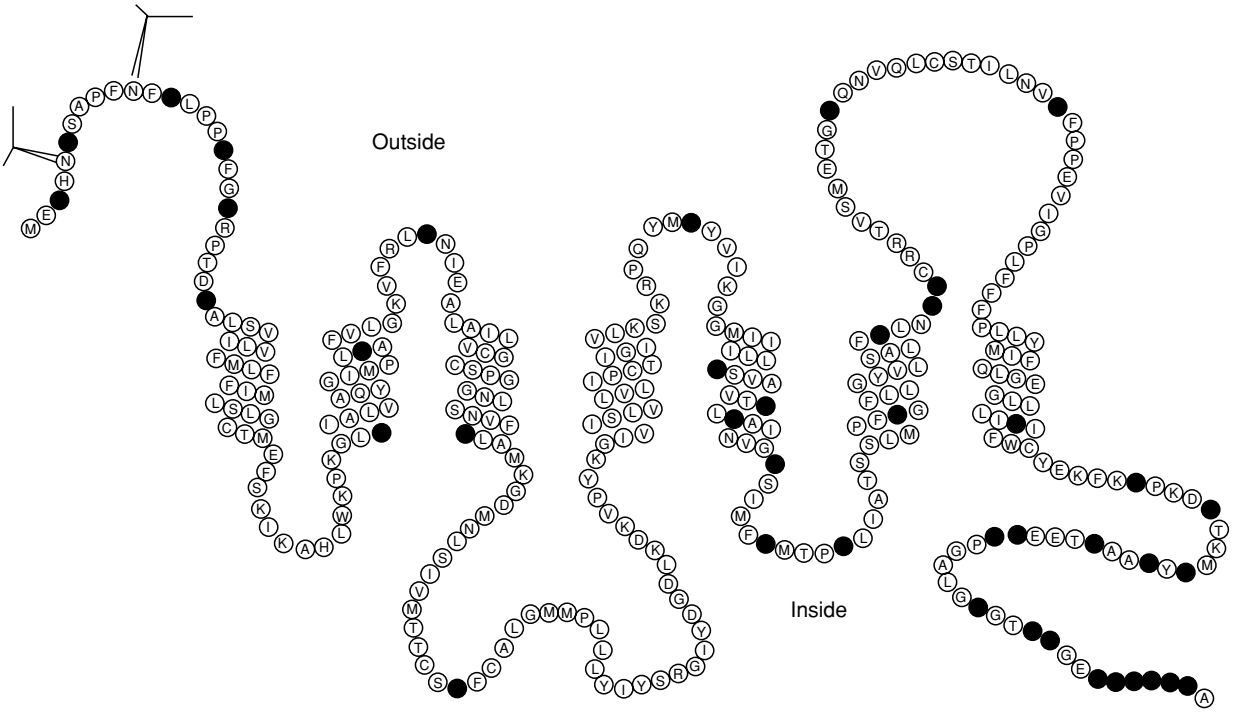

Figure 3 Model of the hepatic Na^+-taurocholate cotransporter. Reproduced from Mejer PJ, Hagenbuch B, and Stieger B (1994) Properties of two-cloned basolateral bile acid uptake proteins of rat and human liver. In: Hofmann AF, Paumgartner G and Stiehl A (eds) *Bile Acids in Gastroenterology, Basic and Clinical Advances*, pp. 139–146. Lancaster, UK: Kluwer Academic Publishers, with permission.

Mechanical Pumps

Gallbladder and intestinal motility provide the main propulsive forces for bile acids to reach the site of intestinal absorption, thus acting as mechanical pumps for the enterohepatic circulation. By contrast with the very rapidly acting chemical pumps, mechanical pumps have storage capacity for the bile acid pool and therefore comprise the slow limb of the enterohepatic circulation (Figure 4).

There is a striking inverse relationship between the recycling frequency of the bile acid pool and bile acid pool size (Figure 5). If one assumes that bile acid pool size is the dependent variable and that the chemical pumps are not saturated under physiological conditions, then gallbladder and small intestinal motor function represent the main factors affecting the kinetics of the enterohepatic circulation. Two main lines of evidence support this concept. First, bile acid pool size has been reported to vary inversely with gallbladder emptying rate in healthy male subjects. Furthermore, the smaller pool size in subjects with a faster gallbladder emptying rate is associated with a greater fractional turnover rate for primary bile acids, and with no change in their synthesis rate. These observations indirectly suggest an effect of gallbladder emptying on the recycling frequency of the bile acid pool.

There is also a negative relationship between small intestinal transit rate and total bile acid pool size. By contrast with gallbladder emptying, it is synthesis rate for both primary bile acids, and not their fractional turnover rate, that is significant associated with small intestinal transit rate. Taken together, these observations suggest that, whereas gallbladder emptying is an important factor in affecting the recycling frequency of the pool, small intestinal transit rate may be more important as a regulating factor for bile acid synthesis, probably by affecting the rate of bile acid return to the liver. This hypothesis is supported by the finding that hepatic microsomal cholesterol 7α-hydroxylase, the rate-limiting enzyme of a major synthetic bile acid pathway, is subject to feedback repression by hydrophobic bile acids returning to the liver via the enterohepatic circulation.

A second line of evidence supporting a role for the mechanical pumps as regulatory factors in bile acid kinetics is provided by studies involving manipulation of gallbladder emptying and small intestinal transit rate. Reduction in postprandial gallbladder emptying by means of dietary measures (sugar diet) results in increased bile acid pool size. This effect is accompanied by a decreased fractional turnover rate for the primary bile acids, with no change in synthesis rate. Similar results are achieved by prolonging small intestinal transit time by chronic administration of anticholinergic drugs. Opposite effects occur with chronic reduction in small intestinal transit time with sorbitol administration, or with regular injections of cholecystokinin octapeptide.

Bile Acid Biotransformation

Bile acid biotransformation occurs at two sites in the enterohepatic circulation – the intestine and the liver. During enterohepatic cycling, bile acids are exposed

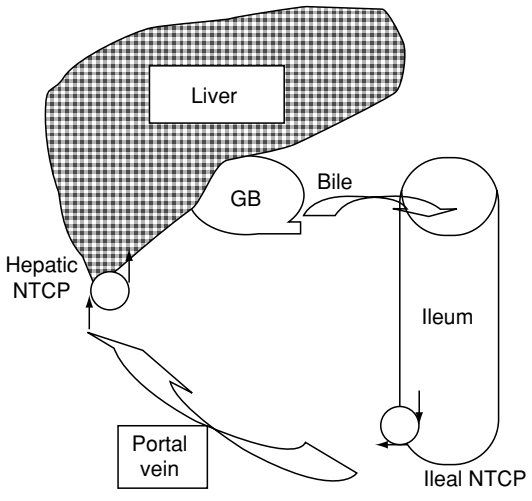

Figure 4 Schematic illustration of the main mechanical (GB, gallbladder, and ileum) and chemical pumps (ileal and hepatic Na^+-taurocholate cotransporter (NTCP)) of the enterohepatic circulation.

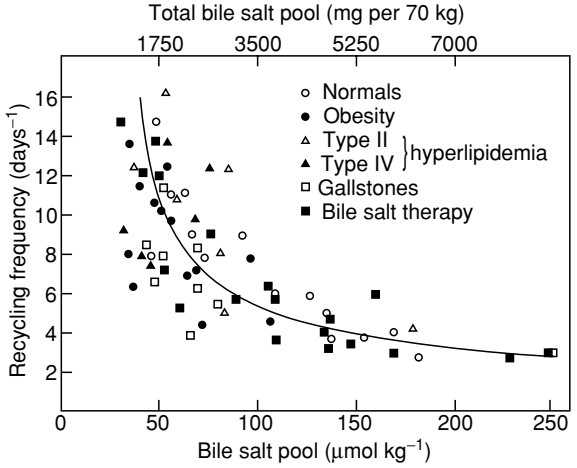

Figure 5 Inverse relationship between bile acid pool size and recycling frequency of the pool in various pathophysiological conditions. Reproduced from Carey MC and Duane WC (1994) Enterohepatic circulation. In: Arias IM, Boyer JL, Fausto N, Jakoby WB, Schachter D and Shafritz DA (eds) *The Liver: Biology and Pathobiology*, 3rd edn, pp. 769–786. New York: Raven Press, with permission.

to an increasing concentration of anaerobic bacteria from the mid-ileum down to the rectum. These bacteria are capable of a variety of metabolic biotransformations of bile acids, and the three most important are deconjugation, 7-dehydroxylation, and 3- (or 7)-oxidation. A small proportion of conjugated bile acids is deconjugated in the mid-ileum and absorbed by passive nonironic diffusion. Bile acids reaching the distal ileum after each meal are absorbed by active transport. Only about 10% of conjugated bile acids reaching the distal ileum after each meal escape absorption and are deconjugated in the colon by cholylglycine hydrolase, an enzyme produced by a great variety of bacterial species. The two primary bile acids, cholic and chenodeoxycholic acid, undergo further biotransformation by bacterial 7-alpha dehydroxylase with formation of deoxycholic and lithocholic acid respectively. By contrast with deconjugation, dehydroxylation of bile acids at C-7 is mediated solely by a relatively small number of anaerobic bacterial species. A total of 20–50% of the secondary bile acids is reabsorbed by the colonic mucosa, returned back to the liver, conjugated with glycine or taurine and secreted in bile as secondary bile acids. The human liver has the capacity further to conjugate glyco- and taurolithocholic acid with a sulfate group, a phenomenon favoring fecal excretion of this potentially toxic bile acid. As a result of efficient fecal excretion lithocholic acid is less than 5% of total bile acid pool in all species examined. By contrast, the proportion of deoxycholic acid varies between 0 and 60% in humans in health and in disease depending on variable input of newly formed deoxycholic acid from the colon.

As a result of bacterial dehydrogenase activity, 3- and 7-oxo bile acids are formed in the intestine. These compounds are absorbed in the colon and reduced stereospecifically in the liver. About 20% of the 7-oxo bile acids are reduced in the liver with formation of the beta-epymers and are called 'tertiary' bile acids. This mechanism accounts for the small proportion of ursodeoxycholic acid and ursocholic acid, the 7-beta-epymer of chenodeoxycholic and of cholic acid respectively, present in human bile.

Physiological Effects

The distribution of the bile acid pool changes during the day, as illustrated by the diurnal variation of bile acid concentration in blood, bile, and intestine. These two latter phenomena have important effects on the physicochemical state of bile and on the digestion and absorption of dietary lipids.

Hepatic bile acid secretion rate declines progressively in humans from 10 to 30 $\mu mol\,kg^{-1}\,h^{-1}$ during the first hour following an evening meal, to less than 5 $\mu mol\,kg^{-1}\,h^{-1}$ before the following breakfast. These changes are accompanied by about 50% net storage in the gallbladder of the hepatic bile during nocturnal fasting, indicating 50% interruption of the enterohepatic circulation. These diurnal changes in bile acid secretion rate are accompanied by changes in the relative proportion of cholesterol and phospholipid in hepatic bile, especially at low bile acid secretion rates. This phenomenon is accounted for by the hyperbolic relationships between bile acid and cholesterol secretion and between bile acid and phospholipid secretion (Figure 6). These relationships explain why the cholesterol/phospholipid ratio is relatively constant in all animal species at high bile acid secretion rate, and why it sharply increases at bile acid secretion lower than about 12 $\mu mol\,kg^{-1}\,min^{-1}$. This phenomenon also explains why hepatic bile is supersaturated with cholesterol at bile acid secretion rates < 20 $\mu mol\,kg^{-1}\,h^{-1}$ in healthy subjects.

The diurnal variation in cholesterol saturation of hepatic bile which accompanies the diurnal fasting–eating pattern is mirrored by a similar but smaller diurnal variation in cholesterol saturation of gallbladder bile. The diurnal variation in bile acid concentration entering the intestinal limb of the enterohepatic circulation also has important physiological effects on the digestion and solubilization of dietary lipids. As a result of dietary stimuli to gallbladder contraction, intraduodenal bile acid concentration increases above the critical value of 4–8 mmol required for normal lipid digestion and absorption. Disease conditions causing detective bile acid secretion secondary to cholestasis or to interrupted enterohepatic circulation (ileal diseases or resection) result in lipid malabsorption and steatorrhea.

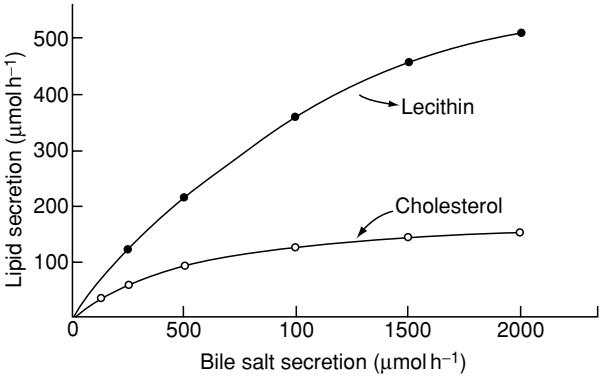

Figure 6 Relationship between bile acid and cholesterol, and between bile acid and phospholipid hepatic secretion rate. Reproduced from Carey MC and Duane WC (1994) Enterohepatic circulation. In: Arias IM, Boyer JL, Fausto N, Jakoby WB, Schachter D and Shafritz DA (eds) *The Liver: Biology and Pathobiology*, 3rd edn, pp. 769–786. New York: Raven Press, with permission.

Other Endogenous Compounds

Apart from bile acids, no other major organic compounds excreted in bile undergo an enterohepatic circulation. Although both biliary cholesterol and phospholipids are absorbed in the small intestine together with their dietary sources, their biliary secretion originates from a preformed hepatic pool. Daily bilirubin secretion equals its daily production, a phenomenon indicating no enterohepatic recirculation for this pigment under physiological conditions. This is because mono- and diglucuronated bilirubin molecules are too large and polar to be absorbed in the small intestine. In the colon, bacterial β-glucuronidase hydrolyzes bilirubin conjugates and unconjugated bilirubin either precipitates as an insoluble calcium salt or is further catabolized to urobilinogen. This latter may be partly absorbed in the colon and undergo a limited enterohepatic circulation.

Studies in rodents suggest that bilirubin absorption may occur under conditions of increased bile acid concentration in the colon resulting from ileal bile acid malabsorption. Under these circumstances excess colonic bile acid concentration may solubilize unconjugated bilirubin, thus favoring passive intestinal absorption and reentry in the enterohepatic circulation of this pigment. This phenomenon may explain the incidence of pigment gallstones in patients with ileal disease and the phenomenon of acquired gallstone calcification in a minority of patients with cholesterol gallstones treated with ursodeoxycholic acid, a bile acid causing malabsorption of endogenous bile acid.

Other endogenous compounds present in very low concentrations in human bile undergo an enterohepatic circulation. This is the case for some vitamins, such as 25-hydroxyvitamin D_3, 1,25-dihydroxyvitamin D_3, vitamin B_{12}, and folic acid. Enterohepatic circulation has also been reported to contribute to the conservation of several hormones, such as corticosterone, hydrocortisone, androsterone, estrone, and thyroid hormones. These endogenous compounds are mainly excreted in bile as their glucuronide or sulfate conjugates, and deconjugation by colonic bacteria is essential for them to be passively reabsorbed by the colonic mucosa.

Exogenous Compounds

Many environmental pollutors, toxins, and drugs undergo an enterohepatic circulation. For the majority of these substances the evidence supporting an enterohepatic circulation is based on animal studies, and the large interspecies variation in biliary excretion of xenobiotics indicates that extrapolation of results to humans must be taken with caution.

Among environmental pollutants, heavy metals such as mercury, arsenic, manganese, and copper undergo an enterohepatic circulation. Methylmercury poisoning has been reported to occur in Iraqi and Japanese populations exposed to this pollutant. Oral administration of a polythiol-binding resin interrupts the enterohepatic circulation of methylmercury, and has been reported to benefit exposed populations. An enterohepatic circulation has been reported for many insecticides and for polycyclic aromatic hydrocarbons. Mutagenic metabolites of benzo-[*a*]-pyrene, an environmental carcinogen, are excreted in rat and rabbit bile and undergo an enterohepatic circulation, 1-nitropyrene, a combustion product of diesel engines, is also a potent mutagenic substance which is mainly excreted in bile and reabsorbed in the gut in rat.

Certain fungal toxins exert their effect by accumulating in the body via the enterohepatic circulation. This is the case for ochratoxin, a mycotoxin that may contaminate food, and for α-amanitin, a toxin produced by mushrooms of the *Amanita phalloides* species. *Amanita* poisoning in humans is due to enterohepatic recirculation of α-amanitin for up to 48 following ingestion of *Amanita* mushrooms. This toxin is harmless in some herbivorous animals lacking an enterohepatic circulation of α-amanitin.

Many drugs undergo enterohepatic circulation, including the following examples:

- Demeclocycline
- Rifampicin
- Digoxin
- Digitoxin
- Imipramine
- Sulindac
- Eterophine hydrocloride
- Estradiol
- Mycophenolate mofetil
- Verapamil
- Colchicine
- Oxazepam
- Phenytoin
- Spironolactone
- Indometacin
- Diclofenac
- Valproic acid
- Morphine
- Warfarin
- Lormetazepam
- Adriamycin

For some of these drugs, conservation via the enterohepatic circulation is beneficial because it prolongs

their therapeutic efficacy. Thus, for example, the enterohepatic circulation of morphine and of other opiates may prolong their analgesic effect. On the other hand, accumulation of the anticoagulant warfarin, or of the tranquillizers benzodiazepines, or of digitoxin may expose patients to the risk of drug overdose. For most of these drugs, administration of activated charcoal or ion-exchange resins (cholestyramine, for example) is of proven value in the treatment of overdose by interrupting their enterohepatic circulation, thus favoring fecal excretion.

Colonic Bacteria and the Enterohepatic Circulation

Both endogenous and exogenous substances are excreted in bile in conjugated forms. These are mainly glucuronate and sulfate conjugates, with the noticeable exception of bile acids which are conjugated almost exclusively with glycine and taurine in humans. Conjugation, on the one hand, makes these substances sufficiently hydrophilic to be excreted in bile and, on the other hand, makes them too hydrophilic to be absorbed by passive diffusion in the gut. Bile acids are unique in being actively absorbed in the distal ileum in the conjugated form. For all other substances, deconjugation is a necessary step to increase their lipophilicity prior to passive colonic diffusion The human colonic flora is capable of producing glucuronidases and sulfatases, and passive diffusion of the resulting hydrolyzed compounds is usually quantitatively small, because of the relatively small surface-to-volume ratio in the colon, and because binding to bacteria and to nonabsorbable dietary components favors fecal excretion. This explains why the enterohepatic circulation is quantitatively small for all substances relying on a colonic deconjugation step to enter the enterohepatic circulation following biliary excretion.

Nutritional Management of Liver and Biliary Disorders

E Medici, King's College Hospital, London, UK

Background

Nutrition intervention in liver disease is both challenging and well researched. Intervention will depend on the individual patient needs and is related to symptoms rather than disease state. Hence, patients with liver cirrhosis will suffer much the same range of problems irrespective of the etiology. Preserving the patient's nutritional status is central to the treatment of all liver patients. Liver transplantation is now well established as the treatment for end-stage liver disease and restores the patient's nutritional status; however, patients often develop different nutritional complications, predominantly excess weight gain and hyperlipidemias. This section will aim to give a brief understanding of the current evidence-based nutrition practice in liver disease and transplantation.

Type of Liver Disease

Acute or fulminant hepatic failure (FHF) refers to massive hepatocellular necrosis resulting in hepatic

encephalopathy and coma within 8 weeks from the onset of symptoms and in the absence of previous liver disease. Most common forms of FHF in the UK are due to exogenous hepatotoxins such as paracetamol (acetaminophen). FHF carries a mortality rate of 50–80%. Nutrition intervention is short-term until the patient recovers, is transplanted, or dies. Diet manipulation is rarely required, and standard ICU feeding protocols will apply.

Chronic liver failure refers to the progressive damage and cirrhosis of the hepatocytes over a prolonged period. Complications are stage-dependent and often reflect degree of damage to the liver. A patient with cirrhosis can be asymptomatic for up to 40 years. Normally, the patient will alternate between an asymptomatic or controlled symptoms state (compensated liver disease) and a symptomatic state (decompensated liver disease). A decompensated state may result in any one or a combination of symptoms such as ascites, variceal bleeding, diabetes, steatorrhea, and/or encephalopathy. All of these symptoms will require dietary manipulation.

Protein Energy Malnutrition

As the liver is central in the metabolism, assimilation, and synthesis of protein, it is not surprising that protein-energy malnutrition (PEM) is common in patients with chronic liver disease. PEM refers to the increased catabolism of muscle and other visceral proteins for gluconeogenesis. PEM in chronic liver disease has been well documented with a prevalence of 27–100%. The severity of PEM is dependent on etiology and length of disease, with alcoholic liver disease patients being worst effected.

PEM in chronic liver disease has been demonstrated as an independent risk factor to clinical outcome and, therefore, is always prioritized in the treatment of cirrhotic patients. Protein energy malnutrition has been associated with:

- worsening encephalopathy;
- poor control of ascites;
- increased infection rate;
- increased hospital admissions;
- increased mortality.

The reasons for this gross PEM are multifactorial; however, the imbalance of catabolic and anabolic hormones plays a pivotal role. Factors associated with PEM in chronic liver disease include:

- increased energy and protein requirements;
- increased levels of catabolic hormones, predominantly catecholamines, but also corticosteriods and glucagon;
- resistance to the anabolic hormones, insulin and growth hormone;
- reduction of the anabolic hormones, growth factor 1 and its carrier proteins;
- alteration in nutrient utilization;
- reduced glycogenolysis;
- increased gluconeogenesis;
- increased lipolysis

PEM is exacerbated in cirrhotic patients by accompanying anorexia and malabsorption. Aggressive nutrition support is often needed to meet increased energy and protein requirements in order to attenuate catabolism and PEM.

Dietary intervention commences with appropriate assessment of the patient's muscle status and not simply body weight. The latter may be affected by ascites and/or edema, and does not differentiate between fat and muscle stores. Normal weight or obesity may mask PEM, as normal or excessive fat stores can be present in such patients. The patient's requirements will need to be calculated and met, orally, nasoenterally or intravenously.

Elevated Energy and Protein Requirements

Increased requirements for energy and protein have been demonstrated in compensated as well as decompensated liver disease, acute liver failure, and post-liver transplantation by a number of authors. Basal metabolic rate (BMR) has been found to be 40% higher than in healthy individuals, and protein requirements have been estimated at 1–1.8 $g\,kg^{-1}\,day^{-1}$ (healthy individual requirements 0.8 $g\,kg^{-1}\,day^{-1}$). Energy and protein requirements have been found to be closely associated with lean body mass; hence, standard calculations should use dry body weight, and adjustments have to be made for excess fat stores, fluid overload, and ascites (see Table 1). It has been suggested, that patients with a dry body mass index (BMI) of $\geq 30\,kg\,m^{-2}$ and $\geq 40\,kg\,m^{-2}$

Table 1 Estimating fluid weight

Estimated ascitic weight (kg)	
Mild	2.2
Moderate	6.0
Severe	14.0
Estimated peripheral edema weight (kg)	
Mild	1.0
Moderate	5.0
Severe	10.0

From Wicks C and Madden A (1994) *A Practical Guide to Nutrition in Liver Disease*, 2nd edn. Birmingham, UK: The Liver Interest Group of the British Dietetic Association.

(see Table 2) should have their requirements calculated at 75 and 65%, respectively, of their actual body weight.

Some authors strongly recommend that resting energy expenditure should be measured and not predicted. However, as indirect calorimetry carts are not readily available and may be impractical, the use of predictive equations and stress factors is inevitable. Two validated equations for calculating requirements are used in the UK and are shown with examples in Tables 3–5.

Table 2 Calculating body mass index

$$\text{BMI kg m}^{-2} = \frac{\text{Weight in kilograms}}{\text{Height in meters}^2}$$

Interpretation of BMI values (kg m^{-2}):
≤ 15 = critically underweight – Increase weight
15.9–19.9 = underweight – increase weight
20–24.9 = ideal weight – grade 0 obesity – maintain weight
25–29.9 = overweight – grade I obesity – maintain or lose weight
30–39.9 = obese – grade II obesity – must reduce weight by at least 10%
≥ 40 = grossly obese – grade III obesity – must lose weight by at least 10%

Table 3 ESPEN guidelines recommendations

	Protein g kg^{-1} day^{-1}	*Energy kcal kg^{-1} day^{-1} (kJ kg^{-1} day^{-1})*
Compensated liver disease	1.0–1.2	25–30 (105–125)
Decompensated liver disease	1.0–1.5	25 (if ventilated) – 40 (105–167)

Diabetes

The incidence of diabetes is higher in patients with liver disease resulting from hepatitis C virus and alcohol. The prevalence has been quoted at 27–39%. It is essential to maintain good glycemic control (i.e., 4–8 mmol l^{-1}). Hyperglycemia exacerbates muscle catabolism and can increase infection risk. A standard diabetic diet should not be prescribed, as it encourages a low intake of protein and total energy and will compromise the patient's nutritional status. A modified diet encouraging the avoidance of simple carbohydrate whilst increasing fat and protein dense foods should be followed. This will allow for normal glycemic control whilst still meeting energy and protein requirements. Hypoglycemic agents (oral or insulin) will often be required in conjunction with diet.

If the patient is anorectic and not meeting requirements, oral sip feeds and/or nasogastric feeding will be indicated. As these feeds will contain maltodextrins, hypoglycemic agent therapy will need alteration to compensate for the expected elevation in blood sugar.

Ascites

This is the excessive accumulation of extracellular fluid in the peritoneal cavity, usually as a late complication of cirrhosis. The development of ascites is a complex multifactorial process of which the precise mechanism is still unknown. It is probably due to sodium retention (enhanced by secondary hyperaldosteronism), compounded by hypoalbuminemia and portal hypertension. A diagrammatic representation

Table 4 Estimating energy requirements using basal metabolic rate with activity and stress factors (estimated daily requirements = BMR × (% stress + % activity) + BMR)

	BMR kcal (kJ)	
Age	*Men*	*Women*
15–18 years	17.6W + 656 (74W + 2742)	13.3W + 690 (56W + 2884)
18–30 years	15.0W + 690 (63W + 2884)	14.8W + 485 (62W + 2027)
30–60 years	11.4W + 870 (48W + 3637)	8.1W + 842 (34W + 3520)
> 60 years	11.7W + 585 (49W + 2445)	9.0W + 656 (38W + 2742)
Stress factors		
Compensated liver disease	0–20%	
Acute (fulminant hepatic failure)/ventilated/transplant	20–30%	
Decompensated liver disease	30–40%	
Activity factor		
Bed-bound/immobile	10%	
Bed-bound mobile/sitting	15–20%	
Mobile on ward	25%	
Protein requirements		
Compensated liver disease	0.8–1.2 g kg^{-1} day^{-1}	
Decompensated liver disease/transplant	1.2–1.8 g kg^{-1} day^{-1}	

W, dry lean body weight.

Table 5 Example for calculating requirements using both methods

Subject: 36-year-old female with moderate ascites and hepatic encephalopathy secondary to chronic liver disease; the patient is bed-bound
Height = 1.6 m
Weight = 86 kg
(1) Estimate dry body weight: 86 kg − 6 kg = 80 kg
(2) Calculate BMI: $80/(1.6)^2 = 31\ kg\ m^{-2}$
(3) Estimate lean body weight: 75% of 80 kg = 60 kg (the weight to be used for requirement calculations is 60 kg)
Estimated daily requirements using the ESPEN guidelines:
1800–2400 kcal (7524–10032 kJ) per day
60–90 g of protein per day
Estimating daily requirements using BMR and stress factors
BMR = (8.1 × 60) + 842 = 1328 kcal (5551 kJ)
Daily energy requirements = 1328 × (10% activity + 30% stress) + BMR = 1860 kcal (7771 kJ)
Daily protein requirements = 70–108 g

is shown in Figure 1. Ascites usually develops when the patient has advanced 'decompensated' disease. Ascites causes discomfort and shortness of breath, reduced appetite, increased risk of infection (spontaneous bacterial peritonitis), and increased mortality. In addition, ascitic patients will also display even higher energy and protein requirements than nonascitic liver patients.

Ascites is normally managed by a combination of dietary sodium restriction and diuretic therapy. The aim should be to achieve a net fluid loss of 500 ml day^{-1} (equivalent to a weight loss of 0.5 kg), until the ascites clears. Serum urea, creatinine, and electrolyte concentration should be checked at least once a week at the start of treatment. A rising serum urea or creatinine and falling serum sodium concentration indicate impending renal failure and should lead to

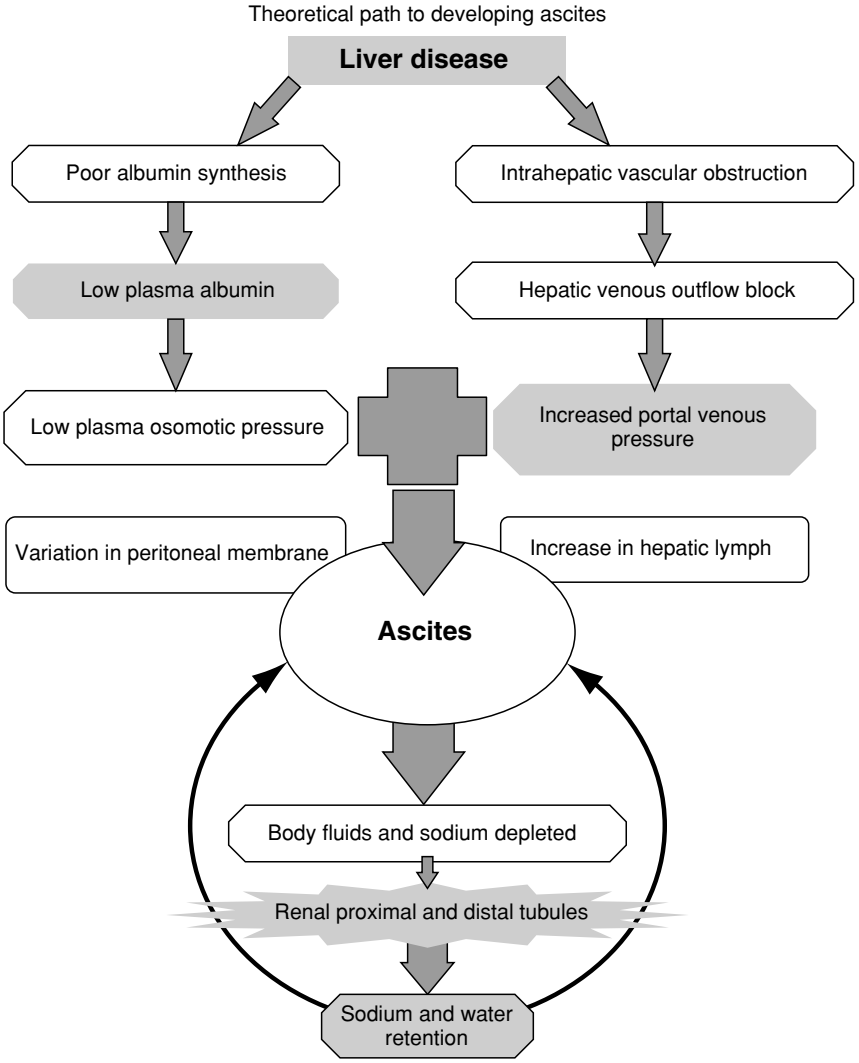

Figure 1 Theoretical pathway to the development of ascites.

a reduction in diuretic treatment. A combination of frusemide and spironolactone diuretic therapy is often used. The latter is potassium-sparing and may result in hyperkalemia after prolonged use. Other interventions include paracentesis (removal of large volumes of ascitic fluid via a cannula).

If a low-sodium/no-added-salt diet and diuretic therapy do not work, the ascites is classified as refractory/resistant, and transplantation or surgical procedures will be required to alleviate the symptoms.

Sodium Restriction

These patients will be extremely catabolic, and display anorexia. Meeting their nutritional requirements is paramount and also extremely difficult without supplementary feeding. Reducing salt intake will automatically result in reduced palatability and possibly further reduce the patient's intake. During hospitalization, it is much easier to impose a sodium restriction on patients whilst ensuring that energy and protein requirements are met. Once discharged, this level of restriction is very difficult to maintain, and a 'realistic' diet of no added salt must be prescribed. An example of a no-added-salt diet is shown in Table 6. This will depend on the patient's socio-economic background, motivation, mental acuity and prognosis. Cutting down salt intake will also help with adherence to the fluid restriction, which is often imposed at 750–1500 ml day^{-1}.

Oral supplements and nasogastric feeds should be chosen carefully. Feeds low in sodium and volume (i.e., 2 kcal ml^{-1}) will be ideal.

Confusion often arises over serum sodium levels. Irrespective of the serum levels (patients are normally hyponatremic), no-added-salt diets should always be prescribed/encouraged for all patients with ascites.

Varices

These are veins that have become grossly enlarged as a consequence of portal hypertension. They are caused by the development of venous back flow as a result of portal vein obstruction by the cirrhotic liver. They are more often seen in the lower 5 cm of the esophagus and fundus of the stomach. The most significant complication of varices is hemorrhage, which is fatal for 50% of patients.

Table 6 Low-sodium alternatives

Low-sodium energy and protein-dense foods	*High-sodium foods – to be avoided*
Meat, fish, poultry	
Fresh or frozen meat, fish, poultry (roast, fry, cook with unsalted butter or oil), tinned fish in oil or water (not brine)	Sausages, tinned meat, tinned fish in brine, corned beef, bacon, ham, gammon, burgers, pies, ready meals, smoked/pickled meat/fish, fish in batter, pâté, sandwich spreads, salami, etc.
Dairy products	
Full-cream milk, yogurt, fromage frais, all creams, cream cheese, mozzarella, cottage cheese, ricotta cheese, eggs	Lassi, most cheeses not mentioned in the 'USE' list, all processed cheeses, e.g., cheese spreads/slices
Fats and oils	
All oils, unsalted butter	Dressings, bottled sauces, mayonnaise
Cereals and breads	
Shredded Wheat, Raisin Splitz, Sugar Puffs, puffed wheat, porridge, unsalted muesli, all flours, bread, rolls, pasta	Most other breakfast cereals, rich breads, e.g., brioche, focaccia, ciabatta, croissant, pot noodles
Fruit and vegetables	
Fresh, frozen, tinned or dried fruit, fresh or frozen vegetables, tinned tomatoes, tomato purée, tinned vegetables in water only, all fruit juices	Dried, pickled, and most tinned vegetables, olives, gherkins, etc.
Savory snacks	
Unsalted nuts, peanuts and raisins, Smiths 'Shake + Salt' crisps (throw away the salt sachet), all butter popcorn	Salted nuts, crisps, Twiglets, salted popcorn and other salted snacks
Biscuits	
Most biscuits – especially Jaffa Cakes, wafers, Kit-kat, Malted milk, Bourbon creams, Nice, plain Hobnobs, Matzo crackers	Digestives, shortbread cheese biscuits, Ryvita
Sweet snacks/condiments	
All milky puddings, custard, cakes, gateaux, chocolate, especially Smarties, Walnut whips, plain chocolate, Fry's chocolate cream, After Eights, fruit sweets – boiled sweets, jelly babies, pastilles, Opal Fruits, marmalade, jam, honey, chocolate spread	Fudge, toffees, Marmite, peanut butter, Vegemite
Drinks and miscellaneous	
Whole milk, hot chocolate, milk shake, yogurt shakes, Lucozade, cordials	Soup, stock cubes, Bovril, Marmite, Build Up Soup

Diet

The presence of varices is not necessarily a contraindication to nasogatric feeding. Two randomized controlled trials investigating the benefit of aggressive nutrition support via nasogastric feeding to full requirements compared with no feeding found no increase in variceal bleeds between the study and control groups. Nasogastric feeding is often not appropriate when a patient is actively bleeding or within 48 h of variceal treatment (banding/sclerotherapy).

No dietary modifications are required for these patients, except to reassure and encourage a normal consistency diet. Many patients will self-regulate their diet to soft/sloppy consistency, because of a misconception that solid foods will rupture their varices. This would only be encouraged if the patient finds swallowing painful, because of variceal treatment such as sclerotherapy or banding.

Hepatic Encephalopathy

Hepatic Encephalopathy (HE) in patients with chronic liver disease (CLD) is a common complication, with a prevalence of 50–70%. HE as a result of FHF is accompanied by intracerebral edema, and intervention relies on the reduction of the cerebral pressure and/or liver transplantation.

HE is a neuropsychiatric condition as a result of portal vein shunting away from the cirrhotic liver. Toxins present in the portal vein shunted away from the liver and hepatocytes without detoxification are thought to be able to cross the blood–brain barrier, with resultant alteration in the patient's consciousness, personality, intellectual capacity, and speech. HE in chronic liver disease can be reversed with medical and nutritional intervention.

The pathogenesis for HE remains unknown but is thought to be multifactorial. Several theories have been proposed and researched. The more popular theories to HE are those relating to the elevated ammonia levels and disturbance in the branched chain amino acid (BCAA) to aromatic amino acid (AAA) ratio in the blood.

The onset of HE in patients with CLD is often precipitated by a number of factors, which, once treated, alleviate the encephalopathy.

Such factors include:

- constipation;
- sepsis;
- gastrointestinal bleed;
- alcohol binge;
- dehydration;
- enthusiastic use of diuretics;
- paracentesis;
- electrolyte imbalance;
- hypokalemia (increased renal NH_4 production);
- protein-rich diet.

Ammonia Theory

Elevated circulating ammonia and ammoniagenic substances are probably the result of portal vein shunting and the inability of ammonia from the gastrointestinal tract to reach the hepatocytes for urea production. Once ammonia diffuses across the blood–brain barrier, neurotoxicity results, as the brain does not have a urea cycle. Toxicity on the central nervous system may be direct or indirect. The latter has been suggested, as ammonia serum levels correlate very poorly with the presence or level of encephalopathy. It is now well established that the action on luminal content by colonic gut flora and glutaminase in the ileum are major contributors of ammonia in the portal vein. The small and large intestine are therefore targeted for treatment.

This theory encouraged the use of low-protein diets to try and reduce ammoniagenic compounds in the portal vein. However, this practice has been proven to be ineffective and, in many cases, detrimental to the patient's well-being.

False Neurotransmission Theory

The false neurotransmission theory in the 1970s was based on the altered ratio of BCAA to AAA in the serum seen in most cirrhotic patients. In healthy individuals, BCAA (leucine, isoleucine, and valine) serum levels are three to four times greater than AAA (free tryptophan, phenylalanine, and tysosine). The higher BCAA concentration results in a greater affinity for the receptor sites of the single carrier system and transport across the blood–brain barrier for normal neurotransmission. In cirrhotic patients and especially encephalopathic patients, this level is altered to 1:1.

AAAs are predominantly utilized by the liver, whereas BCAAs are predominantly utilized by peripheral muscle. During liver disease, BCAAs continue to be metabolized by the muscle for energy, but AAA metabolism by the cirrhotic liver is heavily reduced and results in the reduced ratio.

With this altered amino acid plasma ratio in the blood, AAA can compete with more affinity to diffuse across the blood–brain barrier. Elevated serum ammonia indirectly favors the uptake of AAA into the brain (see Figure 2).

The use of altered amino acid feeds with encephalopathic patients was therefore encouraged. It was hypothesized that altering the amino acid composition of these patients would lead to an improved

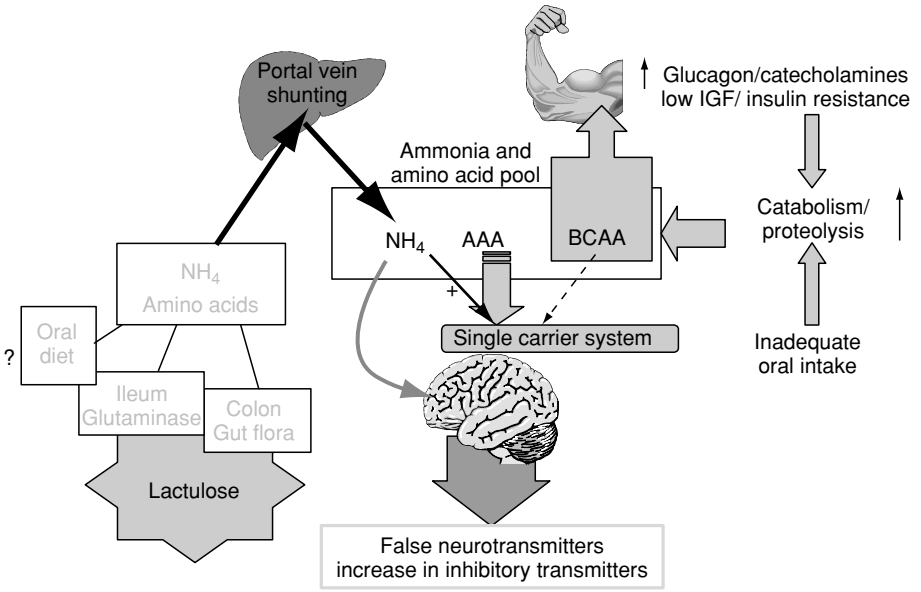

Figure 2 Route of ammonia and amino acids during portal shunting. Ammonia and amino acids from gastrointestinal metabolism enter the portal vein. As the portal vein is shunted away from the cirrhotic liver, ammonia and amino acids are in the systemic circulation. BCAAs are rapidly taken up and utilized by peripheral muscle for energy and serum levels become reduced. AAAs cannot be cleared from the circulation, as they require the urea cycle in the liver. In addition, gluconeogenesis and muscle catabolism increase the release of ammonia and AAA in the circulation. Ammonia may diffuse across the blood–brain barrier, resulting in neurotoxicity, and also increases the affinity of the single carrier system for AAA to cross into the brain and result in the production of false neurotransmitters.

BCAA:AAA serum ratio and improved encephalopathy. Unfortunately, the trials have not been conclusive on the benefit of these expensive and less palatable supplements. Improvement in HE has not always been accompanied by an improvement in the amino acid ratio.

