responsible for histidine synthesis, making it impossible for the bacteria to grow in the absence of histidine. The *Salmonella* test is a reverse mutation assay in which back-mutation of the *his* operon will allow the bacteria to grow in the absence of histidine. Bacteria are exposed to the test chemical with and without a metabolic activation system (usually rat liver S9, a cofactor-supplemented postmitochondrial preparation of rat liver microsomes prepared from rats exposed to Aroclor 1254, a PCB (polychlorinated biphenyl) inducer of the cytochrome P450 hydroxylation enzymes) and spread on to minimal medium agar plates. After a suitable period of incubation, revertant colonies are counted and compared to those found on control plates containing either vehicle alone or a known mutagen. Several strains with different sensitivities are available with TA98 and TA100 detecting frameshift and basepair mutations, respectively, while strains TA102 and TA104 respond to oxidative damage. Other frameshift-specific strains such as TA1535 and TA1537 are also available. Recently, related strains have been developed which are each reverted by specific basepair changes, allowing a mutational spectrum of test chemical activity to be generated. Specialized strains have also been created which express various metabolic activation enzymes to examine specific classes of chemicals. A luminescent version of the assay is also commercially available which substitutes luminescence in place of colony formation as a measure of revertant cell growth.

***E. coli* tryptophan (*trp*) reversion assay** The *E. coli trp* reversion assay using *E. coli WP2* and related strains is a microbial assay which measures trp^- to trp^+ reversion induced by mutagenic chemicals. Various strains are available which are deficient in different aspects of DNA repair, making them more susceptible to reversion. As well, both frameshift and basepair mutations can be detected using different strains. The assays are carried out in a similar manner to the Ames *Salmonella* test.

Assays in Somatic Cells in Culture

Mammalian cell culture systems may also be used to detect mutations induced by chemical substances. Widely used cell lines include L5178Y mouse lymphoma cells as well as the Chinese hamster ovary (CHO) and V-79 lines of Chinese hamster cells. The most commonly used systems measure mutation at the thymidine kinase (TK, L5178Y cells), hypoxanthine-guanine-phosphoribosyl transferase (HGPRT, CHO, and V-79 cells) and Na^+/K^+ ATPase (V-79) genetic loci. The TK and HGPRT mutational systems detect basepair mutations, frameshift mutations, and small deletions, while the Na^+/K^+ ATPase assay detects only basepair mutations.

Cells are exposed to the test agent with and without metabolic activation for a suitable period of time. They are then subcultured to determine cytotoxicity and to allow phenotypic expression prior to mutant selection. The cultures are analyzed for mutant frequency at the end of the expression time by seeding known numbers of cells in medium with and without a selective agent which is lethal to the parental cells but ineffective against the mutant cells. After a suitable incubation time, cell colonies are counted. The number of mutant colonies in selection medium is adjusted by the number of colonies in normal medium to derive the mutant frequency. Cell lines are now available which express a variety of metabolic enzyme activities introduced by genetic engineering. These cell lines can be used to probe the effects of various metabolic activities on carcinogen activation and to avoid the need for adding an exogenous metabolic activation system.

Fungal Mutagenesis Assays

A number of fungal systems have been developed for mutagenicity assays, including *Aspergillus nidulans* and *Neurospora crassa*, which can be used to detect both forward and reverse gene mutations by nutritional, biochemical, or morphological changes in the treated population. Similar methods have been developed using the yeast *Saccharomyces cerevisiae* to measure forward and reverse mutations as well as mitotic gene conversion, the nonreciprocal exchange of DNA between sister chromatids.

Characterization of Mutations

Mutations in specific DNA sequences can be detected by heteroduplex analysis. Heteroduplexes are formed when wild-type and mutated sequences are annealed to form double-stranded mismatched structures. Heteroduplexes can be distinguished from perfectly matched homoduplexes by techniques such as denaturing gradient gel electrophoresis, single-stranded conformation polymorphism, constant denaturant gel electrophoresis, chemical mismatch cleavage, Rnase A cleavage, and cleavage with bacteriophage resolvases. The ligase chain reaction is one method which allows the detection of specific DNA sequences and point mutations. Primers to specific wild-type and mutated gene sequences are designed such that they anneal side by side when the complementary sequence is present. The primers are then ligated together and subsequent cycles of annealing and ligating amplify the amount of product produced, which can then be detected by several means.

Chromosomal Analysis

Detection of Chromosomal Aberrations in Bone Marrow

Assays for chromosomal aberrations can detect changes in either the structure or number of chromosomes. However, in practice, cells are analyzed at the first mitosis after treatment, and therefore number changes are not usually found. Chromosome preparations are made from the bone marrow cells of exposed animals, stained and examined under a microscope for metaphase cells which are scored for chromosomal aberrations. A more recent development is fluorescent *in situ* hybridization (FISH) in which chromosomal aberrations are detected with fluorescent-labeled DNA probes which hybridize to specific chromosomal regions.

Micronucleus Assay

The micronucleus test is a mammalian *in vivo* and *in vitro* test which detects chromosomal or mitotic apparatus damage. Micronuclei are small cytoplasmic particles consisting of acentric fragments of chromosomes or entire chromosomes, which become separated from the nuclei of daughter cells. Polychromatic erythrocytes in the bone marrow of rodents form a useful model for this assay since the nuclei are lost during development from erythroblasts. The lack of a nucleus makes the scoring of micronuclei, either by microscope or flow cytometry, easier in these cells.

Rodent Dominant Lethal Assay

A dominant lethal mutation is one which occurs in a germ cell and results in the death of the fertilized egg or developing embryo. Dominant lethals are generally accepted to be the result of both structural and numerical chromosomal aberrations. In this assay, male animals are usually exposed to the test substance and mated to untreated females. The females are sacrificed after an appropriate period of time and the numbers of live and dead embryos in the uteri determined. The ratio of dead to live embryos from the treated group compared to the ratio of dead to live embryos from the control group is used as a measure of dominant lethality. Several treatment protocols are available. The most widely used require either single administration of the test substance or treatment on five consecutive days.

The Rodent Heritable Translocation Assay

In this assay, males are treated with the test chemical, mated, and the male progeny screened either for chromosomal translocations, or for sterility, which is indicative of translocations between nonhomologous chromosomes in the treated male gametes.

Sister Chromatid Exchange Assay

The sister chromatid exchange (SCE) assay detects the ability of a chemical to enhance the exchange of DNA between two sister chromatids of a duplicating chromosome. The test may be performed *in vitro*, using continuous cell lines, or *in vivo* using animal models such as mice, rats, and hamsters. For *in vitro* assays, cell cultures are exposed to test chemicals, and allowed to replicate in the presence of bromodeoxyuridine. The cells are then treated with colchicine or colcemid to arrest cells in a metaphase-like stage of mitosis, and following harvesting chromosome preparations made. Preparations are stained and metaphase cells analyzed for SCEs using a microscope.

Transformation Assays

Both *in vivo* and *in vitro* assay systems have been developed which assay chemicals for their abilities to induce morphological transformation, changing the morphology of cells from normal or near-normal monolayer growth-inhibited cultures to multilayered altered foci resembling neoplastic cell growth. Depending upon the assay, test chemicals may be tested for activity as complete carcinogens, tumor initiators, or tumor promoters.

Rodent Skin *in vivo* Assay

When chemicals are tested for activity as complete carcinogens in the rodent skin transformation assay, they are applied repetitively over several weeks to a shaved area on the backs of the animals, and the area observed for tumor formation. Tumor initiators can be detected by a single application followed by repetitive application of a known tumor promoter such as benzoyl peroxide or chrysarobin. Similarly, tumor promoters can be assayed by first applying a known initiator such as 3-methylcholanthrene to the shaved area followed by repeated applications of the test chemical.