In the 1980s and 1990s, many metabolic and prospective randomized trials investigating the effect of dietary protein intake and use of BCAA feeds in encephalopathy have concurred that:

- Treatment and elimination of precipitating factors often lead to the improvement and elimination of HE without manipulation of the diet.
- Spreading the protein loads throughout the day results in more effective ammonia clearance.
- Endogenous ammonia production from muscle catabolism often exceeds oral protein intake. This is due to the imbalance of anabolic and catabolic hormones and push toward gluconeogenesis in cirrhotic patients. This picture is often exacerbated by the patient's inability to consume adequate nutrition (owing to confusion and/or drowsiness).
- Protein requirements are elevated at 1.2–1.8 g kg^{-1} day^{-1}.
- Positive nitrogen balance is directly linked to improvement and/or elimination of encephalopathy.
- Negative nitrogen balance has been directly linked to the presence and worsening of HE.
- Positive nitrogen balance is achieved by meeting protein requirements. Supplementary feeding with oral sip feeds, nasoenteral, or intravenous nutrition is often required. Similar outcomes have been achieved from standard feeds or BCAA feeds.
- Peripheral muscle is responsible for clearing 50% of the circulating ammonia. Therefore, the more muscle-wasted a patient is, the greater the circulating ammonia.
- Peripheral muscle utilizes BCAA for energy and preservation of muscle mass, and so BCAA feeds have improved nitrogen balance quicker than standard feeds.
- BCAA (predominantly leucine) in cirrhotic patients have been found to:
  - reduce the flux of AAA from muscle cells;
  - reduce proteolysis;
  - increase protein synthesis;
  - increase uptake of AAA by the liver;
  - increase uptake and metabolism of ammonia in muscle cells.

Current Practice for Hepatic Encephalopathy

Diet

Any precipitating factors must be dealt with before dietary effectiveness can be of benefit.

Meeting energy and protein requirements, which often requires supplementation (oral and/or nasoenteral), will normally resolve HE. The use of BCAA feeds in HE is not established in the UK but may benefit patients with particularly persistent encephalopathy. Low-protein diets are contraindicated and should not be used. However, some patients with persistent HE, good muscle mass who are exceeding their protein requirements, may benefit from reducing dietary protein intake to recommendations and possibly using BCAA supplements.

Lactulose/lactitol

The effectiveness of lactulose/lactitol is undisputed and is one of the first-line treatments. This is not surprising, as constipation is cited by many authors as a common precipitating factor for HE. As mentioned earlier, colonic flora and glutaminase in the ileum are responsible for the significant production of free ammonia carried in the portal vein.

It is desirable for a patient with a history of hepatic encephalopathy to open their bowels two to four times per day and the stools to be soft and acidic (pH < 6). Lactulose/lactitol remove both dietary and endogenous ammonia from the gut lumen by osmotic cathartic action.

Antibiotics – Neomycin and Metronidazole

Antibiotics work similarly to lactulose but can only be used for a short time, owing to their ototoxicity and nephrotoxicity.

Lactobacillus acidophilus

Lactobacillus acidophilus populates the colonic lumen with nonurease-producing bacteria, and the research has been extremely controversial.

Ornithine Aspartate Treatment

Ornithine is essential for converting NH_4 to urea, whereas aspartate is essential for the conversion of NH_4 to glutamine in the urea cycle. Ornithine aspartate via enteral or parenteral infusion has been found to be effective in resolving mild encephalopathy in small trials.

Zinc Supplementation

It has been well documented that patients with chronic liver disease have low serum zinc levels as a result of increased urinary losses. In addition, two out of the five urea cycle enzymes are zinc-dependent. Trials investigating zinc supplementation to increase the activity of the urea cycle have been inconclusive.

Steatorrhea

Steatorrhea is a common complication as a result of a mechanical block in the biliary tract or by intrahepatic lesions. When bile salt entry into the duodenum is hindered, the emulsification of dietary fats is incomplete. Steatorrhea is more frequently seen in patients with cholestatic disease, e.g., primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC). The reduced absorption of fat results in nausea, indigestion, and steatorrhea, with accompanying calcium and fat-soluble vitamin malabsorption. The patient's nutrition status will obviously be compromised if steatorrhea is profuse. However, steatorrhea varies from patient to patient.

The prescription of low-fat diets should only be prescribed if the steatorrhea is socially unacceptable for the patient or is causing muscle loss, or the patient reports nausea and/or indigestion when consuming fats. Blanket fat restrictions will compromise a patient's intake of energy and make nutrition support difficult. Therefore, fat restrictions should never be applied to patients not experiencing any of the above symptoms.

Malabsorption may also be caused or exacerbated by concomitant inflammatory bowel disease. There is a high prevalence of ulcerative colitis in patients suffering from PSC, whereas celiac disease has been associated with PBC patients. It is therefore important for bowel motions to be assessed carefully.

If fat restrictions are indicated, energy intake will need to be manipulated and monitored. The level and type of fat restriction required are extremely variable from patient to patient. Increased use of carbohydrates and carbohydrate-only supplements is often beneficial. There is also a vast range of fat-free oral supplements. If energy requirements cannot be met with increased carbohydrate alone, then medium-chain triglyceride (MCT) emulsions and oils can be utilized. MCTs are water-soluble and do not require emulsification by bile salts. The emulsion can be taken on its own at a maximum dose of 45 ml qds or added to drinks such as milkshakes and low-fat milk. The oil can be used in various recipes but has a low smoking point, often making it unsuitable for frying. If supplementary feeding is required, oral and enteral feeds are available, containing MCT as its predominant fat source.

Plasma levels of fat-soluble vitamins A, D, E, and K should be routinely checked and supplementation given accordingly. Blanket supplementation should not be encouraged, as excessive intake is toxic.

Prevalence of osteoporosis is much higher in patients suffering from PSC and PBC. It is therefore

advisable to use a calcium supplement with active vitamin D.

Patients suffering from celiac disease need further adaptation to their diet to exclude gluten.

Liver Transplantation

Immediately Post-transplant

Aggressive nutrition support immediately post-transplant is essential to ensure quick and rapid recovery. Initially, nasogastric feeding may not be tolerated, as gastric stasis is common. In such instances, nasojejunal feeding should be used. These patients' requirements have been estimated at 140% BMR and protein up to $2\,g\,kg^{-1}\,day^{-1}$. Aggressive nutrition support has been shown to reduce the patients' ICU stay and time on the ventilator.

Medication interaction Patients are placed on immunosuppressive drugs (Tacrolimus or Neoral), steroids, and antibiotics. Immunosuppression drugs are gradually reduced, and a minimal dose must be taken daily for the rest of the patient's life. The steroids are used to reduce inflammation and are stopped within a few months. The antibiotic therapy is prophylactic and lasts for a few weeks only.

Diet Once the patient is on the ward, elevated protein and energy requirements should continue to be met. The patient's appetite (usually) returns to normal as a result of the steroids, the cessation of restrictive diets, and a general feeling of well-being. Food-safety advice is necessary for up to the first four months, because of the initial high dose of immunosuppression medication. The patient should also be advised to avoid grapefruit and grapefruit juice, as these have been shown to interfere with the absorption of Tacrolimus and neoral from the gut.

Glucose intolerance and diabetes are also common posttransplant. They may be short-lived until the patient stops prednisolone therapy. However, the incidence of diabetes post liver transplantation is high and thought to be related to immunosuppression therapy. Hyperkalemia is also a common side-effect seen with immunosuppression therapy but normally resolves with a reduction in the dose. Low-dietary-potassium advice may be required.

Long-term Post-transplant

Unfortunately, up to 65% of transplant patients, at one year post-transplant, become obese with hypercholesterolemia and an increased risk of coronary heart disease. This is more common in patients transplanted for chronic liver disease. Healthy eating advice is therefore instigated once a normal BMI of $20–25\,kgm^{-2}$ is achieved. The exact reason for obesity is not known. However, it has been suggested that the patient's inactive lifestyle, increased appetite, enjoyment of foods, and immunosuppression therapy all play a role. Premorbid obesity has been found to correlate with postransplant obesity. Therefore, such patients should be encouraged to follow a healthy eating and exercise plan as soon as possible post transplantation.

Diabetes Diabetes in post liver transplant patients is common, despite cessation of steroids from their therapy. Once a patient achieves a good appetite and is eating regularly, standard healthy eating diabetic advice should be given.

LOW-FAT FOODS

Contents

Types and Manufacture

A J Rosenthal, Oxford Brookes University, Headington, Oxford, UK

Introduction

In a weight-conscious society where obesity is a common cause of death, and where icons of beauty are portrayed by a thin stature, there are social pressures to believe that we are empowered to control our weight through selecting low-fat foods. Inspired by this idea, the food industry has invested in developing processes and ingredients which enable the production of traditional products but with a fraction of the fat and therefore a fraction of the energy content.

The idea of reduced-fat foods has led to a variety of paradoxes in the public's perception, such as being abstemious with the selection of low-fat foods may be rewarded by high-fat treats (such as chocolate). Clearly this kind of logic is flawed. Furthermore there is evidence that the energy deficit resulting in the selection of low-fat foods is made-up by additional food consumption.

Figure 1 charts some high-energy foods in relation to their energy contribution from fat.

Strategies for Fat Reduction

Fats are often defined as food components which are soluble in organic solvents. Triglycerides are the predominant chemical species in food fats.

For a limited number of foods the fat may be removed without any adverse effect on the product. Such a simple approach has been successful with some dairy items in which whole milk has been replaced by skimmed. However, changes can occur in the functional properties of foods when fat is removed and generally one of three strategies is employed.

1. Fat may be wholly or partially replaced with one or more ingredients which have a lower energy content, but which contribute the essential functional and sensory attributes which were previously offered by fat. Reformulation is implicit in this approach. Alternative ingredients rarely behave identically to fat and often more than one new functional ingredient needs to be incorporated in order that the sensory and functional properties of the traditional food are maintained.

   A fat substitute is a compound which, like triglycerides, is soluble in an organic solvent, but whose chemical structure is neither metabolized nor adsorbed in the human digestive process. Chemists have rationally assessed the structure of triglycerides and produced analogs which do not occur in nature, for example by esterifying sugars with fatty acids one can produce compounds which have many similarities to triglycerides (Olestra is an example of such a product). In contrast to fat substitutes, a fat mimetic merely mimics the effects of fats but is predominantly water-soluble. Fat mimetics include water-soluble hydrocolloids (such as β-glucan from oat or

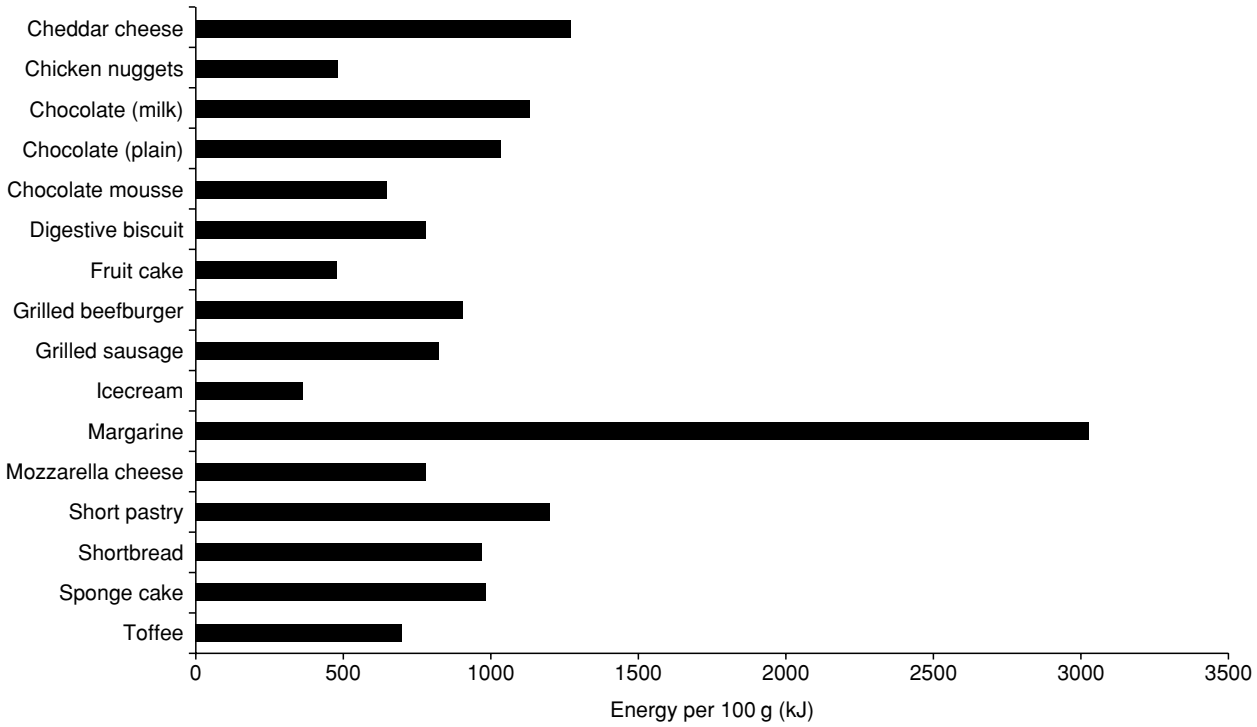

Figure 1 Energy contribution from fat.

barley) as well as microparticulate proteins (Simplesse is an example of such a product).

Many of the fat mimetics create the same mouth feel as fats by offering a viscous yet homogeneous texture. For example, tapioca dextrin can be hydrated to form a gel which can be used to replace < 50% oil in products like salad cream, providing viscous smooth mouth feel reminiscent of fat.

2. Fat may be diluted by the addition of air or water. In the past cynics have criticized the food industry for adding water to certain products (e.g., glaze on frozen foods). In contrast, the addition of air to whipped desserts, icecream, and mousses is often seen as desirable, producing a lighter, fluffier texture – this is despite the fact that these products are normally sold on a volume basis!

   Food emulsions consist of two immiscible phases – a high-energy oil phase and the lower-energy aqueous phase. The stability of emulsions may be controlled by increasing the viscosity of the continuous phase. In the case of oil-in-water emulsions, one often adds hydrocolloid stabilizing agents to the aqueous continuous phase, thus maintaining a high apparent viscosity. Since the gelation of such emulsions depends largely on the hydrocolloid concentration, one can effectively reduce the fat content while maintaining the texture. The texture of many hydrocolloids is smooth and creamy, thus furthering the illusion, without the energy from the fat.

   Another approach is to produce a three-phase water-in-oil-in-water emulsion in which oil droplets within the aqueous phase are further thinned out by a suspension of smaller water droplets inside. Multiple emulsions are normally achieved by two-stage homogenization. First, fine droplets of water are dispersed in oil emulsion using a lipophilic emulsifier. This primary emulsion is then dispersed in an aqueous phase using low concentrations of a hydrophilic emulsifier and a relatively gentle homogenizer pressure.

3. A limited number of products may be produced in the conventional way and subsequently have the fat removed by solvent extraction to produce reduced-fat foods. Solvent extraction has long been used in the production of cooking oils by extracting them from seed cake. One drawback of solvent extraction is the potential loss of desirable fat-soluble flavor compounds; this is relevant, as much of the flavor of volatiles in fried foods is produced during frying.

   Supercritical carbon dioxide has also been used to produce low-fat foods by extraction of fractions from conventional products such as potato crisps. A solid food like a flaked almond, whose shape and structure are defined, can have almost half the

fat removed without any appreciable loss in shape. The result is a lower-energy, lower-bulk-density nut with a relatively high protein content.

Considerations when Reducing Fat

To achieve successful reduction in the fat content of foods one needs to understand the roles which it plays during processing and subsequent storage, for example, its effect on the rheological and thermal properties of the food, its influence on the chemical and physical stability during storage, and, most importantly, its impact on sensory properties.

It has been suggested that one deciding factor in the enjoyment of fat is the smooth, creamy, homogeneous viscous mouth feel. Fats tend to be plastic in behavior and, when they melt, lubricating oils are produced. This is the desirable characteristic of cocoa butter with its unusually sharp melting point of 34 °C which happens to be just below internal temperature of the mouth, hence cocoa butter in chocolate elicits the sensation of melting away to a smooth creamy texture in the mouth.

The resolving power of the tongue and palate to small particles is in the region of 3 μm. Particulate materials with a diameter which is less than the resolving power of the tongue are therefore perceived as smooth homogeneous materials and can be used to mimic the smooth creamy mouth feel of fats. Microparticulate materials which have been used include microcrystalline cellulose, milk, and egg proteins.

Since fats are made up of mixtures of triglycerides, each with its own melting point, fats exhibit varying physical properties with temperature. When cold they tend to be solid and hard; as the temperature rises they soften as some of the triglycerides melt. Consequently melting occurs over a broad temperature range. Melting behavior is further complicated by the ability of fats to crystallize into different polymorphic forms, each with its own structure and melting point. For example, cocoa butter has six polymorphic forms (denoted I–VI). Type V is the most desirable, giving commercial chocolate its characteristic appearance; however if the chocolate melts during storage and then cools slowly, the more stable type VI can form with its less attractive appearance. The tempering step during chocolate manufacture is intended to form the desired polymorph preferentially.

In bakery shortenings, the β′ polymorph is reputed to be necessary to whip air into batters. This stabilization has been attributed to the lower level of crystal–crystal interaction compared with the β polymorph; this allows the β′ polymorph to adsorb as a dense layer at the interface, raising the interfacial viscosity.

Within emulsions, fats are of structural importance, providing one of the bulk phases. A high viscosity in the continuous phase helps to achieve emulsion stability. In the case of water-in-oil emulsions fat crystals present within the oil phase are found to adsorb on to the interface of the aqueous droplets and can help to stabilize the emulsion. Moreover as the crystals grow they form a solid matrix around the aqueous-phase droplets.

People sometimes ask ‘why do fried foods taste so good?’ In addition to the residual frying fats on the surface, with its lubricating properties, chemical changes such as the Maillard reaction occur during frying, which leads to the development of flavor, brittle, crisp textures, and characteristic golden-brown colors.

Many flavor volatiles are fat-soluble and may be introduced to the food in fatty ingredients. Replacing fats with substitutes or mimetics can significantly reduce the overall flavor.

Technological and Sensory Aspects of Selected Low-Fat Foods

Food Emulsions

Numerous food emulsions exist; the small size of the dispersed-phase droplets gives rise to the desirable sensation of creaminess. The high-calorie oil phase of emulsion-based foods makes them prime candidates for calorie replacement. Emulsion-based foods include margarine and butter substitutes, icecream, mousses and frozen desserts, salad cream, sandwich spread, and mayonnaise. Emulsions require stability against phase separation and attempts to replace their fat must take this into account. Emulsions also occur as intermediate products in the manufacture of other items, such as cakes, and emulsion stability during processing is important for product success.

Frozen desserts such as icecream are often high-fat products. A variety of fat replacers have been tried in frozen milk systems; temperature is a key parameter in terms of both product melting and ingredient solubility. It has been shown that carbohydrate-based fat mimickers are not able to achieve the high overruns found in conventional icecreams; moreover their consistency adversely affects the sensory properties of the products (making them coarser, more watery, and less creamy).

Intensity of flavor volatiles is reduced at low temperatures and clearly oil-soluble flavors are affected by replacing fat with microparticulate or hydrocolloid-based substitutes. Changes in flavor intensity become more apparent with storage and compensation in the product formulation is necessary.

Low-fat alternatives for butter are a burgeoning market. Several approaches have been taken in creating these products, for example, the formation of multiple-phase emulsions which dilute the dispersed fat droplets by filling them with smaller droplets of water. Another approach has been the incorporation of fat replacers into the formulation.

Melting of characteristics of low-fat spreads is important in producing the right mouth feel. Some starch-based low-fat spreads have long melting profiles on heating, which contrast with the melt-in-the mouth behavior of butter. Another important characteristic is rheological behavior. Spreads should behave as plastic solids, that is to say, they must resist small stresses and then start to flow when a small yield stress has been applied.

When dealing with products that contain raw egg, the protective effects of hydrocolloids must be considered if pathogens are to be destroyed during pasteurization. Such effects are well documented and rates of destruction of pathogens have been studied. It has been found that the destruction of *Listeria monocytogenes* is directly correlated with aqueous-phase concentration, thus reduced-calorie mayonnaise dressings offer greater protection than traditional mayonnaise.

Dairy Products

Though its composition changes with season, breed, and feed, the fat content of bovine milk is in the region of 4%. Removing the fat results in a change in the viscosity and color. Moreover the appearance markedly affects the perceived thickness and residual mouth coating of the milks. Attempts to enhance the color of skimmed milk have included the addition of whiteners such as titanium dioxide.

Low-fat, lite or light cheeses have had their fat content reduced by 50%, while reduced-fat cheeses have a fat content which is at least 25% less than the original reference fat content. Reduced-fat cheeses have been produced since the mid-1950s, though, as with other low-calorie products, demand has increased in recent years. Most of the work on fat replacement in cheese has tended to focus on a small number of cheeses, notably cheddar and mozzarella. Two basic approaches have been taken to achieve low-fat cheese and these are based on either modifications to the manufacturing procedure or the incorporation of fat replacers.

As far as modifying the manufacturing is concerned, increasing the moisture content can provide some of the creamy mouth feel offered by fat. Water content of the final cheese can be increased in a variety of procedures such as lowering the cook temperature, shortening the cook time, or curd washing. Flavor of low-fat cheese can be a problem. Rapid growth of the starter culture can lead to accelerated acid production which results in bitter flavors. It is better to have a small inoculum of starter culture to limit acid production and possibly to incorporate adjunct cultures which produce specific flavor compounds through increased proteolysis. Some adjunct cultures are deliberately attenuated by heat treatment to achieve particular flavor nuances. Commonly used adjunct cultures include *Lactobacillus* spp. and the growth of conditions in cheddar cheese requires a salt concentration of 1.8%. Considering that the market for low-fat cheese is likely to be a health-conscious one, concern about salt concentrations have prompted product development of low-fat, low-salt cheese replacing salt with potassium chloride.

A variety of fat replacers, including sucrose polyesters, microparticulate proteins, and hydrocolloid products, such as pectin or gelatin, have been used to produce low-fat cheeses. While fat substitutes successfully produce a similar mouth feel to full-fat cheese, they do not necessarily provide the flavor characteristics of the traditional product and some recipe compensation may be required. In practice, combining the two approaches of modifying the manufacturing process and incorporating fat replacers may give products of optimum quality. (*See* **Cheeses**: Types of Cheese.)

The essential properties of a cheese have to reflect the use to which it is being made, for example, when it is an ingredient used as a pizza topping, its meltability and rheological properties are fundamental. Microparticulate fat replacers interact with the casein from the milk, becoming embedded in the curd and forming links between adjacent bits of curd. Relatively large microparticulate fat replacers therefore create wide serum channels and a high degree of openness in the cheese. When melted, fat-replaced cheeses have a similar viscosity to conventional cheese.

Milk fat is often used as a food ingredient and consequently when fat replacement is an issue, the melting characteristics and consistency at different temperatures become important. If sucrose polyesters are used to replace milk fat in foods, then care must be exercised in the choice of the fatty acid esters used, as the chain length affects the hardness and melting characteristics. (*See* **Milk**: Physical and Chemical Properties.)

Reformed Meat Products

The main approach in fat reduction within meat products is to increase the water-holding capacity of the meat. A certain amount of water is lost from meats as a result of postmortem drip; further losses

can occur if the meat is cured because the curing salts draw water and soluble proteins out of the flesh by osmosis. With the advent of mechanization in food processing, attempts were made to speed the curing process and to limit the amount of water lost during curing. One solution is to incorporate water-binding salts, such as phosphates, into the brining solution. A similar approach has been taken in enhancing the water-holding capacity of reformed meat products, by adding phosphates. In the case of frankfurters, the addition of acid phosphate allows the incorporation of more connective tissue into the meat emulsion, thus adding to the value of the product and further diluting the fat content. The arguments for using phosphates in restructured meat products is not just one of economy, for, in addition to the ability to reduce the proportion of fat, added phosphates and water improve on some of the textural characteristics such as juiciness, tenderness, and overall palatability in meat patties.

Water binding of restructured meats has also been achieved by incorporating grain or bean flours, starches, as well as purified hydrocolloid gums like carrageenans or cellulose esters. These materials bind water but tend to modify the texture of the product. By way of reiterating the need to reflect on the desired product characteristics when selecting a fat replacer, consider the use of λ-carrageenan which has been investigated as a water-binding agent in a variety of low-fat meat products such as beef patties, restructured pork nuggets, and bologna sausage. This gum appears to soften products such that beef patties are juicier and more tender, but a firm product like bologna is also softer than the normal high-fat version.

Addition of low-fat protein extenders can also serve as a means of reducing the relative fat content of comminuted meat products. Lean meats such as goat can be incorporated into patties replacing 60% of the beef without consumers detecting any difference. Other extenders which have been used to extend the protein and lower the fat include connective tissue and soya flour.

Flour Confectionery

Butter has traditionally been used as the fat in most flour confectionery. Industrialization brought with it butter substitutes such as shortenings which, unlike butter, are not emulsions and contain little water. Butter, margarines, and shortenings are used in many bakery products such as cakes, cookies, crackers, and pastries. It has been observed that the addition of certain surfactants to biscuit dough and cake batters can help to maintain the texture of reduced-fat biscuits. Many commercial bakery shortenings actually have high levels of emulsifier. (*See* **Emulsifiers:** Phosphates as Meat Emulsion Stabilizers.)

In puff pastry the fat is laminated into the dough and forms an impervious layer which traps steam during subsequent baking, resulting in the formation of a light flaky characteristic texture. Various approaches have been taken to reduce the calorie content of the laminating material. Carbohydrate-based fat replacers are unsuitable as their hydrophilic properties prevent them from being able to form an impervious layer which means that steam is not trapped during baking. Instead it is necessary to use an oil-soluble, restructured lipid to form a water-insoluble barrier.

A variety of sweet biscuits and cookies have been the subject of fat replacement. A simple removal of fat without the addition of any substitute leads to a hard biscuit, with a reduction in spread during baking and a pale appearance. The incorporation of emulsifiers helps to soften the dough, enabling some spread during baking and resulting in a softer biscuit. Since reducing the fat content of biscuits generally makes a harder product, it might be assumed that reducing the fat of soft dough-type cookies is more difficult to achieve. Oat fiber may be used to replace 30% of the fat in soft-type cookies. The increased water content required to handle the dough insures a reduction in calories by one-third and also assists them to rise during baking. Care has to be exercised to avoid large particles of oat fiber which might result in a gritty mouth feel.

High levels of fat replacement in biscuits using microparticulates can lead to an increased mouth coating, a reduction in the fracturability and sensory firmness, as well as a reduction in the flavors. Being water-based, carbohydrate fat replacers lead to an increase in the moisture content which in turn results in denser and tougher biscuit. Overall it can be seen that studies on the replacement of fat in biscuits have not been altogether successful; only limited reductions in the fat content have been achieved and replacement tends to result in artifacts compared to the conventional product.

In cake batters the fat has several functions: it acts as a vehicle for some of the oil-soluble volatile flavor compounds; it traps air during mixing, and then during baking it becomes integrated into the protein matrix, adding to the tenderness of the final crumb. Complete substitution of fat in high-ratio cakes has been achieved using a variety of hydrocolloid-based fat replacers; however this is accompanied by a reduction in batter overrun, leading to a reduced baked volume.

Bakery fillings and coating mixtures are conventionally based on a fatty formulation. Usually such

materials have a continuous phase of fat into which sugar, milk solids, and cocoa are dispersed. When the coating is in the mouth, the fat melts, releasing the flavors and the characteristic creamy mouth feel. If the continuous phase is replaced with a water-soluble hydrocolloid, such as microcrystalline cellulose, then the sugar present forms a concentrated solution which may be pumped to the enrobing machines in the factory. When the mixture is cooled the sucrose solution becomes saturated, the solids present dominate, and the mixture sets. The higher temperature in the mouth causes the coating to liquefy, releasing the flavor and the same characteristic creamy mouth feel of a fat.

Frying Oils and Batters

The high-fat content, yet desirable characteristic flavors and textures of fried foods, make them important targets for fat replacement. The high temperatures involved in frying make most of the hydrocolloid-based and microparticulate fat mimetics unsuitable for the operation. High-boiling, noncalorific fat replacers such as sorbitol esters or polyorganosiloxanes may be used as alternatives to frying oils.

A different approach to reducing fat uptake during deep-fat frying is the incorporation of materials which provide barrier properties to the batter or breaded layers of the food. For example, an edible film of hydroxypropyl methylcellulose can reduce the fat uptake of chicken pieces by one-third.

Fried food analogs such as 'oven-ready' foods often have coatings or batter mixtures which contain fats with the intention that during cooking they yield some of the flavors and textures of their fried counterparts.

Some low-fat fried snack foods are produced in the conventional way and then the fat is extracted using supercritical carbon dioxide.

Conclusions

The promise of low-fat foods has enticed our society and captivated food technologists. Simple reduction in the fatty ingredients can result in a change in the sensory and functional properties of the food. Three approaches to reducing fat have been taken: (1) substitution of the fat with one or more functional ingredients; (2) dilution of the fat with water or air; and (3) extraction of the high-calorie constituents after conventional manufacture.

Low-fat Spreads

J Dostálová, Institute of Chemical Technology, Prague, Czech Republic

Introduction

It is now generally recognized that a high-calorie diet with inadequate physical activity results in overweight or obesity, which in turn could lead to diseases such as noninsulin-dependent diabetes, hypertension, cardiovascular diseases, endometrial cancer, and gallstones. The apparent connection between diet and health has increased awareness for 'healthier' eating; the reduced-fat diet is especially in vogue. This trend is reflected, in particular in the USA and in Europe, in the increased market for low-fat products, including low-fat spreads. Most of the market surveys carried out in recent years indicate that the demand for 'healthier' food will increase, but not at the cost of sensory quality and at too high a price. The sensory characteristics (flavor, taste, color, and texture) of low-calorie products have to be comparable with those of traditional products. These requirements present the industry with a challenge and an opportunity to develop new technologies and new and novel additives and food ingredients. A great deal of these targets were realized with the development of low-fat and very-low-fat spreads or fat-free spread products.

Brief History

Margarine, which was developed in France in 1869, must contain a minimum of 80% fat. Health concerns have led to the development of many low-fat spread products, which have lower energy content. Some interesting data from the history of margarine with lower fat content are as follows:

- Diet margarine, containing half the calories of regular margarine, was introduced in 1964 in the USA. The US Food and Drug Administration (FDA) questioned the legality of the product but lost an ensuing court case, which confirmed diet margarine as a table-spread product. (*See* **Margarine**: Types and Properties; Methods of Manufacture.)
- A product containing 60% fat was introduced in 1975 that could not be identified as either margarine, as it did not contain 80% fat, or diet margarine, which must contain 40% fat or half the calories of a regular margarine.
- In 1981 margarine butter blends containing as much as 40% to as little as 5% butter were introduced by several margarine and butter processors. Some were in the low-fat form. These premium products, priced between butter and margarine, had a more characteristic butter flavor, but improved spreadability and the health benefits of margarine.
- Lower-fat-content spreads of less than 20% fat were introduced in 1989.
- In the 1990s, low-fat spreads containing plant sterols which decrease cholesterol level in human blood serum were developed.
- Spreads, which ranged from zero to 68% fat, and were free of *trans* fatty acids, were introduced in 1997. (*See* **Emulsifiers**: Organic Emulsifiers; Phosphates as Meat Emulsion Stabilizers; **Fatty Acids**: Properties.)

Statistical data in the western countries identify the shift in consumer table-spread popularity to low-fat spreads. The spread market share increased, for example, in the USA from less than 5% in 1976 to more than 74% in 1995. In the European Union, 75–80% of commercial spreads in 1985 contained 80% fat. By 1993, 75–80% of spreads marketed contained 40% fat.

Description, Terminology, and Classification

The food category referred to as table spreads consists of several types of products, including butter and margarine. Commercial table spreads now exist that contain fat levels ranging from a high of 80% all the way down to 0%. The standards in most countries require that butter and margarine contain not less than 80% by weight of fat. Products resembling margarine containing less than 80% fat are usually called spreads. After regulations in some countries, only products containing less than 80%, but more than 40%, fat, 40–70% fat, 62–80% or less than 75% fat are labeled as spreads. Products with 60–80% fat or with 41–60% are reduced-fat spreads, and products containing less than 40% fat are referred to as low-fat spreads. The term very-low-fat spread is used for spreads of 5–15% fat and even less. The spreads with extremely low fat content are sometimes called ultra-low-fat products.

The terminology and classification are not unified and they are laid down by national legislation in accordance with the needs of each individual country. Therefore different terms can be found for low-fat spreads, e.g., halvarine, minarine, half-fat margarine, margarine 40, margarine with low fat content, light or lite margarines, etc.

The sixth edition of the *Dictionary of Nutrition and Food Industry* defines halvarine as 'a name sometimes given to low-fat spreads with less than the statutory amount of fat in a margarine.' The same definition is used for minarine in this encyclopedia.

Codex Alimentarius defines minarine as follows: 'minarine is a food in the form of spreadable emulsion, which is mainly of the type water/oil, produced principally from water and edible fats and oils which are not solely derived from milk, and in which the fat content is not less than 39% m/m and not more than 41% m/m.'

The term 'halvarine' is sometimes used for a product with the same fat content as minarine, defined by Codex Alimentarius, i.e., a fat product with fat content of not less than 39% m/m and not more than 41% m/m.

The above-mentioned definitions for minarine and halvarine are more precise than the definitions used in the *Dictionary of Nutrition and Food Industry.*

It is possible to find other terms for low-fat spreads with a fat content of not less than 39% m/m and not more than 41% m/m in national legislations as well. For example, half-fat margarine in Germany and Austria, margarine 40 in Denmark, margarine with low-fat content in the Czech Republic.

Fat products with a fat content less than 39% m/m and more than 41% m/m but less than 80% m/m are called spread fat x% m/m in the above-mentioned national legislation, with the exception of products with a fat content not less than 60% m/m and not more 62%. Those products are called three-quarter-fat margarines in Germany and Austria, margarine 60 in Denmark, margarine with reduced fat content in Czech Republic, and elsewhere mellarines.

In some literature and legislative sources, products with 40% fat or less are identified as 'light' or 'lite' margarines. The 'light' product must contain no more than one-half the fat and one-half the energy of the reference product.

There are no published regulations for some types of low-fat spreads in some countries but labels on such products must list the total percentages of fat, and in some countries, sources of fats in weight order as well.

Products based only on all-vegetable oil and fats blends are mostly defined as low-fat spreads. From the nutritional and culinary points of view, spreads with low fat content based on milk fat (milk-fat product) or blends of vegetable oils and fats with milk fat (mixed-fat products) are also considered to be low-fat spreads. The terminology of these products is analogous to that of vegetable low-fat spreads. Half-fat butter or half-fat blend are terms for products with a fat content of not less than 39% m/m and not more than 41% m/m. Fat products with a fat content less than 39% m/m and more than 41% m/m but less than 80% m/m are called dairy spread fat x% m/m or blended spread fat x% m/m, with the exception of products with fat content not less than 60% m/m and not more than 62%. These products are called three-quarter-fat butter or three-quarter-fat-blend. The terms low-fat butter (blend) or 'light' butter are used as well.

Low-fat mayonnaise with a thick texture can serve as fat spread on bread or biscuits as well. Hence, we can also rank low-fat mayonnaise (fat content can be less than 30%) among low-fat spreads. The composition of an oil phase of low-fat mayonnaise resembles the oil phase of low-fat spreads, but low-fat mayonnaise differs significantly from low-fat spreads in that it is an 'oil-in-water' emulsion. Various food ingredients (vegetables, spices, etc.) are often added to those products.

Classification systems used for global national statistical purposes do not differentiate spreads according to their fat content in most cases. For example, the list of the industrial production Prodcom (product of the European Community), which is obligatory in the states of the European Union, only differentiates the group 'spreads with reduced or low content of fat (less than 80% fat).'

The Procome (Eurostat (Statistical Office of the European Communities) version) used for household budget survey data only groups together 'margarine and other vegetable fats.' The new classification system Eurocode 2 was proposed, therefore, by the Cost Action 99 project. This system classifies spreads as follows:

- fat spread > 65% fat, > 25% saturated fatty acids
- fat spread > 65% fat, < 25% saturated fatty acids
- fat spread 45–65% fat, > 25% saturated fatty acids
- fat spread 45–65% fat, > 25% saturated fatty acids
- fat spread 30–45% fat
- fat spread < 30% fat

Formulation and Processing

Low-fat spreads designed for spreading on bread and biscuits from a refrigerated store are now typically based on all-vegetable-oil blends in the form of water-in-oil emulsions. In the margarine, fat or oil is the continuous phase and the majority phase; water is the discontinuous phase and the minority phase of the emulsion. In low-fat spreads the oil-continuous phase is still a major factor (in ultra-low-fat products water is the continuous phase). The oil phase must still have a structure which is determined by the size, shape, and arrangement of fat crystals. This network of crystals determines the distribution of melt point types and provides the form and texture of the finished spread. The amount of these crystals, expressed as the solid fat index or solid fat content, is important. In addition to the amount of solid fat, the crystalline form is also very important.

Two considerations – formation and stability of the emulsion, and the structure of the aqueous phase – take on greater importance in low-fat spreads in comparison with full-fat products.

The formation of an emulsion requires the presence of surface-active agents (called emulsifiers or surfactants) to facilitate the formation of the dispersion of one immiscible liquid (water) into another (oil). The emulsifier reduces the interfacial tension between the aqueous phase and the oil phase, and stabilizes the spread during its storage by preventing the aqueous phase from coalescing. The stabilization of emulsion becomes more important as the percentage of fat phase is lowered and the percentage of the aqueous phase is increased. Therefore, low-fat spread should contain larger amounts or more efficient emulsifiers. Water is still the dispersed phase of the emulsion but becomes the majority phase of the emulsion. The volume of water fraction is much larger and can create a far greater degree of instability in low-fat spreads.

Structuring of the aqueous phase is the second focus to obtain long-term shelf stability. Low-fat spreads can be stabilized in the following ways:

- Adding bulk ingredients (e.g., maltodextrin) to take up or hold the increased level of added water. Some of these ingredients may also increase the viscosity and thickness of the aqueous phase and contribute to better sensory quality similar to that of 'full-fat' products.
- Using various gelling agents which reduce syneresis, such as alginate, pectin, carrageenan, starch, whey protein, soy protein, casein, and gelatin.
- Adding gelled microparticles which have a spherical or globular shape which act as fat mimetics.

Very-low-fat spreads are water-continuous systems (oil-in-water emulsions). It is not difficult to disperse oil in water but it is difficult to provide a good sensory quality of a spread, comparable with that of full-fat products. Several systems have been developed for this purpose, mostly on the basis of proteins, polysaccharides, or blends of them.

The composition of the fat phase in low-fat spreads is very important. Low-fat spreads are usually formulated from the same fat and oil blends as those used for regular margarines, but certain basic features must be considered in terms of the solid fat content. The solid fat index profile determines spreadability, defines how the fat blend melts in the mouth, and determines the thickness on the palate, and speed of flavor release. Processors modify and blend oils in order to achieve optimal characteristics. It is now becoming increasingly appropriate to define oil blends for spreads by their triacylglycerol types. Nutritional aspects as well as shelf-life must be considered.

There are varieties of blends used, adjusted according to the fat level and sensory and nutritional characteristic targets. Selectively and nonselectively hydrogenated oils, interesterifed fractions, vegetable fats, or their selected fractions and blends are utilized as hardstock.

Milk fat is also used in some products. Margarine products usually contain milk fat maximum 3% of total fat and mixed-fat products minimum 15%, maximum 80% of total fat. Restrictions with respect to the proportion of milk fat to other types of fat may be imposed in accordance with national or other relevant legislations.

The use of other ingredients in low-fat spreads differs form their use in full-fat products in the following points:

- Most spread formulations are milk- and milk protein-free, because milk protein acts as an oil-water emulsifier and consequently, the use of milk, casein, or caseinates can result in a phase reversion.
- Emulsifier levels are increased to improve physical characteristics of the emulsion and its stability.
- Lecithin may decrease the emulsion stability and increase the tendency to oil off. However, it also functions to slow down emulsion breakdown in the mouth. Therefore, the use of lecithin and its level must be evaluated for each formulation.
- Hydrocolloids, such as gelatin, pectin, carrageenans, agar, xanthan gum, starch, alginates, or methyl cellulose derivatives, are used in some spreads as thickening agents to improve the body.
- Flavor content and types must be defined to produce oral response similar to full-fat products because the higher emulsifier levels used for spreads can produce tighter emulsions, and gelling or thickening agents can affect the rate and how flavor is perceived.
- Preservatives are more important in spreads than in regular margarines because of higher moisture content.
- The light reflection of a spread is different from that of a regular margarine because of the increased number of water droplets present. Therefore, it is necessary to add about twice the amount of color used in normal margarine to obtain the same color intensity in low-fat products.

During processing of low-fat spreads the preparation of an emulsion becomes of greater importance. Chilling and crystallization may be similar to those used for margarine.

Finished low-fat products have to meet all sensory requirements as for full-fat products – clean and full taste and smell, uniform and sheen color, even and smooth surface and pleasing melt in the mouth. Spreadability from the refrigerator and at room temperature must be good, without syneresis and separation.

Composition

Essential Composition of Minarine according to Codex Standard

- Raw materials: water and/or milk and/or milk products; edible fats and/or oils, or a mixture of these, whether or not they have been subjected to a process of modification.
- Fat content: not less than 39% m/m and not more than 41% m/m.
- Water content: not less than 50%, as determined by loss on drying.
- Optional ingredients: the following substances may be added: vitamins (vitamin A and its esters, vitamin D, vitamin E and its esters, other vitamins), egg yolk, sodium chloride, sugars, suitable edible proteins, gelatin, natural starches.

Food Additives for Minarine According to Codex Standard

- Colors: the following colors are permitted: beta-carotene, annatto extracts, curcumin or turmeric, beta-apo-8′-carotenal, methyl and ethyl esters of beta-apo-8′ carotenoic acid.
- Flavors: natural flavors and their identical synthetic equivalents, except those which are known to represent a toxic hazard, and other synthetic flavors approved by the Codex Alimentarius Commission are permitted.

- Antioxidants: propyl gallate, butylated hydroxytoluene (BHT), butylated hydroxyanisole (BHA), tertiary butyl hydroquinone (TBHQ), any combination of propyl gallate, BHA, BHT and/or TBHQ, natural and synthetic tocopherols, ascorbyl palmitate, ascorbyl stearate, dilauryl thiodipropionate.
- Antioxidant synergists: citric acid, sodium citrate.
- Thickening/stabilizing agents: agar, ammonium alginate, carboxy methyl cellulose, carrageenan (including furcelleran), guar gum, methyl cellulose, pectin (amidated and nonamidated), alginate (K, Ca, Na salts), locust bean gum, propylene glycol alginate, sodium carboxy methyl cellulose, xanthan gum.
- Emulsifiers: lecithin, mono- and diacylglycerols, polyglycerol esters of interesterified ricinoleic acid, polyglycerol esters of fatty acids, polyoxyethylene (20) sorbitan mono-oleate, monopalmitate, monostearate, tristearate.
- Preservatives: sorbic acid and its sodium, potassium and calcium salts, benzoic acid and its potassium and sodium salts.
- pH-correcting agents: lactic acid and its sodium and potassium salts, citric acid and its sodium salt, sodium hydroxide, sodium carbonate, sodium phosphate, sodium tartrate.

The composition of fatty acids in the product depends on the type and ratio of oils and fats used. Table 1 presents the fatty acid composition of 10 low-fat spreads produced in Europe and the USA. From a nutritional point of view, the composition of individual low-fat spreads does not differ too much. All low-fat spreads have a relatively high content of unsaturated fatty acids.

Table 1 Contents of saturated, monosaturated, and poly un-saturated fatty acids in 10 low-fat spreads (40% fat) produced in Europe and the USA (% of total fatty acids)

Spread	*Saturated fatty acids*	*Monounsaturated fatty acids*	*Polyunsaturated fatty acids*
1	30.4	43.3	26.3
2	21.3	36.4	42.3
3	32.7	22.3	45.0
4	32.3	23.6	44.1
5	17.2	39.0	43.8
6	19.5	49.7	30.8
7	22.4	38.4	39.2
8	27.3	38.1	34.6
9	17.6	45.1	37.3
10	20.7	42.2	37.1

1–4, low-fat spreads produced in Europe (Czech Nutrient Database).
5–10, low-fat spreads produced in the USA (USDA Nutrient Database for Standard Reference).

Dietary Importance and Use

Nutrition value, including energy value, of low-fat spreads is in good agreement with health authority recommendations for the populations of developed industrial countries to reduce their intake of energy, total fat, saturated fat, and cholesterol. The amount of energy in low-fat spreads containing 40% fat is reduced to 50% in comparison with classical margarine or butter. Average daily intake of fat spread used for spreading on bread or biscuits is 20–25 g, and this represents 16–20 g fat in the case of classical margarine. The same amount of low-fat spread represents only 8–10 g fat. The reduced intake of fat (about 15% average recommended daily fat intake) is not negligible. As has been discussed elsewhere, the decrease of fat in low-fat spreads is partially compensated by an increase in the consumption of complex carbohydrates. Hence, the total energy intake is not much lower but nutrition balance is better because fat intake is lower and complex carbohydrate intake is increased. Low-fat spreads help consumers to meet their needs in terms of low intake of saturated fat and high intake of polyunsaturated fatty acids.

Research over recent years has shown that *trans* fatty acids have adverse affects on health with regard to coronary heart disease, and therefore companies are now offering some low-fat spreads free of *trans* fatty acids.

Low-fat spreads are free of cholesterol (except trace amounts, which are insignificant from a nutritional point of view). In contrast, they contain serum cholesterol-lowering plant sterols (phytosterols) and therefore they have a significant role in decreasing the risk of heart disease. Clinical studies indicate that an intake of 2–3 g day^{-1} of these plant sterols or stanols reduces serum cholesterol level. Therefore plant sterol-enriched margarines or low-fat spreads have been developed. These contain 8 g plant sterols or stanols per 100 g, so that 25 g of margarine or low-fat spread ensures a recommended daily intake of 2–3 g plant sterols. This dose will reduce total cholesterol by around 10% and low-density lipoprotein-cholesterol by 10–15%, with minimal change in high-density lipoprotein-cholesterol and triacylglycerols. (*See* **Cholesterol**: Properties and Determination; Absorption Function, and Metabolism; Factors Determining Blood Cholesterol Levels.)

Low-fat spreads are formulated to supply amounts of fat-soluble vitamins (A, D, E) which are similar to or higher than those supplied by butter, and absorption is unlikely to be impaired. Low-fat spreads might thus be viewed positively as a vehicle for lipophilic nutrients without excessive lipid, and can contribute to fulfillment of the recommended daily intake of A, D and E vitamins.

Low-fat spreads are intended solely as spreads on bread or biscuits. They should not used for cooking or baking and definitely not for frying, on account of their high water content and in some cases (low-fat butter, low-fat blends) of their high protein content.

Safety

The safety of low-fat spreads is assured by special regulations. The use of raw material, optional ingredients, and food additives are regulated by national standards. Contents of contaminants are regulated as well. The products have to be prepared in accordance with the general principles of food hygiene. A safety issue, which is not commonly discussed in relation to light products, is that relating to microbiological stability and hazard. Where traditional foods are replaced by light foods with a higher water activity, the consumer may not recognize that they must be stored differently from traditional foods unless they contain preservatives. In traditional butter and margarine, salt is present not only for sensory reasons. The amount of 2% salt in whole butter is equivalent to 13–14% in the aqueous phase and exerts a significant preservative effect. Low-fat substitutes of butter with a higher water content are not preserved in this way and should be stored in a refrigerator. Instructions on special storage requirements need to be displayed prominently on the label so that the risks of spoilage and pathogenic mold growth are avoided.

Low-fat spreads are generally filled in plastic tubs, which are designed not only to give mechanical protection but also to protect the product from light and oxygen. Evaporation of water from the surface, which leads to an unsightly dark-yellow coloration, is prevented by use of a sealed aluminum foil.

Nutritional demands have led to the manufacture of blends containing a high content of polyunsaturated fatty acids. These products are more susceptible to oxidative deterioration and damage of texture, and therefore require storage and transport at low temperatures, preferably at less than 5 °C; these conditions reduce the risk of oiling out, and maintain flavor and textural qualities. Oxidative changes may be diminished by the use of antioxidants.

Conclusions

Low-fat spreads belong to progressive food products. They meet the demands of consumers for 'healthy eating' very well. Now, many types of low-fat spreads with varying fat content are available on the market. They have a high content of polyunsaturated fatty acids, and many of them are *trans* fatty acids-free. The sensory characteristics of low-fat spreads are comparable to those of full-fat products. The main trends in the development of low-fat spreads are towards tailor-made products to provide health benefits, e.g., low-fat spreads with plant sterols or stanols, *n*-3 fatty acids of fish origin as added ingredient.

Introduction

Lupin is a legume plant from which the seeds have been used as food and feed from ancient times. The green plant has been used extensively in some countries as forage for animal feeding and also as organic material for soil enrichment or in crop rotation. Despite its qualities and potential, it has not become a major world crop. This article will review the main characteristics of this plant, the nutritive value of its seeds, and the uses and potential for more extensive production.

The Plant and its Origin

Lupin or lupine are trivial names for plants of the genus *Lupinus* belonging to the Leguminosae family, subfamily Papilonoideae. This genus is very diverse and contains several known species. It is an annual plant, usually 0.3–2 m in height, with a highly branched stem, digitated leaves, and a shrubby growth pattern. The flowers formed high above the leaves, may be of several different colors (white, yellow, purple, blue), and exude a honey-like aroma. The roots are relatively long, usually nodular, and may grow down to 3 m. The lupin plant has the ability to fix nitrogen and mobilize phosphorus and other elements by the exudation of citrate to the soil. This is very important for soil enrichment in infertile areas. The pods are normally flat and with a hairy aspect on the outside. They vary in length (4–10 cm) and, depending on the species, have different types of seeds that may vary in size, shape, or color. However, the endosperm is usually yellowish, and the most common seeds are flattened (*Lupinus albus*) or ovoid (*Lupinus mutabilis*) with diameters in the range 2–15 mm. It is a plant well adapted to poor sandy and acid soils and also to high altitudes, and to temperate climates, as found in Europe. The most important species that are produced on a commercial scale are *L. albus*, *L. angustifolius*, *L. luteus*, and *L. mutabilis* (see color plate 101).

The lupin has its origin in the Old World in the Mediterranean region, and also in the New World, in North America and in the Andean highlands. Some representative examples of the former are *L. albus*, *L. angustifolius*, *L. luteus*, and *L. consentinii*. Tarwi is the indigenous name of *L. mutabilis*, which is the lupin found in the Andes (Table 1). However, there are probably more than 200 wild species, most of them in the New World. *L. albus* was cultivated as a food by the ancient Romans, Egyptians, and Greeks; however, due to its bitter taste, the mature seed had to be submitted to prolonged washing before consumption. A similar treatment was also used by the ancient inhabitants of the Andes. The seeds of tarwi were boiled, thoroughly washed in a river for several days, and then properly cooked for immediate consumption or dried for future use. Presently, several different species of lupins are grown in Europe, some parts of Africa, South America, Australia, and New Zealand, including a number of sweet low-alkaloid varieties that are now commercially available.

Nutritive Value

Lupin seeds show similar nutritive attributes to soya beans, particularly with respect to protein and fat content. Some species may have protein contents up to 50 g per 100 g and up to 22 g per 100 g of fat in the seeds. The proximate composition of seeds of some relevant lupin species are presented in Table 2. The protein and fat content may be further increased by dehulling the seeds.

Protein

The lupin seed is one of the richest sources of plant protein. The protein content varies largely between species, with *L. mutabilis* and *L. luteus* presenting unusually high values (near 50 g per 100 g), surpassing most soya bean cultivars, whereas *L. albus* presents an intermediate protein content and *L. angustifolius* lower values. Lupin seed protein provides all the

essential amino acids, but some of them are not found in sufficient amounts for all sectors of the population. When lupin seed is used for animal feeding, such as ruminants or single-stomach animals, the relatively low level of methionine may be complemented by adequate formulation of the ration or by supplementation with the synthetic amino acid. Table 3 shows the amino acid composition of seeds of some relevant lupin species and the amino acid requirements for infants and adults established by a Food and Agriculture Organization/World Health Organization/United Nations University (FAO/WHO/UNU) joint committee (1985). When comparing the lupin amino acid profiles with the requirements for adults, all lupin species show ranges of essential amino acids with adequate amounts, and this will be observed also for most pulses. However, if the requirements for infants are used for comparison, it is apparent that lupin protein will show many essential amino acid deficiencies, with tryptophan being the most limiting, having a chemical score (CS) of 47–59%, followed by methionine plus cystine. The chemical score (CS) is the ratio of the content of an individual essential amino acids in food protein to the content of the same amino acid in a reference pattern expressed as a percentage. It must be taken into account that, if requirements for infants are used for comparison, even beef protein will be deficient in leucine, lysine, methionine+cystine, tryptophan, and valine, and egg protein will be deficient in leucine and lysine. However, if the previous FAO/73 amino acid pattern is used as a reference, methionine+cystine will be the limiting amino acids for lupin (56–71% CS), as in most pulses (soya bean 83% CS). Consequently, it is strongly recommended that the intended nutritional application of lupin seeds or lupin products be defined to allow a more realistic assessment of the protein quality. From Table 3, it can be seen that the amino acid profile varies considerably with lupin species. Large variations are also observed in biological indicators for protein-quality assessment. Nevertheless, protein utilization, as measured by the net protein utilization (NPU) index, does not correspond exactly to the amino acid CS of different lupin species. For example, *L. angustifolius* shows a relatively high CS (60%, FAO/85 for infants) but presents the lowest NPU (43%). Despite its amino acid composition, active biological components appear to have a negative influence on the NPU of *L. angustifolius* protein in rats. *L. albus* shows the highest NPU (70%) followed by *L. mutabilis* (64%). These figures approach the NPU of the soya bean (69%). Overall, lupin protein should be considered a good plant source of protein for

animal and human nutrition. However, the appropriate application and the variation encountered between species must be considered for assessing lupin protein quality. (*See* **Amino Acids**: Metabolism; **Protein**: Quality.)

Fat

The fat content of lupin seeds varies considerably between species. In some species, the lipid fraction contributes substantially to the total energy value, whereas in others, it is present in relatively small amounts (Table 2). *L. mutabilis* has the highest oil content (up to 22 g per 100 g) and is considered to be a potential material for oil production. *L. albus* has a combination of high protein and an intermediate fat content, which are important attributes for a food, especially if it is to be used in developing countries where protein and energy are scarce. The fatty acid distribution in the oil fraction is also variable between species. However, low levels of saturated fatty acids are normally found. A very high content of linolenic acid is present, particularly in *L. albus* and *L. luteus*. As in other seeds, high levels of oleic acid are common for all species, particularly *L. albus* and *L. mutabilis* (Table 4). The ratio of polyunsaturated fatty acids (PUFA) to saturated fatty acids (SFA) in lupin seeds is in the range 1.3–2.9:1, which is considerably higher than beef but lower than the soya bean (4.0). Higher rates are important, since it has been strongly recommended that a reduction of SFA in favor of an increase of PUFA in the diet should be achieved, to assist coronary heart disease prevention. Linoleic acid, which is an essential fatty acid, is found in significant amounts in lupin seed, with *L. luteus* being the richest source (44%). Linolenic acid, which is the most important source of ω-3 fatty acids, is found at very high levels in *L. albus* and *L. luteus*, but at relatively low levels in *L. angustifolius* and *L. mutabilis* (Table 4). *L. mutabilis* may be commercially used for oil production, and its low linolenic acid content, although not so nutritionally important as in other sources, may be advantageous to improve its conservation in comparison with other vegetable oils. Considering the fatty acid profile of lupin seeds, it is noted that *L. mutabilis* and *L. albus* are more similar to peanut oil, whereas *L. angustifolius* and *L. luteus* resemble maize oils, although they differ in flavor. (*See* **Essential Fatty Acids**; **Fatty Acids**: Properties; Gamma-linolenic Acid; **Peanuts**.)

Carbohydrates

In contrast with many legumes, lupin seeds are practically devoid of starch, and the major carbohydrates in mature seeds are oligosaccharides and nonstarchy polysaccharides, particularly from the cell wall structure. The oligosaccharides found in the cotyledons are sucrose and nondigestible galactosides of the raffinose family. The main galactosides present in lupin seeds are raffinose (degree of polymerization, DP, of 3), stachyose (DP of 4) and verbascose (DP of 5) (Table 5). These oligosaccharides are derived from sucrose, with increasing numbers of α-galactosyl units linked to C6 of glucose. They are present in most legumes and are not digested by monogastric animals and hence contribute to the flatulent property of legumes. More recently, nondigestible sugars have been used as agents for fermentation in the intestines, thus helping to maintain and regulate the microbial intestinal flora. In this aspect, lupin may be an important row material for production of oligosaccharides of the raffinose family to be used as functional food ingredients. The polysaccharides are present as major components of the cell wall surrounding the cytosol. Only a small number (1%) of polysaccharides are water-soluble, and, together with oligosaccharides, they are important as a source of energy for seed germination. The amount of

[a]Results expressed in grams per 100 g of dry matter.

polysaccharides in lupin seeds is dependent on the species, with high contents found in *L. albus* and *L. angustifolius* and the lowest in *L. mutabilis*, due to its thinner seed hull. Due to the polysaccharide composition, lupins are extraordinarily rich sources of fiber. Crude fiber data are presented in Table 2, but even higher figures will be encountered if dietary fiber is considered. Lupin carbohydrates are important sources of energy only for ruminants, but due to their characteristics, they may provide useful material to produce a special high-fiber food for humans. (*See* **Carbohydrates**: Classification and Properties; **Dietary Fiber**: Properties and Sources.)

Vitamins and Minerals

The vitamin pattern of lupin seeds is somewhat similar to other legumes. Lupin seeds are good sources of vitamins of the B group, particularly niacin, with levels above 4 mg per 100 g. The thiamin content is about 0.5 mg per 100 g, and that of riboflavin about 0.4 mg per 100 g. Carotenoids and tocopherols are present, with the former being mainly responsible for the color of the oil fraction. The mineral composition is similar to other legumes in relation to the major elements, except for calcium, which is low in all species. However, some differences are found in respect to trace elements. Manganese is found in lupins in unusually high amounts, especially in *L. albus*. In some varieties of this species, it may reach values of 83.5–143 mg per 100 g, and this must be taken into account when it is used in daily animal or human diet. Nevertheless, common figures are in the range 2.5–38 mg per 100 g. Lupin seed is also a good source of iron and zinc, with values in the range 2.5–14 and 3–18 mg per 100 g, respectively. Refer to individual vitamins and minerals.

Bioactive compounds

Some components found in natural products may present biological activity but no nutritional properties. In fact, some of them may be undesirable for human and animal nutrition. In lupin, some compounds with these characteristics have been reported. Compounds sometimes called 'antinutritional factors' are present in lupin seeds in the same range as in other legume seeds, except for trypsin inhibitor, which is virtually absent in the lupin. Allergenic proteins that may cause allergenic food reactions sometimes observed in children are less intense with lupins than with other legume seeds and cow's milk. However, because peanut allergies are quite common, further studies are needed to check some sort of peanut–lupin cross-allergy when lupin is used as an ingredient of mixed flour. Some relevant bioactive compounds found in lupin are the alkaloids, phytates, saponins, tannins, and flavonoids. (*See* **Allergens**; **Alkaloids**: Properties and Determination; **Phytic Acid**: Properties and Determination; **Plant Antinutritional Factors**: Characteristics; **Saponins**; **Trypsin Inhibitors**.)

Alkaloids

The major alkaloids present in lupin are from the quinolizidine family, although some gramine alkaloids may also be found in *L. luteus*. Quinolizidine alkaloids have received much attention, because they have a strong bitter taste and may be toxic in high doses. Lupanine, sparteine, lupinine, and some forms of hydroxylated lupanine are some relevant examples. They have a sedative effect on the central nervous system, with sparteine producing the strongest effect. The total alkaloid content in bitter lupins is usually in the range 1.0–4.5 g per 100 g. Intensive breeding work carried out, mainly by Sengbush in Germany, Gladstones in Australia, and Baer in Chile, have led to the establishment of new lupin varieties practically devoid of alkaloids. Presently, sweet varieties of *L. luteus, L. angustifolius, L. albus, L. mutabilis, L. consentinii*, and *L. atlanticus* are defined, of which the first three are commercially productive. However, bitter lupins are still largely used in some regions where the new sweet varieties are not well adapted. In those cases, the preliminary soaking and washing procedure before consumption is essential. (*See* **Alkaloids**: Properties and Determination.)

Phytate

Phytate is sometimes considered an antinutritional factor because it is implicated with the impaired absorption of minerals. It is found in lupin seeds roughly

in the same concentration range as in other pulses, but it is usually lower than that found in soya beans. The average amount found in lupin seed is around 0.8 g per 100 g. The phytate:zinc molar ratio, which may be an indication of zinc bioavailability, is generally lower than in other legume seeds, making lupin a better dietary source of this mineral. The enzymatic degradation of phytate in the digestive tract or in food products submitted to special processing may lead to the formation of inositol phosphates with different degrees of phosphorylation. Some of these derived components may be detected as phytates by nonspecific methods, although they may not present mineral chelation activity. Consequently, more comprehensive information on inositol phosphate composition of different food items is becoming more important to assess the real role of food phytate in the daily diet. More recently, some attention has been directed to the desirable properties of vegetable phytates, particularly due to its antioxidative characteristics, which may be beneficial to counteract free-radical activity. Other biological properties may be derived from the lower inositol phosphates since some of them are involved in cell-signaling mechanisms.

Saponins

Saponins are compounds formed by triterpenoids or steroidal aglycones and a carbohydrate moiety by ester or ether linkages. They are present in different classes of plants, particularly in legumes, roots, and some medicinal herbs. Their presence in food products has been considered to be deleterious if consumed frequently. They are toxic to fish and promote retardation of growth in livestock and laboratory animals. They may also produce erythrocyte lysis *in vitro* and may alter intestinal epithelium function making the mucosa more permeable. Consequently, their continue use in the diet may jeopardize the process of nutrient absorption. Conversely, it has been claimed that they can also be beneficial since they show the ability to lower plasma cholesterol, they have anticancer activity, and they may act as an inhibitor of viral replication. It is not yet clear, though, whether the net effect in the diet would be negative. Some lupin species such as *L. luteus, L. mutabilis*, and *L. angustifolius* may present a saponin content from 57 to 470 mg kg^{-1}, but they are not present in *L. albus*. However, these figures are still low compared with soyabeans, which present values in the range 2000–5000 mg kg^{-1}.

Tannins

Tannins are complex polyphenolic substances found in plants, particularly pulses, with the property to precipitate proteins in aqueous medium. They interact with one or more protein molecules forming large cross-linked complexes that are insoluble in water. This property makes food tannins undesirable since they will make part of the dietetic protein indigestible. There is a wide variation on the content of tannins in legume seeds with higher values being found in faba bean and in peas. Lupin seeds present relatively low values of tannins in the range 0.2–0.5 g%. No correlation has been found between the tannin content and the bitter taste of some lupin seeds, and the impact of tannin from lupin seed in the diet has not yet been demonstrated both in humans or animals. However, the level of tannin in *L. angustifolius* has been considered to be low enough for use in pig diets without any kind of problem.

Flavonoids

Flavonoids are a class of phenolic compounds widely distributed in plants. Quercetin and rutin are among the most largely found flavonoids in a great variety of fruits and vegetables, including tea, coffee, and other grains. As it has been observed with other biological active nonnutrient components, flavonoids may promote desirable and nondesirable physiological effects in humans. The property of flavonoids to induce goitre has been suggested by studies using peanuts and millet as foods with millet flavonoids presenting a strong inhibition effect on thyroperoxidase activity. The healthy properties of flavonoids may be derived from their antioxidative characteristics as free-radical neutralizers. However, some more specific functions have been reported, including their effect on cancer prevention, antiinflammatory and antiviral activities, and their positive effect on capillary fragility and vascular protection. Data on the presence of flavonoids in lupin are scarce, and although it is not clear whether they are encountered in significant amounts in lupin seeds, different flavonoids have been reported recently in the plants of *L. luteus* and *L. albus*, including those with the aglycones apinegin, genistein, and kaempferol. (*See* **Phenolic Compounds**.)

Crop Diseases

Fungal and virus diseases are the most common forms of lupin crop contamination such as anthracnose, fusariose, and phomopsis. The first is the main threat for lupin cultivation in Central and South America, whereas the latter is the cause of a disease called lupinosis in animals fed from the infected plant. As it has been demonstrated in Australia, this problem may be overcome with an appropriate crop management and plant breeding for resistance. Necrotic and nonnecrotic strains of mosaic viruses may also be responsible for crop damage, but to a lesser extent than fungal diseases.

Food Uses

At the present time, the main applications of lupins are their utilization as green manure and as animal feed. Due to the ability of lupin plants to fix nitrogen and to make insoluble phosphorus available in the soil, they have been used increasingly in the crop-rotation system as an efficient and less expensive means of fertilization. For animal feeding, the whole lupin plant has been used as pasture or forage, or the dry seeds have been used as a direct soya bean substitute, or in feeding formulae for pigs, sheep, chickens, dairy cattle, and other livestock. It has been recommended that no more than 10–15% of bitter lupins should be used in pig rations as pigs seem to be more sensitive to alkaloids than chickens. As mentioned earlier, lupin seeds have long been an available protein source for human nutrition. It was a common procedure to submit the grains to prolonged washing to remove the bitter taste, and this washing process is still used, particularly in some regions of South America, where bitter lupin seeds are mainly used. Although the washing process may increase the total cost of lupin products, the water treatment will in fact wash out not only the bitter alkaloids but also the oligosaccharides responsible for the flatulence of legumes. In addition, the end product will show increased relative amounts of protein and oil, on a dry matter basis, due to differences in component solubilities. It is a common procedure in the Andean regions to use leached and cooked bitter lupin seeds directly for consumption as snacks, in soups, salads, and stews. Alternatively, they may be dried and/or milled for future use in several dishes, including baked products. Lupin flour may be used for cereal protein enrichment since lupins and cereals have complementary amino acid compositions. Bread or other bakery products have been made successfully using lupin flour as an additive in the proportion of 10–20%. Many attempts have been made to use lupin seeds as direct substitutes for soya beans, e.g., in fermented products, soya milk, or soya bean protein isolate. However, lupin protein does not have exactly the same functional properties as soya bean protein, being less stable to heat and forming a milk-like water suspension. Nevertheless, lupin protein may be added to soya products without major modifications to the end product. It is apparent that investigation is still needed to develop a lupin-specific technology and new genuine lupin products for human nutrition.

The Potential of Lupin

The world lupin seed productions is at present mainly concentrated in Australia, which has produced 1.38 million tonnes in 1993 and around 2 million tonnes in the year 2000. This represents 2–4% of the world pulse production. Other lupin producers are the countries of the former USSR, Poland and Germany in Europe, Chile, Bolivia, and Peru in South America, and also South Africa. However, the lupin seed shows a real potential for the grain world market due to its nutritional and agricultural properties. The high alkaloid content that used to be one of the major limitations for a wider application of the lupin seed has been gradually overcome by the introduction of commercial sweet varieties, mainly of *L. albus* and *L. angustifolius*. Although a new sweet variety of *L. mutabilis* is already available, work is still needed to establish a productive line with increased seed size and protein content. Besides the improvement in lupin nutritional qualities, research in specific areas such as plant breeding and biotechnology, crop protection and food lupin technology are vital for lupin to gain a stronger foothold in the international market, with a substantial increase in Europe and South America production. To consolidate this status, an appropriate international price policy together with a strong marketing strategy is mandatory. (*See* **Vegetable Oils:** Dietary Importance.)

MACROBIOTIC DIETS

J Dwyer, Jean Mayer US Department of Agriculture, Human Nutrition Research Center on Aging at Tufts University, Boston, MA, USA

Definition

Macrobiotics is a philosophical system that was founded by a Japanese named Georges Ohsawa and popularized in the USA by Mishio Kushi. Macrobiotics advocates a diet that is virtually devoid of animal foods because of the belief that foods biologically far away from humans are better for them, and that these foods should form the basis of the diet to prolong life and health. Animal foods, if they are used at all, are used in very small amounts as condiments rather than in main course portions. Ohsawa believed that all disease could be cured by a proper therapy that consisted of balancing the forces of Yin and Yang. The optimal macrobiotic diet is viewed by practitioners as one that balances Yin and Yang foods, as defined by their activity characteristics in the universe, supposedly opposing and complementing each other. This dualistic Yin–Yang classification does not correspond to food grouping systems based on nutrient composition. Extensive chewing of food is recommended to enhance the strengthening Yang properties of the diet. It is important to recognize that macrobiotics is a life view and philosophy that involves far more than diet alone. The philosophy views disease as resulting from Yin–Yang imbalances that can be restored by an ideal diet.

History

In the 1960s and early 1970s, an extreme form of the macrobiotic diet, the Zen macrobiotic diet, gained some popularity. The final stage of an elaborate 10-stage dietary regimen consisted of brown rice, salt, and fluids such as herbal teas, and was viewed as bringing not only health but also spiritual enlightenment. Michio Kushi revised the Ohsawa diet and emphasized less extreme patterns in the 1970s. The macrobiotic diet, as currently practiced, although it may have nutritional deficiencies, is less restrictive. Nevertheless, for individuals who are ill, especially with diseases such as cancers of the gastrointestinal tract, such a high bulk diet may cause, rather than alleviate, symptoms. Macrobiotic leaders often complain that there is a bias in the scientific literature against macrobiotics. However, evidence that the macrobiotic diet has a place in the treatment of cancers is not available. Moreover, the proponents of macrobiotic diets claim that the negative health effects that were associated with the diet in the past are no longer present. However, population-based studies are available that indicate ill effects in infants and young children, and similar studies refuting them are not available, testifying that this is no longer the case. This is surprising, since several individuals trained at the doctoral level in nutritional sciences are adherents to these regimens.

Composition of Diet

The macrobiotic diet is similar nutritionally to a vegan–vegetarian regime with additional prohibitions against sugar, alcohol, and processed foods. Most of the energy comes from cereal staples, including rice, soy, and aduke and other beans. This basic diet is supplemented by soybeans, vegetables, some fruits, nuts, seeds, and very small amounts of fish. The diets prescribed in writings by the various authorities and that are actually eaten probably vary a good

deal from eater to eater, however. (*See* **Vegetarian Diets**.)

Dietary planning and menu selection are based on combinations of foods that are thought to be philosophically appropriate according to macrobiotic criteria but may not be so from the nutritional standpoint. Certain food groups, such as dairy and meats, are avoided. Milk and milk products are major sources in American diets of calcium, phosphorus, magnesium, vitamin D, riboflavin, and high-quality protein. Meat, fish, poultry, eggs, and beans are good sources of high-quality protein, ion, zinc, copper, and many of the B-complex vitamins. Without careful planning, when these food groups are avoided, it is difficult to meet recommended levels of energy, vitamins B_{12} and D, iron, calcium, zinc, and riboflavin. Dietary deficiencies result when appropriate substitutions of other foods rich in these nutrients are not made. The extent to which dietary deficiencies arise varies by life stage, type of diet adopted, and the eater's health status.

Lifestyles of Macrobiotic Practitioners

Macrobiotic beliefs affect ways of living that influence health and go beyond diet. Macrobiotics practitioners have some lifestyle habits that promote health, such as abstinence or moderation in the use of alcohol, nonuse of illicit drugs, and a physically active life with adequate rest. However, some macrobiotics smoke, and others eschew anticipatory guidance from conventional health professionals, avoid or delay the use of preventive measures such as immunizations, and refuse to use vitamin mineral supplements and prescription drugs. Some delay seeking medical treatment for some illnesses until they are quite ill, thus increasing the risks of secondary malnutrition. These attitudes are at variance with vegetarians of other types. (*See* **Malnutrition**: Malnutrition in Developed Countries; **Vegetarian Diets**.)

Health Effects of Macrobiotic Diets over the Life Cycle

Acceptable and appropriate diets must fulfill the dietary reference intakes and the recommendations of other expert groups on dietary balance, variety, and moderation. Finally, they must be developmentally appropriate. Table 1 presents a summary of the risks and benefits of macrobiotic diets. Generally, macrobiotics breast-feed their children through the first year of life and introduce some complementary feeding after 6 months. However, macrobiotic diets are very bulky for weanlings. In addition, a source of vitamin D should be provided after 6 months of age. It is difficult to make the diet nutritionally adequate and follow the pronouncements of macrobiotic leaders. Use of at least 20–25 g of dietary fat, and at least 100–150 g of fatty fishes, which are good sources of vitamin D and also provide some vitamin B_{12}, improve the diets of weanlings in more favorable directions. At least 150–250 g of milk and milk products per day are advised to assure adequate intakes of calcium in early childhood. Alternatively, soy milk that is fortified with vitamins B_{12} and D and calcium, highly fortified cereals, or vitamin mineral supplements may be used as sources of nutrients rich in the milk group. During later infancy and weaning, iron intakes may also be unsatisfactory, and iron-deficiency anemia may result. Iron-fortified cereals, plant foods high in iron such as iron-fortified soy formula, and iron-fortified cereals eaten with ascorbic acid-rich foods enhance iron bioavailabiliy and decrease the risks of iron-deficiency anemia. The macrobiotic diet also increases the risks of dietary deficiencies at other times of life when nutrient needs are particularly high. Similar adaptations of the diet to increase intakes of essential nutrients are also prudent during pregnancy and lactation, at adolescence, and during recovery from illness. During pregnancy, vegan-vegetarians and some macrobiotics who eat virtually no animal foods at all may have very low stores of DHA and EPA, and of vitamin B_{12}. Weight gain during pregnancy may not be satisfactory either, increasing the risks of low birth weight.

During the past 25 years, adherents to the macrobiotic philosophy have had a higher prevalence of dietary deficiency disease than other vegetarians. The reasons for this are probably several, and include the restrictions on consumption and sources of nutrients (prohibitions against vitamin mineral supplements and fortified foods, other processed foods) over and above those involving a vegan diet, attitudes toward health and use of conventional medical care, and the difficulties of fitting recommendations based on philosophical considerations with nutrient intakes based on modern knowledge of nutrition.

Most of the positive aspects of macrobiotic diets associated with health benefits are because they are not excessive. Among them are modest caloric intakes, very low intakes of saturated fat, cholesterol, alcohol, and caffeine, relatively low intakes of refined carbohydrates, and high intakes of dietary fiber. The health advantages associated with the macrobiotic diet are due only in part to dietary composition. Other positive lifestyle characteristics of the macrobiotic lifestyle are also health-promoting. Macrobiotics generally are lean rather than obese, tend to eschew alcohol and illicit drugs, and lead orderly lives. The macrobiotic dietary pattern provides no unique

health advantages over those accruing to other vegetarian or vegan patterns, however.

Environmental factors are the major reasons why the nutritional status of macrobiotics differs from that of other vegetarians or omnivores. However, macrobiotics are not exempt from genetic disorders that require nutritional treatment either, such as vitamin D-dependent rickets, or polymorphisms in the vitamin D receptor that are associated with differences in bone mineral density and perhaps calcium absorption. They are also affected by more subtle variations in genetic endowment that contribute to the variability in nutrient requirements. For example, a genetic polymorphism has been found that adversely affects homocysteine concentrations in individuals with a relatively poor float status. Macrobiotics with such polymorphisms may be the individuals who fall ill first when diets are inadequate (See Table 1).

Nutritional Value of Macrobiotic Diets

Energy

Macrobiotics urges moderation in consumption. The regimen is low in fat, high in bulk, and high in fiber, and thus it tends to be low in energy. Macrobiotic practitioners are usually lean, in part because their energy intakes are low and in part because they lead physically active lives. Some malabsorption may occur. The risks of low energy intakes are most evident among macrobiotic infants who are not breast-fed weanlings, and young children. The practice of feeding a very-low-fat-cereal-based infant food to infants, called 'kohkoh', is no longer common; it was associated with frank protein calorie malnutrition in many infants. Macrobiotic children are usually smaller, lighter, and leaner than their peers. Some catch-up growth usually occurs in the preschool

and school years. (*See* **Energy**: Measurement of Food Energy.)

Protein

Human beings require nine essential amino acids that they cannot synthesize, the nonessential amino acids, and additional nitrogen to fulfill their protein needs. The amino acid composition of protein, the amount of protein, the bioavailability of protein and the availability of the protein for building tissue instead of being burned for energy are therefore all important. (*See* **Amino Acids**: Metabolism; **Protein**: Requirements; Quality.)

A major concern is that the individual be in energy balance rather than in a hypocaloric state, since, under such circumstances, protein will be used for energy. The macrobiotic regimen potentially poses both protein quality and quantity problems. On all but the most severe macrobiotic regimes, enough protein is present to be adequate if sufficient energy is provided. With regard to protein quality, legumes are moderately high in protein quality. When they are consumed along with rice and other plant proteins, the biological value of the protein is adequate. Animal proteins lack fewer amino acids than do plant proteins, but macrobiotic diets are virtually devoid of animal flesh, eggs, milk, and poultry, all of which provide relatively complete proteins and all the amino acids needed for building bodily protein. Fish and seafood are consumed by macrobiotics in small amounts, and these proteins are relatively complete. Plant tissues are somewhat more variable in the extent to which the nitrogen present in them is found in protein, ranging from a high of about 95% in seeds down to 50% in roots such as potatoes, carrots, and cassava. The nonprotein nitrogen is in the form of peptides and free amino acids. The amino acid composition of different plant proteins can complement each other, making up their various deficits. Thus, the aggregate of individual plant proteins provides a mixture that matches body needs. The lack of most animal protein does not necessarily mean that protein nutritional status must be compromised. Macrobiotics consume legumes such as soya beans and aduke beans, which are high in the essential amino acids lysine and threonine, and soya beans are also high in tryptophan. However legumes are limited in methionine, cystine, and (except for soya beans) tryptophan. Grain proteins are high in methionine, cystine and tryptophan (with the exception of cornmeal and rye, which are low in tryptophan). Moreover, grains are low in the essential amino acids lysine and isoleucine, although these are high in legumes. Thus, combinations of grains and legumes complement each other and together provide for the amino acid needs of the body if eaten in sufficient amounts. Mixtures of grains, milk or eggs, and legumes with seeds or nuts also complement each other well. Most nuts and seeds are high in cystine, methionine, and tryptophan, and low in lysine and isoleucine. The only exception is peanuts, which are low in both methionine and threonine. Other plant proteins are low in these amino acids, whereas they are relatively high in lysine and tryptophan. Thus, nuts, seeds, and legumes complement other plant proteins well, as do grains and legumes. Small amounts of animal foods such as seafood, milk products, and eggs also complement the amino acid profile of plant proteins well. Therefore, when a variety of complementary plant proteins are consumed in sufficient quantity, and energy is provided in sufficient amounts, there is little reason for concern. However, on the most rigorous macrobiotic diets, at least in the past, energy intakes were sometimes inadequate, and when only one or two plant protein sources were relied upon exclusively, protein calorie malnutrition sometimes ensued. These problems were reported more commonly in the 1960s and 1970s than later. Practices may have changed, but recent rigorous surveys of the nutritional status of macrobiotics are not available. Caution is warranted for the ill, who often consume hypocaloric diets, for young infants who are growing rapidly and have been weaned from the breast who may not be able to consume sufficient energy on exclusively plant diets, and for pregnant women and others who have especially high protein needs for growth. (*See* **Protein**: Digestion and Absorption of Protein and Nitrogen Balance; Deficiency.)

Fat and Cholesterol

Macrobiotic diets are low in fat (e.g., < 25% of energy, and often as little as 15%), and especially saturated fat and cholesterol. Those who consume such diets often have low total and low-density lipoprotein cholesterol levels, with decreased dietary risks of coronary artery disease. Macrobiotics' high intakes of soluble fiber and their relatively low weights also cause low serum cholesterol levels and lower the risk of coronary artery disease.

When diets are below approximately 15% of food energy, special care must be taken to ensure that intakes of essential fatty acids are met. At least 3% of energy should be from ω-6 fatty acids and 2% from ω-3 fatty acids. Both of the essential fatty acids, linoleic acid, an ω-6 fatty acid, and α-linolenic acid, an ω-3 fatty acid, are required by human beings. Linoleic acid is found in seeds, nuts and grains. α-Linolenic acid is found in the green leaves of plants, and in phytoplankton and algae, in certain seeds, nuts and legumes, such as flax, canola, walnuts, hazelnuts, and

soy. These can be converted into more highly unsaturated fatty acids, with linoleic acid producing arachidonic acid, and α-linolenic acid being converted to eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Arachidonic acid is found in animal foods such as meat, poultry, and eggs. EPA and DHA are largely found in fish and seafood. Arachidonic acid and EPA serve as precursors for the eicosanoids. Recommended intakes for these polyunsaturated fatty acids range from 3 to 10% of total energy intakes. Vegan vegetarians have no direct sources of long-chain ω-3 fatty acids EPA and DHA in their diets, and thus must convert α-linolenic acid to them. There is concern that pregnant women who are vegan-vegetarians, or macrobiotics who consume little or no fish or other animal foods, may not obtain enough of these fatty acids, especially during pregnancy and in early infancy, especially if the infants are premature, and their conversion capacity of α-linolenic acid to DHA is very limited. Such individuals may need DHA supplements, either from fish oils or from cultured microalgae. However, they should only be dispensed under a physician's direction, since they are also anticoagulants. ω-3 fatty acids are rich in flaxseeds and flaxseed oil, hemp seed oil, purslane, a dark green leafy vegetable, canola, walnut, and soy oil. Flaxseed oil is also rich in α-linolenic acid.

Carbohydrate and Fiber

Raw fruits, especially berries, vegetables, legumes such as beans and peas, nuts, seeds, whole-grain products, and seaweed provide relatively high amounts of dietary fiber in the macrobiotic diet, helping to promote laxation and perhaps lessening symptoms of asymptomatic diverticular disease. It is possible, but not yet proven, that high intakes of dietary fiber reduce the risks of colon cancer; there is no evidence that macrobiotic diets are especially efficacious in these respects. The macrobiotic diet is high in soluble sources of dietary fiber, such as legumes, whole grain rice, barley, oats, and raw fruits and vegetables. Soluble fiber may enhance glycemic control and also lower serum cholesterol, contributing the low total and low-density-lipoprotein cholesterol levels often evident in macrobiotics. Fiber increases the dietary bulk and lowers the energy density per gram of food consumed. The ill effects of dietary fiber arise if very large amounts are fed to young infants and weanlings under 2 years of age. Macrobiotics sieve cereals, pulses, and vegetables that are fed to infants to increase their digestibility, but fiber intakes and bulk may still be rather high, and the nutrient density of such feeds may still be quite low. The partial replacement of whole-grain cereals with more highly refined cereals that are lower in fiber increases energy intakes and decreases bulk in feeding infants.

Macrobiotics' intakes of refined sugar are very low, but other fermentable carbohydrates, such as sugars found in fruits and starches, are consumed, so the risk of dental caries is still present, especially if these are consumed in forms that are retained in the oral cavity, and oral hygiene is poor. (*See* **Carbohydrates**: Requirements and Dietary Importance; **Glucose**: Glucose Tolerance and the Glycemic (Glycaemic) Index.)

Vitamins

Vitamins B_{12} and D may be in particularly short supply in macrobiotic diets fed to rapidly growing infants and children.

Vitamin B_{12} Reliable plant sources of vitamin B_{12} are vitamin B_{12}-fortified soyamilk and formulas, yeast grown on, and mixed with, vitamin B_{12}-enriched media, highly fortified breakfast cereals, and vitamin B_{12} supplements. Vitamin B_{12}-containing foods that are sometimes acceptable to those who practice macrobiotics include fish such as sardines, pilchard, mackerel, herring, salmon, and tuna. In amounts of about an ounce a day, they may be sufficient to avoid deficiencies in young children.