In vitro methods for assaying cellular transformation include: the Syrian hamster embryo (SHE) cell transformation assay, using primary cultures derived from 2-week-old SHEs, epithelial cells, the BALB/c-3T3 and C3H-10T½ cell lines and a number of cells which have been infected by a transforming virus, such as Rauscher leukemia virus-infected Fisher rat embryo cells or simian adenovirus SA7-infected SHE cells. While the SHE cells maintain may of their metabolic capabilities, many of the other cell types require the addition of a metabolic activation

system such as primary hepatocytes and microsomal fractions. Many of these systems can also be used for identifying tumor promoters by first treating the cells with a low concentration of known initiator.

Gap Junctional Communication

Adjacent cells form contact points called gap junctions which allow the exchange of small molecules in a form of communication. The exposure of cells to carcinogens causes a blockage of gap junctional communication. Presumably the loss of communication with neighbors alters cells in such a way that they act in isolation and ignore neighboring signals to limit growth, a process thought to be involved in the development of carcinogenesis. The activity of gap junctions can be measured by several systems.

Metabolic Cooperation

Wild-type and 6-thioguanine-resistant V79 Chinese hamster cells are cultured together in the presence of 6-thioguanine. With active gap junctions, the lethal metabolites formed from 6-thioguanine in the wild-type cells can disperse into the otherwise resistant cells, causing cell death. If gap-junctional communication is blocked, treated resistant cells survive to form colonies, which can be enumerated.

Dye Transfer

The fluorescent dye lucifer yellow, a fluorescent dye, is introduced into cells either by preloading or through a scratch in the monolayer. In the presence of intercellular communication, the dye spreads to neighboring cells in the culture and the fluorescent area increases. When chemical treatment causes gap junctions to be blocked, fluorescence remains concentrated at the original site.

Gene Expression

The blockage of intracellular communication can be reflected by the altered expression of mRNA coding for gap junction components, such as connexin 43, which is involved in gap junction formation.

Peroxisome Proliferation

Peroxisomes are cytoplasmic organelles responsible for the oxidative degradation of fatty acids and other molecules. It has been observed that several nonmutagenic rodent liver carcinogens, including some lipid-lowering drugs and plasticizers, cause liver enlargement and the proliferation of numbers of peroxisomes within hepatocytes. The enumeration of peroxisomes in liver tissue is sensitive for several nongenotoxic rodent hepatocarcinogens but peroxisome proliferation does not appear to occur in humans and its relevance is not known.

In vivo Assays for Tumor Formation

A number of animal models have been used to assess test chemical carcinogenicity. However, considerations of time, cost, and ease of handling have favored the use of rodents instead of other animals such as dogs or primates since assays require animals to be exposed to the test agent over a significant portion of their lifespan. Although animal models provide the most complete and dependable surrogates for the identification of human carcinogens, they are not entirely representative of the human situation due to a number of factors, including species differences in metabolism and susceptible tissues, differences in time and route of exposure as well as amount of chemical tested, and lack of exposure to other chemicals which may act as cocarcinogens. The interpretation of results obtained when chemicals are tested in rodents at the maximum tolerated dose (MTD, the largest dose possible which does not shorten the lifespan or produce clinical signs of toxicity) may be difficult to relate to human exposures. Many chemicals identified as rodent carcinogens have been found to cause inflammation and oxidative damage leading to tissue death and regeneration only at these elevated levels far removed from any expected human exposure.

Rodent Carcinogenicity Assay

The rodent carcinogenicity assay remains the most reliable and validated system for the identification of possible human carcinogens. With minor variations, the methods used for the rodent carcinogenicity assay have been standardized both nationally and internationally, and by law all new chemicals introduced for human use must be tested for long-term effects using the assay. In order to address possible species differences in carcinogenic response, a chemical is tested using two species, usually rats and mice, for comparison, although hamsters may sometimes be substituted. Animals of both sexes are treated with increasing doses of chemical, which are included in the diet or given orally by gavage for food-related studies. Each dose group may contain 50 or more animals and the dosing is maintained over most of the animal's remaining lifespan (18 months for mice and 2 years for rats), after which tissues are collected at necropsy and examined by a pathologist for malignant tumors and preneoplastic lesions.

The duration of the study and number of animals required make the rodent carcinogenicity assay an extremely expensive and time-consuming undertaking. Several other *in vivo* assays have been developed

to reduce the number of animals, length of time, and costs involved. At present, none of these tests has been sufficiently validated to replace the full carcinogenicity test.

Neonatal Mouse Assay

The exposure of newborn mice to carcinogens has been found to provide a sensitive assay for tumor production, primarily in the liver. Since the newborn liver is rapidly replicating, tumors develop relatively quickly compared to adults. Neonatal mice are exposed to two treatments of test chemical in the first and second weeks after birth, and allowed to grow for 1 year, when the study is ended. This assay is sensitive to genotoxic chemicals which form adducts with DNA.

Transgenic Mouse Carcinogenicity Assays

Several mouse models which display faster tumor formation compared to parental strains have been created through genetic engineering. These include the $p53^{+/-}$ heterozygous mouse model which contains one active copy of the wild-type *p53* tumor suppressor gene, the CB6F1-TG-rasH2 hemizygous mouse model containing five to six copies of the human c-Ha-ras oncogene, the Tg.AC transgenic mouse model produced by introducing the *v-Ha-ras* oncogene linked to a fetal zeta-globin promoter and containing 40 copies *v-Ha-ras* per allele, and the $XPA^{-/-}$ knockout mouse, which lacks the XPA component of the nucleotide excision repair pathway. Each treatment group can contain 15 animals and studies are continued for 26 weeks, after which the background of spontaneously occurring mutations begins to increase. The $p53^{+/-}$ and $XPA^{-/-}$ strains generally respond to genotoxic carcinogens while the CB6F1-TG-rasH2 and Tg.AC transgenic strains can respond to both genotoxic and nongenotoxic carcinogens. Bigenic strains combining more than one transgenic alteration, such as $XPA^{-/-}$. $p53^{+/-}$ and $p53^{+/-}$. Tg.AC, have also been produced to increase the responsiveness of the assays.

Preneoplastic Foci

Preneoplastic foci are small, contained proliferative lesions that precede the development of either benign or malignant neoplastic tumors. They may be detected as proliferating regions by measuring uptake of bromodeoxyuridine or tritiated thymidine into the DNA by immunohistochemistry or autoradioraphy, respectively. Preneoplastic foci can also be identified by the use of immunohistochemistry to measure expression of proliferating cell nuclear antigen or the placental form of glutathione *S*-transferase. Preneoplastic foci can be enumerated in various tissues, but the liver is examined most frequently. Tissues can be examined for preneoplastic foci at the close of the rodent carcinogenicity assay or animal studies can be carried out specifically for this endpoint. More preneoplastic foci are usually found than would form eventual tumors, a finding which allows assessments to be carried out in a shorter time period with fewer animals compared with the complete rodent carcinogenicity assay.

Assays for Monitoring Human Population Exposures

Obviously, techniques for monitoring human exposure to carcinogenic compounds must be relatively noninvasive and a number of assays have been applied to samples of blood and urine. The presence of DNA adducts and oxidized DNA bases or nucleosides such as 8-hydroxyguanine or 8-hydroxyguanosine can be detected in urine and the DNA of leukocytes (white blood cells) using specific antibodies or instrumental analysis. The comet assay can be used to detect strand breakage in leukocyte DNA and levels of repair replication can be measured as well. The ^{32}P-postlabeling assay has proven to be very sensitive to examine adduct formation. Levels of mutagenesis in lymphocytes can be detected using a variation of the HGPRT mutagenesis assay and chromosome aberrations and sister chromatid exchange can also be assayed.