Animal foods have a high content of vitamin B_{12} because they ingest vitamin B_{12}-containing microorganisms or because the microflora in their guts synthesize the vitamin. The richest sources of vitamin B_{12} provide over 19 μg per 100 g. They are lamb or beef organ meats such as kidney and liver, bivalves such as clams and oysters, which extract many microorganisms containing vitamin B_{12} from sea water, soyamilk that is fortified with vitamin B_{12}, and vitamin supplements. Other types of red meats, eggs, and milk products are also good sources. Macrobiotics rarely eat large amounts of any of these products on a regular basis. Therefore, inadequate intakes of vitamin B_{12} may be a problem. Moderately good sources, providing 3–10 μg per 100 g of vitamin B_{12} include seafood, such as lobster, scallops, haddock, tuna, swordfish, and flounder, and egg yolks, fermented cheeses, such as Camembert or Limburger, and nonfat milk solids. Most other red meats and fish provide less than this amount. Grains, fruits, and vegetables are virtually devoid of B_{12}, except for tiny amounts present in root nodules of some legumes. Seaweed is sometimes contaminated by plankton rich in vitamin B_{12}, but these are unreliable sources of the vitamin. 'Sea vegetables' such as wakame, arame, and kombu and a seaweed known as spirulina contain very few corrinoids that are available to humans. Other plant foods such as certain fermented soya products like miso (which is often served as a soup) and tempeh

have not been tested for the bioavailablity of their corrinoids to humans, although they may test positive in microbiological assays for the vitamin. They cannot be relied upon to provide sufficient amounts of vitamin B_{12}. Small amounts of vitamin B_{12} may also be present in some plant foods, owing to contamination of food with insects or feces.

The major risks of vitamin B_{12} deficiency are in pregnant women, growing infants, and children of mothers who have followed a macrobiotic diet for many years. Infants may be born with low stores of the vitamin, are reported to exhibit biochemical indices of vitamin B_{12} deficiency, even when they are suckling, and are at risk of deficiency after they have been weaned from the breast to vegan-like diets. (*See* **Cobalamins**: Physiology; **Food Fortification**.)

Vitamin D Humans can synthesize vitamin D endogenously when the skin is exposed to ultraviolet irradiation, but those who live in northern latitudes, use sunscreen, or are confined indoors by illness may not receive enough stimulation to meet their needs. Supplies of the vitamin may pose problems for macrobiotics. The naturally occurring food sources rich in vitamin D are human milk, which provides low but adequate amounts of the vitamin for human infants in the first few months of life, egg yolks, liver, and some fatty fish such as eel, herring, sardines, and salmon. In the USA, milk and milk products are fortified with vitamin D at approximately $0.5\,\mathrm{IU\,g^{-1}}$ (0–0.01 $\mu\mathrm{g\,g^{-1}}$) wet weight, and margarine at about $5\,\mathrm{IU\,g^{-1}}$ (or $0.10\,\mu\mathrm{g\,g^{-1}}$), so that food products containing them will also contain some vitamin D. Vitamin D-fortified milk products are also available in many other Western countries. In the USA, highly fortified cereals are sometimes fortified with vitamin D, often at levels of $1.2\,\mathrm{IU\,g^{-1}}$ (0.02–0.04 μg) dry weight, as packaged. Cod liver oil and menhaden oil macrobiotics refuse to eat liver, egg yolk, butter, fluid milk, and dried skim milk powder. The natural sources of vitamin D they may be willing to eat are margarine and fatty fish, and vitamin D-fortified soyamilk and other plant foods. Vitamin D supplements are also available without prescription in the USA at levels not exceeding 5 μg (the current adequate intake) per capsule, or at higher levels by prescription.

Minerals

Certain mineral elements in the macrobiotic diet are also sometimes limited.

Calcium Macrobiotics rarely include foods from the dairy group in their usual diets. Some plants including kale, collards, dried peas, and beans provide considerable amounts of calcium. However, absorption of calcium from spinach, kale, collards, and Swiss chard is inhibited by the presence of oxalates that bind with calcium during digestion to form insoluble calcium oxalate, which cannot be absorbed. Whole grains contain phytates, substances that interfere with calcium and zinc. However, some of the calcium is available. Foods that may be acceptable to macrobiotics that contain calcium include bony fish such as sardines and foods fortified with calcium (fortified soy milk, fortified rice beverage, fortified juices, highly fortified breakfast cereals, and tofu precipitated with calcium sulfate), and these provide considerable amounts of calcium.

Iron Macrobiotics exclude all heme iron sources, because they do not eat meat. Even lacto-ovovegetarians have a very much lower iron absorption than do omnivores. The bioavailabiliy is probably about 10% compared with about twice that in omnivores, so this is a potential risk factor. However, many other factors affect iron absorption, and in many studies, iron status does not seem to be adversely affected. It is possible to estimate bioavailabiliy in the diet of dietary iron. The amount of ascorbic acid and presence of other iron absorption enhancers as well as the presence of inhibitors must be measured. Foods high in iron include peas, beans, and highly iron-fortified breakfast cereals. During pregnancy, iron supplements are required, because the iron needs are so high.

Zinc The macrobiotic diet is low in meat and low in other foods that are high in zinc. Milk products are a good source of zinc for those who consume them. Zinc absorption from plant foods is poor when the foods contain phytate and oxalate inhibitors. Macrobiotic diets are high in foods high in the zinc inhibitor phytic acid (e.g., soy products, beans, lentils, peas, nuts, and whole grains). Good plant sources of zinc are zinc-fortified cereals, and yeast-fermented foods that reduce the phytic acid content of whole-grain breads, rather than refined white bread. Zinc supplements are also good sources of zinc that may be acceptable to some macrobiotics. Fermented soyfoods, like tempeh and miso, and sprouted legumes may have more bioavailable zinc than unfermented foods like tofu and soymilk.

Conclusion

Many of the aspects of the macrobiotic diet that convey risks to health can be easily corrected without losing the positive aspects of the regimen or violating philosophical principles. Vegetarian or vegan diets that are carefully planned to include modern scientific

knowledge of nutrition are associated with good health. This is also possible for macrobiotic diets, although, in reality, it does not always occur.

MADEIRA AND RELATED PRODUCTS

R W Goswell, Stoke Bishop, Bristol, UK

Definition

Madeira is the name given to a number of related types of dessert wine originally developed in the islands of Madeira and Porto Santo. It owes much of its characteristic flavor to a period of maturation at a relatively elevated temperature. Similar products are produced elsewhere under other names. Nowadays, the designation 'Madeira' is rarely used for wines not produced on the island.

Legal Definition

The Madeira wine region is one of the oldest demarcated areas of Portugal. Since April 1979, the method of production of Madeira has been controlled by the newly created Madeira Wine Institute.

Vineyards

The soil is volcanic, of acid pH, and with a high organic content. Vineyards are typically small (2 ha or less), at altitudes of between 100 and 700 m, and southerly aspects are preferred.

The climate is temperate, humid, and often misty.

Planting, Training, and Pruning

Vines are trained on very low trellises or low wires. Planting density is high (7000 vines per ha). A variety of virus-free rootstocks, including R99, 1103P, and R110, are available to suit the various soils and climatic conditions.

The Guyot pruning system is most often used, leaving many buds and cropping heavily to give 10–15 t ha^{-1}.

Grape Varieties

Historically, the important (noble) varieties in Madeira were Sercial, Verdelho, Boal, and Malvasia; their origin is not known for certain, but except for Malvasia, they probably originated in Portugal. There seem to have been several different types of Malvasia; the desirable version is the Malvasia Candida, which is thought to be of Greek origin. Less important 'noble' varieties, also capable of producing superior wine, are Terrantez, Bastardo, and Listrao. Because of the humid climate, the viticulture was

severely affected by *Oidium* and *Plasmopora* when these fungus diseases arrived in the nineteenth century, and also by *Phylloxera*, a bug which attacks the vine roots. Most farmers, searching for a cure, replaced the sensitive classic varieties by direct producing hybrids, such as Jacquez, Cunningham, or Isabella, or at best by more robust vinifera varieties, such as Malvasia Complexa and Tinta Negra Mole. The viniferas were of course grafted on to American root stocks. Since Portugal joined the European Community, growers have come under pressure to eliminate the direct producing hybrids, and vineyards are being converted by grafting to vinefera varieties. Good clones of the classic varieties Malvasia Candida, Verdelho, Boal, Sercial, Terrantez, Bastardo, and Listrao are available from the official service, but the grapes are not yet widely available for processing.

Vintage

Near sea level, the vintage begins in August but continues into October on the highest ground. The steep slopes and difficult terrain mean that the grapes must be picked by hand and often carried considerable distances on the pickers' backs.

Wine-making

Practices vary: roller crushers are used with or without destalking; red grapes are normally fermented on skins; white wines may or may not be pressed before fermentation. Depending on the scale, fermentation may be in stainless steel tanks, concrete tanks, Algerian-type autofermenters, or wooden casks. The same casks are used from year to year. There seems to be no temperature control, so that in the larger vessels, 35 °C may be reached. In contrast to other areas, such temperatures are not considered deleterious. Grape concentrate is sometimes added to the fermentation to increase alcohol production. Cultured yeast is rarely required. Traditionally, all wines were fermented dry, and sweetening wine was added later as in sherry production, but nowadays, some producers, particularly of wines intended for the sweeter styles, prefer to stop the fermentation at the required sweetness by adding brandy, as port producers do. (*See* **Port**: The Product and its Manufacture; **Sherry**: The Product and its Manufacture.)

Fortification

Some producers fortify immediately; this prevents the malolactic fermentation and inhibits acetic acid bacteria. Other producers delay fortification until January, accepting the slight increase in volatile acidity, which they regard as traditional and a contribution to the complexity of flavor. Fortification is to between 17 and 18% alcohol by volume: grape alcohol obtained from the Instituto da Vinha e do Vinha must be used. Cheaper wines are sometimes not fortified until after the heating process, 'estufagem,' (see below) to avoid heavy losses of alcohol during the heating process.

Maturation

As soon as a suitable vessel becomes available, estufagem takes place, and it is largely this process which gives Madeira wines their characteristic flavor. Estufagem must take place during the first 3 years and involves heating in a concrete tank at 40–50 °C for a minimum of 3 months. Lower temperatures and a longer heating period are conducive to quality.

Some wines are not heated in concrete tanks but matured in wooden casks stored in a warm part of the warehouse. Sometimes, they are transferred between hot and cool areas alternately each 15 days.

Before estufagem, the wine is sweetened to between 1 and 5 ° Baumé according to style. (For the purposes of comparison, it can be assumed that 1 ° Baumé ≡ 1.79 ° Brix ≡ 1.79 g of sucrose per 100 g of solution at 20 °C.) Because of its relatively high total acidity, Madeira is not normally consumed completely unsweetened. Three sweetening materials are in use: surdo, which is essentially a mistela, i.e., fortified grape juice; caldo, which is essentially hydrolyzed cane sugar syrup; and rectified concentrated grape must. Caldo has probably the longest history and gives the authentic Madeira style, but there is a prejudice against nongrape sugar in wines in some markets.

After estufagem, the wine requires some clarification, and albumen and bentonite are used. Some, but not all, producers regard a treatment with charcoal immediately after heating as highly beneficial. Whatever treatment is given, a further extended maturation in oak casks at normal temperatures is required.

Commercial Styles of Madeira

Vintage Madeira, while a year-old wine, is selected as being of superior quality. Once selected, the casks are sealed and monitored by the Madeira Wine Institute. Storage must last a minimum of 20 years in wood, and at least 2 years in glass. Rebottling, under supervision, every few years is not unusual.

Superior Madeira is a wine of outstanding quality produced from the noble varieties. The denomination is usually used for single variety wines, e.g., Superior Bual.

Reserva Velha or Muito Velho requires a minimum of 10 years' maturation, Reserva or Velho requires a minimum of 5 years' maturation, and Selecionado requires a minimum of 3 years' maturation.

Solera is matured in a fractional blending system, and a number of restrictions apply, e.g., no wine can be withdrawn in the first 5 years and only 10% per annum thereafter. The year when the system was established may be given.

Wines may be labeled according to sweetness as follows:

- Sercial: 1–1.2 ° Baumé
- Verdelho: 2–2.2 ° Baumé
- Boal: 3.5 ° Baumé
- Malmsey: 4.5–5 ° Baumé.

This is a traditional way of indicating sweetness, except that, in the case of vintage and superior wines, it is not an indication that the corresponding noble varieties have been used.

California Baked Sherry

This wine, which originated in the Central Valley in the nineteenth century, is produced by a technique very similar to that used for Madeira. Although the amount manufactured has declined significantly since 1960, it is still substantially greater than that of Madeira wine, and, together with the Madeira wines of Russia, probably represents the most significant volume of heat-matured dessert wines.

Vineyards

The wine is manufactured from grapes grown in the high-yielding Central Valley of California. The Palomino, the traditional grape of the sherry district of Spain, has been preferred, but historically, there was a surplus of Thompson Seedless, a high-yielding, neutral grape that has proved adequate for standard-quality wine.

Acid grapes (pH 3.2) are preferred, and fermentation at 25–30 °C is carried out by cultured yeasts, the Montrachet strain of *Saccharomyces cerevisiae* or similar, until more or less dry. The wine is fortified with neutral grape spirit to 17–18% alcohol by volume.

An acidity of 0.4–0.5 (g per 100 ml of tartaric acid) is preferred. Most producers sweeten the wine to about 2% before baking.

Baking

Temperatures of 55–60 °C are maintained for 9–20 weeks. The tendency is for lower temperatures and shorter times to be used than in the past. Some producers also expose the wine to contact with oak chips to increase the complexity of flavor. Relatively little further ageing after cooling is used. The wine is stabilized usually with charcoal, bentonite, and refrigeration.

Commercial Styles

Dry sherry is characterized by 1–2.2% reducing sugar, medium sherry by 2.7–3.5% reducing sugar, and sweet (cream) by 7.5–10% reducing sugar.

Baked Sherry of the Eastern USA

Most types of baked sherry are produced by a method patented by Tressler in 1939. The base wine is a fortified wine made from the non-*Vinifera labrusca* varieties grown locally (Concord, Catawba, etc.). The heating is for approximately 6 weeks at 60 °C. Oxygen is injected through fine diffusers. The oxygen leaving is passed through a trap of cold wine, which retains some of the alcohols and esters that would otherwise be lost.

Heated Dessert Wines made in the UK

There is a substantial production in the UK of alcoholic beverages made by the fermentation of reconstituted concentrated grape musts imported from Mediterranean countries. Selected yeasts are used to produce highly alcoholic wines (15–17% alcohol) without fortification with distilled spirit. The best of the wines are subjected to an extended period of maturation at elevated temperatures to improve the flavor. Specific information on the times and temperatures used is not available. In some cases, oak chips may be exposed to increase the complexity of the flavor.

MAGNESIUM

I J Griffin, Baylor College of Medicine, Houston, TX, USA

Introduction

Magnesium, a soft, silvery-gray metal, is the eighth most common element in the earth core, with an abundance of 2.5%. Magnesium is found in many geological minerals, including asbestos, brucite, magnesite, dolomite, talc, and meerschaum. It has an atomic number of 12, and a mass of 24.31. Magnesium is a member of the alkaline earth metals (Periodic Table IIa), which include calcium, barium, beryllium, and strontium. It exists as three natural isotopes, the most common being magnesium-24 (79%), with magnesium-25 and magnesium-26 each comprising 10–11% of naturally occurring magnesium.

Magnesium was known to the ancient Romans as *magnesia alba* in acknowledgment of the white color of its carbonate salts found in Magnesia, Greece. Sir Humphry Davy in England first described the element in 1808, when he mixed magnesia, water, and mercuric oxide, heated them, and found that a previously unknown element, magnesium, was left after evaporation. Antoine Bussy further purified and isolated the metal in 1828. Magnesium was first detected in the serum of healthy adults by Denis in 1915. In 1926, LeRoy demonstrated that it was essential for the health and well-being of animals.

Magnesium is relatively reactive, and is rarely found in its metallic form in nature. When exposed to air, magnesium is rapidly oxidized, producing a dull-gray layer of magnesium oxide that protects the rest of the metal from oxidation. Magnesium is best known as a component of Epsom salts (magnesium sulfate) and magnesia or milk of magnesia (magnesium oxide). Sea water, which contains about 0.13% magnesium, is the most important commercial source of metallic magnesium. Eighty percent of commercial magnesium is extracted from sea water by precipitation with calcium hydroxide, chloride conversion with hydrochloric acid, and electrolysis. The remaining 20% of commercial production is achieved by thermal extraction from the magnesium-rich mineral, dolcite.

Magnesium has proven useful in numerous industrial applications. Its reactivity has been employed in photographic flashes, fireworks, and incendiary devices, which take advantage of the rapid, explosive oxidation of finely divided magnesium powder in air. Because of its light weight, magnesium has found uses in the automobile, aviation, and space industries. Magnesium has poor intrinsic structural strength, but can be bolstered by alloying it with other metals (particularly aluminum, zinc, and manganese).

In recent years, much has been learned about its biological importance, but many areas of uncertainty remain, especially the effects of marginal magnesium status on human health.

Biological Role of Magnesium

Magnesium is the second most common cation within living cells, exceeded only by potassium. The body of a typical adult contains 20–28 g of magnesium, the majority within skeletal and cardiac muscle ($\cong 60\%$) and bone ($\cong 30\%$). Only 1–2% of magnesium is found in extracellular tissues, and less than 0.5% is found in plasma. The concentration of magnesium in the plasma is about 0.75–1.25 mmol l^{-1} (1.5–2.5 mEq l^{-1}), and is regulated within a relatively narrow range by poorly understood mechanisms. Hypomagnesemia is generally diagnosed when serum magnesium levels fall below 0.75 mmol l^{-1}, and hypermagnesemia when the levels exceed 1.25 mmol l^{-1}. Red blood cells contain about 2–3 mmol l^{-1} magnesium, while skeletal and cardiac muscle contains 5–10 mmol l^{-1} magnesium.

Magnesium plays a number of vital physiological and biochemical roles in humans. Its highest concentration within the cell is in the mitochondria, where it is an essential cofactor for carboxylase and coenzyme Q. It is vital for energy metabolism and the conversion of adenosine diphosphate (ADP) to adenosine triphosphate (ATP). It is important in maintaining normal chromatin structure, hence, normal gene transcription. It is present in a variety of metalloenzymes, is a component of teeth and bones, and takes part in complex interactions (both antagonistic and synergistic) with calcium metabolism. Magnesium is required for normal vitamin D metabolism; patients with hypocalcemia may not respond to treatment with calcium if coexisting magnesium depletion is not recognized and treated. Magnesium is required for cyclic adenosine monophosphate (cAMP) production and associated intracellular signaling. Intracellular ionized magnesium is essential for muscle contraction and nerve function. Many magnesium-containing enzymes have been identified, including enolases, phosphates, transphosphates, choline oxidase, and pyruvate oxidase. Magnesium is required for purine and pyrimidine biosynthesis, and therefore, synthesis

of RNA and DNA. Finally, magnesium in the form of magnesium-porphyrin is present in plant chlorophyl, and is therefore essential for fixing the solar energy upon which all life on earth ultimately relies.

Magnesium Metabolism and Homeostasis

Absorption

Magnesium is absorbed predominantly in the small intestine, mainly in the ileum. A small amount of magnesium may be absorbed in the colon and a number of prebiotic sugars, such as inulin and oligofructose, may enhance colonic magnesium absorption, either through a change in colonic flora, or, less likely, via a trophic effect on the gut. Other factors are known to inhibit or enhance magnesium absorption (Table 1).

Typically, 20–50% of dietary magnesium is absorbed, but much more can be absorbed when dietary magnesium intakes are low. Studies in humans have shown that up to 75% of dietary magnesium can be absorbed when intakes are low, a figure that falls to 10–15% when intakes are high. The kinetics of magnesium absorption are consistent with a relatively low-capacity, saturable, active transport mechanism, and a higher-capacity, nonsaturable, passive transport mechanism. Although the molecular basis of magnesium absorption is not clear, congenital cases of isolated magnesium malabsorption have been described.

Distribution

Magnesium is transported in the plasma, where about 45% is bound to proteins and other ligands, and about 55% is in the ionized form. Magnesium uptake into the cell is an active process, and is probably coupled to sodium efflux. It is modified by a number of hormones and drugs, including insulin, growth hormone, and β-agonists.

Excretion

Some magnesium is secreted into the gut in digestive secretions, but most of this is absorbed in the enterohepatic circulation. Magnesium is also excreted into the urine. Approximately 70% is filtered into the glomerulus, and most is subsequently reabsorbed. Between 30 and 40% is reabsorbed in the proximal convoluted tubule, and most of what remains is reabsorbed in the ascending loop of Henle. This is a major source of magnesium homeostasis. Reabsorption in the proximal convoluted tubule appears to be passive, but reabsorption in the loop of Henle is active, although the hormone or hormones regulating this are not clear. Renal losses increase with alcohol consumption and diuretic use, both of which may predispose to magnesium deficiency. Under normal circumstances, at least 90% of filtered magnesium is reabsorbed in the kidney. During periods of severe magnesium restriction, however, urinary magnesium excretion can fall to very low levels within 7 days. High levels of magnesium supplementation, in contrast, increase the filtered magnesium load at the kidney, and urinary magnesium excretion increases significantly. Because of the high percentage of magnesium that is reabsorbed in the kidney, medications that interfere with this (such as some diuretics) may lead to magnesium deficiency and hypomagnesemia.

Table 1 Enhancers and inhibitors of magnesium absorption

Enhancers of magnesium absorption	*Inhibitors of magnesium absorption*
Lactose	Calcium
Vitamin D	Phosphate
Parathyroid hormone	Phytate
	High-fiber diets
	Oxalic acid
	Some fats

Homeostasis

The molecular control of magnesium homeostasis is not known. Homeostasis seems to be achieved by a combination of the regulation of absorption and urinary excretion. Endogenous fecal excretion does not appear to be important in magnesium homeostasis, as most of this magnesium is reabsorbed by the enterohepatic circulation. The kidney is remarkably adept at maintaining magnesium homeostasis; it is only in the latter stages of chronic renal failure that magnesium concentrations begin to rise in the plasma.

Assessing Magnesium Status

It is difficult to assess magnesium status accurately. Studies in humans have been limited, as the radioactive isotope magnesium-28, and the two stable isotopes, magnesium-25 and magnesium-26, are poorly suited to metabolic studies. The radioisotope is too short-lived to be useful, and the stable isotopes are insufficiently rare to be easily used as tracers. It is possible to measure the magnesium concentration in serum, either total or ionized. The former can vary with albumin concentration and serum pH, but the serum magnesium concentration does fall during experimental magnesium depletion in humans. It has been suggested that ionized magnesium may be a more useful measurement of magnesium status. In practice, however, the two correlate well, and there is

little evidence to suggest the superiority of ionized magnesium concentrations.

Magnesium can be measured in red blood cells, white blood cells, and hair. It has been suggested that the magnesium concentration in mononuclear cells is a better index of magnesium status than the serum magnesium concentration, although definite evidence is lacking.

The urinary excretion of magnesium after an intravenous load has been used as a measure of magnesium status, but its usefulness as an assessment of magnesium status is limited.

Magnesium kinetics can be measured using stable isotopes and compartmental models, but this remains an evasive research technique. This model can identify one pool corresponding to plasma magnesium, another approximating to magnesium in muscle, and a third approximating magnesium in bone. The use of such models has demonstrated a reduction in these pool sizes in rats placed on magnesium-deficient diets. However, these measures are complex and expensive, and very few centers are able to carry them out. They are unlikely to become a clinical measure of magnesium status, although they may prove of use in research settings. Similarly, intracellular magnesium concentration can be measured by nuclear magnetic resonance spectroscopy, but the clinical utility of this method is unclear.

Greater understanding of the importance of marginal magnesium status in human disease is severely limited by the lack of a reproducible, sensitive, and specific measure of magnesium status. Although many measures have been proposed, there is little conclusive evidence to support their use.

Dietary Sources of Magnesium

The highest concentration of magnesium is found in nuts, vegetables, and legumes. Cashew nuts are the richest source, containing 270 mg magnesium g^{-1}, mostly in the outer layers; a significant proportion is lost during processing. Green vegetables contain significant amounts of magnesium. Meat, fish, and diary products contain relatively little magnesium. Drinking water contains variable amounts of magnesium, but particularly high levels are found in so-called hard water.

The average intake of magnesium has steadily declined during most of the twentieth century as the consumption of processed foods has increased and the intake of unprocessed whole foods has decreased.

In 1994, the US Department of Agriculture's Continuing Survey of Food Intake in Individuals (CSFII) estimated that magnesium intake in males aged 9 years or older averaged 323 mg, but only 228 mg in females in the same age range. Ethnic differences have also been found in magnesium intake. The third National Health and Nutrition Examination Survey, known as NHANES III, showed that African-Americans consumed significantly less magnesium than Caucasians or Hispanics.

Magnesium Deficiency

Overt magnesium deficiency is rare in otherwise healthy humans. However, it is seen in association with a number of other diseases (Table 2). These are usually associated with excessive losses (e.g., renal disease, aldosteronism) or poor absorption (gastrointestinal causes).

After starting on a magnesium-free diet, symptoms of deficiency can appear with a month, but in some individuals, they may not be seen for more than 3 months. Symptoms include nausea, muscle weakness, anorexia, ataxia, tetany, convulsions, mental confusion, and irritability. Often, magnesium deficiency will coexist with deficiencies of vitamins, calcium, and potassium, especially if the underlying cause is malnutrition. Magnesium deficiency is characterized by a fall in urinary magnesium and a decrease in loss of magnesium into the gastrointestinal tract. These are presumably adaptive mechanisms designed to conserve magnesium and ameliorate magnesium deficiency. Magnesium absorption may be very low during magnesium deficiency if poor absorption is the underlying cause, or increased as an adaptation to magnesium deficiency from other causes.

Table 2 Conditions associated with magnesium deficiency

Causes	*Examples*
Renal dysfunction	Renal tubular acidosis
	Diuretic use
	Chronic glomerulonephritis
	Bartter's syndrome
Endocrine causes	Hyperthyroidism
	Primary aldosteronism
	Secondary aldosteronism
Gastrointestinal causes	Malabsorption
	Steatorrrhea (e.g., cystic fibrosis)
	Short-gut syndrome
	Prolonged diarrhea
	Celiac disease
	Tropical sprue
	Inflammatory bowel disease
	Excessive losses
	Prolonged vomiting
	Prolonged diarrhea
Inadequate intake	Malnutrition
	Iatrogenic (e.g., TPN with Mg^{2+})
Others	Alcoholism
	Primary idiopathic hypomagnesemia

TPN, total parenteral nutrition.

One study has produced experimental magnesium deficiency by feeding magnesium-deficient formulas to humans recovering from surgery for oral cancer. When subjects were switched from a magnesium-adequate formula to a magnesium-deficient one, urinary and fecal magnesium losses fell sharply, but were not sufficient to prevent a steady decline in serum magnesium. In these subjects, hypocalcemia (low serum calcium) and hypokalemia (low serum potassium) were also seen, even though the magnesium-deficient formula provided adequate calcium and potassium. It would therefore seem that the hypocalcemia and hypokalemia seen in magnesium-deficient individuals are not solely due to low intakes, as magnesium appears to have a profound effect on potassium and calcium homeostasis.

Magnesium Excess

Magnesium toxicity is rare. This condition is characterized by smooth-muscle relaxation, nausea and vomiting, mental confusion, cardiac arrhythmias, and, ultimately, coma and cardiac arrest. Hypotension is one of the earliest signs, occurring by the time magnesium serum levels are doubled. Death does not usually occur until serum levels exceed 7–8 mmol l^{-1}.

It is unusual for excessive dietary intakes of magnesium to cause toxicity, but some cases have been reported following excessive use of medical magnesium salts such as Epsom salts (magnesium sulfate, used as a laxative) or milk of magnesia (magnesium hydroxide, an antacid and laxative). In humans, the most likely cause of magnesium toxicity is renal failure and an inability to excrete magnesium in the urine. It is possible for magnesium toxicity to occur during therapeutic use of intravenous magnesium to treat preterm labor or pregnancy-induced hypertension.

Recommended Dietary Intakes of Magnesium

Due to the lack of a reliable measurements of magnesium status, current recommendations for magnesium intake are largely based on metabolic balance studies and estimates of the magnesium required for 'normal' growth.

The Food and Nutrition Board of the Institute of Medicine recently published a comprehensive report of dietary reference intake for magnesium. Its findings are summarized in Table 3. A number of different definitions were used:

- The estimated average requirement (EAR) is the intake that will meet the needs of half of a given population. At this intake, therefore, half of the population will have an inadequate intake.
- The recommended dietary allowance (RDA) is the intake that will meet the needs of most (97%) of a given population.
- The adequate intake is given if insufficient data are available to define the RDA. At this intake, the needs of essentially all the population are met.

In addition, it was recommended that the EAR for pregnant women should be 35 mg higher than for nonpregnant women of the same age. No increase was deemed necessary for lactating women.

Table 3 Dietary reference intakes for magnesium

Age	*Gender*	*AI*	*EAR*	*RDA*
0–6 months	M/F	30 mg	•	•
7–12 months	M/F	75 mg	•	•
1–3 years	M/F	•	65 mg	80 mg
4–8 years	M/F	•	110 mg	130 mg
9–13 years	M/F	•	200 mg	240 mg
14–18 years	M	•	340 mg	410 mg
	F	•	300 mg	360 mg
19–30 years	M	•	330 mg	400 mg
	F	•	255 mg	310 mg
> 31 years	M	•	350 mg	420 mg
	F	•	265 mg	320 mg

AI, adequate intake; EAR, estimated average requirement; RDA, recommended dietary allowance. •, if insufficient data were available to determine the RDA and EAR, an AI was recommended instead.

Magnesium and Human Disease

Magnesium deficiency or low magnesium intakes have been suggested as risk factors for a number of important human diseases, particularly hypertension and coronary heart disease.

Hypertension

Magnesium plays an important intracellular role in decreasing the excitability of smooth muscle, leading to a reduction in smooth-muscle tone. In addition, intravenous magnesium therapy is a useful treatment of hypertensive emergencies in pregnant women (pregnancy-induced hypertension). Animal studies have shown a consistently inverse relationship between magnesium intake and blood pressure, and an inverse correlation between intracellular magnesium concentration and blood pressure. For these reasons, there has been considerable study of the effect of magnesium nutrition on blood pressure.

The results of a number of observational studies have suggested that low serum or urinary magnesium

concentrations may be risk factors for hypertension. But these studies are contradictory, and negative results have been reported in many other studies. Some interventional studies have evaluated the effect of magnesium supplements on hypertensive individuals. Preliminary evidence suggests that, in hypertensive individuals treated with thiazide diuretics, magnesium supplementation can lower blood pressure. This is physiologically plausible, as thiazides inhibit magnesium reabsorption in the kidney and may lead to magnesium deficiency. However, a similar effect has been demonstrated with potassium supplementation, with no additional benefit from combined magnesium and potassium supplementation. Further, magnesium supplementation of hypertensive individuals with normal serum magnesium levels has not been of any benefit. Clearly, the current literature is confusing, and further work to determine potential interactions among hypertension, diuretic use, and magnesium supplementation is urgently needed.

Cardiovascular Disease

There is increasing evidence that populations residing in areas supplied with hard water (which has higher mineral content, including magnesium) have a lower risk of cardiovascular disease than people who live in similar regions supplied with soft water. Early studies, however, suggested that higher levels of serum magnesium can be detected in serum immediately after myocardial infarcts. More recent studies have suggested that this is a result of magnesium released from dying heart cells, rather than an indication that an existing high serum magnesium concentration is a risk factor for myocardial infarct *per se*. Some intervention studies have shown that intravenous magnesium may be a useful adjuvant therapy in acute myocardial infarcts.

Diabetes Mellitus

Diabetics have increased urinary magnesium losses. Such losses are especially high in individuals with poorly controlled diabetes, those with high amounts of glucosuria, and those with diabetic complications. It is unclear whether the correlation between low serum magnesium concentrations and diabetic complications is a cause and effect relationship, or whether both are independent effects of poor glycemic control. However, magnesium supplementation has been reported to improve insulin sensitivity and glycemic control in adults with noninsulin-dependent diabetes mellitus. In 1992, the American Diabetic Association (www.diabetes.org) convened a consensus panel to evaluate the possibility of a relationship between magnesium deficiency and diabetes mellitus. The panel members felt that there was evidence to suggest that magnesium deficiency might be related to some of the underlying causes of diabetes, such as insulin resistance and carbohydrate intolerance. However, they recognized the difficulty of diagnosing magnesium deficiency, and did not recommend universal magnesium supplementation for diabetics.

Osteoporosis

Thirty percent of total body magnesium is in bone. Magnesium is important for normal bone growth and mineralization. Some studies have suggested that magnesium supplementation can increase bone mineral content in subjects on relatively low magnesium intakes, but such benefits were not seen in women on higher magnesium intakes. Two studies have shown that magnesium supplementation may have beneficial effects on bone mineral content in women with established osteoporosis.

Magnesium as a Pharmacological Agent

Magnesium is unusual in that it has physiological effects as a nutrient, and in much higher doses, has a pharmacological effect as well.

One of the important biological functions of magnesium is to alter the excitability of nerves and muscles, either directly or through an interaction with calcium. Large doses of intravenous magnesium have been used to treat medical conditions involving excessive excitability of nervous tissues. The classic example is the use of intravenous magnesium to treat pregnancy-induced hypertension. This condition, also called preeclampsia, is characterized by proteinuria, edema, and hypertension. Untreated, preeclampsia leads to central nervous system excitability, convulsions and, ultimately, death. It is the most common cause of maternal morbidity in western countries. Intravenous magnesium has been widely used for many years to treat this condition; it has been shown to decrease the risk of seizures and improve maternal and fetal outcome.

Magnesium is also used to delay the progression of preterm labor, again by relaxing excitable cells, in this case, uterine muscle cells. It is also used as a treatment for primary pulmonary hypertension of the newborn (or persisting fetal circulation). This latter condition is caused by abnormal contraction of the blood vessels entering the lung, and leads to profound hypoxia and, ultimately, death. Magnesium acts to relax these pulmonary blood vessels and improve oxygenation. Unfortunately, it may also relax other blood vessels and lead to hypotension, counteracting its beneficial effect on pulmonary vessels.

There are conflicting data on the benefit of intravenous magnesium following acute myocardial

infarcts. The LIMIT-2 study suggested that intravenous magnesium reduced mortality from 10.3% to 7.8%, and also significantly decreased the risk of congestive heart failure. The much larger ISIS-4 study found no such benefit in a much larger sample size (≅ 60 000 subjects), and a possible increase in mortality in subjects with heart failure who were treated with magnesium.

Once again, magnesium offers possible benefits for treating human disease, but the evidence (particularly for the treatment of heart attacks) is confusing, and further studies are needed before magnesium can be recommended in these conditions.

Conclusions

Magnesium is a vital component of the plant protein chlorophyl, which is responsible for fixing solar energy into chemical energy in green plants. In this respect, most life on earth is dependent on magnesium.

In humans, magnesium is an essential nutrient, and is widely available in the diet. Severe magnesium deficiency is very rare in otherwise healthy individuals, but is seen in a number of disease states, particularly renal disease, malabsorptive syndromes, and in alcoholics. There is increasing concern about the effect of marginal magnesium status, or low dietary intake, on chronic diseases, including osteoporosis, myocardial infarct, and stroke. Over the next 5–10 years, more information is likely to accumulate to help us understand the effect of dietary magnesium on these conditions, and the potential use of magnesium as a therapy for these conditions when they occur.

MAIZE

S R Eckhoff and M R Paulsen, University of Illinois, Urbana, IL, USA
S C Yang, Providence University, Taiwan, Republic of China

Introduction

Maize, *Zea mays* L. (corn), is the second most abundantly produced cereal in the world, exceeded only by rice. Maize is grown in every continent except Antarctica. North America grows over 43% of the world's maize crop, with 90% of the US total grown in the Corn Belt consisting of 12 midwestern and north central states. Other world leaders in maize production include China (18%), the EU (7%), Brazil (6%), the Balkan area (3%), and Mexico (where maize is generally agreed to have originated) (3%), Argentina, India, and South Africa (2% each). The ease with which maize can be dried, stored, and transported has made it a major source of energy for animal food and a stable raw material for the production of starch and starch-based industrial products. Maize is also a primary food source in many areas of the world, including South America, Central America, and Africa, where it is converted directly into food products via grinding, alkali processing, boiling/cooking, or fermentation.

This article reviews the structure and composition of maize, the genetic diversity of maize, the issues related to genetically modified maize, the drying, storage, handling, and grading of maize, and the major fractionation/processing methods.

Morphology/Anatomy

The maize kernel is the reproductive seed of the maize plant. As such, its structure and composition exist for the purposes of reproduction rather than processing. Figure 1 shows that the kernel is composed of four main parts expressed as a dry weight percentage of the whole kernel: germ, 12%, endosperm (horny and floury), 82%, pericarp, 5.2%, and tip cap, 0.8%. Each of these sections has distinct compositional characteristics that are important for utilization of the maize kernel (Table 1).

The *germ*, the primary focus of maize kernel from a reproductive standpoint, contains all the essential enzymes, nutrients, and genetic material to produce a maize plant. If the germ is removed from the kernel, planted, and supplied with the necessary chemicals for growth, it will produce a new plant. The remainder of the kernel's purpose is to protect the germ and to provide the energy and structural components necessary for the early growth of the plant.

The germ contains approximately 34% oil, 19% protein, and 28% solubles (sugars, water soluble proteins, mineral, and vitamins), and the balance insoluble materials. Although germ is relatively high in protein, the main interest to processors is the oil it contains. Maize oil is a highly desired food vegetable oil due to its relatively high level of linolenic fatty acid (polyunsaturated oil) and excellent flavor. The germ contains over 65% of the kernel's albumins (water-soluble proteins) and globulins (salt soluble proteins), 25% of the total maize protein, and a high percentage of the kernel's soluble sugars, vitamins, and minerals.

The *tip cap* is the point of the kernel attaching to the cob and the passageway for the movement of nutrients to the developing kernel. Near the end of maturation of the kernel, a black layer (hilar layer) forms across the tip cap region in order to serve as a diffusional barrier and to provide some protection for the kernel from invading insects and microorganisms. This black layer can be seen in Figure 1.

Enveloping the entire kernel (except the tip cap region) is the *pericarp*, which is comprised entirely of dead, empty cells. These cells are high in cellulose and hemicellulose and are arranged in several distinct layers. The epidermis, the outer one or two cell layers, is thick walled and covered with cutin, a waxy substance that restricts the entry of water, water vapor, and many other gases and liquids. Below the

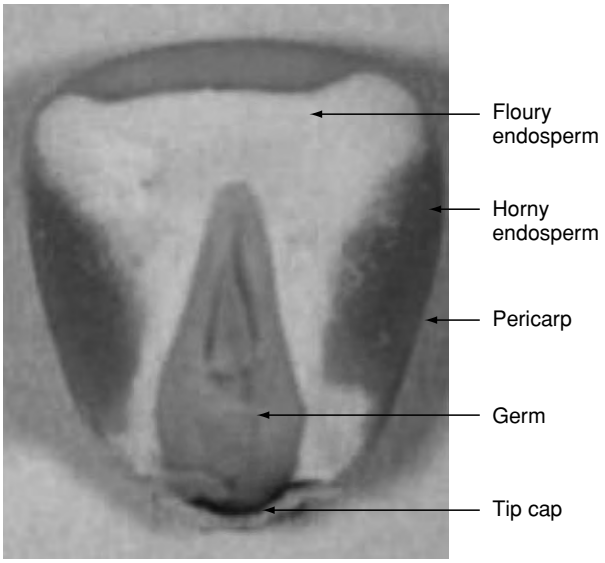

Figure 1 (see color plate 102) Maize kernel.

Adapted from Earle FR, Curtis JJ and Hubbard JE (1946) Composition of the component parts of the corn kernel. *Cereal Chemistry* 23(9): 504–511.

epidermis is the mesocarp, which is composed of 17–25 layers of elongated cells, up to 1 mm long, connected by openings through which liquids and gases can diffuse. The next four to six layers of cells are large open cells, called the cross and tube cells, which allow for a high flux diffusion of gases or liquids. Through these cross and tube cells, water, which enters the tip cap region, can be rapidly transported around the kernel to allow for diffusion into the germ and endosperm.

Below the pericarp is a semipermeable membrane called the seed coat, which resists the movement of macromolecules into and out of the kernel. Just interior to the seed coat is the outermost endosperm layer, the aleurone, composed of large, thick-walled cells of high protein content. This aleurone layer may also impart semipermeable characteristics due to the compact arrangement of the cells in this layer. Damage to the pericarp and/or the seed coat increases the rate of water or chemical absorption.

The *endosperm* comprises hard (translucent, horny, and vitreous) and soft (opaque, floury, and corneous) endosperm. Both comprise a protein matrix, which encapsulates granules of starch. The translucent hard endosperm is composed of densely packed starch granules surrounded by a thick protein matrix, while the less dense soft endosperm has somewhat larger round starch granules surrounded by a thin protein matrix. As moisture escapes from the ear during the in-field drying of the dent type maize, the thin protein matrix ruptures, and the loosely packed soft endosperm structure collapses, leaving many microfissures which interrupt the structural continuity and give the kernel an opaque appearance. The external result of the soft endosperm structural collapse is that the crown region is pulled inward giving a dented appearance. During drying, the thicker protein matrix in the hard endosperm area shrinks but does not rupture. The pressure forces the starch granules into angular shapes, and the density increases. During processing, the hard endosperm structure resists disruption or modification, while the soft endosperm is easily disrupted.

The protein matrix in the endosperm is composed primarily of glutelin, a protein soluble in concentrated alkali, and zein, an ethanol-soluble protein. The glutelin is highly cross-linked with disulfide bonds and provides continuity and the structural characteristics of the endosperm. Zein does not add significantly to the endosperm structure because it primarily exists in spherical balls embedded in the protein matrix.

Starch granules are approximately 99.8% starch. Each granule in dent and flint maize starch is a mixture of two polysaccharides, amylose and amylopectin. Amylose is a linear polymer of glucose (several thousand anhydroglucose units per molecule), and amylopectin is a large multibranched polymer

(50 000–200 000 anhydroglucose units per module). The spherical starch granule consists of a radial arrangement of the amylose with the amylopectin interdispersed. Dent maize starch contains ~ 25% amylose and ~ 75% amylopectin, while waxy maize starch contains ~ 100% amylopectin, and high amylose maize starch contains 65–85% amylose. (*See* **Starch**: Structure, Properties, and Determination.)

Genetic Diversity

Zea mays is a member of the grass family and is one of the most diverse species of plants. Maize plants contain both male and female reproductive structures and reproduce by both cross-pollination and self-pollination. In most commercially viable maize genotypes, the female structure (the ear) projects outward from a central stalk, while the male structure (the tassel) projects out the top of the stalk. Pollen from the tassel is carried by the wind to other maize plants, where fertilization of the individual kernels on the ear occurs. The ears of maize may range in size from about 2.5 to over 45 cm long. The kernel size, shape, and color also vary widely.

Although there are hundreds of 'races' of maize, most of the commercially grown hybrids emanated from only a few major races. For the purposes of discussing the commercial importance of maize, maize types can be subdivided into four categories not related to race.

Dent maize is the primary type of maize grown in the US Corn Belt as well as in Europe, South Africa, and China. Dent varieties have been adapted through hybridization and selection to provide a wide range of agronomic and kernel characteristics. Special dent varieties have been produced with unique starch characteristics. High-amylose (linear starch) and waxy (branched starch) maize genotypes have been grown commercially for many years. Other unique genotypes such as high-oil maize and high-lysine maize are also being produced.

Flint maize is genetically different in ancestry from dent maize and is characterized by hard, round kernels. Flint maize endosperms consist predominantly of hard or vitreous endosperm. The hard endosperm allows flint maize to withstand greater impact forces before being damaged, which has advantages in commerical merchandizing. The agronomic characteristics of flint maize differ from dent maize, primarily due to the unique needs of the historical growing regions.

Popcorn is a flint-type maize that has been genetically selected for its ability to expand or 'pop' when heated. Popping occurs when the kernels are rapidly heated to ~240 °C. The dense endosperm restricts water vapor diffusion that causes pressure to build within the kernel until it explodes. It is the starch granules that explode and in the process stretch the protein matrix. As the protein matrix cools, it becomes rigid. The white fluffy part of popped popcorn is gelatinized starch splattered on the surface of the expanded cell protein matrix.

Sweetcorn is dent-type maize that is harvested while still immature for canning, freezing, and direct consumption as a vegetable. Sweetcorn hybrids contain a gene that retards the conversion of glucose to starch in the endosperm. There are generally three to four times more short-chain polysaccharides accumulated in sweetcorn than in other maize varieties.

Genetically Modified Maize

Biotechnology has made it possible to transfer genetic material within a species as well as between species. As a result of this development, the first genetically modified (GM) maize seed to resist pests, known as Bt (*Bacillus thuringiensis*) maize, was released in 1997. Bt maize has saved farmers millions of dollars annually due to the reduction of pesticides needed to reduce corn-borer infestations. It has been estimated that 25% of the maize area planted in the USA in 2000 was GM.

While biotechnology offers many opportunities to enhance maize production yields, functionality and millability, genetic engineering of crops has been met with resistance. Scientific data support the safety of genetically engineered crops. However, there are still a variety of nontechnical sociological issues surrounding the acceptance of these crops. Concerns vary from a general distrust of new technology to ethical concerns. Resistance to GM crops has been exacerbated by inflammatory press releases and action by some who view the issue as a means of passive tariffs. It appears that the controversy will not be settled in the near future. In the meantime, marketing systems for keeping GM grain separate from conventional grain are developing to provide customers with a choice.

Drying, Storing, Handling, and Grading

Maize is generally mechanically harvested at moisture contents ranging from 18 to 30% by weight and dried to a safe storage moisture. If the maize is harvested on the ear, it is harvested at moisture contents not exceeding 21% and dried in cribs or wire bins by using natural ventilation. Once dried, the ears are shelled by a stationary sheller. Nearly all maize in the major maize-growing regions is now harvested using mechanical picker-shellers, which separate the

kernels from the cob while in the field. The shelled maize can then be dried using one of a variety of drying procedures including high-temperature continuous driers, batch-in-bin high-temperature driers and low-temperature in-bin driers. The selection of a drying procedure depends upon the availability of equipment, energy cost, harvesting rate, and harvesting/drying weather.

Drying kernels at temperatures above 55 °C can decrease product yields and cause processing problems, as will be discussed in the following sections. Rapid drying causes internal stress fractures that reduce the mechanical strength of the kernel and results in more broken kernels during handling. An increase in the amount of broken maize during handling is the primary factor leading to grade reduction.

Most grades and standards for the merchandizing of maize contain the similar criteria of test weight (bulk density), broken maize, mold-damaged kernels, heat-damaged kernels, and foreign material (nonmaize material). In any grading standard, specific levels of the grade factors are assigned for any designated grade. Nongrade determining factors such as moisture content, mycotoxin levels, etc. can be added to the grade certificate depending upon contract specifications.

For long-term safe storage of maize, a moisture content of 13% is required; however, for storage up to one year in the temperate climates of the US Corn Belt, maize can be stored at 14% moisture content. The actual maximum moisture allowed for safe storage varies with the temperature and relative humidity of the air in the interstitial spaces surrounding the kernels. Fluctuations in temperature and atmospheric moisture can result in moisture migration within a mass of maize, which can result in quality reduction due to growth of fungi and insect infestation.

Maize may be handled as many as 20 times between harvesting in the field and final use. Each handling provides a series of impacts that can cause an increase in breakage. Breakage is measured in the USA as the percentage of the maize mass that passes through a 12/64 inch (4.76 mm) rounded hole sieve. This value may be 0.5–1.0% at the farm gate, 2.0–3.0% at in-land grain terminals, 2.5–4.0% at export terminals, and 5–15% at the ultimate international user. Breakage accumulates at each handling and depends upon the breakage susceptibility of the maize kernels and the impact experienced by the kernel during handling. The drying temperature and rate of drying have the greatest effect upon breakage susceptibility. Variety differences are significant, with hard endosperm maize having a lower breakage during handling as compared to softer dent hybrids. Breakage also increases with decreasing grain temperature. To reduce breakage during maize movement, gentle handling is needed. Long spout drops should be reduced so that the kernel velocity does not exceed $12\,m^{-1}$ (less than a 12-m free-fall drop). Velocity reduction equipment and proper facility design can greatly help reduce maize damage.

Processing and Food Uses

Although the major portion ($\sim 80\%$) of maize grown worldwide is used directly as animal food, processing maize for human food or chemicals is growing rapidly. In the USA, the amount of maize used for these purposes has grown from 7.2×10^6 t in 1960 to over 4.98×10^7 t in 2000. Worldwide growth in maize processing is expected to continue as the demand for processed food increases.

There are three major processes utilized in the production of maize for human food usage: dry milling, wet milling, and alkali processing. All three processes have developed specific products and markets.

Dry Milling

Dry milling is the simplest method of producing maize products for human consumption. Grinding whole kernel corn in a grind stone or roller mill to produce flour or meal is a simple method used worldwide when the ground products are to be consumed shortly after processing. The storability of such products is limited due to the presence of crushed germ in the flour and/or meal. Oil from broken germ cells is easily oxidized, producing a rancid odor and flavor. Whole ground maize can also be used as the substrate for beverages or fuel-ethanol production. (*See* **Milling**: Principles of Milling.)

To overcome any storage problems, most larger dry milling facilities remove germ as the first step in processing. Maize is tempered with water to a moisture level of 18–24% to toughen the germ and induce differential swelling of the germ, endosperm, and pericarp for ease of separation. A degerminator mechanically impacts the kernel to break loose the germ and pericarp from the endosperm. The resulting material is sieved, aspirated, gravity-separated, and roller-milled to separate the germ, pericarp, and endosperm pieces of different sizes.

The large grits (flaking grits) are used in the production of flaked breakfast cereals. Smaller grits are also used in some breakfast cereals, extruded maize snacks, and alcoholic beverage brewing. Meal fractions are used in extruded snack foods, food mixes, and brewing. Flour is used in food mixes, food coatings, and breadings. The low cost of maize flour relative to wheat flour makes it a good choice for many food applications where the strength of wheat

Table 2 Comparison of product yield for laboratory dry-milled medium-hard endosperm and medium soft endosperm dent maize dried at two temperatures

Drying temperature (°C)	*Product yield (percentage dry-weight basis)*

[a]Standard US mesh.

gluten is not important. Maize dry-milled products also have a number of nonfood uses, including the manufacture of gypsum board, plywood, enzymes, chemical binders, and biodegradable plastic fillers and in intermediate chemical and biochemical fermentations.

Dry-milled germ can be pressed or solvent-extracted to recover the valuable oil. The defatted germ meal is most often combined with the pericarp fraction to produce an animal food product know as hominy food. Because the mechanical separation processes used in dry milling are imprecise, the germ and pericarp fractions often have significant amounts of attached endosperm material. The maize hybrid, drying temperature, tempering conditions, and degerminator adjustment affect the amount of attached endosperm in the pericarp and germ fraction, and the amount of broken germ in the endosperm products.

Table 2 lists representative dry milling yields of degerminated maize products. When properly degerminated, the larger grits will be low (0.45–0.55%) in oil. As the degerminated product size decreases, the amount of oil in the fraction increases to the content of 1.5–2.5% oil in the flour. Low-fat maize flour can be derived by the roller milling of larger low-fat grits or meal. Dry milling provides a variety of ingredients for use in food products, but the heterogeneous nature of the dry-milled products makes it difficult to find new markets. Maize dry milling in the USA only grew at an annual rate of *sim* 1.5% per year during the last several decades, from 2.9×10^6 t in 1960 to 3.5×10^6 t in 1998. The major advantages of maize dry milling are the lower use of energy in fractionation and lower capital costs as compared to wet milling.

Wet Milling

In the USA, the growth area in the utilization of maize has been wet milling, which has grown from 3.9×10^6 t in 1960 to over 43.2×10^6 t in 1998 due to the increasing demand for high-fructose corn syrup and ethanol. The relatively clean separation of maize into its functional components offers wet milling many opportunities for future growth. Maize yields several large molecules (starch, protein, and oil), which can be used as feed stocks for conversion to a wide variety of new food and industrial chemicals, including intermediate chemicals, amino acids, citric acid and other organic acids, synthetic fibers, plastic and styrofoam filler, and low-calorie fat. Environmental issues and regulations concerning petrochemical and crude oil transportation and utilization will likely allow these and other maize-based products to become more economically competitive in the future.

Wet milling is the use of biochemically and chemically induced changes in the maize kernel to facilitate mechanical separation of components. The kernel is first steeped for 20–48 h in a counter-current manner, which results in microaerophilic lactic acid fermentation during hydration of the kernel, followed by exposure to increasing levels of sulfurous acid (sulfur dioxide in water, 1000–2000 p.p.m.). Steeping toughens the germ, removes solubles from maize, which increases the oil content of the germ, loosens the interfacial forces between the endosperm germ and pericarp, and disrupts the protein matrix, in which starch granules are embedded by reducing disulfide bonding and enzymatic hydrolysis of the matrix protein, and hydrates the kernels to 45–50% (by weight) moisture. Concentrated steepwater, containing ~7% of the total solids, 3–5% protein and most of the soluble sugars, vitamins, and minerals, is often used as nutrient source for biochemical fermentations.

The kernels are then lightly milled to cause the germ to separate from the pericarp and endosperm. Germ recovery is accomplished in cyclones utilizing the density difference between the light germ and the heavier endosperm. The germ containing 45–50% oil is dry-pressed or solvent-extracted to recover the oil. Extracted germ meal is sold as a 20% protein animal food or added to the gluten feed fraction.

Nongerm material is further milled to mechanically disrupt the protein and starch in the endosperm. This fine grinding allows for the separation of cellular fiber from the starch and protein. The pericarp and cellular fiber are recovered using a series of bent pressure fed screens (4–7 units). The fiber is dewatered in a press, dried, and combined with concentrated steepwater to produce corn gluten feed (21%) protein. The underflow from the screens is thickened and centrifuged, resulting in a primary starch–protein separation.

The lighter protein fraction is further centrifuged to concentrate and purify. Belt filters are used to dewater the protein to 35–45% (by weight) moisture and then dried to produce corn gluten meal. The underflow of the primary centrifuge is starch containing ~ 1% protein. This starch slurry is pumped through a series of small cyclones (10–14 units) and washed with fresh water. The resulting starch, with a protein content of 0.25–0.50%, is dried in a flash drier. The starch can be chemically modified to enhance its functional characteristics for food or industrial use, chemically or enzymatically hydrolyzed for use in the production of fructose syrups, dextrose syrups, dextrins, or acid- or enzyme-thinned starch, or left unmodified for use in a variety of food and industrial applications.

Wet milling of specialty maize hybrids (high-amylose, waxy, high-oil, and high-lysine), produces starch or other components with enhanced characteristics. The steeping parameters of these specialty hybrids are often different from those of ordinary yellow dent maize. Currently, there is considerable interest in the USA in the development of specific maize hybrids which will have unique starch characteristics or which could increase wet milling profitability by enhancing millibility.

Flint and flint-type maize is less desirable than yellow dent maize for wet milling. In general, the flint maize takes longer to steep (50–60 h) and yields slightly less starch. Softer endosperm maize is more desirable for wet milling. Recent tests with all soft endosperm maize has shown that steep times can be reduced to 8–12 h, with no loss in starch yield and good starch quality.

The most deleterious factor affecting wet milling is the temperature at which the maize was dried when harvested (Table 3). When the drying temperature is about 50 °C, there is potential for starch gelatinization, protein denaturation, and endogenous protease inactivation. Processing of high-temperature dried maize results in a reduced starch yield, difficulty in protein (gluten) dewatering, increased starch in the fiber, and lower hydration of the maize kernels during steeping. Most US millers purchase US No. 3 or better maize because of the volume of maize purchased, although there has long been interest in being able to delineate high-temperature-dried maize from low-temperature-dried maize in the marketplace. International millers have observed major differences in the way in which US No. 3 maize mills is compared to natural-dried South African or Chinese maize. Natural air-dried or low-temperature-dried maize, as in South Africa or China, steeps easier, is less variable, has lower amounts of broken maize, and creates less dust. During wet milling, the fiber dewaters easier, gluten filters easier, and the starch yield is greater.

Alkali Processing

Alkali processing is the traditional lime cooking method employed by the Native Latin American Indians and Mexicans to produce tortillas. Tortillas are the major source of energy and nutrition in many Central American countries. In the USA, alkali-processed ethnic food and snack food is increasing at a faster rate than most other food uses of maize.

In alkali processing of maize, the maize is mixed with water and lime in a ratio of 1:1.2–3.0:0.0005 (maize:water:lime) and cooked at 94 °C for 50 min. The cooked maize is then steeped for 14 h in the lime solution before being washed with fresh water to remove loosened pericarp and residual alkali from the maize. The washed maize is milled to a gritty textured product, called *masa*. This masa is rolled into flat cakes and baked in an oven for 1–2 min to produce the traditional tortilla. Masa can also be deep-fried to produce tortilla chips or maize chips, or dried and finely milled to produce masa flour. The specific conditions and procedures for alkali processing maize vary with each processor.

[a]From Anderson RA and Watson SA (1982) The corn milling industry. In: Wolff IA (ed.) *CRC Handbook of Processing and Utilization in Agriculture, Vol. II: Part 1 Plant Products* Boca Raton, FL: CRC Press.

The quality of maize used in the alkali process is very important. The largest US processor desires hard endosperm yellow dent maize in order to provide a uniform endosperm texture for cooking. Mechanical damage to the kernel results in increased rates of water absorption and thus increased rates of cooking. Damaged or stress-cracked kernels tend to be overcooked, and they leach out more starch into the nejayote (steep water). Drying temperature is also important as high-temperature drying increases stress-crack damage and damages the starch prior to cooking. The use of hard-endosperm maize is not required for masa production, and quality masa products can be produced from high-quality soft endosperm or average dent maize with appropriate changes in processing conditions.

High-lysine hard-endosperm maize, called quality protein maize (QPM), is being developed to increase the nutritive value of alkali-cooked products. Maize protein as a total protein source is deficient in the amino acids tryptophan and lysine. The QPM is ~ 20–35% higher in these amino acids, and alkali processing of QPM results in masa products with improved levels of both amino acids. (*See* **Amino Acids**: Properties and Occurrence.)

MALABSORPTION SYNDROME

J F T Glasgow, Queen's University of Belfast, Belfast, Northern Ireland, UK

Introduction

Malabsorption syndromes are characterized by the clinical triad of chronic diarrhea, abdominal distention, and failure to thrive or grow. Until about 40 years ago the principal recognized disorders were celiac disease (gluten-sensitive enteropathy), tropical sprue, and cystic fibrosis, conditions in which fat malabsorption was the predominant feature. Since then, advances in basic concepts, such as lipolysis at the dietary lipid interface, micellar solubilization, sodium-coupled solute transport, together with the widespread use of diagnostic intestinal biopsy and an appreciation of the brush border as a digestive

organelle, have allowed the generic syndrome (of malabsorption) to be subdivided into disorders affecting specific stages in the physiological sequence of nutrient assimilation. The term malabsorption syndrome has therefore come to include a wide variety of clinical disorders of the following:

1. Intraluminal digestion (strictly speaking, maldigestion syndromes).
2. Intestinal absorption.
3. Carbohydrate absorption.
4. A number of specific defects in intestinal uptake or transport have also been described. These concern elements (zinc, magnesium, copper), amino acids (cystinuria, Hartnup disease, blue diaper, oasthouse, Lowe's and Joseph's syndromes; lysinuric protein intolerance, etc.), and hematinics (vitamin B_{12}, folic acid), but are not usually associated with stool abnormality.
5. There is also a miscellaneous group of disorders in which the cause of the diarrhea is uncertain. Here the only condition of clinical importance is so-called toddler's diarrhea. This group also includes very rare malabsorption states such as that caused by neuroendocrine-secreting tumors (e.g., ganglioneuroma). (*See* **Celiac (Coeliac) Disease; Cystic Fibrosis.**)

Disorders of Intraluminal Digestion (DID) (Table 1)

Diarrhea caused by exocrine pancreatic insufficiency (EPI) is the principal cause of DID. The physical characteristics of the stools are striking. They tend

Table 1 Disorders of intraluminal digestion

Pathophysiology	*Diagnosis*	*Supporting evidence*
Maldigestion of all macronutrients		
Exocrine pancreatic insufficiency	Cystic fibrosis	Sweat chloride > 65 mmol l^{-1}
	Pancreatic hypoplasia (lipomatosis) (Shwachman-Diamond syndrome)	Neutropenia, metaphyseal dysplasia
	(Johanson-Blizzard syndrome) (fibrosis)	Ectodermal defects
	(Pearson syndrome)	Sideroblastic anemia
	Severe malnutrition	Clinical circumstances
	Pancreatic trauma (pseudocyst)	History of abdominal trauma
	Chronic pancreatitis	Clinical history, plasma amylase
	Multiple endocrine deficiency, autoimmune candidiasis syndrome	Hypoparathyroidism or other endocrinopathies
	Cystinosis	Tubular dysfunction
	Advanced celiac disease	Table 2
Inactivation of pancreatic enzymes (Zollinger-Ellison syndrome; ZES)		Peptic ulcers, fasting serum gastrin > 100 pg ml^{-1}
Maldigestion of fat alone		
Pancreatic secretion	Congenital lipase or colipase deficiency	Assay in duodenal contents
Bile salts		
Synthesis-secretion	Extrahepatic biliary atresia	Cholestasis, liver biopsy
	Intrahepatic bile duct hypoplasia	Pulmonary artery stenoses, embryotoxon
	Various syndromes of infantile cholestasis	
	Hepatic cirrhosis	
	Preterm or mature newborn	Liver biopsy
	Impaired bile acid synthesis	
		Assay bile salts (ABS) duodenum, blood, stool
Deconjugation	Bacterial overgrowth proximal small bowel (obstruction, anastomoses, disturbed motility, blind loops)	Clinical history, H_2 breath test, trial of lincomycin
Enterohepatic circulation broken	Ileal resection(s) fistulae, Crohn's disease	Clinical history, radiology, tissue biopsy
	Congenital malabsorption of bile salts	ABS duodenum, blood, stool
Precipitation, etc.	ZES	See above
	Drugs: neomycin, laxatives, cholestyramine, sulphonamides	Clinical history
Maldigestion of proteins alone	Congenital enterokinase deficiency	Assay in duodenal mucosa
	Congential trypsinogen defiency	Assay in duodenal contents

to be loose and homogenous, pale and pasty with an offensive, penetrating, cheesy odor. These are often greasy and patients describe undigested dietary fat oozing like oil from the passed stool or floating on the water surface in the toilet. Under the microscope, fat droplets and partially digested meat fibers are seen. Balance studies reveal a more bulky stool than normal, containing large amounts of fat, nitrogen, and volatile fatty acids. The coefficient of fat absorption varies from 40% to 70%. Huge nitrogen losses of up to 3–4 g day^{-1} (normal < 0.5 g day^{-1}) are also recorded. Volatile fatty acids – acetic, butyric, and propionic – are usually > 30 mmol day^{-1} (normal < 10 mmol day^{-1}), although only trace or small amounts of lactic acid are present. These large fecal losses are typical of EPI, the commonest cause of which is cystic fibrosis. If the sweat chloride level is normal, however, the cause is likely to be congenital hypoplasia of the pancreas, several forms of which have been described, each with distinct extraalimentary features. (*See* **Fats**: Digestion, Absorption, and Transport; **Gallbladder.**)

Disorders of intraluminal digestion may occasionally affect only one class of nutrient. Congenital absence of pancreatic lipase results in a massive steatorrhea, which may be confirmed by enzymatic assay of lipase activity in aspirated duodenal contents. In isolated colipase deficiency steatorrhea is less severe.

Where the jejunal bile salts level falls below the critical physiological concentration, impaired micellar solubilization results in severe malabsorption of dietary fat and fat-soluble vitamins. Absorption of nitrogen and carbohydrate is normal. This is most usually seen in children with obstructive jaundice, such as extrahepatic biliary atresia or intrahepatic cholestasis (e.g., Alagille's syndrome). When cholestasis is complete or hepatocellular failure is present, fat excretion tends to be greater and may reach 20 g day^{-1} (normal up to 4.3 g day^{-1}). Fatty acids with one or more double bonds are malabsorbed, as well as saturated fats. In extensive Crohn's disease or surgical resection of the terminal ileum, there may be failure to absorb sufficient bile salts to maintain their enterohepatic circulation (and pool size), which is said to be broken. Inborn errors in both the synthesis and the absorption of bile acids have also been reported in occasional families. The Zollinger–Ellison syndrome (ZES), by markedly lowering jejunal pH and also the action of certain drugs (e.g., neomycin), interferes with the complex of events which affect intraluminal digestion. (*See* **Inborn Errors of Metabolism**: Overview.)

Isolated, massive proteolytic insufficiency has been described in the rare inherited disorder congenital enterokinase deficiency. This can be confirmed by finding reduced or absent proteolytic activity in duodenal fluid and assay of small-bowel mucosal enterokinase activity.

Disorders of Intestinal Absorption (DIA) (Table 2)

Although usually not fatty-looking, the stool is loose or watery, often with an acidic smell. Balance studies show that stool volume is more variable than in EPI and steatorrhea, and stool nitrogen losses are moderate (coefficient of fat absorption, 70–85%; nitrogen excretion, 1–2 g day^{-1}, respectively). Stool volatile fatty acids and lactic acid are modestly increased. Sheaves of fatty acid crystals may be appreciated microscopically.

Small-bowel capsule biopsy may reveal a nonspecific enteropathy with either a flat jejunal mucosa (subtotal or total villous atrophy) or a degree of partial villous atrophy (PVA). The degree of atrophy of the mucosa is but one feature of histological abnormalities which include the presence of enterocyte damage, crypt hyperplasia, cellular infiltration, and edema of mucosa and lamina propria. A flat jejunal mucosa in a child greater than 9–12 months of age is highly suggestive of celiac disease. This is confirmed by observing the clinical and histological response to exclusion of dietary wheat or rye gluten. The European Society for Paediatric Gastroenterology and Nutrition (ESPGAN) diagnostic criteria for celiac disease are as follows: (1) small-bowel mucosa usually flat; (2) clinical and histological improvement on a gluten-free diet; (3) histological, and sometimes clinical, relapse following dietary gluten challenge.

Partial villous atrophy is found in various disorders: under 6 months of age it is most likely to be caused by food protein intolerance(s) – most often cows' milk protein, less often to soya, wheat, rice, or multiple food proteins. Other causes include postinfective enteritis syndrome or *Giardia lamblia* infestation, where motile trophozoites may be seen in aspirated intestinal juice and histologically in the jejunal crypts. PVA has also been reported in various immunodeficiency states. Small-bowel bacterial overgrowth might be responsible, possibly linked to deconjugation of intraluminal bile salts. A very similar bowel lesion is found in infants with the syndrome of protracted diarrhea in which a combination of factors may be etiological – primary bowel infection, food intolerance, subadequate nutrition, a depressed immune status, bacterial overgrowth, etc.

A specific lesion on small-bowel biopsy is much more rarely found. In abetalipoproteinemia, mucosal architecture is generally normal but there is a dense accumulation of triglyceride droplets, especially

within mature enterocytes. This may be confirmed by the presence of peripheral blood acanthocytes and absent very-low-density lipoprotein (VLDL), low-density lipoprotein (LDL), and apolipoprotein B in plasma. There is severe impairment, if not virtual absence, of absorption of fat-soluble vitamins. Anderson's disease is a genetically distinct but similar disorder of chylomicron release. In each of these disorders early clinical features are similar to celiac disease. In intestinal lymphangiectasia, dysmorphic lacteals distort the normal villous contours and there is mild steatorrhea with evidence of a protein-losing enteropathy and lymphopenia. Infiltration by clones of abnormal or neoplastic cells (α-chain disease, histiocytosis X, tumor) has occasionally been reported. Crohn's disease may also involve the proximal small bowel. (*See* **Lipoproteins**.)

Disorders of Carbohydrate Absorption (DCA) (Table 3)

The DCA form a heterogeneous group of disorders, the common feature of which is carbohydrate malabsorption. The stool contains large amounts of volatile fatty acids. It is the presence of these small, osmotically active molecules (stool osmolality is greater than

Table 2 Disorders of intestinal absorption

Pathophysiology	*Diagnosis*	*Supporting evidence*
Intestinal biopsy: nonspecific inflammatory lesion		
Flat mucosa (total or subtotal villous atrophy)	Celiac disease	ESPGAN criteria (see text)
Partial villous atrophy (in severe cases villous atrophy may be subtotal)	Food protein intolerance (various – CMP, wheat, rice, etc.)	Response exclusion diet and challenge (see Table 3)
	Postenteritis syndrome	Clinical history
	Dermatitis herpetiformis	Dermal IgA deposit
	Giardia lamblia infestation	Trophozoites in jejunal juice/biopsy
	Immune deficiency states (hypogamma; SCIDS)	Plasma Ig, etc.
	Radiation damage, drugs (e.g., methotrexate, neomycin)	Clinical history
	Eosinophilic gastroenteropathy	Anemia, eosinophilia, jejunal biopsy
	Graft-versus-host disease	Clinical history
	Intractable diarrhea	Clinical history
Intestinal biopsy: specific lesions		
Fat-filled enterocytes	Abetalipoproteinemia	Acanthocytes, absence plasma VLDL. LDL, apo-B
	Anderson's disease	Decreased plasma VLDL, LDL, apo-B
Villi distorted by ectatic lymphatics	Lymphangiectasia	Protein-losing state, lymphopenia
Mucosal infiltration	α-Chain disease	Monoclonal abnormal plasma IgA
	Histiocytosis X	CT scan brain, tissue biopsy
	Crohn's disease, lymphoma, tumor	Clinical history, tissue biopsy
Intestinal biopsy: normal	Lysinuric protein intolerance	Dibasic aminoaciduria, osteoporosis
	Congenital chloride-losing diarrhea	Hydramnios, stool electrolytes
	Specific disaccharidase deficiencies	Table 3
	Transport defects: amino acids; zinc, copper; vitamin B_{12}, folic acid	Not part of malabsorption syndrome triad

CMP, cows' milk protein; SCIDS, severe combined immune-deficiency syndrome; IgA, immunoglobulin A; VLDL, very-low-density lipoprotein; LDL, low-density lipoprotein; apo-B, apolipoprotein B; CT, computed tomography.

Table 3 Disorders of carbohydrate absorption

Pathophysiology	*Diagnosis*	*Supporting evidence*
Intestinal biopsy: normal or almost normal	Congenital sucrase–isomaltase, congenital lactase, late-onset lactase, and congenital trehalase deficiencies	Assay disaccharidases jejunal mucosa; one specific activity affected
	Congenital glucose–galactose deficiency	In Ussing chamber, absence of glucose-induced short-circuit current
Intestinal biopsy: nonspecific inflammatory lesion	Acquired carbohydrate intolerances, especially celiac disease, cows' milk protein intolerance, postenteritis syndrome	All mucosal disaccharidases affected; Table 2

$2[Na^+ + K^+]$) that determines stool volume, which is therefore largely proportional to the amount of carbohydrate ingested. Stool lactic acid is increased and, accordingly, its pH is < 5.5. Large amounts of hydrogen, generated during the process of colonic fermentation and passed as flatus, form the basis of the breath hydrogen test. Stool fat and nitrogen tend to be normal. Reducing substances (sugars) can be detected by adding equal volumes of stool and tap water to a Clinitest tablet. A color change toward orange indicates the presence of up to 2% reducing sugar. (Sucrose is not a reducing sugar and must first be hydrolysed by $0.1\,mol\,l^{-1}$ hydrochloric acid.) (*See* **Carbohydrates: Digestion, Absorption, and Metabolism.**)

If, as is more likely, a nonspecific inflammatory lesion is present, causation has been discussed (Table 2). Disaccharidase and peptidase activities are reduced in the microvilli. Such secondary changes in celiac disease may be the main factor responsible for stool volume. A variety of specific inherited disorders of sugar absorption have also been described in the presence of microscopically normal jejunal mucosa. Specific enzymatic assay of mucosal disaccharidases, or more sophisticated studies, will confirm the diagnosis.

In the rare condition of congenital microvillous atrophy, electron microscopy reveals the presence of abortive microvilli as intracellular enterocyte inclusions with extreme stunting or absence of microvilli projecting into the lumen. As would be expected, carbohydrate intolerance, secretory diarrhea, and severe malabsorption result. In the majority of patients the outcome is fatal.

Clinical Features

The principal clinical expression of malabsorption is diarrhea. When this becomes a chronic symptom, i.e., of more than 14 days' duration, malnutrition and failure to thrive may follow. Depending upon etiology, nutritional failure may be compounded by symptoms such as poor appetite, anorexia, abdominal pain, or vomiting.

A careful clinical history will focus first upon stool number, size, color, smell, and fluidity. The pale, cheesy, homogeneous stools of cystic fibrosis, the loose, bulky motion of celiac disease, and the watery stool passed with much flatus of the child with sugar malabsorption have already been referred to.

The mode of onset of diarrhea is of special importance and may provide the most important pointer to diagnosis. For example, an onset at birth might suggest a congenital absorptive anomaly, such as chloridorrhea. Watery diarrhea which persists on treatment with intravenous fluid suggests a secretory diarrhea, such as congenital microvillous atrophy. Symptoms may be related to dietary changes: that from breast to cows' milk (cows' milk protein intolerance), introduction of cane sugar (sucrase–isomaltase deficiency), or weaning on to wheat- or rye-containing foods (celiac disease). There may be a close family history of similar patients. Persisting diarrhea may follow acute gastroenteritis and suggest postinfective enteritis syndrome with accompanying dietary sugar or protein intolerances.

Associated symptoms can be important: for example, weakness, anorexia, or vomiting may suggest celiac disease; increased appetite or pulmonary symptoms cystic fibrosis; dyspepsia, abdominal cramps, perianal pain, or discomfort may suggest Crohn's disease; bloating, abdominal cramps, or discomfort may suggest sugar malabsorption. Extraintestinal complaints are especially important in cystic fibrosis, Crohn's disease, and immune deficiencies.

The aims of the physical examination are essentially: (1) to determine clinical pointers toward a specific diagnosis and (2) to assess the degree of malnutrition. The general appearance of the child is possibly of greatest benefit, together with comparison of height (or length) and weight with charts of normal growth. Parental height is relevant in short children, together with any previous known weight or height measurements (calculate growth velocity) which may show age-related evolution of the condition. The Tanner stages of puberty may indicate delay in sexual maturation.

A measure of malnutrition is provided by the degree of weight loss, best seen as wasting of subcutaneous fat and/or muscle bulk around the groins, buttocks, shoulder girdles and neck. Malnourished children under 2 years of age often show delayed psychomotor development. Abdominal distention should be assessed in profile, allowing for the toddler's exaggerated lumbar lordosis. The presence of dehydration, edema of face or extremities, skin or conjunctival pallor, hair quality, and length of eyelashes should be assessed. The presence of chest deformity, finger clubbing, perianal abnormalities (e.g., excoriation, superficial ulceration, edema, fissures, fistulae, tags), skin rashes (e.g., erythema nodosum) and arthritis may be of great diagnostic assistance. The oropharynx should be carefully examined. Cheilosis and aphthous ulceration are seen in celiac disease, while in Crohn's disease there may be shallow ulcers, furrowed tag-like nodules, or swollen, inflamed, fissured lips.

In spite of much evidence of protein and energy malnutrition in the malabsorption syndromes, evidence of vitamin deficiencies is surprisingly uncommon, with the exception that in prolonged

obstructive jaundice clinical stigmata of fat-soluble vitamin deficiency are often found, e.g., defective dark adaptation, osteomalacia, bone pain, fractures, and a coagulopathy. Neurological features – loss of deep tendon reflexes and proprioception with ataxia, nystagmus, ophthalmoplegia, and retinitis pigmentosa – have been seen as a result of protracted deficiencies of vitamins E and A. Similar features have been reported in abetalipoproteinemia and, less commonly, in cystic fibrosis. In chronic small-bowel disorders (celiac disease, Crohn's disease), there may be angular stomatitis and other evidence of vitamin B complex deficiencies.

Two very common and confusing disorders are toddler's diarrhea (nonspecific chronic diarrhea) and the postenteritis syndrome. The former is characterized by persistent bouts of loose, mucusy, foul-smelling stools which often contain undigested vegetable material, punctuated by periods of normal or infrequent stools. Absorption and nutrition, well-being, and growth are normal. Postenteritis syndrome follows mucosal damage by enteric viruses or bacteria, and is in part caused by diminished enzyme activity in the damaged enterocytes. It persists until a new generation of normal enterocytes has been developed, a process which takes much longer in the malnourished patient.

Unless a sweat test or a jejunal biopsy reveals a diagnosis of cystic fibrosis or celiac disease, more detailed studies will be required. Careful 3-day balance studies of net intake and excretion, although used less frequently than in former times, may be necessary to identify malabsorption together with specific investigations set out in Tables 1–3.

The Consequent Malnutrition

Malnutrition varies a great deal and will depend on both the child's age and the diagnosis. The greater the age-related demands of growth, the more severe will be the effects upon nutrition, particularly in the first 2–3 years of life. In general, macronutrient malabsorption is more severe when the pathophysiological abnormality occurs in the intraluminal phase of the assimilation sequence. Thus EPI is associated with greater fecal losses of fat and protein than are celiac disease or disorders of lymphatic transport. The same cannot be said of micronutrient malabsorption, which tends to be relatively more severe in DIA, e.g., in celiac disease or extensive small-bowel Crohn's disease. Fat-soluble and probably water-soluble vitamins, minerals (iron, calcium), folic acid, vitamin B_{12}, and trace elements (zinc, magnesium) are poorly absorbed. In a specific, inherited condition such as abetalipoproteinemia there is profound, refractory deficiency of all fat-soluble vitamins (see above). (*See* **Malnutrition**: The Problem of Malnutrition *and also* individual nutrients.)

It should be pointed out, however, that important factors other than maldigestion or malabsorption contribute significantly to the degree of nutritional failure:

1. Poor dietary intake is probably the most important factor and is the result of poor appetite, altered taste, dyspepsia, vomiting, and abdominal discomfort or frank abdominal pain. These symptoms are relatively common in celiac disease and small-bowel Crohn's disease. In DCA a poor diet probably accounts for virtually all of the malnutrition.
2. Cystic fibrosis is an example of a disorder in which, in early life, the child may compensate for the considerably increased fecal losses by an increase in dietary intake. With the development of bronchopulmonary infections, however, appetite wanes, growth velocity diminishes, weight is lost, and this is compounded by increased work of breathing and, perhaps, elevation of resting energy expenditure.
3. Protein-losing states are associated with a threefold increase in the fractional catabolic rate of the plasma albumin pool which is not compensated by increased hepatic synthesis of up to 24%. This may be a factor in, for example, up to one-third of children with celiac disease; it is also common in Crohn's disease, intestinal lymphangiectasia, and eosinophilic gastroenteropathy. (*See* **Protein**: Synthesis and Turnover.)
4. Chronic inflammation has been shown in Crohn's disease to increase protein turnover with a consequent increase in resting metabolism.
5. Small-bowel bacterial overgrowth leads to further nitrogen loss and hypoalbuminemia, and results in sugar intolerance and steatorrhea.

In addition to malabsorption, each of these developments result in protein malnutrition with consequent lowering of plasma levels of insulin-like growth factor 1 (IGF-1, somatomedin C, basic somatomedin). This possibly explains why the growth rate is usually reduced, even though secretion of growth hormone, thyroid, and adrenal hormones is unimpaired. Where malnutrition is severe or long-lasting, IGF-2 may eventually be depressed also. The precise means by which nutrition influences IGF-1 production in liver and other tissues is unclear, although intake of protein and energy appears to be important. None the less, IGF-1 seems to be more sensitive than other commonly used indices of malnutrition, such as prealbumin, retinol-binding protein, or transferrin.

Likewise, when nutrition is corrected, IGF-1 increases more rapidly and to a greater degree than the other proteins. Clinically, serial measurement of IGF-1 has been proposed as a means of following nutritional progress in gastrointestinal disorders, such as chronic inflammatory bowel disease. (*See* **Colon**: Diseases and Disorders.)

Weight loss (wasting) of course occurs before reduction in height or length velocity results in stunting. The effects are seen most obviously in the infant and toddler. In the past, children occasionally presented with celiac disease in a state of crisis (vomiting, hypoalbuminemia, hypovolemia) which had a significant mortality. In older, untreated children, the effects on growth are less dramatic, although there tends to be a progressive falling away from the normal range of weight- and height-for-age. In adolescents this is associated with delayed pubertal development, psychological, and peer-group maladjustment and, ultimately, a reduced adult height. Reference has already been made to the specific effects of vitamin and mineral deficiencies.

Nutritional Management

Nutritional management should begin with diagnosis and thence a rational approach to management. Where there is deficiency, this is replaced, as for example in cystic fibrosis (pancreatic enzyme supplements must match the load of macronutrient being ingested, whereas in congenital enterokinase deficiency a small amount of enzyme (trypsin) is sufficient to activate pancreatic proenzymes secreted into the duodenum). Alternatively, the substrate is avoided or altered, as in congenital sucrase–isomaltase deficiency (dietary sucrose omitted); in congenital glucose–galactose malabsorption, dietary glucose and lactose are replaced by fructose. In celiac disease, a gluten-free diet is prescribed and it must be both strict and lifelong, provided that the diagnosis has been made according to ESPGAN criteria. (*See* **Carbohydrates**: Metabolism of Sugars.)

In many malabsorption disorders, however, management is nonspecific, and consists of dietary manipulations which ameliorate the pathophysiology and correct malnutrition by minimizing the degree of malabsorption. For example, in disorders in which there is sub-optimal small-bowel bile salt concentration (Table 1), a large proportion of dietary long-chain triglycerides (LCTs) are substituted by medium-chain triglyceride (MCT) which fully corrects the steatorrhea. In practice, this is simpler in infants, where a variety of commercially available formulae provide a feed with up to 80% of the lipid as MCT. It is important, however, to insure that the diet contains adequate amounts of essential fatty acids, either in the form of LCT or as a supplement of linoleic acid (e.g., safflower oil). Generous oral supplements of fat-soluble vitamins should be prescribed, but if this fails to produce normal plasma levels, parenteral preparations, especially of vitamins A and E, should be administered.

Where there has been extensive ileal resection or pathology which interferes significantly with the enterohepatic circulation of bile salts, cholestyramine may be required in addition to MCT, in order to prevent the production of disabling cholerrheic diarrhea; this results when large quantities of bile salts pass into the colon and inhibit electrolyte and water absorption. When cholestyramine is being used, supplements of fat-soluble vitamins and folic acid are required since these will be unavailable for absorption as they become bound to the anionic resin; supplements should be administered at times other than when the drug is being taken.

In the small, severely malnourished infant or toddler, prior to, or immediately after, diagnosis, there is often a need to replace enteral nutrition with a balanced intravenous supplementation mixture (amino acids, glucose, fat, electrolytes, minerals, vitamins, and trace elements). The classic example is the baby with intractable diarrhea (Table 2) for whom survival may depend upon this approach. Supplementing the oral intake using a glucose polymer, usually with a source of lipid (often rich in MCT), vitamins, and minerals, is reserved for those who are less ill and able to tolerate the extra oral intake (e.g., those with cystic fibrosis or celiac disease). Nasogastric feeding may be necessary if poor appetite, nausea, or other problems interfere with achieving a satisfactory nutrient intake. When longer-term supplementation is required, especially in older patients, a percutaneous, endoscopically positioned gastrostomy may be employed.

Such nutritional additives need to be used judiciously, starting with smaller volumes in order not to increase the diarrhea already present – as when excessive amounts of glucose polymer are used. Caution is needed in infants with advanced liver disease, or those with hypoalbuminemia, lest the feed volume per se precipitate fluid retention. Supplements of intravenous salt-poor human albumin may be necessary.

Finally, knowledge of a specific pathophysiological abnormality may suggest an appropriate therapy. For example, patients with abetalipoproteinemia, Anderson's disease and congenital lymphangiectasia respond well to oral MCT substituted for LCT. This relates to the fact that MCT is absorbed directly into the portal venous system rather than via the small-bowel

lacteals. In addition, supplements of fat-soluble vitamins are required both to prevent nutritional, particularly neurological sequelae and to treat those who are already showing clinical deficiency.

In disorders of carbohydrate absorption, avoidance of the offending dietary sugar is usually sufficient, although rehydration may also be necessary, together with the general management of the severely malnourished child.

MALNUTRITION

Contents

The Problem of Malnutrition

K K Sinha, T.M. Bhagalpur University, Bhagalpur, India

Background

Malnutrition literally means 'bad nutrition' and refers to the imbalance between the body's supply and demands for nutrition. Thus, malnutrition can be defined as 'an impairment of health resulting from a deficiency, excess, or imbalance of nutrients.'