CAROTENOIDS

Contents

Occurrence, Properties, and Determination

D B Rodriguez-Amaya, Universidade Estadual de Campinas, Campinas, SP, Brazil

Introduction

Current knowledge on the structures, distribution, and properties of food carotenoids is presented. Their role as food colorants and changes during processing and storage of foods are discussed. Trends in the inherently difficult analysis of these compounds are described, pointing out sources of errors, as well as means to guarantee the reliability of results.

Structures and Occurrence in Foods

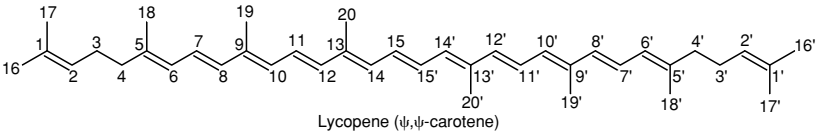
Among the naturally occurring pigments, carotenoids are notable for their wide distribution, structural diversity, and varied functions and actions. In nature, about 100 million tonnes of these compounds are produced annually. More than 600 carotenoids, exclusive of *cis* and *trans* isomers, have now been isolated and characterized from natural sources. This remarkable number includes the enormous variety of carotenoids in algae, bacteria, yeast, and fungi. In foods, the number is much more restricted, but the carotenoid composition can still be complex.

Food carotenoids are generally C_{40} tetraterpenoids formed from eight C_5 isoprenoid units joined head to tail, except at the center, where a tail-to-tail linkage reverses the order and results in a symmetrical molecule. Lateral methyl groups near the center are separated by six carbon atoms and the others by five (**Figure 1**). An important feature is a centrally located, extended double-bond system. The π electrons are highly delocalized over the entire polyene chain, although electron density appears to be greater at or towards the end of the chain. The basic skeleton may be modified in many ways, such as cyclization, hydrogenation, dehydrogenation, introduction of oxygen functions, rearrangement, chain shortening, or combinations thereof, resulting in an immense array of structures.

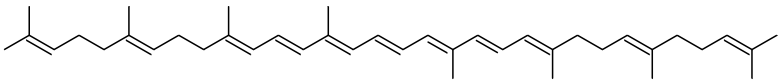
A semisystematic nomenclature that conveys structural information has been devised for carotenoids. In this chapter, the semisystematic names are given in parentheses in the figures and table; those of other carotenoids will be cited with the trivial names when first mentioned in the text. Thereafter, only the better known trivial names will be used.

Hydrocarbon carotenoids (e.g., β-carotene, lycopene) are known as carotenes; oxygenated derivatives are called xanthophyls. Common oxygen substituents are: hydroxy (as in β-cryptoxanthin), keto (as in canthaxanthin), epoxy (as in violaxanthin), and aldehyde (as in β-citraurin) groups. Carotenoids may be acyclic (e.g., ζ-carotene, lycopene), monocyclic (e.g., γ-carotene), or bicyclic (e.g., α- and β-carotene). Cyclization is limited to the formation of a six-membered (occasionally five-membered) ring at one or both ends of the molecule.

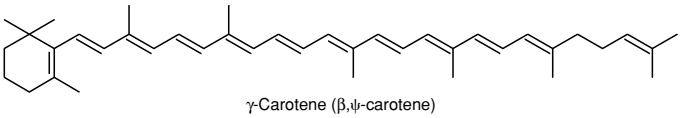
In nature, carotenoids exist primarily in the more stable all-*trans* (or all-*E*) form, but *cis* (or *Z*) isomers do occur. The first C_{40} compound in the biosynthetic pathway has the 15-*cis* configuration in most natural sources. Bixin, the principal pigment of the colorant annatto, also occurs naturally in the *cis* form (**Figure 2**) Small amounts of *cis* isomers of other carotenoids have been increasingly reported. Commonly encountered *cis*-β-carotenes are shown in **Figure 3**.



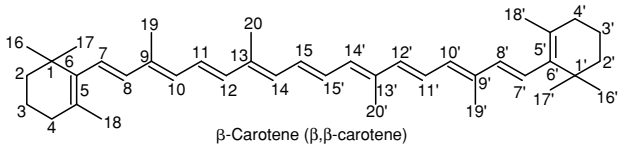
Lycopene (ψ,ψ-carotene)



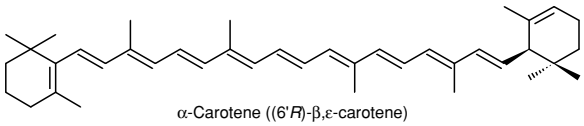
ζ-Carotene (7,8,7',8'-tetrahydro-ψ,ψ-carotene)



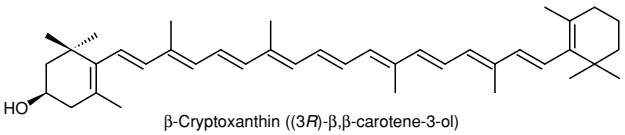
γ-Carotene (β,ψ-carotene)



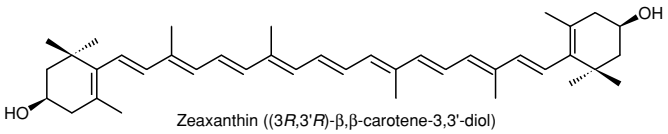
β-Carotene (β,β-carotene)



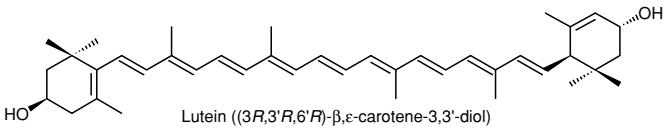
α-Carotene ((6'*R*)-β,ε-carotene)



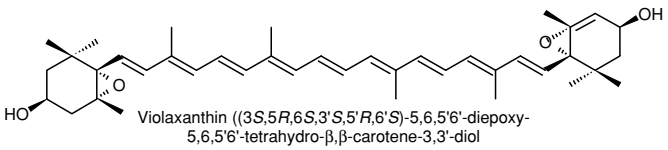
β-Cryptoxanthin ((3*R*)-β,β-carotene-3-ol)



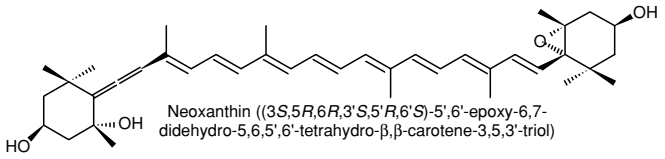
Zeaxanthin ((3*R*,3'*R*)-β,β-carotene-3,3'-diol)



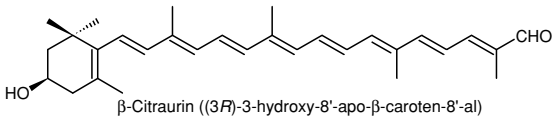
Lutein ((3*R*,3'*R*,6'*R*)-β,ε-carotene-3,3'-diol)



Violaxanthin ((3*S*,5*R*,6*S*,3'*S*,5'*R*,6'*S*)-5,6,5'6'-diepoxy-5,6,5'6'-tetrahydro-β,β-carotene-3,3'-diol

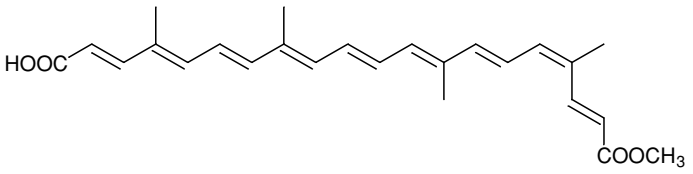


Neoxanthin ((3*S*,5*R*,6*R*,3'*S*,5'*R*,6'*S*)-5',6'-epoxy-6,7-didehydro-5,6,5',6'-tetrahydro-β,β-carotene-3,5,3'-triol)

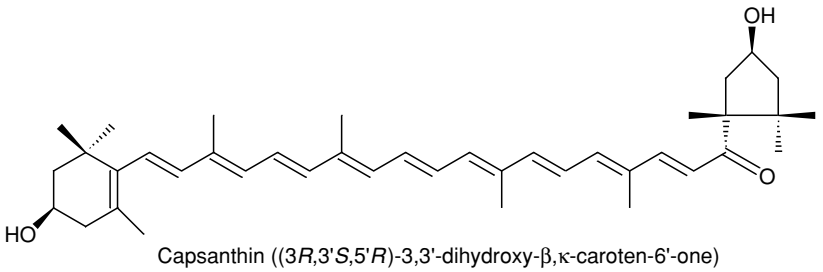


β-Citraurin ((3*R*)-3-hydroxy-8'-apo-β-caroten-8'-al)

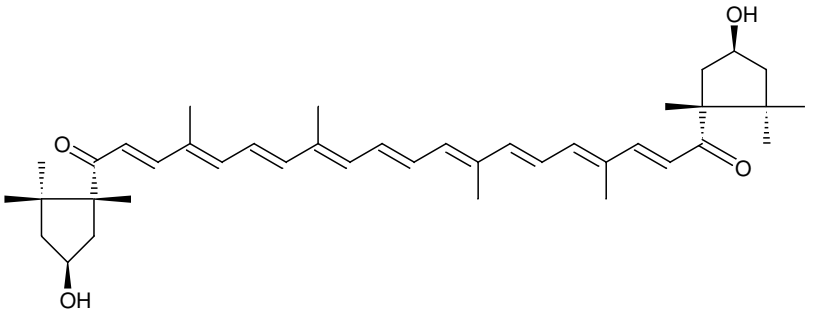
Figure 1 Structures of common carotenoids in foods of plant origin.



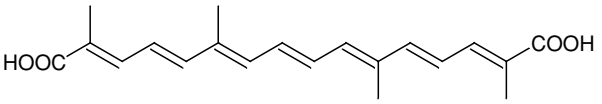
Bixin (methyl hydrogen 9'-*cis*-6,6'-diapocarotene-6,6'-dioate)



Capsanthin ((3*R*,3'*S*,5'*R*)-3,3'-dihydroxy-β,κ-caroten-6'-one)



Capsorubin ((3*S*,5*R*,3'*S*,5'*R*)-3,3'-dihydroxy-κ,κ-carotene-6,6'-dione)



Crocetin (8,8'-diapocarotene-8,8'-dioic acid)

Figure 2 Principal carotenoids of natural extracts used as food colorants.

The major structural differences that account for variations in properties and biological activities of carotenoids, therefore, are: length and rigidity of the molecule, length of the conjugated double-bond system, cyclized or acyclic nature of the end groups, and presence of polar substituents in the predominantly hydrocarbon molecule.

Although masked by the green chlorophyls, carotenoids are found universally in the chloroplasts of photosynthetic tissues. Leaves of all species studied revealed the presence of the same major carotenoids: lutein, β-carotene, violaxanthin, and neoxanthin. Small amounts of α-carotene, α-cryptoxanthin ((3′*R*,6′*R*)-β,ε-caroten-3′-ol) or β-cryptoxanthin, zeaxanthin, antheraxanthin ((3*S*,5*R*,6*S*,3′*R*)-5,6-epoxy-5,6-dihydro-β,β-carotene-3,3′-diol), and lutein-5,6-epoxide ((3*S*,5*R*,6*S*,3′*R*,6′*R*)-5,6-epoxy-5, 6-dihydro-β,ε-carotene-3,3′-diol) may also be found. The xanthophyls are unesterified, and the relative ratios are fairly constant, but the absolute concentrations vary considerably. Lettuce also has lactucaxanthin ((3*R*,6*R*,3′*R*,6′*R*)-ε,ε-carotene-3,3′-diol) at levels comparable with, or slightly higher than, neoxanthin.

In ripe fruits carotenoids are located in chromoplasts and the hydroxycarotenoids are mostly esterified with fatty acids. The composition varies dramatically from fruit to fruit, but eight major patterns can be discerned: (1) insignificant levels of carotenoids; (2) small amounts generally of chloroplast carotenoids (e.g., grape); (3) considerable amounts of lycopene (e.g., tomato, watermelon, red-fleshed guava and papaya); (4) predominance of β-carotene and/or β-cryptoxanthin (e.g., apricot, peach, loquat); (5) large amounts of epoxides (e.g., mango,

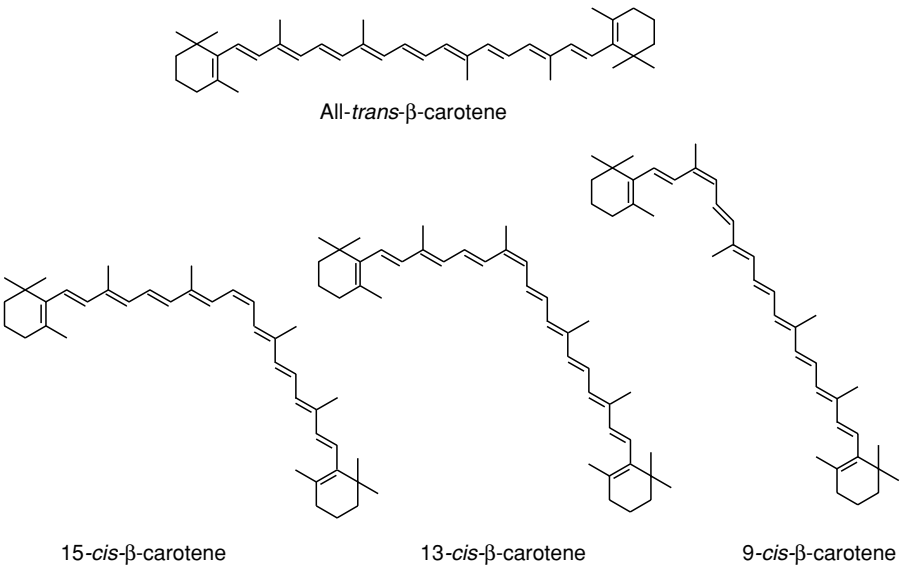


Figure 3 Common geometrical isomers of β-carotene.

carambola); (6) preponderance of unusual or species-specific carotenoids (e.g., red pepper); (7) substantial amounts of poly-*cis*-carotenoids (e.g., tangerine tomato); (8) significant levels of apocarotenoids (carotenoids with shortened carbon skeleton) (e.g., citrus species). Some merging of these patterns can be seen in some fruits.

In the few carotenogenic roots (e.g., carrot, sweet potato), the carotenes are preponderant. In corn (seed), the xanthophyls predominate.

Since plants are able to synthesize carotenoids *de novo*, the composition of plant foods is enriched by the presence of trace amounts of biosynthetic precursors along with derivatives of the main components (Figure 4, Table 1). In a given food, compositional variations occur as a consequence of varietal differences, climatic conditions, agricultural variables, stage of maturity, postharvest handling, conditions during storage, and transportation. Ripening of fruits is generally accompanied by enhanced carotenogenesis, the carotenoids increasing in number and quantity.