It can be classified further into 'undernutrition' and 'overnutrition.' Undernutrition deals with the deficiency of nutrients and their consequences, while overnutrition relates with cases of consumption of excess nutrients and their effects. In this communication, the problem of malnutrition has been discussed under various heads, viz. causes and signs of malnutrition as well as the important diseases induced by the deficiency of essential nutrients.

Causes of Malnutrition

Overnutrition

Problems resulting from overnutrition are known to be comparatively less common than the problems associated with undernutrition. So many persons consume diets that are excessively high in calories, saturated fat, cholesterol, and sugars and that are also excessively refined. Each of these excesses is supposed to be one of the major factors for increasing the risk of chronic diseases.

Excessive caloric intake leads to obesity, which is highly prevalent in urban population. Obesity can also be seen in persons who sit in their offices for longer duration. In fact, these persons may not take food in excess of their requirements, but the poor physical activities fail to consume the energy they receive daily. In these circumstances, the normal diet may prove to be an overdiet, and the extra energy made available goes for deposition. Obesity may lead to many chronic diseases like diabetes mellitus, gall bladder disease, gout, cardiovascular diseases, etc. Excessive intake of fats and sugars may also induce some of the chronic diseases described earlier.

Consumption of excess amount of saturated fats and cholesterol are believed to be among the important risk factors in the incidence of cardiovascular and cerebrovascular diseases, while excessive intake of salt may lead to hypertension. An increase in the incidence of gastrointestinal disorders like diverticulosis, irritable colon, and possibly colon cancer has also been reported to be caused by the consumption of excessive refined foods.

Vitamins A and D are essential for human health, but consumption of excessive amounts of these vitamins may lead to toxicosis, which is characterized by dry itchy skin, lethargy, fatigue, general weakness, nausea, vomiting, headache, etc.

Undernutrition

Many problems have been related to cases of undernutrition or nutritional deficiencies. Primary malnutrition is the result of an insufficient intake of essential nutrients, because of the unavailability of a food supply, ignorance, or poverty. The regional unavailability of food and crop failure are basic causes of undernutrition in most parts of the world. Likewise, poor practices in processing, marketing, and storage can result in a serious reduction of the available food supply as well as losses in the nutritive values of foods consumed. Some of the important causes for inadequate consumption of food that can be prevented by sufficient motivation, knowledge, and income are as follows:

- lack of knowledge about kinds and amounts of food to be taken at specific growth periods;
- lack of means to procure foods essential for good nutrition;
- poor and faulty environment at the time of food consumption;
- refusal to take food due to poor appetite caused by prolonged illness or allergy to some specific foods;
- lack of teeth and inability to chew certain nutritive foods; and
- loss of desire to eat good foods owing to loneliness.

Several causes of malnutrition in individuals are not necessarily the result of a deficient dietary intake but are caused by physiologic failure beyond the ingestion stage. For example, a nutritional deficiency may develop as a result of a failure to absorb normally an essential nutrient that is supplied by the diet in adequate quantities. Similarly, nutritional deficiency may be brought about by impaired digestion, abnormal intermediate metabolism, excessive excretion, and increased biologic requirements. Such secondary or conditioned deficiencies may occur in the case of gastrointestinal diseases with rapid emptying time, vomiting, and diarrhea; in pancreatic or biliary diseases that interfere with normal digestion and absorption; in liver diseases with impaired hepatic function or when rapid growth, closely spaced pregnancies, lactation, surgery, injuries, extensive burns, or febrile or metabolic diseases increase the body's requirement for one or more nutrients.

The conditions that predispose to nutritional deficiency are usually multiple and simultaneous in operation. In most of the underdeveloped areas of the world, widespread malnutrition is not just the result of one factor, poverty; ignorance, religious or cultural taboos, and intercurrent chronic parasitic infection also play an important compounding role. If more than one predisposing condition is working naturally, more than one nutritional factor is in deficient supply. Underweight preschool children are prevalent in different parts of the world (Table 1).

Thus, the individual who suffers from a well-defined deficiency of a single essential nutrient is the exception. As a rule, a number of deficiencies involving more than one dietary factor are at work concurrently, bringing about an impaired nutritional status and multifaceted disease picture simultaneously or sequentially. The occurrence of simultaneous multiple deficiencies complicates the nutritional rehabilitation of the malnourished individual considerably. The

treatment of a single deficiency in a chronically malnourished patient is as effective in bringing about an improvement as the granting of a loan to settle a single debt of a business burdened by a long-standing accumulation of financial obligations.

Signs of Undernutrition

As discussed earlier, undernutrition leads to several classic deficiency diseases, which are more prevalent in the developing and underdeveloped countries and can be diagnosed easily on the basis of their specific symptoms. However, there are some common physical, behavioral, and pathological signs that can be observed in people affected by undernutrition. In fact, these are not the symptoms of any specific deficiency disease, but anybody can recognize the disease based on their personal observations. Those signs can be summarized as follows:

- frequent absence from school and work;
- lower rate of weight gain;
- poor appetite;
- dull, dry, and thin hair, which can be pulled out easily;
- dry-looking face with inflammation in the nose, lips, and mouth; fissuring at the corners of the lips;
- red and inflammed eyes with congested eyelids;
- loss of enamel and decay in teeth;
- pale and rough skin with pigmented patches and scaling around the nose and ears;
- muscular weakness and flabby muscles;
- mental depression with apathetic behavior, often showing irritability, restlessness, nervousness, or sleeplessness;
- high susceptibility to infections as well as poor wound-healing.

Pathogenesis of Deficiency Diseases

It would be difficult to separate and pinpoint the individual stages, but the pathogenesis of a deficiency disease may be a continuous, progressive development, which, if not interrupted at some point by remedial action, may advance to the final full-blown clinical picture characterizing the specific disease.

This development starts with nutritional inadequacy because of primary or secondary deficiencies; eventually, the body resources of the nutrients in inadequate supply become depleted. When tissue depletion has reached a critical point, it interferes with the normal biochemical reactions in selected tissues or in the body at large. This will initially result in functional changes such as increased fatigue or abnormal gastrointestinal or neurologic function. As the nutritional deficiency continues, minor or eventually major anatomic lesions develop, and gross clinical signs and symptoms become manifest.

Problem of Undernutrition or Deficiency Diseases

Deficiency diseases can be grouped broadly into two categories: one caused by vitamin deficiency and another caused by a deficiency of other nutrients.

Disorders resulting from vitamin deficiency

Several important diseases in humans are caused by the deficiency of some common vitamins, viz. vitamins A, C, D, thiamin, riboflavin, niacin, etc. The names of the diseases, along with the symptoms and methods of treatment, are detailed below:

Beriberi Beriberi is principally a thiamin-deficiency disease that is quite common when pregnancy and lactation raise the individual's thiamin requirement, and breast-fed infants may acquire the symptoms of this disease, since the milky, malnourished mother may be deficient in thiamin.

Important symptoms of beriberi include a loss of appetite and disturbances in the gastrointestinal tract. Affected individuals feel extreme weakness, become lean and thin, develop cardiac trouble and edema, and show mental depression, loss of memory, anxiety, etc.

Because beriberi is a complex vitamin-deficiency disease, patients make the greatest improvement when B-complex vitamins, rather than thiamin alone, are prescribed. The persons may also consume a diet rich in thiamin or high in protein and calories.

Cheilosis and glossitis These are riboflavin-deficiency diseases (*ariboflavinosis*) that are common in persons who consume a marginal diet devoid of dairy products or other animal protein sources and leafy vegetables.

Cheilosis is characterized by the appearance of crack at the corners of the lips as well as bifurcation at certain points. Sometimes, blood also oozes out at those points. In the case of glossitis, small pimple-like eruptions arise on the tongue that become red and sometimes inflamed.

These diseases are treated by administration of riboflavin coupled with an improvement in the diet. Riboflavin supplementation should continue at the rate of 5–10 mg daily until complete recovery. A well-balanced diet rich in milk and milk products, meats, and leafy vegetables should accompany the specific vitamin therapy.

Keratomalacia, xerophthalmia, night blindness, and Bitot's spot All of these diseases are caused by a

deficiency of vitamin A (*avitaminosis A*) or its precursors, the carotenoids in the diet. These are the most prevalent vitamin-deficiency diseases in the world.

One of the earliest signs of vitamin A deficiency is the secretion of watery fluid from the eyes and, if unchecked or not treated in good time, leads to night blindness, or *nyctalopia*. The affected person is unable to see well in dim light, especially when coming into darkness from a brighter environment.

The term 'xerophthalmia' means 'dryness of the eye,' i.e., of the cornea and conjunctiva. This is prevalent mostly in young children. The full-blown syndrome of xerophthalmia is characterized by a wrinkled and lusterless conjunctiva and haziness and dryness of the cornea with small erosions or punctate superficial infiltrations. Subsequently, perforation occurs, and there may be a prolapse of the iris, or the lens may be expelled. Inflammation resembling conjunctivitis may also develop.

The above symptoms may lead to 'keratomalacia,' which is characterized by dryness and ulceration of the cornea as well as softening and destruction of the eyeball and blindness.

In some cases, a grayish shiny spot (Bitot's spot) appears on the conjunctiva, which also leads to xerosis of the cornea.

Vitamin A deficiency diseases can be prevented if carotene-rich foods are included in the diet. Treatment is rapidly effective with large doses of vitamin A, provided that the eye conditions have not become irreversible. Massive doses of vitamin A every 3–6 months given under medical supervision have been found to be successful in preventing high incidences of blindness.

Scurvy Scurvy results from a deficiency of vitamin C in the diet. It is common in infants and individuals who consume a diet devoid of fruits and vegetables, the main sources of vitamin C.

Pain, tenderness and swelling of the thighs and legs are frequent symptoms of infantile scurvy, accompanied by weight loss, fever, diarrhea, and vomiting. If the teeth have erupted, the gums are likely to be swollen, tender, and hemorrhagic. Scurvy in adults results after several months of a diet devoid of ascorbic acid. The symptoms include swelling, infection, bleeding of the gums ('*gingivitis*'), tenderness of the legs, anemia, and petechial hemorrhages. The teeth may become loose and eventually may be lost. There is degeneration of the muscle structure and of the cartilage, with impaired wound healing.

Scurvy patients respond dramatically and specifically to the administration of vitamin C. The patients can receive ascorbic acid either in synthetic form or in the form of fresh, unheated processed orange juice of standardized vitamin C content or in the form of noncitrus juices enriched with vitamin C.

Rickets and osteomalacia These are diseases resulting from a deficiency of vitamin D. In fact, a deficiency of vitamin D leads to inadequate absorption of calcium and phosphorus from the intestinal tract and to faulty mineralization of bone and tooth structures. The inability of the soft bones to withstand the stress of weight results in skeletal deformities.

Premature infants are more susceptible to rickets than full-term infants, since the growth rate and calcification of the skeleton impose additional demands for vitamin D. In early rickets, there may be few physical findings except irritability and restlessness during sleep. Closure of the cranial fontanelles is delayed, and the affected infant crawls or walks late. Softening of the skull ('craniotabes') and bulging or bossing of the forehead give the head a box-like appearance. Bones become soft and fragile, leading to a widening of the ends of the long bones, bowing of the legs, and enlargement of the costochondral junction with rows of knobs or beads ('*Rachitic rosary*'). In rachitic infants and children, there may be delayed dentition and malformation of the teeth.

Frequently referred to as 'adult rickets,' osteomalacia literally means 'bone softening.' In this disease, softening of the bones becomes so severe that the bones of the legs, spine, thorax, and pelvis bend into deformities. Rheumatic-type pain in the bones of the legs is also common.

As long as the dietary calcium and phosphorus intake is adequate, uncomplicated rickets may be treated solely by administration of sufficient doses of vitamin D. The first sign of improvement is a rise in serum phosphorus, which is commonly observed by the second week. This is usually followed by bone mineralization within 2–4 weeks of initiation of treatment.

Vitamin D deficiency diseases may also be prevented by adequate exposure of the infants to sunlight or by giving vitamin D in a variety of forms, such as cod-liver oil, other fish-liver oils, or vitamin D milk.

Pellagra 'Pellagra' is a term of Italian origin, which means 'rough skin.' The cause of pellagra is a severe deficiency of niacin and its precursor, the amino acid tryptophan. It is one of the important public health problems in many parts of the world.

Pellagra involves the gastrointestinal tract, the skin, and the nervous system. Primary symptoms include a sore tongue, mouth, and throat, with glossitis extending throughout the gastrointestinal tract. The tongue and lips become abnormally red in color. The mouth becomes so sore that it is difficult to eat and

swallow. Nausea and vomiting are followed by severe diarrhea. A characteristically symmetric dermatitis, especially on the exposed surfaces of the body (hands, forearms, elbows, feet, legs, knees and neck), appears. The dermatitis is sharply separated from the surrounding normal skin. At first, the skin becomes red, somewhat swollen, and tender, resembling a mild sunburn. If the condition is untreated, the skin becomes rough, cracked, and scaly, and may become ulcerated. Sunshine and exposure to heat aggravate the dermatitis. Some neurologic symptoms like confusion, dizziness, poor memory, and irritability, leading to hallucinations, delusions of persecution, and dementia, are also noted as the severity increases. The classic 'Ds' are the final stages of the disease – dermatitis, diarrhea, dementia, and death.

The patient should be confined to bed until convalescence is well under way. Specific therapy consists of the oral administration of a sufficient amount of niacinamide daily. In conjunction with specific niacinamide therapy and supportive multivitamin (particularly vitamin B complex) supplementation, a well-balanced diet is given, containing 100–150 g of high-quality protein (preferably from meat, milk, and eggs) and provides about 3500 cal. In case of gastrointestinal symptomatology, the diet initially should be a full liquid diet devoid of roughage. As the patient improves, a general diet high in good-quality proteins is given.

Disorders Resulting from Deficiency of other Nutrients

In addition to vitamins, there are many other nutrients whose deficiency in the diet can lead to several important human diseases. Some of these nutrients include iron, folic acid, iodine, calcium, phosphorus, protein, calorie, etc. The diseases resulting from a deficiency of these nutrients, along with the symptoms and methods of treatment, are as follows:

Anemia Anemia is a deficiency in the circulating hemoglobin and results from inadequate synthesis of hemoglobin or of red blood cells or both. It is caused by an inadequate supply of one or more nutrients such as iron, vitamin B_{12}, folic acid, vitamin C, and trace elements, or by many non-dietary factors such as blood loss, excessive blood destruction, or defects in blood formation.

Iron-deficiency anemia is the most common disease in different parts of the world and occurs more frequently in infants, preschool children, adolescent boys and girls, and women in childbearing years (Figures 1 and 2). Insufficient iron in the diet, faulty absorption of iron from the small intestine, and blood loss are causes of iron-deficiency anemia.

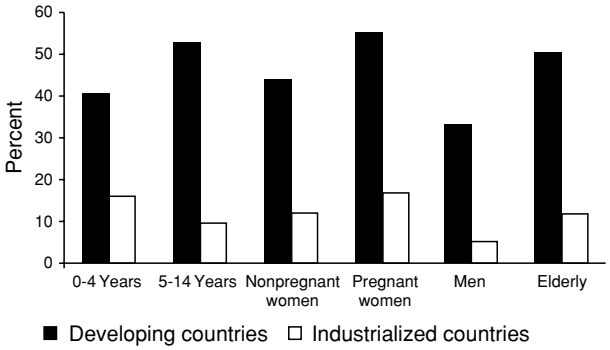

Figure 1 Prevalence of anemia by age group in industrialized and developing countries, 1998. Source: ACC/SCN (2000) Fourth Report on the World Nutrition Situation. Geneva: WHO.

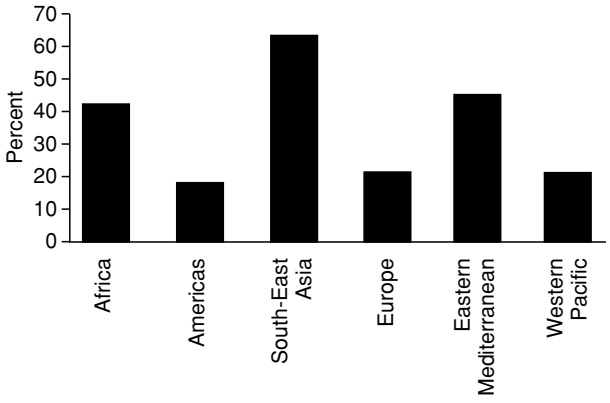

Figure 2 Prevalence of anemia in children 0–5 years old by WHO region, 1998. Source: ACC/SCN (2000) Fourth Report on the World Nutrition Situation. Geneva: WHO.

The symptoms of nutritional deficiency disease include weakness, fatique, pallor, dyspensia on exertion, and a constant feeling of tiredness. The onset is usually insidious. There may be vague gastrointestinal symptoms, and achlorhydria is not uncommon. The skin, mucous membrane, and nails are pale in proportion to the reduction in the circulating hemoglobin. Many adults with hypochromic anemia exhibit atrophy of the papillae of the tongue. There may be a slight cardiac enlargement, with eventual failure if the anemia becomes severe. Nails may be brittle, longitudinally ridged, or even concave and spoon-shaped. Individual blood cells are pale (hypochromic) and smaller than normal (microcytic).

Many instances of nondeficiency anemia can be prevented by appropriate diet. Once anemia is present, treatment requires iron salts such as ferrous sulfate, although attention should also be focused on correcting a faulty diet. Good sources of iron include meats, especially offal, whole-grain breads and cereals, as well as dark green leafy vegetables.

Anemia in infancy can be easily prevented by using an iron-fortified formula throughout the first year or introducing iron-rich foods, such as cereals, early and continuing their use throughout childhood. The requirements of pregnant women can be met only by using an iron supplement.

Kwashiorkor and marasmus These are diseases of protein-calorie malnutrition, which includes a wide spectrum of disturbances ranging from mild deficiency to the severe forms of kwashiorkor and marasmus. The disease is widely prevalent in the tropical and subtropical underdeveloped parts of the world and is a major health problem of young children among the poor strata of the population of those areas.

The term 'kwashiorkor' means 'the evil spirit that infects the first child when the second child is born.' In the developing and underdeveloped countries, babies are usually breast-fed until 18–24 months of age, and occasionally longer. When another baby is born, the older child generally subsists on the foods typical of the household – usually a high-carbohydrate, low-protein diet, and this results in the symptoms of kwashiorkor.

The symptoms start to appear after a few months of weaning. The increase in stature and tissue development is retarded, and the muscles become flabby and lose their tone. The severe protein levels are reduced so that the tissues hold water, especially evident by the swollen face and legs, and the large potbelly. The hair often changes color, appears lifeless, and can be easily plucked out. Diarrhea is frequently observed probably as a result of poor sanitation in the home. The child with diarrhea advances rapidly from mild to severe kwashiorkor.

Marasmus is another protein-calorie-deficient disease prevalent mostly in the urban areas of developing countries, where infants are usually weaned from the breast at a much earlier age (before 1 year) than in rural areas. The result is severe growth failure and emaciation in the first year of life. Muscle wasting is extreme, and subcutaneous fat is absent, so the ribs become visible. Retarted mental development is likely in children suffering from marasmus, as deprivation of protein occurs at a time when the division of brain cells occurs most rapidly.

Treatment of the above diseases is based on the administration of proteins of high biological value and correction of any existing dehydration and electrolyte imbalance. A diet rich in milk protein has been the treatment of choice. Fruit juice, eggs, meat, vegetables, and cereals are gradually added to the diet throughout the period of recovery. Several inexpensive vegetable and animal protein mixtures have also been developed on a regional basis for human feeding that increase the quantity and improve the quality of dietary protein.

Endemic goiter Endemic goiter is an iodine-deficiency disease (IDD) that occurs in those areas where the iodine content of the soil is so low that insufficient iodine is obtained through food and water and occurs when no provision is made for supplying iodized salt.

A lack of iodine leads to an increase in the size and number of epithelial cells in the thyroid gland and thus an enlargement of the gland. This condition is known as simple or endemic goiter and presents no other abnormal physical findings. The deficiency is more prevalent in females than males and is more frequent during adolescence and pregnancy. Tables 2 and 3 list the number of countries affected and the current magnitude of IDD.

Consumption of iodized salt is the most common treatment of this disease. Some natural sources of iodine like sea foods (fish, crabs, etc.) and green vegetables grown in marine soil can also provide sufficient amounts of iodine in the body.

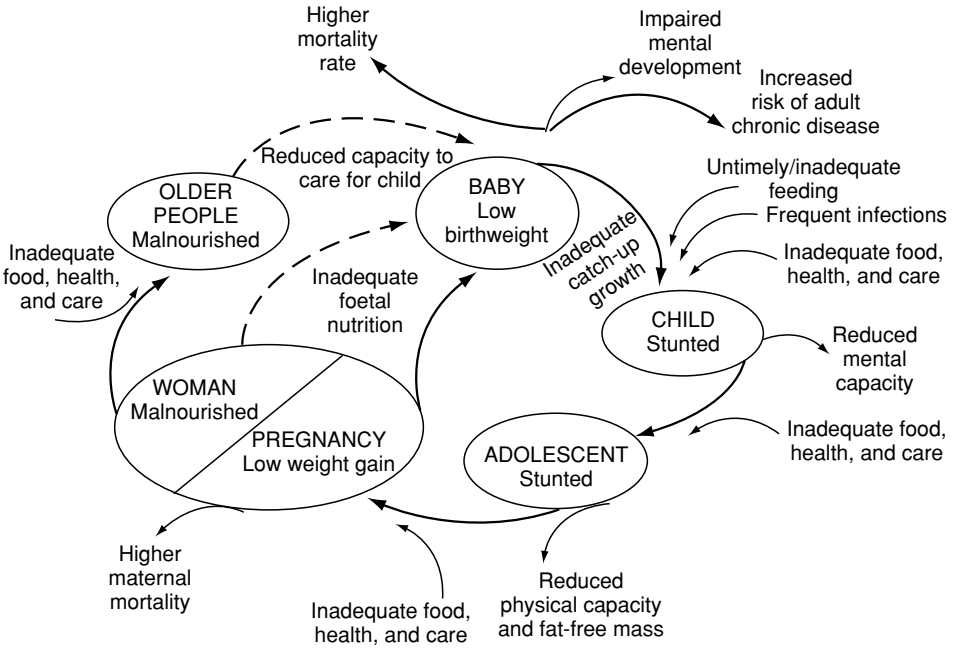

Figure 3 Nutrition throughout the life cycle. Source: ACC/SCN (2000) Fourth Report on the World Nutrition Situation. Geneva: WHO.

It is thus clear that nutrition challenges continue throughout the life cycle, as shown in Figure 3. Poor nutrition often starts *in utero* and extends, particularly for girls and women, well into adolescent and adult life. It also spans generations. Undernutrition occurring during childhood, adolescence, and pregnancy has an additive negative impact on the birthweight of infants. Low-birthweight infants who have suffered intrauterine growth retardation as fetuses are born undernourished and are at a far higher risk of dying in the neonatal period or later infancy. If they survive, they are unlikely to catch up significantly on this lost growth late and are more likely to experience a variety of developmental deficits. A low-birthweight infant is thus more likely to be underweight or stunted in early life.

The consequences of being born undernourished extend into adulthood. Epidemiological evidence from both developing and industrialized countries now suggests a link between fetal undernutrition and an increased risk of various adult chronic diseases – the 'fetal origins of disease hypothesis.'

Malnutrition in Developed Countries

M Astier Dumas, Centre de Recherches Foch, Paris, France

Introduction

Although food is available to excess in developed countries, malnutrition is probably not infrequent, even in people free of disease. Malnutrition in developed countries is not the same as malnutrition in the developing world, where people are undernourished. In developing countries malnutrition is generally characterized by deficiencies, such as vitamin and mineral deficiencies.

Paradoxically, in developed countries, overnutrition leading to obesity, diabetes, or cardiovascular diseases can coexist with nutrient deficiencies, and fad diets can lead to an inadequate intake of nutrients. Whether these deficiences can really lead to diseases is not certain, but it is generally accepted that they are undesirable.

In developed countries it may be more accurate to speak of groups at risk of malnutrition than of malnutrition itself, and it is necessary to include overnutrition and undernutrition, depending on the groups concerned.

Correlations between fat and energy intake and obesity, diabetes, cardiovascular diseases, and cancer have been thoroughly investigated. Beyond all the discussions made on this point, there is general agreement that excess calories, whatever their source, can be a cause of disease ranging from cardiovascular disease to cancer and diabetes. Changes in the composition of food eaten, towards processed foods rich in fat, with a high energy density and poor nutritional content, may be an important factor, as vitamins and minerals are sometimes described as protective factors (mainly vitamins A, C, and E, β-carotene and selenium in studies of cancer and cardiovascular diseases). (*See* **Cancer**: Diet in Cancer Prevention.)

There are few data on the nutritional status of the obese subject compared to the nonobese, but in a French study red blood cell transketolase activity – a measure of thiamin status – was lower in obese subjects of both sexes. (*See* **Obesity**: Etiology and Diagnosis.)

Apart from diseases that produce malnutrition by altering either digestive processes or the metabolic use of nutrients (e.g., traumas, surgery, cancer, and burns), malnutrition in developed countries can affect poor people (often immigrants), old people, those on weight-reducing diets, youngsters, those who are unable to buy food or have difficulty eating it, those on special diets, or those who eat for fun rather than from hunger. **Table 1** gives an estimation of the

Table 1 Groups at risk of poor vitamin status in the US population (estimation)

Group	*Percentage of population group at risk*	*Nutrients*
Aged 10–19 years	14.6	Folates, vitamin A
Alcohol users	22	Vitamins B_1, B_6, A and D, carotene and folates
Smokers	28.6	Vitamins B_6, E and C, carotene and folates
Diabetics	4.6	Vitamins B_2, C and D
Dieters	20	Potentially any or all
Elderly people (aged over 65 years)	12.1	Vitamins C and D, folates
Oral contraceptive users	10.4	Vitamin B_6, folates, carotene
Pregnant women	3.9	All, especially folates
Strict vegetarians	> 0.9	Vitamins B_{12} and D

percentage of population groups at risk of vitamin deficiency in the US population.

Evidence from Consumption Data

Many surveys have been made on food consumption levels, comparing the results with dietary reference values (DRVs) or recommended dietary allowances (RDAs) in the various countries. However, the fact that the RDA is not attained by a small fraction of the population does not mean that these people are malnourished. The RDAs are supposed to cover the needs of almost all the population, and a level of intake that is inferior by 20%, or even by 40%, can still be compatible with adequate nutrition. It is necessary to know the physiological status of these people in order to understand the meaning of an inadequate intake. For example, a serum level of a nutrient that is inferior to the reference level (biochemical index) is not automatically a sign of disease, but its significance is more reliable than the level of food consumption. In some instances the physiological signs of deficiency are difficult to obtain on a large scale in surveys. For example, identification of good bone health – the bone mass – is not easy to study, and calcium intake is therefore used to identify the population at risk. The percentage of the population with intakes of calcium well below the RDA is sometimes important: in Belgium, inadequate intakes were found in 67% of 13–19-year-olds, 73% of 9–12-year-olds, and 85% of 5–8-year-olds. It has been shown that the proportion of girls aged 11–19 years consuming less than 1200 mg of calcium per day is 91% in Portugal, 85% in the USA and 78% in Canada. Between 1980 and 1985 in the UK the mean daily intake of calcium fell from 960 mg per day to 850 mg per day; 33% of boys (10–11 years) and 53% of girls (same age), and 25% of boys and 57% of girls (14–15 years) were found to have intakes of calcium below 800 mg per day. Evidence suggests that the bone mass of an adult is largely influenced by the calcium intake during adolescence, indicating that these population groups are at risk of bone disorders later in life. (*See* **Dietary Surveys**: Measurement of Food Intake; Surveys of National Food Intake; **Nutritional Assessment**: Anthropometry and Clinical Examination; **Nutritional Surveillance**: In Industrialized Countries; **Dietary Reference Values**; **Dietary Requirements of Adults**.)

Evidence from Biochemical Data

Biochemical evidence given by serum levels is available for many nutrients, mainly vitamins but also for iron. (*See* **Nutritional Assessment**: Biochemical Tests for Vitamins and Minerals.)

Elderly People

The reasons for malnutrition in the elderly are numerous and can coexist. They include the following: lack of money to buy food; poor dentition; depression and loneliness; inadequate exposure to sunlight in housebound elderly people, leading to poor vitamin D status; lack of appetite; effects of drugs; loss of dexterity of hands, hindering food preparation; and, sometimes, disease. Some elderly people are on self- or medically prescribed diets unsuited to their needs. (*See* **Elderly**: Nutritional Status; Nutritionally Related Problems.)

Food intake is generally lower in institutionalized elderly people than in free-living elderly people. Drugs are more commonly taken and depression is more frequent in institutionalized elderly people. Results of biochemical studies in institutions show generally lower serum vitamin levels than for free-living elderly people. Nevertheless, some general deficiencies have been described in elderly people.

In the Dutch elderly population study published in 1990, anemia according to the criteria of the World Health Organization (WHO) was found in 4% of men and 1% of women. Frank nutritional deficiencies were not observed, but compared to younger adults a substantial percentage of the elderly had relatively lower values of folate (men, 30% below $5\,\text{nmol}\,l^{-1}$; women, 17% below $5\,\text{nmol}\,l^{-1}$), pyridoxal 5′ phosphate (men, 43% below $19\,\text{nmol}\,l^{-1}$; women, 13% below $19\,\text{nmol}\,l^{-1}$), total carotenoids (men, 22% below $1\,\mu\text{mol}\,l^{-1}$; women, 13% below $1\,\mu\text{mol}\,l^{-1}$), and 25-hydroxyvitamin D. It was underlined that 'since the health consequences of these low levels at old age are unknown, no conclusion can be drawn whether this indicates marginal status among these elderly.' Elderly people following a vegetarian diet were more at risk of iron, zinc, and vitamin B_{12} deficiencies.

In one study in France of 70 institutionalized elderly people, 24% of subjects had biochemical signs of malnutrition (low serum proteins and hemoglobin values). The energy consumption of these subjects was below the RDA, as it was for iron, calcium, and vitamin C, but not for protein. In another study of 204 institutionalized patients (convalescent elderly), 65 were found to have low serum albumin levels, 27 being severely malnourished. In 59 disease-free subjects in an institution it was found that 20% had serum folate deficiency. Later, 235 institutionalized subjects were studied and 72.8% found with folate deficiency and 11.4% with vitamin B_{12} deficiency.

In Belgium, the vitamin D status of 240 elderly subjects was analyzed and it was concluded that the deficiency of both the vitamin D substrate and hormone was frequent in the elderly population in Belgium.

In Italy, the results of a nationwide study on nutritional status of the elderly was published. Only 47% of subjects were found to be free from vitamin deficiencies, and three out of 10 had multiple vitamin deficiencies. Vitamin B_1 and vitamin B_2 deficiencies were most prevalent (25% and 20%), followed by folate (15%) and vitamin C (14%). Vitamin A and vitamin E deficiencies were negligible (6% and 2%). In Naples, low intakes of calcium, iron, and nicotinic acid, and a low status of vitamin B_1 for 20% of men and women, and low riboflavin status for 40% of men and 20% of women were reported.

In the USA, a biochemical study of 70 women found 14% of all subjects deficient or low in vitamin A, 17% low in vitamin B_1, and 15% low in vitamin B_2. Serum ascorbic acid levels were acceptable, but low or deficient levels of total serum protein and albumin were observed for 36% and 20% of the subjects; low hemoglobin and elevated total iron-binding capacity values were recorded for 19% and 40% of subjects. In other surveys in the USA, Sweden and Netherlands, a prevalence of iron-deficiency anemia, instances of potassium deficiency, and possible vitamin D and/or calcium deficiency – with or without osteoporosis – have been observed.

Obviously the situation can be worse in poor elderly people. Folacin, iron status, and hematological parameters of 193 people from urban low-income households in Florida were reported and, of these subjects, 60% could be classified as high risk for folacin levels (under $140\,ng\,ml^{-1}$) and 11% at medium risk ($< 160\,ng\,l^{-1}$). An incidence of 14% of anemia and 32% of leukopenia, with no iron deficiency, was found.

Adults

In one recent study in France, in a sample of 1039 subjects aged from 6 to 97 years, from a defined area, no major deficiency in vitamin A was reported – less than 3% of serum levels were in the range indicating high risk of anomalies, but approximately 20% of women showed moderate risk. For vitamin E, slight deficiencies are more frequent in young people. For vitamin C, around 10% of men and less than 5% of women can be considered at high risk, with three times more at moderate risk. For vitamin B_1, erythrocyte transketolase activity corresponding to a high risk of deficiency was found in 22% of adults. For vitamin B_2 the risk was judged high in up to 31% of women and 22% of men. For vitamin B_6, high risk was present in up to 16% of men and 25% of women. Only 60% of the population showed no biochemical defect related to any vitamin deficiency.

The authors of this report underlined the correlation between tobacco smoking, alcohol consumption, use of oral contraceptives, and vitamin status. (*See* **Alcohol**: Metabolism, Beneficial Effects and Toxicology; **Contraceptives: Nutritional Aspects**; **Smoking, Diet, and Health**.)

The most documented nutrient is iron. In Germany diminished iron body stores in a considerable proportion of blood donors were found. An incidence of 9% of completely exhausted iron stores in male blood donors was reported – a figure also observed in Scandinavia. An even higher rate was found in female blood donors (25%).

Women of Child-Bearing Age and Infants

Studies in North America and Scandinavia show that 1–6% of women of child-bearing age (for men in the same age range only 1–2%) are anemic. In France, in one group studied, 2–3% of women and up to 25% of pregnant women were anemic. In Germany, it was reported that 10% of pregnant women had iron deficiency during the first trimester and 50% had iron deficiency at the end of pregnancy.

Iron deficiency is also a problem in infants. A 10% incidence of anemia and a 40% borderline iron status was found in 10–12-month-old infants in France.

Rickets still exists in developed countries. Despite supplementation of infant formulae with vitamin D, and the drops prescribed daily to infants when this supplementation is not made, some groups at risk have been identified. These include the following: native Indians in Canada because of poor lifestyle, lack of exposure to the sun, and lack of vitamin supplementation; the Asian population in the UK; Turkish and Moroccan infants in the Netherlands; and, in France, infants with dark skin coming from Africa. (*See* **Infants**: Nutritional Requirements.)

Another population group at risk is that eating a macrobiotic diet. Fifty-three Caucasian infants aged 10–20 months were compared to 57 matched omnivorous infants in the USA. Of the children in the former group, 55% had rickets, and the 25-hydroxy-vitamin D level was $34\,nmol\,l^{-1}$ (SD 15.3) against $49.7\,nmol\,l^{-1}$ (SD 21.9) in the control group. (*See* **Macrobiotic Diets**.)

Children

Although some real cases of severe malnutrition (kwashiorkor) have been described in North America or Europe, these are limited to instances in which a deliberate deviation from normal infant practices is made, sometimes for pseudophilosophical purposes

(e.g., by sects). (*See* **Children**: Nutritional Requirements.)

Dutch children fed macrobiotic diets were compared to omnivorous children (controls) for iron, vitamin B_{12}, and folate status. Iron deficiency was observed in 15% of the macrobiotic group (none in the control group: $P = 0.003$). Plasma vitamin B_{12} concentrations in the macrobiotic group were far below those of the control group ($P < 0.001$), and plasma folate concentrations were higher in the macrobiotic group.

The main nutritional problem in children is dental decay. High consumption of sucrose in young children is a characteristic feature of developed countries, particularly in Anglo-Saxon countries, and less so in Latin countries. In a communication in Edinburgh in the UK, it was reported that in some children aged 2–4 years the proportion of energy derived from sugar was as high as 30%. The main source is fruit juices, generally considered as 'healthy' drinks.

A decrease of dental problems in children has been observed over the past few years and this is believed to result from: (1) supplementation of water or salt (depending on the country) with fluoride; (2) improved hygiene education; and (3) use of sugar substitutes. However, dental decay remains an important problem. (*See* **Dental Disease**: Role of Diet.)

An excess of sugars in children's diets can also lead to nutrient deficiencies, and one study found that 8% of children had a high risk of vitamin B_1 deficiency.

Biochemical data about the nutritional status of healthy children are infrequently obtained, but consumption studies are numerous. The pattern of consumption is rather similar in different countries, with a high percentage of sugar and fat, and a relatively low intake of calcium and iron.

The consequences of these inadequate intakes are not well known, although iron deficiency for pregnant and lactating women and their newborn babies can be a consequence of insufficient intakes during adolescence. Osteoporosis can be linked with development of insufficient bone mass during adolescence. It is also suggested that excessive fat intake during childhood and adolescence may be instrumental in the development of arteriosclerosis. (*See* **Atherosclerosis; Osteoporosis**.)

These studies suggest that malnutrition in the developed world is mainly the result of poor food selection in affluent societies. The shift of consumption from traditional basic foods towards convenience, value-added foods can lead to higher intakes of fat and sugar, and lower intakes of vitamins and minerals.

Information and nutrition education would seem to be the obvious approach to preventing these problems of malnutrition in developed countries. Refer to individual nutrient deficiencies.

Malt Types and Products

M J Edney and M S Izydorczyk, Canadian Grain Commission, Winnipeg, Manitoba, Canada

Introduction

Malt is a natural food product produced by germinating grains and pulses. The three steps of malting, steeping, germinating, and kilning, can be altered to produce different types of malt. Barley malt is by far the most common malt, and its major use is in the brewing of beer. Barley malts are also used in the production of spirits, vinegar, bread, breakfast cereals, and several other minor products (Table 1). In many parts of the world, sprouted cereals and pulses are eaten directly for the improved availability of their nutrients.

Malting

Malting is the controlled germination of grain or pulses. Proper control of its three major steps, steeping, germination, and kilning, is essential if the desired end product is to be produced without excess losses. A range of malt products, with different constituents and, as a result, different values for end-users, can be produced by altering the conditions of the steps.

The steeping step hydrates the seed, which allows germination to commence. Germination allows the embryo to grow under controlled conditions, allowing the seed to develop enzymes that degrade or modify endosperm structure. Other enzymes hydrolyze and solubilize the reserve starch and protein of the endosperm. The amount of solubilized material, often referred to as 'extract' is an important quality parameter that is used to predict the amount of beer or spirits a malt can produce. Kilning is the final stage of malting, and it halts growth of the embryo by removing moisture. Temperatures and timelines used in kilning are especially important because they determine the final enzyme contents of a malt, the development of desirable flavors, aromas, and colors, as well as the concentration of undesirable flavors and aromas (Table 2).

Barley is the seed most often malted, be it for brewing, distilling, or the food industry. There are several reasons for barley's popularity in addition to simple tradition. The presence of a hull on barley protects the embryo during processing, strengthens the texture of steeped kernels, and serves as a filtration medium during brewing. Barley produces high levels of enzymes during germination, and the endosperm is easily degraded. Finally, the relatively low gelatinization temperature (*c.* 59–63 °C) of barley malt starch allows the heat-labile, starch-degrading enzymes from malt to remain somewhat active and hydrolyze the gelatinized starch. The result is a greater release of fermentable sugars compared with malts of grains with higher gelatinization temperatures. However, several other grains, including wheat, sorghum, rye, triticale, and oats, continue to be malted commercially for both traditional and practical reasons.

Table 1 Major uses of malted grains and pulses and contributions of the malts to the end-uses

Use	*Major contributions of malt*
Brewing beer	1. Source of fermentable sugars 2. Source of enzymes 3. Source of flavor and color
Malt distilling	1. Source of fermentable sugars 2. Enzymes 3. Peat flavor
Grain distilling	1. Source of enzymes 2. Source of fermentable sugars
Baked products	1. Source of enzymes 2. Source of flavor and color 3. Source of fermentable sugars
Breakfast cereals	1. Source of flavor, including sweetness, and color
Vinegar	1. Source of fermentable sugars 2. Source of enzymes
Germinated seeds and pulses for food	1. Source of readily available nutrients (amino acids and vitamins)

Malt Uses

Brewing

The brewing industry is the largest user of malt, and malt is arguably the most important ingredient in

Table 2 Malting steps and conditions, and their effects, in producing different types of malts

Malting steps	*Conditions*	*Options*	*Effects*
Steeping	• Barley placed under water • Periodic air rests to allow the grain to breathe	• Moisture content at end of steeping can vary from 42 to 48% (c. 24–48 h)	• The higher the moisture, the greater the potential to modify • Barley begins to germinate
Germination	• Barley grows at controlled temperatures with a good flow of moist air	• Germination can last from 4 to 7 days • Temperatures can vary from 12 to 20 °C • Temperatures can be raised and air flows reduced towards the end of germination	• Longer germination time gives better modification • Higher temperatures give better modification but greater malt losses • Raising temperatures and reducing air flows at the end of germination can increase levels of free amino acids and simple sugars
Withering (Kilning: Phase I)	• Green malt is dried to a moisture level of 10%	• Temperatures can vary from 45 to 65 °C • Rate of air flow can vary • Amount of recirculated air can vary	• Lower temperatures increase enzyme activity • Fast air flows with no recirculation dry the malt quickly, restricting any additional modification • Slow flow rates with recirculation allows the malt to stew producing free amino acids and simple sugars • Sealed containers with warm temperatures lead to starch conversion
Curing (Kilning: Phase II)	• Moisture content is further reduced to less than 6%	• Temperatures can vary from 65 to 250 °C	• It is at this stage that simple sugars and amino acids or small proteins combine in the Maillard reaction • Products provide color, flavor, and reducing power • Hotter temperatures result in greater production of Maillard products

beer. Malt is the major supplier of the fermentable sugars that are converted to alcohol by the yeast. The malt provides not only a sugar source, starch, but also the enzymes (i.e., α-amylase, β-amylase and limit dextrinase) to degrade the starch into fermentable sugars (i.e., glucose, maltose, and maltotriose). Yeasts do not produce these enzymes. The malt enzymes are even more important in adjunct brewing, where they hydrolyze not only the malt starch but also the starch of adjunct sources.

Malt supplies other essential nutrients for yeast growth. Yeasts require a source of nitrogen, but they lack the enzymes necessary for degrading proteins into products that they can assimilate. Therefore, barley protein needs to be degraded, during malting and brewing, into amino acids and peptides that the yeast can use. Vigorous yeast growth is also dependent on the supply of vitamins from malt including biotin, *myo*-inositol, pantothenic acid, vitamin E, folic acid, nicotinic acid, and thiamin. (*See* **Beers**: Biochemistry of Fermentation.)

Malt provides several components that affect beer quality. The mouth feel or body of beer is an important characteristic that is dependent, to a large extent, on the presence of dextrins in the beer. Dextrins are small fragments of starch that have not been degraded into fermentable sugars. Many beer types require a higher concentration of dextrins in order to develop a characteristic fullness. In contrast, many light, refreshing beer types require less body, and therefore, adjuncts are used that can result in a beer with fewer dextrins. Adjunct brewing can also be used to lower the cost of beer production. Low-calorie beers also require limited amounts of unfermentable dextrins in order to reduce the calorie content. Beers featuring less body require malts with higher levels of starch-degrading enzymes.

Several other properties of beer are also dependent on malt constituents. Malt supplies specific proteins, such as Z-protein, that support a good, stable foam or head in the final product. Reducing agents, such as Maillard products, scavenge oxygen in the beer, which increases the flavor stability. Flavor and color compounds, mainly Maillard products produced during kilning, are essential for developing the unique aroma, taste, and color of beer. (*See* **Browning**: Non-enzymatic.)

Some malt constituents have undesirable effects on beer or its processing. Certain proteins and polyphenols can cause hazes in the final product. Increased levels of nonstarch polysaccharides, for example β-glucan, can result in problems with beer filtration and hazes in the final product. Other components of malts, such as dimethyl sulfide, are sometimes

considered to be off-flavors. Many of these problems can be avoided through the use of appropriate malting conditions.

Distilling

The distilling industry uses malt to provide fermentable sugars and other nutrients for the yeast. In malt distilling, where only malt is added to the mash, all the fermentable sugars come from the malt. This is in contrast to grain distillers, where adjuncts, such as unmalted corn and wheat, are added to the mash as a cheaper source of starch. The malt provides the enzymes that convert the starch, whether from the malt or the cooked cereal, into fermentable sugars. In both types of distilling, malt provides other essential nutrients for the yeast such as free amino acids and vitamins. These must be in higher concentrations for grain distilling because the adjuncts provide only starch, which dilutes the concentration of other nutrients from the malt. In contrast to brewing, distilling malt provides no mouth feel or flavor to the final product, and in fact, a malt with a low concentration of unfermentable dextrins and limited flavor is desired. The only exception is the peat flavor that some malt distillers require in their malt.

Some malt continues to be used in the production of neutral spirits, such as gins, aqua vitae, or vodka, where it provides enzymes for degrading starch in a manner similar to grain distilling. Malt, usually in the form of extract, is the source of fermentable sugars in wine coolers, a recently developed alcoholic beverage in North America.

Food

Baked goods Fermented bakery foods are one of the largest users of food malt. Malt leads to better pan flow, increased loaf volume, as well as better crumb structure and crust color in baked goods. The malt supplies simple sugars, amino acids, vitamins, and enzymes, all of which help promote yeast growth during baking. Darker colored malts can also be added for increased flavor or color.

Malt is often included in cracker formulations to improve fermentation and to aid in sheeting and laminating. Malt also enhances the crust color of crackers allowing for reduced baking times and oven temperatures.

Breakfast cereals Barley malt is the most prevalent flavor material used in breakfast cereals. Most flavors come directly from the malt, but some are formed, during the processing of breakfast cereals, from the simple sugars, peptides and amino acids supplied by the malt. The simple sugars also provide sweetness to the cereals. In contrast to most other uses of malt, enzymes are undesirable in breakfast cereals. Their presence causes flavor instability due to their breakdown of starches during processing. As a result, malts used in breakfast cereals have very low enzyme levels with elevated levels of flavors and flavor precursors.

Vinegar Malt is used as a source of nutrients, including fermentable sugars, for yeast in the production of some vinegars. The object is to produce the maximum amount of alcohol, which requires a good complement of starch degrading enzymes, especially where adjuncts are used. In some cases, the mash is even supplemented with microbial enzymes. Bacteria are eventually used to convert the alcohol into acetic acid.

Other

Malt is also used in a range of other products. It is added to the diet formulation of both infants and the elderly because of the increased availability of nutrients in malt, such as amino acids, simple sugars, and vitamins. Malt enzymes can also increase the availability of nutrients from other ingredients in the diet. Malt is used as a carrier in pharmaceutical products where it increases palatability. Roasted malts are used as the basis for various hot drinks including the production of instant drinks from spray-dried malt extracts. The price of malt restricts its use in feed formulations, but limited amounts are used to increase palatability of pig starter diets and pet formulations.

Malt Types and Products

Pale Lager Malt

Pale lager malts are the most common type of malt. They are the major ingredient in the light lager beers that are so popular around the world. These beers require a malt with maximum extract and good enzyme potential but with limited development of color and flavor (Table 3). Pale lager malts are generally made from two-rowed barley with average levels of protein. In markets with high adjunct use, such as the USA, high protein, six-rowed barley is malted in order to ensure good enzyme potential and adequate levels of amino acids for yeast nutrition. Cheaper pale lager malts can be made from six-rowed, European, winter barleys for price sensitive markets.

Pale lager malts are well-modified and kilned gently. The gentle kilning conditions, with an upper temperature of 85 °C, produce a malt with high levels of enzymes and a low potential for color development.

Table 3 Quality characteristics and primary functions of malt types used in brewing

Malt type	*Type of beer*	*Primary use*	*Fine extract (%)*	*Protein (%)*	*Color (°Lovibond)*	*Diastatic power (°Lintner)*
Pale lager malt	Lager	Fermentable sugars and enzymes	81	10.5	1.5	85
Pale ale malt	Ale	Fermentable sugars and flavors	82	10.0	3.0	45
Vienna malt	Lagers, bocks, various	Fermentable sugars and color	81	11.0	3.5	70
Munich malt	Dark lager, various	Color, flavor and fermentable sugars	79	11.8	8	45
Crystal malt	Ales, light, alcohol-reduced, various	Fuller body, aroma, color, foam retention, flavor stability	75	12.0	50	na[a]
Carapils	Lagers, light, alcohol-reduced	Fuller body, foam retention, flavor stability	78	12.0	12	na
Amber malt	Ales, stouts	Source of color and flavor	75	na	20	na
Chocolate malt	Ales, stouts	Source of color and flavor	75	na	450	na
Black malt	Stouts	Source of color and flavor	73	na	550	na
Acidic malt	Lagers, wheat	Reduce pH in wort	73	10.5	2.0	na

Pale Ale Malt

Pale ale malts are used to produce traditional, top fermented ales. In the past, this market had been restricted to the UK, but with the advent of micro-breweries, demand for pale ale malts has expanded to other parts of the world. The major difference between pale ale and pale lager malts is the darker colors and stronger flavors of the ale malts. This is achieved by using a more modified malt and higher final kilning temperatures (90 °C). The higher temperatures result in a stronger malty flavor and a deeper color, but they also reduce enzyme levels, resulting in more unfermentable dextrins and thus greater body in the final beer. Mild ale malts are less modified and are kilned at higher temperatures than pale ale malts. The result is lower levels of extract and enzymes but a greater production of color and flavor compounds. Beers made from mild ale malts are sweeter with more color and flavor.

Vienna Malt

Vienna malt is a lager type malt characterized by a red/copper color and a faint toffee flavor. This malt is the basic ingredient of the more highly colored lager beers, such as Märzen. It is also used, in minor amounts, to correct the color of beers made from excessively pale malts. The malt is produced by completing the kilning of a typical pale larger malt at a raised temperature (90 °C). Also, the use of recirculated air is increased at lower kiln temperatures in order to help produce the amino acids and free sugars required for color development at the higher final kilning temperature.

Munich Malt

Munich malt is characterized by a rich aroma and dark color. By tradition, it is used to make the dark, aromatic, full-bodied lager beers of Bavaria. The malt brings a more intense flavor and color to the beer than does a Vienna malt. Munich malt is produced from two-rowed barley with above average protein. The malt should be slightly overmodified during germination and then allowed to stew during the first stage of kilning. Stewing is intensified germination that results from a greater use of moist, recirculated air in conjunction with somewhat elevated temperatures. This releases the amino acids and free sugars that develop, during higher final kilning temperatures (100–105 °C), into Maillard products that are known for their intense color and flavor. Maillard products, such as melanoidins, also help to improve the flavor stability of beers. Brewers strive for flavor stability by limiting oxygen levels in their beer. The increased reducing power of Maillard products helps scavenge oxygen in the beer. Reasonable enzyme activity is preserved in Munich malt, despite extreme kiln temperatures, by drying the malt slowly.

Crystal and Carapils Malts

Crystal (caramel malt) and carapils malts are unlike other colored malts in that fully modified green malts are roasted in a sealed roaster (65–70 °C) prior to drying. As a result, the starches of crystal malts are degraded to simple sugars during this early stewing stage of kilning, in contrast to standard malts where the majority of starch conversion occurs later in the brewhouse. After this liquefaction of the endosperm,

crystal malts are dried at higher temperature (150–180 °C) in order to develop colors and flavors. The times and temperatures of the drying are adjusted to meet the color specifications of the customer. Crystal malts give a sweet, caramel flavor to beer. In addition, they produce a golden-colored beer with increased fullness and good foam retention. The significant increase in Maillard products leads to a greater reducing power and the ability to improve flavor stability by as much as 50%.

Carapils is a crystal malt but with less color due to the use of lower temperatures during final drying. This malt, which is sweet but without the caramel notes, is often added in small portions to lager-type beers to improve body, foam retention and flavor stability without changing the color or flavor of the final product. Carapils is used at higher concentrations in light and alcohol-free beers in order to increase the body of these beers without increasing fermentability. Crystal and carapils malts contain no active enzyme activity.

Brown and Amber Malts

Brown and amber malts are specialty dark-colored malts that have little or no enzyme activity. They are used in small proportions to increase beer color and add a biscuit-like flavor to stouts and top fermented ales. Brown malts are made by roasting low-moisture green malts. However, in order to prevent starch conversion, as in crystal malts, brown malts are partially dried at low temperatures with good air flows before roasting at temperatures of 130 °C. In contrast, amber malts begin with a pale ale-type malt that has been previously kilned. The kilned malt is roasted at temperatures of 100–150 °C, depending on the color desired. Amber malt is the more popular of the two types, but demand for both types has decreased in recent years.

Chocolate and Black Malts

Chocolate and black roasted malts are highly colored malts that give strong colors and particular flavors to beer. They are customarily used in stouts where they bring a flavor described as dry, burnt, astringent but with the hint of a rich, sweet taste. The malts start with an undermodified malt that has been kilned at low temperatures to a moisture of 4–6%. The dried malt is transferred to a roaster where temperatures are raised to 215 or 220 °C for chocolate and black malts, respectively. The major differences between the two malts is the length of roasting with the darker-colored black malts requiring longer times. In both cases, the high temperatures destroy all enzymes.

Other Brewing Malts

Several other types of barley malt with specific characteristics are available. Acidic malts are used to improve beer quality by lowering the pH of wort, especially in breweries using water with a high carbonate hardness. During mashing, the lower pH increases enzyme activity, especially proteases, a fact that sometimes results in the name 'proteolytic malt.' Acidic malt produces a beer with a paler color and a more mellow taste. The malt is produced by adding lactic acid or lactic acid bacteria to the barley during malting. Acidic malt can be used to avoid the need for additives such as sulfuric acid.

Chit or short malts are used as a cheaper source of fermentable sugars in areas where adjuncts are illegal. These malts are produced by severely limiting germination and kilning in order to produce an inexpensive product. The undermodification of chit malt, though, can lead to separation and filtration problems in the brewery, and therefore, it is used in limited proportions.

Brumalts are dark-colored and rich in Maillard products due to a high-temperature, anaerobic rest during the final day of germination. They are used to bolster the malt aroma of dark German beers such as Alt beer. Smoked malts are sometimes required in specialty beers such as Rauch beer. The malt is produced by allowing smoke to pass through the malt during the kilning process.

Wheat Malt

Wheat is the second most commonly malted cereal grain. The malt is a major ingredient in traditional wheat beers such as those of Belgium and Germany. Small portions of wheat malt are also added to standard ales and lagers in order to improve foam retention and yeast nutrition, which results from the different types and levels of protein in wheat versus barley malt. As a result of the missing hull, wheat malt produces higher levels of extract and lower levels of tannins, the latter can cause hazes in beer. A small but significant amount of wheat malt also goes into foods, where it produces a sweet luscious flavor. (*See* **Wheat**: Grain Structure of Wheat and Wheat-based Products.)

Wheat can be difficult to malt because the missing hull and smaller kernel size cause kernels to take water up more quickly. Overmodification must be avoided as it leads to excess solubilization of protein and the potential for hazes in the final beer. The smaller size of wheat kernels can also lead to processing problems in the malthouse, such as dense packing. Dark wheat malts are sometimes produced for German wheat beers, and for the food industry, by

malting wheat in a manner similar to that used for Munich malts.

Sorghum Malt

In Africa, sorghum is routinely malted on a commercial basis. The malt is used predominantly to produce traditional opaque beers such as kaffir as well as breakfast cereals. However, with a growing demand for European-type beers and with low barley production and high tariffs on barley malt, sorghum malts are also being used in Africa to make European-type beers.

It is difficult to produce a sorghum malt with appropriate quality for brewing. Germinating sorghum does not produce an abundance of enzymes, especially cell-wall-degrading enzymes. As a result, there is poor modification of the endosperm. Exaggerated malting conditions, such as long germination times and elevated temperatures, tend to increase the breakdown of starch and protein rather than cell walls. These conditions result in increased malt losses, sometimes as high as 20%, and excess levels of soluble protein in beer. Further problems are encountered in the brewery where high starch gelatinization temperatures combined with the heat lability of enzymes lead to incomplete breakdown of starch and thus poor fermentability. The residual starch, combined with high levels of β-glucan, can lead to filtration problems. The problems of malting sorghum are being addressed through the development of new varieties with better enzyme potential and through changes to the brewing process such as the use of microbial enzymes and of mash filters. (*See* **Sorghum**.)

Malt of Other Cereals

Rye, triticale, and oats are the only other cereals that are malted to any extent commercially. Malted rye is used traditionally in the rye whiskey industry, and some malted rye is used to add a 'spicy' flavor when brewing beer. Rye malt can produce extremely high levels of extract and enzymes, but its high levels of nonstarch polysaccharides cause increased viscosities, which result in problems with wort separation and beer filtration. These problems, along with a tendency to form hazes in the finished beer, have limited the use of rye in brewing. Malted triticale has seen limited use in the production of specialty beers, where it produces intense flavors. Beer made from triticale malt also has problems with high viscosity and excess levels of soluble protein, which cause the beer hazes.

The use of malted oats for brewing continues to decrease. The thick husk of oats causes reduced levels of extract, and a high level of lipid can lead to off-flavors in the final beer. Low levels of malted oats are still used in traditional oat stouts.

Malt for Distilling and Vinegar Production

Malt requirements differ between malt and grain distillers who use malt or malt plus adjunct in their mashes, respectively. Malt distillers require a malt that produces a maximum amount of fermentable sugars from its starch. There is no need for unfermentable dextrins. The malt, therefore, must have good levels of starch and starch-degrading enzymes. The malting conditions needed to produce this type of malt are similar to those used for pale lager malts. A plump barley is selected and well modified during germination. Milder kilning conditions are used to conserve enzyme activity. There is no need for color or flavor development in distillers malt, which also strengthens the use of low kilning temperatures. The one unusual practice with this malt can be the burning of peat during kilning. Varying levels of peat smoke can be passed through the bed during kilning in order to impart a lightly or heavily peated flavor, as demanded by distillers.

Grain distillers are primarily concerned with the levels of starch-degrading enzymes in their malt. The malt enzymes must degrade both the malt starch and the adjunct starch into fermentable sugars with, once again, no need for unfermentable dextrins. As with adjunct brewing, grain distiller's malt must have high levels of amino acids in order to support yeast growth. Maltsters meet these specifications by starting with a thinner, higher-protein barley. The barley is well modified and then killed at low temperatures to conserve enzyme activity. Grain distiller's malt is sometimes referred to as 'diastatic malt' because of extremely high levels of starch degrading enzymes (i.e., diastatic power). Diastatic malts are also used in brewing and in food applications when high levels of enzyme activity are required.

Vinegar processors require malt of a quality similar to that demanded by distillers. Processors that use all-malt mashes require a malt with high levels of both enzymes and starches, a profile similar to that demanded by malt distillers. In contrast, vinegar processors that use adjuncts require a malt with high enzyme levels and an adequate supply of amino acids, a quality profile similar to that of grain distillers. Vinegar processors are not interested in the presence of dextrins or the development of flavor and color in their malts.

Malt Extracts and Syrups

Malts are often processed into extracts or syrups in order to facilitate further processing. Extracts are

made by following the first few steps of brewing. A malt is mashed in order to complete the solubilization and conversion of starch into fermentable sugars as well as solubilization of protein. The resulting extract is separated from the spent grains and concentrated through evaporation under vacuum. Extracts destined for brewpubs, brew-on-premise, or home brewing are often supplemented with hops prior to concentration.

Syrups are produced in a manner similar to extracts except that adjuncts replace some of the malt primarily to reduce costs. The quality of syrups differs from that of extracts in that reducing sugars are increased, whereas soluble protein levels are lower, resulting in a lighter color and a distinctly mellower and sweeter flavor. Final levels of enzymes, flavors, and colors, in both extracts and syrups, can be altered by starting with different malts, by changing the mashing conditions or by changing the conditions used for concentrating the extracts and syrups.

Dry extracts and syrups can be formed by spray drying the liquid extracts and syrups. The color, flavor, and sweetness are preserved, but the heat inactivates the enzymes. Dry diastatic malts with a high enzyme activity, therefore, are produced by mixing milled malt with wheat flour. The final product contains enzymes from the malt and potential extract from the wheat but has a limited ability to produce color or flavor.

Malts for Food Products

Food industries require an array of malt types with different levels of flavor, color, and enzymes. They depend on brewing type malts that have been custom-made to meet their specifications. Extracts, syrups, and their dried products are often used, provided they have appropriate specifications, by the food industry as they can simplify processing.

Chemistry of Malting

M S Izydorczyk and M J Edney, Canadian Grain Commission, Winnipeg, Manitoba, Canada

History

Beer, one of the most popular alcoholic beverages, is made from four basic ingredients: malted grain, hops, yeast (*Saccharomyces* spp.), and water. There is evidence that as long as 4000 years ago, the Egyptians and Mesopotamians enjoyed malted barley drinks that were the predecessors of our modern beer. Malt is a natural product of a process, called malting, whereby the grain is allowed to germinate under controlled conditions of moisture, temperature, and air. Early malsters copied the natural process of germination by steeping the grain in containers and then spreading it out in a thin layer across a floor. Once germination was completed, the 'green malt' was dried over open fire. The early maltsters were true craftsman passing down the skills of malting by word of mouth from generation to generation. Nowadays, malting is a large-scale commercial process yielding

value-added, modified grain product used primarily for the production of beer and distilled products such as whiskey, and, to a lesser extent, as an ingredient in certain food stuffs. Although many cereals have been processed into malt, barley (*Hordeum vulgare*) is considered the best malting grain, so the chemical processes described below are those occurring in barley grain during malting.

Technologically, malting is divided into three stages: steeping, germination, and kilning. However, the complex biochemical and chemical reactions occurring during malting are interrelated and often not confined to one stage of malting. Those reactions involve both major and minor constituents of barley grain, which are interconverted under the influence of various enzymes synthesized and/or activated during malting. The main purpose of malting, from a technological point of view, is to render the barley kernel more soluble in hot water and susceptible to fermentation by yeast. Extensive changes that occur in the grain during malting include complete destruction of the endosperm cell walls, breakdown of the protein matrix, controlled solubilization of barley proteins, and formation of hydrolytic enzymes, which carry out degradation of starch granules at subsequent stages of the brewing process. (*See* **Beers**: History and Types.)

Composition of Barley Grain

The husk and pericarp, the two most outer and protective tissues of the barley grain, consist primarily of hollocellulose, hemicellulose, lignin, and lignans (Figure 1). The testa and the nucellar cuticle, the pigment strand, and the micropylar structures make up the semipermeable system that divides the interior from the exterior of the grain and limits the ingress of water and dissolved substances. The husk and pericarp are not extensively altered during malting, but they do play a role in the process by limiting the rate of infusion of oxygen and water in respiring grain. Moreover, the husk protects the acrospire and the entire grain against physical damage. The husk also has major effects on the character, flavor, and stability of beer. Removal of husk from the grain leads to a blander and more insipid beer, whereas grain enriched in husk produces astringent beers with a tendency to form a haze.

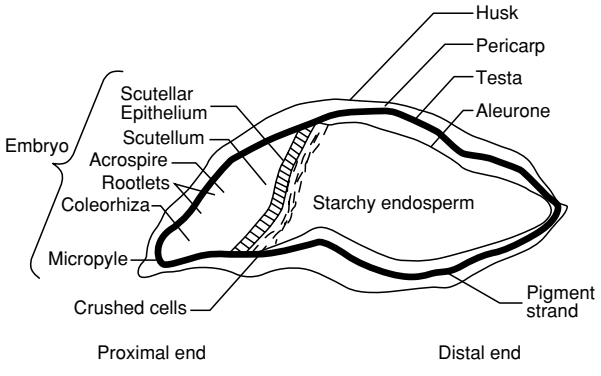

Figure 1 Longitudinal section of a mature barley grain showing component tissues.

The grain embryo contains little starch but is rich in protein (34%), lipids (14–17%), and ash (5–10%) and extremely rich in sugars (sucrose 5–10%; raffinose, 5–10%; fructans). During germination, the embryo synthesizes and releases gibberellin hormones and a complex mixture of hydrolytic enzymes, which are involved in mobilizing the reserves in the grain and supporting the embryo's metabolism and growth.

The rest of the mature grain consists of nucellar material, aleurone and endosperm. The thick walls of the aleurone layer (3–5 μm) contain mainly arabinoxylans (67–71%) and smaller amounts of β-glucan (26%). The tissue contains three layers of cells and no starch but abounds in proteins (17–20%), triacyl glycerol (20%), minerals, phytin, and sugars (including sucrose, raffinose, stachyose, verbascose, and fructans). Aleurone cells have bodies called aleurone grains. These consist of globoids, which contain phytin, and crystalloids, which contain protein and polysaccharides. The cells of the aleurone layer, like those of the embryo, are living. In hydrated grain, they are capable of synthesizing and secreting a variety of enzymes needed for breakdown of the reserves stored in the starchy endosperm.

The starchy endosperm makes up about 75% of the barley grain and is the major reserve tissue. Starch, confined to small and large granules, constitutes about 80% of the endosperm. In addition, the starchy endosperm contains a relatively large amount of proteins ($\sim$9% of the tissue) and smaller amounts of lipids, minerals, and nucleic acids. The cell walls (2 μm) are mainly built up from mixed linkage β-(1 $\rightarrow$ 3, 1 $\rightarrow$ 4)-glucans (70%), arabinoxylans (20%), and small amounts of proteins, β-(1 $\rightarrow$ 3) glucans and other polysaccharides containing galactose, mannose, and uronic acids. In mature grain, the cells of the starchy endosperm are nonliving and function solely as reserves of carbohydrates, proteins, lipids, and nucleic acids awaiting dissolution during germination. (*See* **Barley**.)

Regulation of the Germination Process

Barley germination commences at relatively low levels of grain moisture, but rapid and uniform germination for malting purposes requires a grain

moisture content of 40–45%. Most of the water that penetrates the barley kernel does so near the embryo, probably through the micropylar region. The biochemical processes of germination also require oxygen. The entry of oxygen into the interior of the grain is hindered by the diffusion barriers of the husk and pericarp, and by the water film on the surface of the grain. The proper hydration and oxygen uptake of barley grain for malting purposes are accomplished by multiple submersions in water alternated with air rest during steeping, the first stage of the malting process.

At the onset of germination, the embryo uses its internal reserves of sugar, lipids, proteins, and minerals to initiate development of roots and a shoot. A mixture of hydrolytic enzymes is released from the scutellar epithelium into the endosperm. The gibberellins, a family of plant hormones, are formed in the germinating embryo and migrate to the aleurone layer, where they trigger enzyme production and/or enzyme release.

The mechanisms by which gibberellins trigger the responses of aleurone layers are not fully understood, but there is some evidence for gibberellin receptors on the surface of protoplasts prepared from the aleurone layer. Exactly which gibberellins are present in malting barley also remains unclear. The main gibberellin appears to be GA_1, with smaller amounts of gibberellic acid GA_3 also present (Figure 2). The production and release of gibberellins seem to be affected by the concentration of sugars in the embryo. The process probably involves a feedback control loop, i.e., sugar depletion in scutellum → gibberellin formation and release → gibberellin-triggered enzyme synthesis and release from aleurone layer → endosperm breakdown and sugar release → sugar diffusion into scutellum → increased sugar level in embryo → cessation of gibberellin formation and release. There is no clear evidence that, in germinating barley, other nongibberellin hormones influence the formation of hydrolytic enzymes. However, some hormones such as indolacetic acid, cytokinins, abscisic acid, and ethylene, when added to isolated aleurone, influence the response of the tissue. Abscisic acid, in particular, is a potent inhibitor of gibberellin-induced enzymes synthesis in aleurone cells.

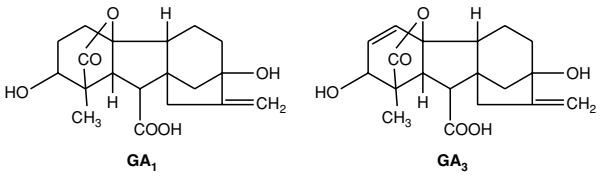

Figure 2 Chemical structure of gibberellins GA_1 and GA_3.

The scutellar epithelium also plays a role in producing hydrolytic enzymes. It has been suggested that the mixture of enzymes released from the scutellar epithelium differs from that produced by the aleurone layer. Embryos do not need an external supply of gibberellins to produce enzymes, but when supplied with amino acids, their productivity increases. It is agreed that some isoenzymes, e.g., carboxypeptidase I, (1 → 3, 1 → 4)-β-glucanase I, and some α-amylases, are generated in the scutellum. Biochemical studies now suggest that the scutellum accounts for approximately 1–10% of α-amylase production; the remaining α-amylase is produced by the aleurone layer.

The enzymes released by 'triggered aleurone' layers include α-amylase, (1 → 3, 1 → 4)-β-glucanase, (1 → 3)-β-glucanase, proteases, peroxidase, and enzymes able to cleave DNA, RNA, various disaccharides, glycosides, phosphates, and peptides.

Although aleurone responses are primarily triggered by gibberellins, it is also possible that other substances act as modulators in this process. It has been shown that tannins can act as gibberellin antagonists. Also, high concentration of sugars and other compounds, which create a high osmotic pressure, reduce enzymes formation by the aleurone layer. However, calcium ions promote the secretion of α-amylase as well as the formation of β-glucanase.

Chemical Reactions During Malting

The migration of hydrolytic enzymes, actively secreted from the aleurone and the scutellar epithelium into the starchy endosperm, where they depolymerize cell walls, storage proteins, starch, and residual nucleic acids, is brought about by a rather slow water-assisted diffusion process. Endosperm dissolution begins in the region immediately adjacent to the scutellum and progresses toward the distal end of the grain. Before they can reach their substrates in the starchy endosperm, the migrating enzymes must first overcome two physical barriers: the walls of the secretory cells themselves and the walls of starchy endosperm cells.

Degradation of Cell-wall Polymers

β-Glucans The β-glucans are linear polymers composed of D-glucopyranosyl residues (Glc*p*) linked via a mixture of β-(1 → 3) (~30%) and β-(1 → 4) (~70%) linkages. The linkage arrangement is not completely irregular; consecutive blocks of β-(1 → 4) linkages, mostly two or three, but occasionally up to 20, are separated at random by single β-(1 → 3) linkage (Figure 3). The β-glucans are high-molecular-weight polymers only partially soluble in water. As no evidence for covalent cross-linking has been found,

it seems likely that less soluble β-glucans are physically entrapped with insoluble proteins, arabinoxylans, or cellulose.

The breakdown of partially soluble β-glucans may have to be initiated by the release and solubilization of these polymers from the cell walls. Enzymes, such as carboxypeptidase, protease, phospholipase, cellulase, and/or esterase may be involved in these initiating processes. The actual depolymerization of β-glucan occurs by the action of two major hydrolyzing enzymes, endo-(1 → 3, 1 → 4)-β-glucanases (isoenzymes EI and EII; EC 3.2.1.73), which are developed in almost equal proportions in germinating barley (Table 1). The enzymes catalyze the hydrolysis of β-(1 → 4) linkages within the polymeric chains.

Table 1 Properties of barley endo-β-glucanases[a]

Property	*Isoenzyme EI*	*Isoenzyme EII*
Amino acids	306	306
Apparent molecular weight (SDS-PAGE)	30 000	32 000
Isoelectric point	8.5	10.6
pH optimum	4.7	4.7
Carbohydrate content (%)	Trace	~4
Thermal stability	Low	Greater
Secretion site	Scutellum, aleurone	Aleurone

[a]Data compiled from Fincher GB (1992) Cell wall metabolism in barley. In: Shewry PR (ed.) *Barley: Genetics, Biochemistry, Molecular Biology and Biotechnology*, pp. 413–437. Wallingford, UK: CAB International; and Fincher GB and Stone BA (1993) Physiology and biochemistry of germination in barley. In: MacGregor AW and Bhatty RS (eds) *Barley Chemistry and Technology*, pp. 247–295. St. Paul, MN: American Association of Cereal Chemists.

These require adjacent β-(1 → 3)- and β-(1 → 4)-linked glucose residues next to the β-(1 → 4) linkage being hydrolysed (Figure 3).

The endo-β-glucanases produce mainly tri- and tetrasaccharides, which may be further degraded to glucose by exo-β-glucanase (EC 3.2.1.74). Three exo-β-glucanases of molecular weight 67 000–70 000 have been purified from grain and shown to hydrolyze both the β-glucans and the oligosaccharides released by the action of endo-(1 → 3, 1 → 4)-β-glucanases to glucose.

During malting, the total amount of β-glucans declines considerably; the content of β-glucans in barley may vary from 3 to 6%, and after malting, it should range from 0.2 to 1%. High levels of β-glucans in malt reflect incomplete cell-wall degradation, affect the yield of malt extract, and produce viscous extracts, causing filtration difficulties in the brewery and contributing to formation of hazes and precipitates in beer.

Arabinoxylans Arabinoxylans are side-chain branched heteroglycans built from pentose sugars, arabinose and xylose. They consist of a linear xylan backbone of β-(1 → 4)-linked D-xylopyranosyl residues (Xyl*p*) to which α-L-arabinofuranosyl units (Ara*f*) are attached mostly as single substituents (Figure 4). Some arabinose side-chains carry esterified residues of ferulic acid. As a consequence, arabinoxylan chains in cell walls may be cross-linked with each other via ferulic acid bridges and/or cross-linked with other cell-wall polymers via ether or ester linkages.

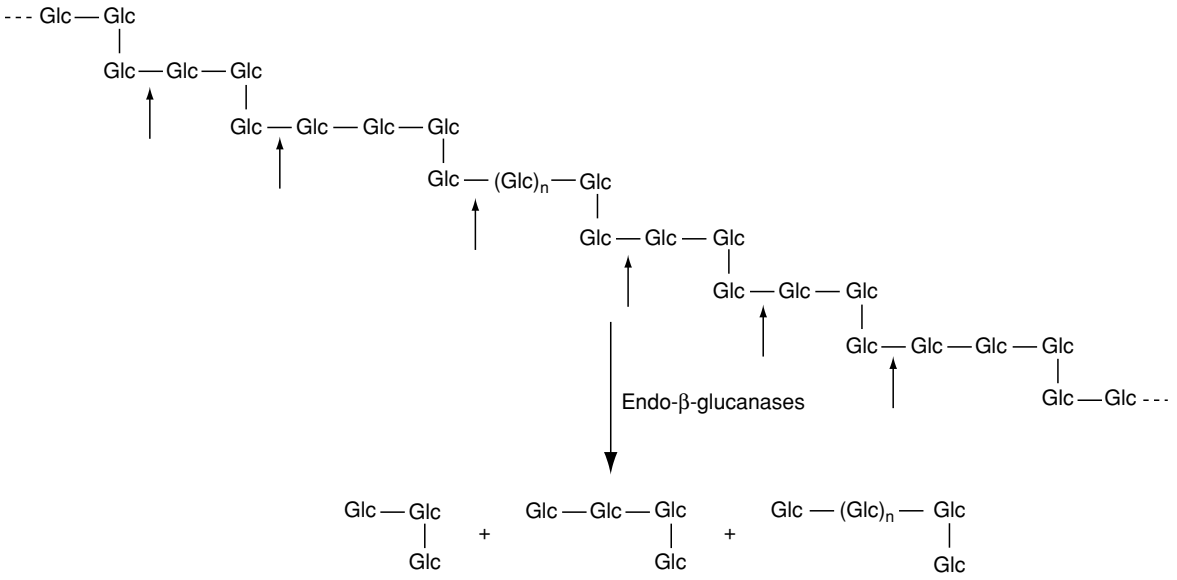

Figure 3 Generalized structure of barley β-glucans. Glc, D-glucopyranose residue; — and |, β-(1→4) and β-(1→3) linkages, respectively, between the glucose residues; n = 1–20; ↑, sites of hydrolysis by endo-β-glucanase.

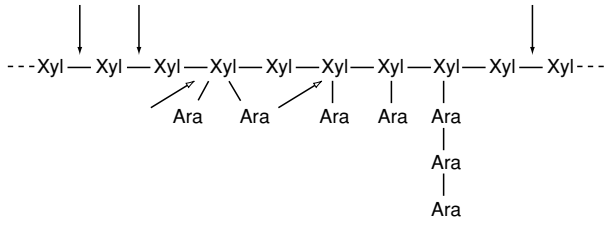

Figure 4 Generalized structure of barley arabinoxylans. Xyl, β-D-xylopyranose residues; Ara, α-L-arabinofuranose residues; ↓ and ↗, sites of hydrolysis by β-xylanase and α-arabinofuranosidase, respectively.

The routes for hydrolytic breakdown of barley arabinoxylans are less known. Their depolymerization to constituent monosaccharides is mediated by the combined action of endo-(1 → 4)-β-xylanases (EC 3.2.1.8), β-xylopyranosidase (EC 3.2.1.37), and α-L-arabinofuranosidase (EC 3.2.1.55). The amount of all these enzymes increases during malting. It is believed that, initially, α-L-arabinofuranosidase catalyzes the removal of arabinose residues from arabinoxylan chains or arabinoxylan oligosaccharides. When a sufficient number of arabinose substituents have been removed, the xylan chain is hydrolyzed by (1 → 4)-β-xylanases to smaller oligosaccharides. Three endoxylanase isozymes have been isolated from barley grain, but their hydrolytic actions have not been fully investigated. β-Xylopyranosidase catalyzes the hydrolysis of xylobiose to xylose and possibly removes the unsubstituted xylose residues from the end of xylan chains. As free pentose sugars do not accumulate in malting grain, they must be rapidly utilized by the living tissues. While β-glucans are degraded extensively during malting, arabinoxylans are not; the majority of barley arabinoxylans remain present in malt. (*See* **Carbohydrates**: Classification and Properties.)

Starch Degradation

The insoluble starch granules stored in the starchy endosperm cells contain two polymers: amylose (20–30%) and amylopectin (70–80%). Although built up from the same glucopyranose units, these polymers differ in the type of glycosidic linkages and require different enzymes for their degradation. Amylose consists predominantly of linear chains of about 2000–5000 of α-(1 → 4) linked D-glucopyranosyl residues. In granules, amylose may be associated strongly with lipids, and the resulting amylose–lipid complexes may be less susceptible to enzymic degradation. Amylopectin consists of very-high-molecular-weight molecules, estimated to be 10^6–10^8 Da. It differs from amylose in that its α-(1 → 4)-linked chains of glucose are highly branched through α-(1 → 6) linkages, and therefore, amylopectin is characterized by an extensively branched structure.

During malting, starch is only partially degraded (15–18%), and the composition of the residual starch may be slightly altered. The amylose content may increase slightly, and the molecular weight of both polymers is decreased. There is some evidence that small starch granules are more susceptible to degradation than the large starch granules. Also, close to the embryo, starch granules are almost completely degraded, whereas those further away show evidence of limited enzymic attack in the form of either roughened surfaces or 'pinholes' (Figure 5). Most important, all enzymes necessary for total degradation of starch, which occurs at subsequent stages of brewing, are synthesized and/or activated during malting. In the germinating grain, a considerable number of enzymes are involved in the degradation of starch.

α-Amylases The α-amylases are able to hydrolyze intact starch granules with the formation of soluble products. They are responsible for the initial degradation of starch granules during malting. α-Amylases (EC 3.2.1.1) are endoenzymes that cleave internal α-(1 → 4) glucosyl linkages of amylose and amylopectin

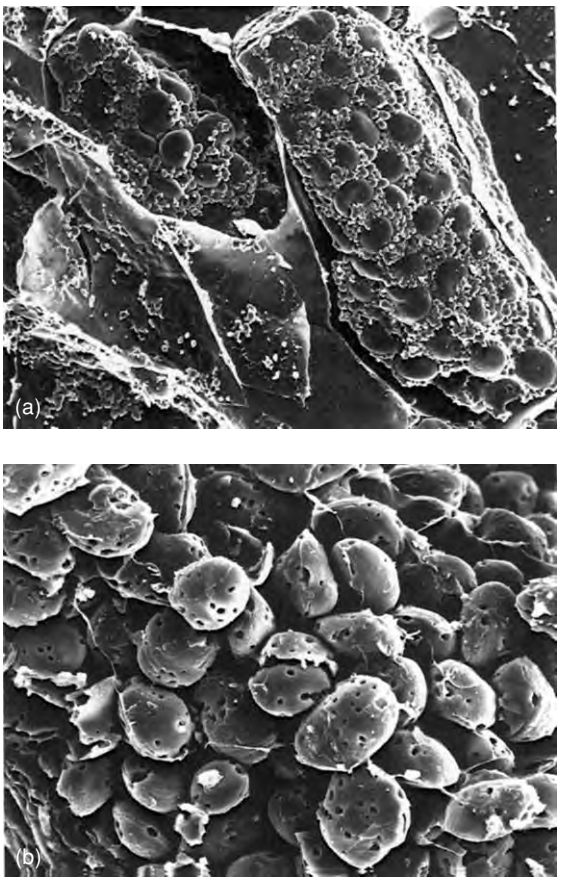

Figure 5 Scanning electron micrograph of the starchy endosperm showing the large and small starch granules (a) before and (b) after germination.

in a random fashion. They are unable to hydrolyze the α-(1 → 6) glucosyl linkages at the branch points in amylopectin. Their hydrolytic action is slower on short chains, and they vary in their ability to hydrolyze the α-(1 → 4) linkages in close proximity to the branch points. α-Amylases, acting on their own, are able to degrade amylose to a mixture of shorter linear α-glucan chains (linear α-dextrins), oligosaccharides, maltose, and glucose. Amylopectin, however, is degraded to a lesser extent, yielding a mixture of still large branched fragments (branched α-dextrins) as well as some linear oligosaccharides, maltose and glucose (Figure 6). Two isoenzymes of α-amylases with the same apparent substrate specificities and action patterns, but different properties, are synthesized in germinating barley (Table 2).

Table 2 Properties of α-amylase I and II from germinating barley[a]

Property	*α-Amylase I*	*α-Amylase II*
Molecular weight	45 342	45 005
Isoelectric point	4.8–5.3	5.9–6.6
pH optimum	3.0–5.5	5.0–5.4
Stability at pH 3.6	Relatively stable	Unstable
Reaction with endogenous inhibitor[b]	No inhibition	Strong inhibition
Ca^{2+} binding	Very strong	Strong
Major secretion site	Aleurone	Aleurone
Proportion in germinating grain	Minor (up to 10%)	Major (up to 90%)

[b]Barley α-amylase/subtilisin inhibitor.

β-Amylases The β-Amylases (EC 3.2.1.2) are exoenzymes that cleave the penultimate α-(1 → 4) linkage from the nonreducing end of the polymeric chains and release the disaccharide maltose. β-Amylase, acting alone, can degrade amylose completely to maltose. This enzyme will not, however, attack the α-(1 → 6) linkages or α-(1 → 4) linkages close to the α-(1 → 6) links; therefore, it degrades only the outer chains of amylopectin and leaves a large portion (called β-limit dextrins), in which the outer chains have been degraded to stubs of two or three glucose residues adjacent to the α-(1 → 6) linkages (Figure 6). β-Amylase is not synthesized during germination. In barley, virtually all β-amylases occur in the starchy endosperm. The four major isoenzymes occur in free or protein-bound forms. During malting, the level of free β-amylase may initially fall but subsequently increases, as nearly all enzymes are liberated by the action of proteolytic enzymes.

Limit dextrinase Limit dextrinase (EC 3.2.1.10) is a debranching enzyme that hydrolyzes specifically α-(1 → 6) linkages in amylopectin or in branched dextrins derived by the actions of α- or β-amylases (Figure 6). The hydrolytic action of this enzyme results in the formation of linear α-(1 → 4)-linked chains that can be extensively depolymerized to glucose and maltose by the combined actions of α- and β-amylases. The limit dextrinase in germinating barley hydrolyzes the α-(1 → 6) linkages of branched dextrins faster than those in large amylopectin molecules. Mature barley contains low levels of the enzyme but during germination, the activity of the enzyme increases due to *de novo* synthesis in the aleurone. However, barley contains a heat-stable protein that inhibits the enzyme. This inhibitor decreases in amount during malting, but there is a sufficient amount left in malt to inhibit most of the limit

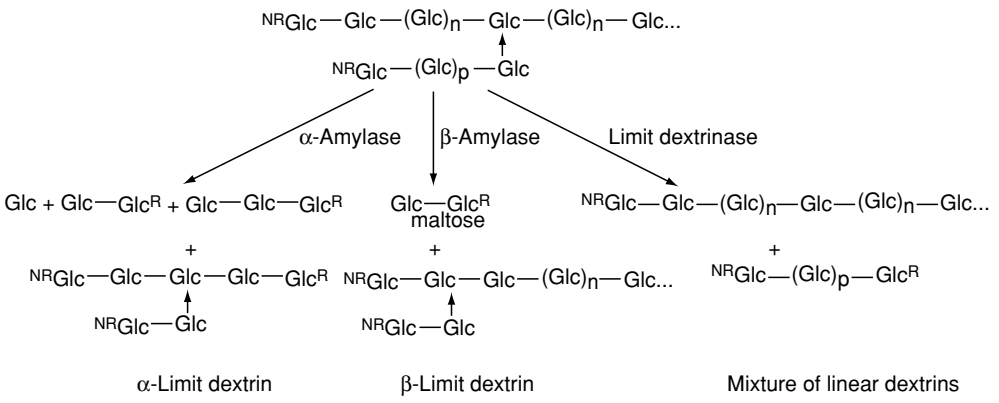

Figure 6 Summary of the modes of action of some enzymes important in degradation of starch polymers. Glc, D-glucopyranose residue; —, α-(1 → 4)-link; ↑, α-(1 → 6)-link; NR, nonreducing end; R, reducing end.

dextrinase. Although purified limit dextrinase has no action on starch granules, it enhances the rate of granule dissolution when combined with the actions of α- or β-amylases.