Carotenoids are not as widely distributed in animal foods, and the total content is much less. Incapable of carotenoid biosynthesis, animals depend on dietary carotenoids, which are selectively or unselectively absorbed, converted to vitamin A, deposited as such or slightly altered to form carotenoids typical of animal species (Figure 5). Astaxanthin is the major carotenoid in most crustaceans, either free, esterified, or as carotenoprotein complexes. β-Carotene, echinenone and canthaxanthin are the other pigments usually encountered. When found in fish, carotenoids are located in the skin and flesh. The xanthophyls predominate over the carotenes; astaxanthin is the most common, followed by lutein (dominant in freshwater fishes) and tunaxanthin (ε,ε-carotene-3,3′-diol) (characteristic of marine fishes).

Avian species preferentially accumulate certain xanthophyls, which provide the color of eggs, body, skin, and fat. Cattle absorb β-carotene efficiently, but not xanthophyls; thus, diet-derived β-carotene predominates in milk.

Physical and Chemical Properties

The conjugated double-bond system constitutes the light-absorbing chromophore that gives carotenoids their attractive color and provides the visible absorption spectrum, which serves as the basis for their identification and quantification. A few examples of the structure–spectrum relationship will be cited, referring to carotenoids in petroleum ether. Most carotenoids absorb maximally (λ_{max}) at three wavelengths. The greater the number of conjugated double bonds, the higher the λ_{max} values. The acyclic lycopene, with 11 conjugated double bonds, is red and absorbs at the longest wavelengths (λ_{max} at 444, 470, and 502 nm). At least seven such bonds are needed for a carotenoid to have a perceptible color. Thus, ζ-carotene is light yellow, and, being also acyclic, its spectrum has three well-defined peaks but at much shorter wavelengths (378, 400, and 425 nm). The two carotenoids that precede ζ-carotene in the desaturation biosynthetic pathway, phytoene (three conjugated double bonds) and phytofluene (five conjugated double bonds), are colorless and absorb maximally at 276, 286, and 297 nm and 331, 348, and 367 nm, respectively. Cyclization results in steric

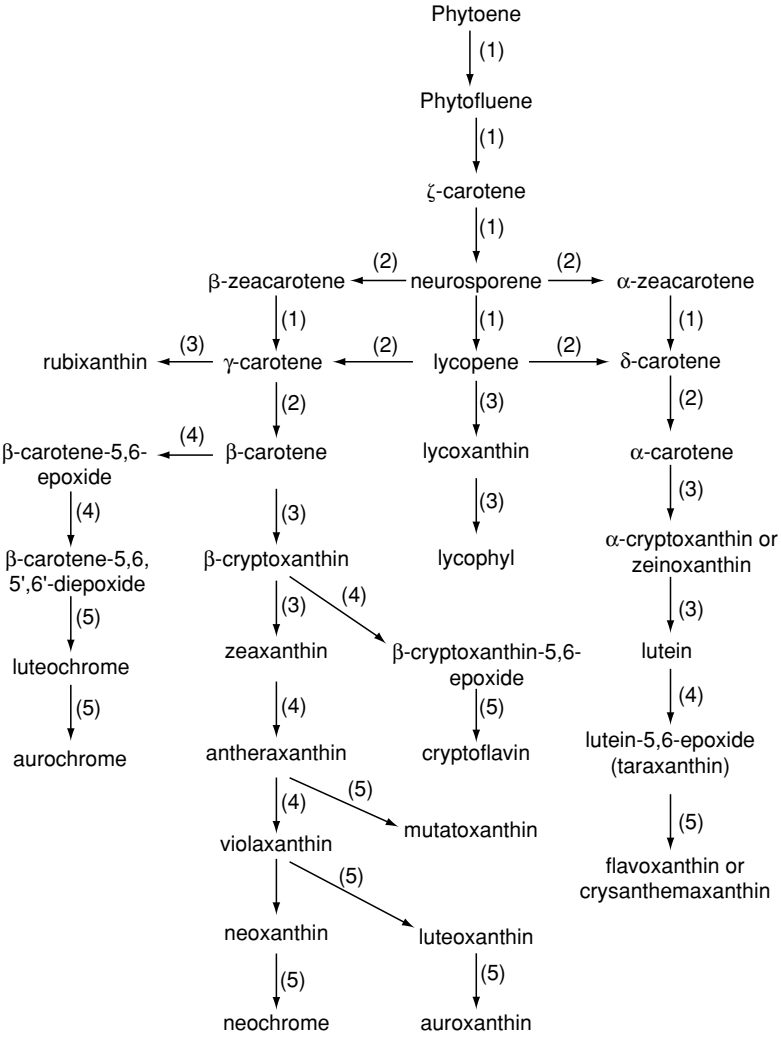

Figure 4 Later stages of carotenoid biosynthesis and possible transformations of carotenoids. Reactions: (1) desaturation, (2) cyclization, (3) hydroxylation, (4) epoxidation, and (5) epoxide–furanoxide rearrangement. From Rodriguez-Amaya DB (1993) Nature and distribution of carotenoids in foods. In: Charalambous G (ed.) *Shelf Life Studies of Foods and Beverages. Chemical, Biological, Physical and Nutritional Aspects*, pp. 547–587. Amsterdam: Elsevier Science, with permission.

hindrance between the ring methyl group at C-5 and the hydrogen at C-8 of the polyene chain, taking the π electrons of the ring double bond out of plane with those of the chain. Consequently, a hypsochromic shift, hypochromic effect, and loss of spectral fine structure are observed. Thus, bicyclic β-carotene, although possessing the same number of bonds as lycopene, is yellow–orange and has a λ_{max} at 450 and 477 nm and a mere inflection at 425 nm. Monocyclic γ-carotene is red–orange and exhibits a spectrum intermediate between those of lycopene and β-carotene. The double bond in the ε-ring of α-carotene is out of conjugation, so it is light yellow, and the absorption peaks are slightly more defined and at slightly shorter wavelengths (422, 445, and 473 nm) compared to β-carotene. Conjugated carbonyl groups cause a bathochromic shift and loss of fine structure to the extent that the three-maxima spectrum is replaced by a broad curve, asymmetrical with a maximum at 458 nm and a shoulder at 482 nm for echinenone (orange) and symmetrical with the maximum at 466 nm for canthaxanthin (red–orange). Hydroxy substituents result in virtually no change in color and absorption spectrum. Thus, lutein resembles α-carotene, and β-cryptoxanthin and zeaxanthin are similar to β-carotene in spectral properties. *Cis* isomerization of one of the chromophore's bond causes slight loss in color, small hypsochromic shift and hypochromic effect, accompanied by the appearance of a *cis* peak in the ultraviolet region, the intensity of which is greater as the *cis* double bond approaches the center of the chromophore. The 5,6-mono- and

Table 1 Carotenoid distribution in some foods

Food	*Major carotenoid concentration (μg/g)*	*Other carotenoids*
Carrot	β-Carotene (40–120) α-Carotene (20–50)	ζ-Carotene, γ-carotene, δ-carotene, lycopene, lutein, neurosporene, β-zeacarotene
Egg yolk	Lutein (6)	Zeaxanthin, isolutein, β-cryptoxanthin, β-carotene, α-carotene, neoxanthin, ζ-carotene
Guava (pink-fleshed)	Lycopene (47–60)	β-Carotene, ζ-carotene, γ-carotene, zeinoxanthin, β-cryptoxanthin, β-carotene-5,6,5′,6′-diepoxide, phytofluene, rubixanthin, cryptoflavin, lutein, neochrome
Loquat	β-Carotene (6–8) β-Cryptoxanthin (5–7)	γ-Carotene, neurosporene, lutein, violaxanthin, neoxanthin, β-cryptoxanthin-5,6-epoxide, phytofluene, ζ-carotene, luteoxanthin, neochrome
Mango	β-Carotene (6–75) Violaxanthin (18–22)	Luteoxanthin, neoxanthin, zeaxanthin, auroxanthin, α-cryptoxanthin, β-cryptoxanthin, ζ-carotene, phytoene, phytofluene, antheraxanthin
Papaya (red-fleshed)	Lycopene (21–40) β-Cryptoxanthin (7–10)	β-Carotene, ζ-carotene, β-cryptoxanthin-5,6-epoxide, γ-carotene, β-zeacarotene, cryptoflavin, antheraxanthin
Peach	β-Cryptoxanthin (4–6)	β-Carotene, ζ-carotene, violaxanthin, luteoxanthin, auroxanthin, lutein, zeaxanthin
Tomato	Lycopene (30–50)	Phytoene, phytofluene, β-carotene, ζ-carotene, γ-carotene, neurosporene
Tree tomato	β-Cryptoxanthin (14) β-Carotene (8)	ζ-Carotene, β-carotene-5,6-epoxide, lutein, zeaxanthin