α-Glucosidase α-Glucosidase (EC 3.2.1.20) releases glucose residues from the nonreducing end of a variety of α-glucosides and, therefore, participates in the final conversion of maltose and other small dextrins to glucose. After germination is initiated, rapid synthesis of two or more isoenzymes of α-glucosidase is observed in both the aleurone layer and the embryo. (*See* **Starch**: Functional Properties.)

Chemical Changes in Proteins During Malting

Proteins account for about 8–15% of the dry weight of the mature barley grain. Albumins and globulins – the water- and salt-soluble proteins, respectively – function as enzymes, metabolic regulators, structural or storage proteins, or inhibitors of particular enzymes. Hordeins are insoluble in salt solution but dissolve in warm aqueous alcohol, whereas the residual insoluble material constitutes the fourth group of barley protein, glutelin. Hordeins belong to the group of cereal proteins known as prolamines because of their high proline and glutamine content. They are the major storage proteins of barley. The glutelin fraction contains storage and structural proteins. The quantities and relative amounts of the fractions change substantially during malting. Following hydration, the protein reserves in the scutellum and aleurone layer are degraded, and at least some of the liberated amino acids are used to synthesize hydrolytic enzymes, which are released into the starchy endosperm. The level of hydrolytic enzymes increases during malting and declines during kilning. The endogenous inhibitors of many enzymes decline during malting. Reserve proteins in the endosperm are substantially degraded to soluble peptides and amino acids by the action of many proteolytic enzymes. The simple peptides, amides, and amino acids diffuse to the embryo, where they may be completely degraded, interconverted, and utilized by the growing embryo to form new proteins in the growing rootlets and acrospire. In a well-modified malt, 40–45% of the total protein is water-soluble.

Degradation of proteins in germinating barley is accomplished by a range of proteolytic enzymes, including endopeptidases (proteases) and exopeptidases (Figure 7). Four groups of endopeptidases (EC 3.4.21), cysteine, serine, aspartic, and metalloproteases, are produced by germinating barley. The cysteine proteases are dominant, accounting for up to 90% of the total protease activity. The endopeptidases can attack proteins and large polypeptides, hydrolyzing peptide bonds from the interior of the chain and thus rapidly diminishing the molecular weight of proteins. During germination, protease activity in the starchy endosperm increases several-fold.

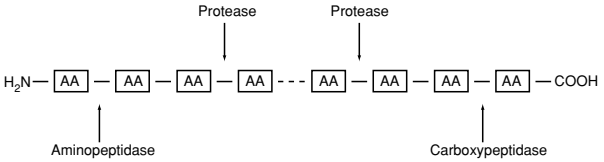

Figure 7 Summary of the modes of action of some enzymes important in degradation of proteins during malting.

Exopeptidases release one amino acid at a time from either the carboxyl or the amino end of the peptide chain. Five carboxypeptidases (EC 3.4.16.1) have been identified in germinating barley. Each enzyme attacks peptides exclusively from the COOH-termini of the chain and has a distinct preference for particular amino acids. However, their specificities are complementary, and together, they effect an extensive degradation of barley proteins. In addition to carboxypeptidase, several other exopeptidases, including four neutral aminopeptidases, leucine aminopeptidase, and dipeptidase, have been identified in germinating barley. The aminopeptidase and dipeptidase are active mainly in the scutellum and are involved in the absorption of amino acids by the growing embryo. The carboxypeptidases, however, are found both in the starchy endosperm and in the scutellum, and can release amino acids from hordeins as well as from smaller peptides. They might also be involved in the solubilization of β-glucans during the early stages of germination.

Chemical Changes in Other Grain Reserves

The total lipid content of barley may vary from 2 to 4.4%. Barley lipids comprise 67–78% of nonpolar lipids (mostly triacylglycerides (TG), some steryl esters and free fatty acids (FFF)), 8–13% of glycolipids, and 14–21% of phospholipids. Lipids associated with starch granules are almost exclusively lysophospholipids and free fatty acids. It is generally accepted that during germination, storage lipids are used as a source of metabolic energy and fatty acids for synthesis of new membrane and structural lipids. The overall decrease of total lipids by 10–50% may occur during malting, but the changes in the composition of lipid classes are minor and/or not clearly elucidated. The lipolytic activities in germinating barley increase. Enzymes such as lipases and phospholipases act in concert with lipoxygenase. When the barley tissue is stimulated by gibberellins, the aleurone bound lipase (EC 3.1.1.3) is activated and responsible for hydrolyzing the ester bonds in TG

and for releasing long fatty acids. Several different phospholipases (EC 3.1.1.32) are responsible for hydrolyzing four different ester bonds in phospholipids. The polyunsaturated fatty acids released from TG and phospholipids are preferentially oxidized by lipoxygenase. Lipoxygenase (EC 1.13.11.12) utilizes atmospheric oxygen to oxidize the *cis*-1, *cis*-4-pentadiene part of (n-6) and (n-3) polyunsaturated fatty acids (linoleate and linolenate) to hydroperoxides and hydroperoxyradicals. Lipoxygenase from germinating barley is more active toward methyl linoleate and trilinolein. It is thought that during steeping, the activity of lipoxygenase decreases and remains low during germination but rises sharply in the middle of kilning only to decrease again to a very low level at the end of kilning.

Inorganic materials also undergo significant changes in barley during malting. Best elucidated have been the changes pertaining to phosphates. The majority of the free phosphate raise occurring during malting originates from degradation of aleurone phytins, potassium and magnesium salts of phytic acid (*myo*-inositol haxaphosphate), by the action of phosphatase (EC 3.1.3.26), the enzyme able to hydrolyze phytic acid. In addition, phosphate is released from phospholipids, DNA, and RNA by appropriate hydrolytic enzymes.

Among the numerous and complex phenolic compounds that have been identified in barley, the most extensively studied have been phenolic acids, flavanols (such as (+)-catechin and gallocatechin), pigments, and condensed tannins derived from catechin. Phenol compounds are important in the brewing process because of their antioxidant properties, their astringency, and their tendency to form hazes in beer. Maltsters sometimes manipulate their content in malt by application of alkaline steeping, which removes a portion of phenolics from the grain. Various oxidase (EC 1.14.18.1) and peroxidase (EC 1.11.1.7) enzymes are able to act on phenolic substances, but little is known about their action during malting. Green malt probably contains oxidases that catalyze the oxidative polymerization of polyphenols to tannins.

Chemical Aspects of Kilning

When the desired enzyme levels and endosperm modification have been achieved, the germination is terminated through kilning, a process in which dry air of increasing temperature is passed through the green malt to produce a dry and friable grain product. Kilning eventually arrests all biochemical reactions, although appropriate manipulations of time, temperature, and air flow parameters allow survival of many hydrolytic enzymes needed in the later stages of the brewing process. Kilning also facilitates formation of a myriad of color, flavor, and aroma compounds that make malt such a unique product. Responsible for these phenomena are primarily the complex Maillard reactions. The malt reducing sugars and amino compounds (amino acids and compounds containing free amino groups), when exposed to higher temperatures, react with each other to form N-substituted glycosylamine, which undergoes a further reaction called the Amadori rearrangement to 1-amino-1-deoxy-2-ketose (Figure 8). Chemical reactions continue taking several possible routes. Enolization of 1-amino-1-deoxy-2-ketose leads to the formation of furfurals and hydroxymethylfurfurals, which polymerize quickly to melanoidins,

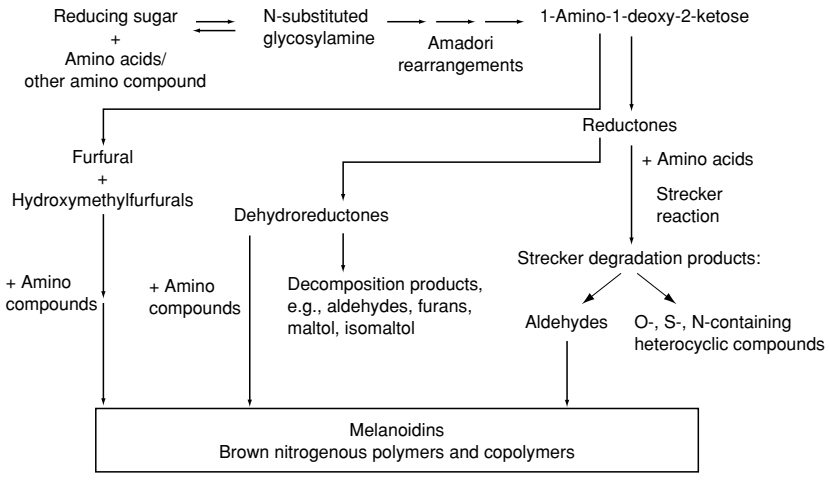

Figure 8 Simplified scheme of chemical reactions involved in the formation of flavor and color during the Maillard reactions. Information compiled from Briggs DE (1998) *Malts and Malting*. Figure 9 Formation of dimethyl sulphide during kilning.

dark-colored insoluble material containing nitrogen. Enolization may also lead to the formation of reductones, which, upon decomposition, yield some flavor compounds such as maltol, isomaltol, acetyl furan, and various aldehydes. Degradation of amino acids in the presence of reductones (the Strecker degradation) leads eventually to the formation of the major aroma compounds, the heterocyclic pyrrole, pyridine, pyrazine, thiazole, and oxazole.

In addition to the Maillard processes, several other reactions occurring during kilning may be responsible for the color and flavor of malt. The polyunsaturated fatty acids may be partially oxidized, via reactions catalyzed by lipoxygenase, to various volatile and nonvolatile aldehydes, alcohols, lactones, and acids, responsible for usually undesirable odors. Polyphenols may be converted to colored phlobaphenes. In specialty malts, still other chemical processes may be required. For instance, the caramelization reactions occurring when malts are kilned at very high temperatures result in the dark color and unique flavors of some food malts. The characteristic flavor and aroma of some lager-type beers are attributed to a high content of dimethyl sulfide (DMS) formed during careful kilning of malts rich in nitrogen; DMS is a degradation product of the sulfonium compound *S*-methylmethionine (Figure 9).

MANGANESE

C L Keen and S Zidenberg-Cherr, University of California, Davis, CA, USA

Background

The essentiality of manganese was established in 1931 when it was demonstrated that a deficit of it resulted in poor growth and impaired reproduction in rodents. It has long been appreciated that a deficiency of manganese can be a practical problem in the pig and poultry industry, and it has been suggested that manganese deficiency may be a problem in some human populations. Here, the recent literature related to manganese nutrition, metabolism, and metabolic function is briefly reviewed. For additional information, the reader is referred to more comprehensive reviews in the bibliography.

Chemical and Physical Properties

Manganese is widely distributed in the biosphere; it constitutes approximately 0.1% of the earth's crust making it the twelfth most abundant element. Manganese is a component of numerous complex minerals including pyroluosite, rhodochrosite, rhodanite, braunite, pyrochroite, and manganite. Chemical forms of manganese in their natural deposits include oxides, sulfides, carbonates, and silicates. Concentrations of manganese in groundwater normally range between 1 and 100 $\mu g\,l^{-1}$, with most values being below 10 $\mu g\,l^{-1}$. Typical airborne levels of manganese (in the absence of excessive pollution) range from 0.05 to 0.10 $\mu g\,m^{-3}$.

Manganese is a transition element located in column 7a on the periodic table. It can exist in 11 oxidation states, ranging from -3 to $+7$, with the most common valences being $+2$, $+4$, and $+7$. The $+2$ valence is the predominant form in biological systems and is the form that is thought to be maximally absorbed. The $+4$ valence occurs in MnO_2, and the $+7$ valence is found in permanganate.

The solution chemistry of manganese is relatively simple. The aquo-ion is resistant to oxidation in acidic or neutral solutions. It does not begin to hydrolyze until pH 10, and therefore, free Mn^{2+} can be present in neutral solutions at relatively high concentrations. Divalent manganese is a d^5 ion and typically forms high-spin complexes lacking crystal field stabilization energies. The above properties as well as the large ionic radius and small charge-to-radius ratio result in manganese tending to form weak complexes compared to other first-row divalent ions such as Ni^{2+} and Cu^{2+}. Free Mn^{2+} has a strong isotropic EPR signal that can be used to determine its concentration in the low micromolar range. Mn^{3+} is also critical in biological systems. For example, Mn^{3+} is the oxidative state of manganese in superoxide dismutase, is the form in which transferrin binds manganese, and is probably the form of manganese that interacts with Fe^{3+}. Given its smaller ionic radius, the chelation of Mn^{3+} in biological systems would be predicted to be more avid than that of Mn^{2+}. Cycling between Mn^{3+} and Mn^{2+} has been suggested to be potentially deleterious to biological systems since it can generate free radicals.

Occurrence and Speciation in Foods

Manganese concentrations in typical food products range from 0.4 $\mu g\,g^{-1}$ (meat, poultry, fish) to 20 $\mu g\,g^{-1}$ (nuts, cereals, dried fruit). Teas, which are often listed as an excellent source of manganese, can contain anywhere from 300 to 900 $\mu g\,g^{-1}$ of the element. An important consideration with respect to food sources of manganese, however, is the extent to which the manganese is available for absorption. For example, while tea contains high amounts of the element, the high content of tannin found in tea binds manganese and prevents its absorption from the gastrointestinal tract. Similarly, while the concentration of manganese in cereal grains is significant, the high content of phytates and fiber constituents may bind manganese, limiting its absorption. Thus, while a calculation of intake based on nutrient composition of foods may show that manganese intake is high, the actual amount of manganese absorbed will vary among food sources. Similarly, although meat products contain low concentrations of manganese, absorption and retention of manganese from them are high, making them good sources of the element in the diet. (*See* **Bioavailability of Nutrients**; **Cereals**: Dietary Importance; **Meat**: Nutritional Value; **Tea**: Chemistry.)

Analysis

Although manganese is widely distributed in the biosphere, it occurs in only trace amounts in animal tissues. Tissue concentrations of 4–8 μM are considered high, while serum concentrations can be

as low as 5 nM. Owing to the high environmental levels of manganese relative to its concentration in animal tissues, considerable effort must be made to minimize contamination of samples during their collection and handling. As a general precaution, all glassware and plasticware used in the storage or processing of samples should be washed in 20% nitric acid for at least 48 h and then rinsed exhaustively with distilled double-deionized water. Washed glassware and plasticware should be stored under dust-free conditions prior to use. To reduce contamination, tissues containing very low manganese concentrations should be dissected with plastic or quartz knives rather than steel knives.

The most common analytical methods that can sensitively measure manganese (18 nmol l^{-1}) include neutron-activation analysis, X-ray fluorescence, proton-induced X-ray emission, inductively coupled plasma emission, electron paramagnetic resonance (EPR), and flameless atomic-absorption spectrophotometry (AAS). Currently, the most common method employed is flameless AAS. All of these methods, with the exception of EPR, measure the total concentration of manganese in the samples. EPR allows selective measurement of bound vs free manganese.

Physiological Role

Tissue Concentrations

The average human body contains between 200 and 400 μmol of manganese, which is fairly uniform in distribution throughout the body. There is relatively little variation among species with regard to tissue manganese concentrations. Manganese tends to be highest in tissues rich in mitochondria; its concentration in mitochondria is higher than in cytoplasm or other cell organelles. Hair can accumulate high concentrations of manganese, and it has been suggested that hair manganese concentrations may reflect manganese status. High concentrations of manganese are normally found in pigmented structures, such as retina, dark skin, and melanin granules. Bone, liver, pancreas, and kidney tend to have higher concentrations of manganese (20–50 nmol g^{-1}) than do other tissues. Concentrations of manganese in brain, heart, lung, and muscle are typically < 20 nmol g^{-1}; blood and serum concentrations are about 200 and 20 nmol l^{-1}, respectively. Typical milk concentrations are in the order of 1 μmol l^{-1}. Bone can account for up to 25% of total body manganese because of its mass. Bone manganese concentrations can be raised or lowered by substantially varying dietary manganese intake, but bone manganese is not thought to be a readily mobilizable pool. In contrast to the situation for several other essential trace elements, the fetus does not accumulate liver manganese before birth, and fetal concentrations are significantly less than adult concentrations. This lack of fetal storage can be attributed to the apparent lack of storage proteins and the fact that most manganese enzymes are not expressed prenatally.

Absorption and Transport

Absorption of manganese is thought to occur throughout the small intestine. The efficiency of manganese absorption is relatively low and is not thought to be under homeostatic control. For adult humans, manganese absorption has been reported to range from 2 to 15% when ^{54}Mn-labeled test meals are used and 25% when balance studies are conducted. Manganese absorption and retention are higher in neonates than in adults. Data from balance studies indicate that manganese retention from human milk and infant formula is elevated during infancy, suggesting that neonates may be particularly susceptible to manganese toxicosis.

The higher retention of manganese in young animals in relation to adults may reflect an immaturity of manganese excretory pathways. The avid retention of the small amount of manganese in milk, and the postnatal changes in its excretory pattern, underscore the fact that important changes in manganese metabolism occur during the neonatal period.

In experimental animals, high amounts of dietary calcium, phosphorus, fiber, and phytate have been shown to increase the requirements for manganese; such interactions presumably occur via the formation of insoluble manganese complexes in the intestinal tract with a concomitant reduction in the soluble fraction available for absorption. The significance of these dietary factors with regard to human manganese requirements remains to be clarified. Studies in avians have demonstrated that high dietary phosphorus reduced manganese deposition in bone by approximately 50%. Given that the average diet of many individuals may be considered marginal in manganese, and high in phosphorus, this antagonism may have important implications for human health. The low fractional absorption of manganese from soy formula has been related to its relatively high phytate content. The mechanism underlying this effect of soy protein on manganese absorption/retention has not been fully delineated. (*See* **Calcium**: Physiology; **Dietary Fiber**: Effects of Fiber on Absorption; **Phytic Acid**: Nutritional Impact.)

An interaction between iron and manganese has been demonstrated in several species. Manganese absorption increases under conditions of iron deficiency

in both experimental animals and humans, whereas high amounts of dietary iron can accelerate the development of manganese deficiency in some species. The mechanisms underlying the interactions between iron and manganese have not been identified; however, they probably involve either a transport site or a ligand. (*See* **Iron**: Physiology.)

Manganese entering the portal blood from the gastrointestinal tract may either remain free or become associated with α_2-macroglobulin, which is subsequently taken up by the liver. A small fraction enters the systemic circulation, where it may become oxidized to Mn^{3+} and bound to transferrin. Studies *in-vivo* suggest that the Mn^{3+} complex forms very quickly in blood, in contrast to the slow oxidation of Mn^{2+}-transferrin complex *in vitro*. Manganese uptake by the liver has been reported to occur by a unidirectional, saturable process with the properties of passive mediated transport. Once entering the liver, manganese enters one of at least five metabolic pools. One pool represents manganese taken up by the lysosomes, from which it is thought to be transferred subsequently to the bile canaliculus. The regulation of manganese is thought to be maintained in part through biliary excretion of the element; up to 50% of manganese injected intravenously can be recovered in the feces within 24 h. A second pool of manganese is associated with the mitochondria. Mitrochondria have a large capacity for manganese uptake, and it is thought that mitochondrial uptake and release of manganese may be related. A third pool of manganese is found in the nuclear fraction of the cell; the roles of nuclear manganese have not been delineated. A fourth manganese pool is incorporated into newly synthesized manganese proteins; biological half-lives for these proteins have not been agreed upon. The fifth identified intracellular pool of manganese is free Mn^{2+}. It is thought that fluctuations in the free manganese pool may be an important regulator of cellular metabolic control in a manner analogous to those for free Ca^{2+} and Mg^{2+}. Consistent with this idea, several studies in pancreatic islets have shown that manganese blocks glucose-induced insulin release by altering cellular calcium fluxes.

The mechanisms by which manganese is transported to and taken up by extrahepatic tissues have not been identified. Transferrin is the major manganese-binding protein in plasma; however, it is not known to what extent transferrin facilitates the uptake of manganese by extrahepatic tissue. Manganese uptake by extrahepatic tissue does not appear to be increased under conditions of manganese deficiency, suggesting a lack of inducible manganese-transport proteins.

Currently, there is limited information concerning the hormonal regulation of manganese metabolism. Fluxes in the concentrations of adrenal, pancreatic, and pituitary–gonadal axis hormones affect tissue manganese concentrations; however, it is not clear to what extent hormone-induced changes in tissue manganese concentrations are due to alterations in cellular uptake of manganese-activated enzymes or metalloenzymes.

Biochemical Functions

Manganese functions as a constituent of metalloenzymes and as an enzyme activator. Manganese-containing enzymes include arginase, pyruvate carboxylase, and manganese-superoxide dismutase (MnSOD). Arginase, the cytosolic enzyme responsible for urea formation, contains 4 mol Mn^{2+} per mol of enzyme. Although the activity of this enzyme can be lower in managanese-deficient animals than in controls, the functional significance of the reduction has not been defined. With experimental diabetes, liver and kidney manganese concentrations and arginase activity can be markedly elevated. This manganese effect on arginase has been suggested to be due to an effect of Mn^{2+} on the conformational properties of the enzyme with a resultant modification of arginase activity. Whether this finding implies an increased manganese requirement for diabetics has not been determined.

Pyruvate carboxylase, the enzyme that catalyzes the first step of carbohydrate synthesis from pyruvate, contains 4 mol Mn^{2+} per mol enzyme. Although the activity of this enzyme can be lower in manganese-deficient animals than in controls, gluconeogenesis is not markedly inhibited in deficient animals.

MnSOD catalyzes the disproportionation of O_2^- to H_2O_2 and O_2. The activity of MnSOD in tissues of manganese-deficient rats can be significantly lower than in controls. That this reduction is functionally significant is suggested by the observation of higher than normal levels of hepatic mitochondrial lipid peroxidation in deficient rats. Tissue MnSOD activity can be increased by several diverse stressors including alcohol, ozone, interleukin-1, and tumor necrosis factor-α, presumably as a consequence of stressor-associated increases in cellular free radical (or oxidized target(s)) concentrations. The increase in MnSOD activity can be attenuated in manganese-deficient animals, potentially increasing their sensitivity to these insults.

For manganese-activated reactions, the metal can act by binding either to the substrate (such as ATP) or directly to the protein, resulting in conformational changes. In contrast to the relatively few manganese metalloenzymes, there are a large number of manganese-activated enzymes, including hydrolases, kinases, decarboxylases, and transferases. Many of

these metal activations are nonspecific in that other metal ions, particularly Mg^{2+}, can replace Mn^{2+}. An exception to the nonspecific manganese activation of enzymes is the manganese-specific activation of glycosyltransferases. Several manganese deficiency-induced pathologies have been attributed to a low activity of this enzyme class. A second example of an enzyme that may be specifically activated by manganese is phosphoenolpyruvate carboxykinase; low activities of this enzyme can occur in manganese-deficient animals.

A third example of a manganese-activated enzyme is glutamine synthetase. This enzyme, found in high concentrations in the brain, catalyzes the reaction $NH_3 + \text{glutamate} + ATP \rightarrow \text{glutamine} + ADP + Pi$. It can be speculated that a manganese deficiency-induced reduction in its activity could help to explain some of the behavioral defects associated with manganese deficiency. It should be noted that this enzyme can be inactivated by oxygen radicals; thus, a manganese deficiency-induced reduction in MnSOD activity theoretically could act to further depress the activity of glutamine synthetase.

Manganese Deficiency

Manganese deficiency has been demonstrated in several species, including rats, mice, pigs, and cattle. Signs of manganese deficiency include impaired growth, skeletal abnormalities, impaired reproductive performance, ataxia, and defects in lipid and carbohydrate metabolism.

The effects of manganese deficiency on bone development have been studied extensively. In most species, manganese deficiency can result in shortened and thickened limbs, curvature of the spine, and swollen and enlarged joints. The basic biochemical defect underlying the development of these bone defects is a reduction in the activities of glycosyltransferases; these enzymes are necessary for the synthesis of the chondroitin sulfate side-chains of proteoglycan molecules. In addition, manganese deficiency in adult rats can result in an inhibition of both osteoblast and osteoclast activity. The implications of this observation for human bone disease need to be ascertained.

One of the most striking effects of manganese deficiency occurs during pregnancy. When pregnant animals are deficient in manganese, their offspring exhibit a congenital, irreversible ataxia characterized by incoordination, lack of equilibrium, and retraction of the head. This condition is the result of impaired development of the otoliths, the calcified structures in the inner ear responsible for normal body righting reflexes. The block in otolith development is secondary to depressed proteoglycan synthesis due to the low activity of manganese-requiring glycosyltransferases.

Defects in carbohydrate metabolism, in addition to those described above, have been shown in manganese-deficient rats and guinea-pigs. In the guinea-pig, perinatal manganese deficiency results in pancreatic pathology, with animals exhibiting aplasia or marked hypoplasia of all cellular components. Manganese-deficient guinea-pigs and rats given a glucose challenge respond with a diabetic-type glucose tolerance curve. In addition to its effect on pancreatic tissue integrity, manganese deficiency can directly impair pancreatic insulin synthesis and secretion. The mechanism(s) underlying the effects of manganese on pancreatic insulin metabolism have not been fully delineated; however, it is known that insulin mRNA levels are reduced in the deficient animal. In addition, insulin sensitivity in adipose tissue is reduced in manganese-deficient rats, a phenomenon that may be related to fewer insulin receptors per adipose cell in the deficient animals. Finally, the effect of manganese deficiency on insulin production may also be due to the destruction of pancreatic β-cells. It is worth noting that constitutive pancreatic MnSOD activity is lower than in most tissues; this, coupled with the observation that most diabetogenic agents function via the production of free radicals with subsequent tissue damage, suggests that an additional mechanism underlying pancreatic dysfunction in the manganese-deficient animals may be free-radical mediated. (*See* **Carbohydrates**: Digestion, Absorption, and Metabolism; **Glucose**: Glucose Tolerance and the Glycemic (Glycaemic) Index.)

Although the majority of studies concerning the influence of manganese deficiency on carbohydrate metabolism have been conducted with experimental animals, there is one report in the literature of an insulin-resistant diabetic patient who responded to oral doses of manganese with decreasing blood glucose concentrations. While this is an intriguing case report, others have reported a lack of an effect of oral manganese supplements in diabetic subjects, and low blood manganese concentrations have not been found to be a characteristic of diabetics.

Abnormal lipid metabolism is also characteristic of manganese deficiency; a lipotrophic effect of manganese has been suggested. Severely manganese-deficient animals can be characterized by high liver fat, hypocholesterolemia and low high-density lipoprotein concentrations. As stated above, tissue lipid peroxidation rates can be increased in manganese-deficient animals, possibly as a result of low tissue MnSOD activity. (*See* **Fatty Acids**: Metabolism; **Lipoproteins**.)

There is considerable debate as to the extent to which manganese deficiency affects humans under free living conditions. It has been shown that manganese deficiency can be induced in humans under highly controlled experimental conditions. In this study, manganese deficiency was induced in adult male subjects by feeding a manganese-deficient diet for 39 days. The subjects developed a temporary dermatitis, and increased serum calcium and phosphorus concentrations and increased alkaline phosphatase activity, suggestive of bone resorption.

During the last decade, several diseases have been reported to be characterized in part, by low blood manganese concentrations. These diseases include epilepsy, mseleni disease, maple syrup urine disease and phenylketonuria, Down's syndrome, osteoporosis, and Perthes disease. The finding of low blood manganese levels in subsets of individuals with the above diseases is significant since blood manganese levels can reflect soft-tissue manganese concentrations. The reports of low blood manganese concentrations in individuals with epilepsy are particularly intriguing, given the observations that manganese-deficient animals can show an increased susceptibility to drug and electroshock-induced seizures and a genetic model for epilepsy in rats (the GEPR rat) is characterized by low blood manganese concentrations. Given that Mn^{2+} is implicated in activation of glutamine synthetase, a Mn^{2+}-specific brain ATPase, production of cyclic-AMP, altered synaptosomal uptake of noradrenalin and serotonin, glutamate, GABA and choline metabolism and biosynthesis of acetylcholine receptors, it is evident that a deficiency of manganese may contribute to the pathology of epilepsy at multiple points.

Although it is evident from the above that the role of altered manganese metabolism in several disease states needs to be clarified, evidence of widespread manganese deficiency in human populations is still lacking. Typically, manganese intakes are within the USA estimated safe and adequate daily dietary intakes, which are as follows: 0.3–1.0 mg d^{-1} for infants, 1.0–3.0 mg d^{-1} for children, and 2.0–5.0 mg d^{-1} for older children, adolescents, and adults.

Manganese Toxicity

In domestic animals, the major reported lesion associated with chronic manganese toxicity is iron deficiency, resulting from an inhibitory effect of manganese on iron absorption. Additional signs of manganese toxicity in domestic animals can include depressed growth, depressed appetite, and altered brain function.

In humans, manganese toxicity represents a serious health hazard, resulting in severe pathologies of the central nervous system. In its most severe form, the toxicosis is manifested by a permanent crippling neurological disorder of the extrapyramidal system, which is similar to Parkinson's disease. In its milder form, the toxicity is expressed by hyperirritability, violent acts, hallucinations, disturbances of libido, and incoordination. The above symptoms, once established, tend to persist even after the manganese body burden returns to normal. While the majority of reported cases of manganese toxicity occur in individuals exposed to high concentrations of airborne manganese (> 5 mg m^{-3}), subtle signs of manganese toxicity including delayed reaction time, impaired motor coordination, and impaired memory have been observed in workers exposed to airborne manganese concentrations lower than 1 mg m^{-3}. Manganese toxicity has been reported in an individual who consumed high amounts of manganese supplements for several years and in individuals who have consumed water containing high levels of manganese. There has been concern recently that the risk for manganese toxicity may be increasing in some areas because of the use of methylcyclopentadenyl manganese tricarbonyl in gasoline as an antiknock agent; however, this is an issue of active debate.

In additional to neural damage, reproductive and immune system dysfunction, nephritis, testicular damage, pancreatitis, lung disease, and hepatic damage can occur with manganese toxicity, though the frequency of these disorders is unknown. Similarly to the cases in humans, chronic manganese toxicity in rhesus monkeys is characterized by muscular weakness, rigidity of the lower limbs, and neuron damage in the substantia nigra. Neural toxicity is a consistent finding in rats exposed to chronic manganese toxicity. The mechanisms underlying the toxicity of manganese have not been agreed upon but probably involve both endocrinological dysfunction and excessive tissue oxidative damage.

To date, cases of manganese toxicity in humans have only been reported for adults; however, infants may be at a high risk for manganese toxicity owing to a high absorptive capacity for the element and/or an immature excretory pathway for it. If manganese is taken up by extrahepatic tissues via the manganese–transferrin complex, the developing brain may be particularly sensitive to manganese toxicity owing to the high number of transferrin receptors elaborated by neuronal cells during development, coupled with the putative need by neural cells for transferrin for their differentiation and proliferation. Studies aimed at evaluating the relative sensitivity of the developing brain to manganese toxicity are needed.

Biomarkers for Manganese Status

At present, reliable biomarkers for the assessment of manganese status have not been identified. Whole-blood manganese concentrations have been reported to be reflective of soft-tissue manganese levels in rats; however, it is not known whether a similar relationship holds for humans. Plasma manganese concentrations have been shown to decrease in individuals fed manganese-deficient diets, and to be slightly higher than normal in individuals consuming manganese supplements. Lymphocyte MnSOD activity has been reported to be increased in individuals who consume manganese supplements; however, its value as a biomarker for manganese status may be complicated owing to the number of cytokines and disease states, which may also increase its expression.

MANGOES

J F Morton†, University of Miami, Coral Gables, FL, USA

Introduction

One of the most celebrated and heavily consumed of tropical fruits, the mango is often represented in ancient Indian artwork and is said to have been seen by Alexander the Great and his soldiers in the Indus Valley in 327 BC. In the past two centuries, it has spread to most parts of the tropics, and some subtropical areas as well; it has entered international commerce, and is in increasing demand, especially by relocated people now outside the warm climates, as well as by gourmets in temperate regions. It has therefore earned the attention of food scientists everywhere. (*See* **Fruits of Tropical Climates**: Commercial and Dietary Importance.)

Description

The mango is borne by a handsome tree which, under favorable conditions, grows up to 40 m or more in height and, with age, reaches an equal canopy spread.

†deceased.

It is densely foliaged, with rosettes of oblong-lanceolate, evergreen leaves, conspicuously red or yellow when immature. Its spectacular, reddish or yellowish pyramidal flower sprays stand out from the foliage in the cool season and the young fruits develop in late spring. The harvesting season extends from early summer through autumn because there are early, medium, and late cultivars.

The mango fruit, hanging in clusters on long stems, is extremely variable; it may be round, oval, egg- or kidney-shaped, or long-elliptical, often oblique at the base, and ranging in weight from 150 to 850 g. The skin is smooth or leathery, and varies from light- or dark-green, or all-yellow, to yellow flushed with pink, rose, bright- or dark-red, or nearly purple, generally with a multitude of minute yellow dots (Figures 1 and 2).

Ripe fruits are agreeably aromatic or, to some degree, redolent of turpentine. The flesh is yellow or orange, juicy, and of fine, melting texture, more or less fibrous ('stringy') in unimproved types. The somewhat peachlike flavor varies from subacid to sweet, is rich and mellow, and usually slightly but agreeably resinous. Some seedlings (now rare) have a pronounced turpentine tang. A 'beard' of fiber clings to the relatively large seed, flattish and firm-shelled. Some types with fiber-free flesh are classed as 'freestone' because the seed separates easily from the flesh. In most mangoes, however, the flesh must be cut from the seed. That which remains clinging to the seedcoat fibers is the most flavorful, and any real mango fancier will relish gnawing it off. In fact, there is a special mango fork to hold the seed for this purpose. The seed kernel is firm but tender, starchy and edible.

Origin and Distribution

It is believed that the mango is native to an area extending from the foothills of the Himalayas of

Figure 1 An assortment of red and yellow mangoes from home gardens in Florida: top row (left to right), Fascell, Brooks, Gibbons, Cecil; second row, Hodges, Yellow Brooks, Borsha, Kent; three in front, Sandersha, Peach, Haden; in saucer, Cecil. Reproduced from Mangoes, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Figure 2 Madame Francis, the leading mango of Haiti, yellow when ripe, is polyembryonic, reproduces true to type, and is grown from seed for export. It comes into season a month or two earlier than most mangoes grown in Florida. Reproduced from Mangoes, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

India and Burma, southward into parts of Malaysia, and ranges from sea level to 1500 m. However, more than 4000 years of domestication have obliterated its natural boundaries. It is cultivated from southern China to the Philippines, in Madagascar, in mild parts of South, Central and even northern Africa, the Near East, Mediterranean Europe, and the Canary Islands, throughout the islands of the Pacific, the Bahamas, the Caribbean Islands, the lowlands of Central America, northern South America, Mexico, and in a few sheltered spots of southern California. It is a very common dooryard fruit tree and a commercial crop in southern Florida and the Florida Keys.

Varieties

There are several species of *Mangifera* in Malaysia, but only *M. indica* has favorable fruit qualities for exploitation. Many of the natural forms of mangoes in India, Cambodia, and the Philippines are excellent but have never been widely promoted in the western world because they lack the red coloration that marketers feel is an essential appeal. Similarly, the Edward mango in Florida, of the highest quality, is modestly (but beautifully) pastel and has the additional handicap of being a shy and irregular bearer. Much selection and breeding in Florida has led to the naming and commercialization of certain high-colored, fairly regular-bearing, and good-shipping cultivars that are now being adopted for practical purposes in Latin America and elsewhere. The three leading cultivars at present are Tommy Atkins, Keitt, and Kent, the last two requiring ethylene treatment to enhance the color. In India, more than 1000 cultivars have resulted from asexual propagation of superior chance seedlings over the past 80 years. Hawaii and many other mango-growing centers of the world have ongoing mango selection and improvement programs aimed at combining the best economic and esthetic factors in a reliably bearing and disease-resistant cultivar, for a particular region. An important goal should be the development of dwarf trees (like the Indian cultivar, Neelum) not only to save space but

also to facilitate harvesting and all other operations. In northern Colombia there is a miniature (egg-size) mango, Azucar, with colorful skin and small seed, which ought to be adopted for gift-box packing.

Propagation

Improved cultivars are propagated vegetatively by various techniques of budding or grafting in order to reproduce the exact characters of the parent. They are not grown from seed because seedlings grown from the usual monoembryonic seeds are noted for their variation. The homeowner may plant a mango seed and be content with the result, but would be better advised to purchase a grafted tree which will bear sooner and provide a crop of predictable quality. Only polyembyronic mangoes are propagated by seed for commercial purposes. The majority of these reproduce 'true' to the parent. Of course, plantations of monoembryonic seedlings are necessary for research and selection in breeding programs.

Soil and Culture

Mango trees are not particularly sensitive to soil type and they will prosper even on oolitic limestone, but they respond well to appropriate fertilization, irrigation, and spraying to control insects and fungus diseases. In humid climates, the mango is subject to anthracnose, which attacks the flowers and considerably reduces production. A much more serious problem is the fungus causing powdery mildew on mango trees from Florida to India. There are a number of scale insects which attack the tree and its fruit. Mangoes to be exported or imported may be subject to fumigation, hot water, or other treatments to avoid the spread of fruit flies and the mango seed weevil. Mango trees may suffer from lack of adequate boron, copper, iron, manganese, or magnesium, and need regular attention to these deficiencies.

Yield and Handling

Mango trees are long-lived and the yield varies with the cultivar but always increases with age. A well-cared-for, fruitful cultivar will bear 200–300 fruits per year during the first 10–20 years, and twice that amount in the next 20–40 years. In the Far East, older trees of special cultivars have borne up to 5000 fruits or more in a single season. In Puerto Rico, some Florida cultivars have yielded roughly 30 000–60 000 kg of fruits per hectare. However, after its first 10 years, the mango is noted for being an irregular bearer, providing a heavy crop one year and a light crop the next. Certain branches may bear one year and other branches the following year, and bearing is strongly influenced by weather conditions. In some tropical climates, mango trees may be partially in bloom and partially in fruit throughout the year. There have been various efforts to enhance pollination, and promote better fruit-setting by smudging, girdling, deblossoming, or by spraying with chemicals to retard vegetative growth, but results are unstable and discouraging.

Mangoes are picked when fully mature but slightly unripe for domestic use, and allowed to soften at room temperature. For marketing, they are harvested earlier and some cultivars are treated with ethylene to achieve uniform color. In any case, the fruit should be washed immediately after clipping to remove the gummy sap that exudes from the stem. Otherwise, it will 'burn' the skin, resulting in black stains which lead to decay.

Fully ripe mangoes keep for several days under home refrigeration. They can be frozen whole for future use but must be eaten immediately after thawing. Sliced mango flesh in sugar syrup, with added lime juice to prevent discoloration, is easily frozen in leakproof, sealed plastic bags.

Keeping quality varies with the cultivar. The best storage treatment for each must be worked out by experimentation. But all mangoes are subject to chilling injury, which generally occurs at storage temperatures below 15 °C. Trials in India with the high-quality Alphonso cultivar demonstrated that the freshly picked fruit can endure 2 weeks of storage at 7 °C and subsequent ripening at 30 °C, but longer refrigeration brings on 'low-temperature breakdown'. Ripening of Tommy Atkins and Kent mangoes has been successfully delayed for 3 weeks at 13 °C, 90–100% relative humidity, and atmospheric pressure of 76–152 mmHg, and the fruits have thereafter ripened satisfactorily. (*See* **Controlled-atmosphere Storage**: Applications for Bulk Storage of Foodstuffs; **Ripening of Fruit**; **Storage Stability**: Mechanisms of Degradation.)

In general, spoilage has been retarded or reduced by prestorage dipping in hot water, or a solution of maleic hydrazide, benomyl, or calcium chloride. Plastic wraps reduce weight loss but do not retard decay. Waxing is beneficial in delaying ripening, but it has the undesirable effect of preventing full coloring.

Preparation for Serving and Various Food Uses

As mentioned earlier, 'freestone' mangoes can be cut through to the stone and then the two halves are held in the palms of the hands and gently twisted to

Table 1 Food value of mangoes (raw)[a]

Nutrients and units	*Mean amount per kg, edible portion*
Proximate (g)	
Water	817.10

separate them from the stone. Ordinary, somewhat fibrous mangoes, can be served 'in the half-shell' by cutting off both plump sides. The center slab is then peeled and the flesh cut from the stone. Otherwise, the whole fruit may be peeled and the flesh sliced for whatever use: eating as dessert, adding to icecream, milkshake, using as pie filling, stewing as sauce, or making into preserves. Of course, if the flesh is fibrous, it should be pressed through a sieve.

In the tropics, there are many seedling mangoes so fibrous that they cannot be sliced. Children and adults will bruise the fruit by massaging it between the hands, then make a hole in the stem end and suck out the juice. This should not be done by anyone who is sensitive to the irritant in the mango peel.

Many immature mangoes are blown down by spring winds. These are usually salvaged by peeling, slicing, and cooking as a substitute for apple in pie. They may also be cooked as a sauce, or used with tamarind pulp and spices in preparing green mango chutney. In India, thin slices of unripe mango are sprinkled with turmeric, then dried and powdered for use as seasoning.

Mango nectars and peeled, seeded, ripe mangoes, halved or sliced, are commonly canned in Latin America and South-east Asia and these products find a good market abroad. However, more attention must be given to the thorough coating of the inside of the metal can, to avoid off-flavors and spoilage.