Semisystematic names: neurosporene (7,8-dihydro-ψ, ψ-carotene); δ-carotene ((6*R*)-ε,ψ-carotene); β-zeacarotene (7′,8′-dihydro-β, ψ-carotene); isolutein ((3*S*, 5*R*, 6*S*, 3′*S*,6′*R*)-5,6-epoxy-5,6-dihydro-β,ε-carotene-3,3′-diol); zeinoxanthin ((3*R*,6′*R*)-β,ε-caroten-3-ol; β-Carotene-5,6,5′,6′-diepoxide (5,6,5′,6′-diepoxy-5,6,5′,6′-tetrahydro-β,β-carotene); rubixanthin ((3*R*) -β,ψ-caroten-3-ol); β-cryptoxanthin-5,6-epoxide (5,6-epoxy-5,6-dihydro-β,β-caroten-3-ol); cryptoflavin (5,8-epoxy-5,8-dihydro-β,β-caroten-3-ol); neochrome (5′,8′-epoxy-6,7-didehydro-5,6,5′,8′-tetrahydro-β,β-caroten-3,5,3′-triol); auroxanthin ((*3S*,*5R*,*8RS*, 3′*S*,*5′R*,*8′RS*)-5,8,5′,8′ diepoxy-5,8,5′,8′-tetrahydro-β,β-caroten-3,3′-diol); luteoxanthin (5,6,5′,8′-diepoxy-5,6,5′,8′-tetrahydro-β,β-carotene-3,3′-diol); phytoene (7,8,11,12,7′,8′,11′,12′-octahydro-ψ,ψ-carotene); phytofluene (7,8,11,12,7′,8′-hexahydro-ψ,ψ-carotene).

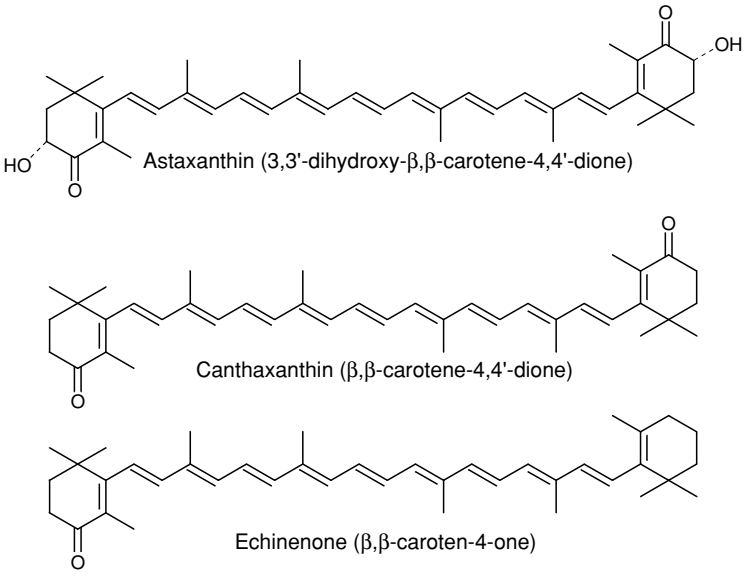

Figure 5 Some carotenoids typical of foods of animal origin. Astaxanthin occurs as a mixture of the (3*S*, 3′*S*), (3*R*, 3′*R*) and (3*R*, 3′*S*) forms.

5,6,5′,6′-diepoxide, having lost one and two ring double bonds, respectively, absorb maximally at wavelengths some 5 and 10 nm shorter and are lighter colored than the parent compounds. On transformation to the 5,8-furanoid oxide, two double bonds (one ring, one chain) are lost. Thus, the 5,8-mono- and 5,8,5′8′-diepoxide are 20–25 and 50 nm lower, respectively, than those of the parent compounds. Solvent effects can be pronounced; the λ_{max} values are higher relative to petroleum ether by 2–6 nm in acetone, 10–20 in chloroform and dichloromethane, and 18–24 nm in toluene.

The intensity and hues of plant foods depend on which carotenoids are present, their concentrations,

and physical state. In animals, complexation of carotenoids with proteins extends the color to green, purple, blue, or black. A well-known example is the blue carotenoprotein crustacyanin of the lobster carapace, an astaxanthin complex. On denaturation of the protein (e.g., heating), astaxanthin is released, and its vivid red color ensues.

Carotenoids are lipophilic, generally insoluble in water but soluble in organic solvents such as acetone, tetrahydrofuran, ethyl ether, and chloroform. Carotenes dissolve well in hexane and petroleum ether, whereas the more polar xanthophylls dissolve more readily in methanol and ethanol. In plants and animals, carotenoids occur as crystals, in solutions in fat depots, in colloidal dispersions, or combined with proteins in the aqueous phase.

Because of the many double bonds, carotenoids are prone to *trans–cis* isomerization. A large number of *cis* isomers are theoretically possible for each carotenoid. Only a few are actually formed because the *cis* configuration in some double bonds creates steric hindrance between nearby hydrogen atoms and methyl groups, making the isomers unstable. The steric hindrance is small when it occurs between hydrogen atoms, so isomers with *cis* double bonds in this situation are relatively stable and are easily formed (e.g., 9-*cis*, 13-*cis*, 15-*cis*) (**Figure 3**).

The highly reactive, electron-rich polyene chain is also subject to oxidative degradation. Carotenoids apparently have different susceptibilities, ζ-carotene, lutein, and violaxanthin being cited as more labile. In contrast to the wealth of information on the oxidation of lipids, carotenoid oxidation is not well understood. It involves initially epoxidation and the formation of apocarotenoids. The preferred site of epoxidation is the terminal double bond; oxidative chain cleavage appears to commence at the C-7,8 position in β-carotene. Subsequent fragmentations presumably yield low-mass compounds similar to those obtained in fatty acid oxidation.

Also related to the conjugated double-bond system is the antioxidant property attributed to carotenoids more recently. The primary mode of action is quenching of singlet oxygen and interaction with free radicals. The oxygen quenching ability is maximal, with carotenoids having nine or more double bonds. The acyclic lycopene was found to be more effective than the bicyclic β-carotene. In a free radical-initiated system, canthaxanthin and astaxanthin, both with conjugated keto groups, were also shown to be better antioxidants than β-carotene and zeaxanthin. At elevated oxygen pressures, however, carotenoids are reported to act as prooxidants.

Xanthophyls undergo specific group reactions which serve as simple chemical tests in the determination of the structure. For example, primary and secondary hydroxy groups are acetylated by acetic anhydride in pyridine. Allylic hydroxyls, isolated or allylic to the chromophore, are methylated with acidified methanol. Epoxy groups in the 5,6- or 5,6,5′6′-positions are easily detected by acid-catalyzed conversion to the furanoid derivatives. Aldehyde and keto carotenoids undergo reduction with $LiAlH_4$ or $NaBH_4$.

Use as Food Colorants

Carotenoids as food colorants find their way into food products by direct addition or indirectly through an animal's feed. Commercial formulations are of two types: natural extracts and synthetic nature-identical carotenoids.

Annatto, paprika, and saffron as dry powders or extracts have been used for years. Annatto is a series of red coloring preparations all based on the extracts of *Bixa orellana* seeds, where the pigments are concentrated in the thin seed coat. The apocarotenoid bixin (**Figure 2**) is the main component of oil-soluble formulations, and its saponification product, norbixin, the major coloring matter of water-soluble preparations. Oleoresin of paprika is the oil extract of *Capsicum annuum*, which imparts a pinkish yellow to crimson red color to foods, the predominating pigments being capsanthin and capsorubin. Saffron consists of the dried stigma of *Croccus sativus* and is used as a spice and yellow coloring agent. It contains mainly crocin, the digentiobioside of crocetin, a diapocarotenedioic acid. Other commercial sources of carotenoids are lutein-rich marigold petals for poultry feed and β-carotene-rich microalgae. Industrial production of natural carotenoids by biotechnology is gaining more interest. (*See* **Colorants (Colourants)**: Properties and Determination of Natural Pigments.)

The first carotenoid prepared by chemical synthesis, β-carotene, was introduced commercially by Roche in 1954. It was followed by β-apo-8′-carotenal (8′-apo-β-caroten-8′-al) in 1960, β-apo-8′-carotenoic acid ethyl ester (ethyl 8′-apo-β-caroten-8′-oate) in 1962, and canthaxanthin in 1964. In 1968, BASF introduced citranaxanthin (5′,6′-dihydro-5′-apo-18′-nor-β-caroten-6′-one), and in 1984, Roche launched (3*RS*, 3′*RS*)-astaxanthin as feed additives. Crystalline carotenoids suffer from problems that render their commercialization in this form impractical: instability, insolubility in water, and limited solubility in fats and oils. To satisfy the needs of the food industry, special application forms have been developed through sophisticated physicochemical operations. Micronized oil suspensions are the major marketable

forms for coloring fat-based foods. For water-based foods, water-dispersible emulsions or colloidal preparations are available.

Advantages cited for carotenoids as food colorants are: natural connotation, high tinctural potency, unaffected by reducing conditions, noncorrosive, good stability in the pH range of most food products, provitamin A activity, and other beneficial effects on human health. Their disadvantages are: limited color range, higher price compared with synthetic dyes, sensitivity to oxidative degradation, solubility problems. The last two disadvantages have been overcome in the application forms mentioned above.

Stability on Processing and Storage

Naturally present or added carotenoids are subject to isomerization and oxidation during food processing and storage. Isomerization to *cis* isomers, provoked by the release of constituent acids during slicing and pureeing of foods, heat treatment and exposure to light, results in some loss of color and vitamin A activity. Oxidation depends on: availability of oxygen; the carotenoids present and their physical state; water activity; presence of antioxidants (e.g., tocopherols and ascorbic acid); exposure to light; presence of metals, enzymes and peroxides; severity of the processing treatment (i.e., destruction of the cellular structure that protects the carotenoids, increase of surface area, duration and temperature of heat treatment); packaging material; and storage conditions. Completely losing their color and biological activities, the carotenoids give rise to volatile compounds that contribute to the aroma/flavor, desirable in tea and wine and undesirable in dehydrated carrot. (*See* **Retinol**: Properties and Determination.)

Reports on carotenoid retention during processing and storage of foods appear conflicting, some claiming no loss or increase in carotenoid content and others showing considerable reductions. Claimed increases are likely to be artifacts of the analytical process due to loss of carotenoids in fresh samples because of enzymatic activity, greater extractability of carotenoids from processed samples, unaccounted loss of water, and leaching of soluble solids. On the other hand, care must be taken so as not to attribute carotenoid losses during analysis to processing and storage effects.

Notwithstanding the diverging results, processing under good manufacturing practices should have a small effect on carotenoids; stability is good to excellent in frozen and heat-sterilized foods throughout the normal shelf-life. Oxygen content is minimized by hot packing, vacuum packing and oxygen scavenging with ascorbic acid. Stability in dehydrated and powdered fruits and vegetables is generally poor, unless the product has been carefully processed and stored in inert atmosphere in packaging impermeable to oxygen and light. A considerable portion of the carotenoids may be physically removed on peeling and juicing of fruits and by milling of seeds and grains. The time lag between peeling, cutting or puréeing and processing should be kept to a minimum so as not to allow enzymatic oxidation of carotenoids, which can be a more serious problem than thermal decomposition. Crude red palm oil contains a substantial amount of carotenoids, which are degraded on refining.

Analysis

Although more reliable data on food carotenoids are being acquired, erroneous data persist in the international literature. This reflects the inherent difficulty in carrying out this type of analysis. The principal confounding factors are: (1) the existence of a large number of naturally occurring carotenoids, (2) qualitative and quantitative variation in the carotenoid composition among foods, (3) a wide range of carotenoid concentrations in a given food, and (4) the instability of carotenoids.

A major problem in carotenoid analysis arises from their instability. Thus, whatever the method chosen, precautionary measures to avoid artifact formation and quantitative losses must be taken, such as completion of the analysis within the shortest possible time, exclusion of oxygen, protection from light, avoidance of high temperature and contact with acids, and use of high purity solvents, free from damaging impurities (e.g., peroxides in ether and tetrahydrofuran).

The general procedure for carotenoid analysis consists of sampling and sample preparation, extraction, partition, or transfer to a solvent compatible with the subsequent chromatographic step, saponification and washing (for some samples), chromatographic separation, identification, and quantification. Common errors are: samples not representive of the food lots under investigation; inefficient extraction; physical losses during the different steps; incomplete chromatographic separation; erroneous identification, quantification, and calculation; and isomerization and oxidation (enzymatic or nonenzymatic) during analysis.

Carotenoid analysis has been carried out to different extent, depending on the information sought. For a long time, only the major provitamin A carotenoids were determined. With the mounting evidence on the importance of carotenoids in reducing the risk of degenerative diseases and the recognition that this

role is not related to the provitamin A activity, determination of nonprovitamin A carotenoids has also been pursued. The complete carotenoid composition is the ultimate aim of carotenoid analysis. However, considering that the carotenoid composition of foods typically consists of one to four principal components, with a series of carotenoids in trace amounts, it is doubtful that the added information is worth the greater complexity, higher cost, and longer analysis time. The determination of major carotenoids appears adequate for the generation of data for food databases.

Because of the various factors that affect the carotenoid composition of foods, proper sampling and sample preparation to obtain representative and homogenous samples for analysis are of paramount importance. Errors in these initial steps can easily surpass those of the analysis *per se*. In addition, results should be accompanied by pertinent information, such as the variety, stage of maturity, part of the plant analyzed, season, and geographic origin.

The classical technique for separating carotenoids is open-column chromatography (OCC). MgO: Hyflosupercel and neutral alumina are the preferred adsorbents. Fractions are eluted successively with solvents of increasing polarity (e.g., increasing proportion of ethyl ether and acetone in hexane or petroleum ether), the separation being monitored visually. Reproducibility and efficiency of separation depend heavily on the analyst's skill and experience.

Reversed-phase high-performance liquid chromatography (HPLC) on a C_{18} column is currently the method of choice. Reasons for the popularity of the C_{18} column are: its weak hydrophobic interaction with the carotenoids (expected to be less destructive than the polar forces in normal-phase OCC), compatibility with most carotenoid solvents, and the polarity range of carotenoids, and wide commercial availability.

Most carotenoid separations have been carried out with 5-μm C_{18} spherical particles packed in a 250 × 4.6 mm column. Some laboratories are already using shorter and narrower (narrow bore) columns, smaller particles (3 μm) and C_{30} stationary phase (especially for separating geometric isomers).

Monomeric phases are simpler to use and are more reproducible. Polymeric C_{18} phases, however, have an excellent selectivity for structurally similar carotenoids (e.g., geometric isomers, lutein and zeaxanthin). However, the peaks tend to be broader, and columns from different production lots are more variable than the monomeric columns

The most important properties to be considered in selecting the mobile phase are polarity, viscosity, volatility, and toxicity. In addition, it must be inert with respect to the carotenoids. Many solvent systems have been suggested as mobile phases for carotenoids, but the primary solvents are acetonitrile and methanol, and most systems are actually slight modifications of some basic combinations. Acetonitrile has been widely used because of its lower viscosity and slightly better selectivity for xanthophyls when a monomeric C_{18} column is used. However, higher recoveries of carotenoids were reported with methanol-based solvents. Carotenoid recovery with acetonitrile-based solvents can be improved with the addition of ammonium acetate and triethylamine. Methanol is also more available, less expensive, and less toxic than acetonitrile. Small amounts of other solvents (e.g., tetrahydrofuran, ethyl acetate) are added to obtain the desired retention, increase solubility, and improve resolution.

Gradient elution should only be used when the analysis cannot be done isocratically. Isocratic separation is rapid, can be performed with simple equipment, and results in a stable baseline and more reproducible retention times. It is usually sufficient for the determination of provitamin A carotenoids or the principal carotenoids.

Gradient elution offers a greater resolving power, improved sensitivity, and elution of strongly retained compounds. It is more likely to resolve the whole range of carotenoids found in a given food. However, it has several disadvantages: an increased complexity, requirement for more sophisticated and expensive equipment, a need for column reequilibration between runs, a greater differential detector response, and often a poor reproducibility.

Because of the qualitative and quantitative variation of the carotenoid composition of foods, it is doubtful that a single chromatographic condition can be established for the different foods. At least some modification of the mobile phase is needed when changing from one food to another. Analysts should also guard against undue confidence that modern instruments inadvertently give. It is very easy to make errors in HPLC. Unsatisfactory and variable recoveries from the HPLC column, especially of lycopene, have been reported.

The injection solvent must be compatible with the HPLC mobile phase. A chromatogram with peak tailing and broad, doubled peaks is obtained when the carotenoids are much more soluble in the injection solvent than in the mobile phase. However, the sample will not dissolve completely if the injection solvent is too weak.

The retention times and the ultraviolet–visible absorption spectra (λ_{max} and fine structure) provide the first clues for the identification of carotenoids. The availability of the photodiode array detector allows

the spectra to be obtained on-line. However, the widespread use of these two parameters as the only criteria has led to misidentifications. Thus, it has been recommended that the following minimum criteria be fulfilled for identification: (1) the visible (or ultraviolet for shorter chromophores) spectrum in at least two different solvents must be in agreement with the chromophore suggested; (2) chromatographic properties must be identical in two systems, preferably TLC (R_F) and HPLC (t_R), and cochromatography with the authentic carotenoid should be demonstrated; and (3) a mass spectrum should be obtained, which allows at least confirmation of the molecular mass. The requirement of a mass spectrum, however, would limit carotenoid analysis to a very few laboratories around the world, precluding its execution in areas where it is very much needed. Moreover, major well-known carotenoids can be conclusively identified by the judicious and combined use of chromatographic data, absorption spectra and specific chemical reactions to confirm the type, location, and number of functional groups. (*See* **Chromatography**: Thin-layer Chromatography; High-performance Liquid Chromatography.)

Mass spectrometry (MS) and nuclear magnetic resonance spectroscopy (NMR) are indispensable in the elucidation of unknown or inconclusive structures of carotenoids and are increasingly used with food carotenoids. MS gives the molecular mass, and typical fragmentations provide information about the structure. NMR recognizes new end groups and determines the location of *cis* double bonds. The chemical shift data for many end groups and *trans*/*cis* isomers are available from tables for both ^{1}H-NMR and ^{13}C-NMR. (*See* **Spectroscopy**: Nuclear Magnetic Resonance.)

The quantification step in OCC is straightforward. The separated carotenoid fractions are collected and quantified spectrophotometrically through the use of tabulated absorption coefficients. HPLC quantification is carried out by means of internal or external calibration, for which the concentrations of the standard solutions are also determined spectrophotometrically. Unfortunately, few carotenoid standards are available commercially and are of a widely varying purity. Other carotenoids have to be isolated and purified from natural sources by OCC or by accumulating separated fractions from several HPLC runs. Both procedures are time-consuming and require experience and patience. The instability of the carotenoid standards is another serious problem.

Notwithstanding the inherent difficulties and the many possible sources of errors, reliable data on food carotenoids can be obtained in the hands of careful and well-informed analysts.

Background

The carotenoids are polyisoprenoid compounds (usually tetraterpenes); most common carotenoids have 40 carbon atoms, although shorter (apocarotenoids) and longer forms exist. Frequently, carotenoids have

six-membered rings at each end of the polyprenoid chain, although lycopene (with no end rings) is a prominent exception (Figure 1). β-Carotene ($C_{40}H_{46}$, MW 536), with two β-ionone rings connected by a conjugated polyene chain, is the carotenoid prototype; formally, it can be considered to be composed of eight isoprene units joined head-to-tail, except in the center, so that the molecule is symmetrical about the center. The large number of conjugated carbon–carbon double bonds is responsible for carotenoids' high light-absorbing ability and intense red–yellow colors (wavelengths of maximum light absorption are typically 450–500 nm, molar extinction coefficients typically 132 000–185 000 $mol^{-1}l^{-1}$). Effective photoprotection requires at least nine conjugated double bonds, and absorption of visible light requires seven to 13 conjugated double bonds. Higher carotenoids (C_{45} and C_{50}), of bacterial origin, are products of addition of C_5 units to give a ring structure substituted at the 2-position.

The two major carotenoid subgroups are the carotenes (hydrocarbon carotenoids, including lycopene, α-carotene, and β-carotene) and the oxycarotenoids, also called xanthophyls (hydoxy-, oxy-, epoxy-, and furanoxy derivatives, such as lutein, canthaxanthin, and astaxanthin) (Figure 1). The prefix 'neo-' was previously used to designate carotenoids with at least one *cis* configuration in the polyisoprene chain, and the prefix 'pro-' designates some poly-*cis*-carotenoids. The prefix 'apo-' designates a chain-shortened structure (e.g., β-apo-8′-carotenal). Because the basic structures can be further metabolized by the introduction of hydroxyl, keto, or methoxyl groups, and by hydrogenation, cyclization, isomerization, and oxidative degradation, a great variety of structures exist; it has been estimated that more than 600 carotenoids have already been identified in nature. Good reviews on the structures and physical properties of carotenoids have been provided by Isler *et al*. and by Bauernfeind, and in a series edited by Britton, Liaaen-Jensen, and Pfander.

Carotenoids are synthesized by higher plants and by certain fungi, algae, and bacteria; they are not synthesized by animals but may be biochemically modified by them. Carotenoids are ubiquitous in the plant kingdom (no naturally occurring green plant lacks carotenoids), which suggests that their two functions are irreplaceable: as protectants against reactive singlet oxygen and as accessory photopigments. In photoprotection, chlorophyl and other cellular components are protected against irreversible destruction by preferential reaction of reactive singlet-state oxygen (electronically excited) with carotenoids. As accessory photopigments,

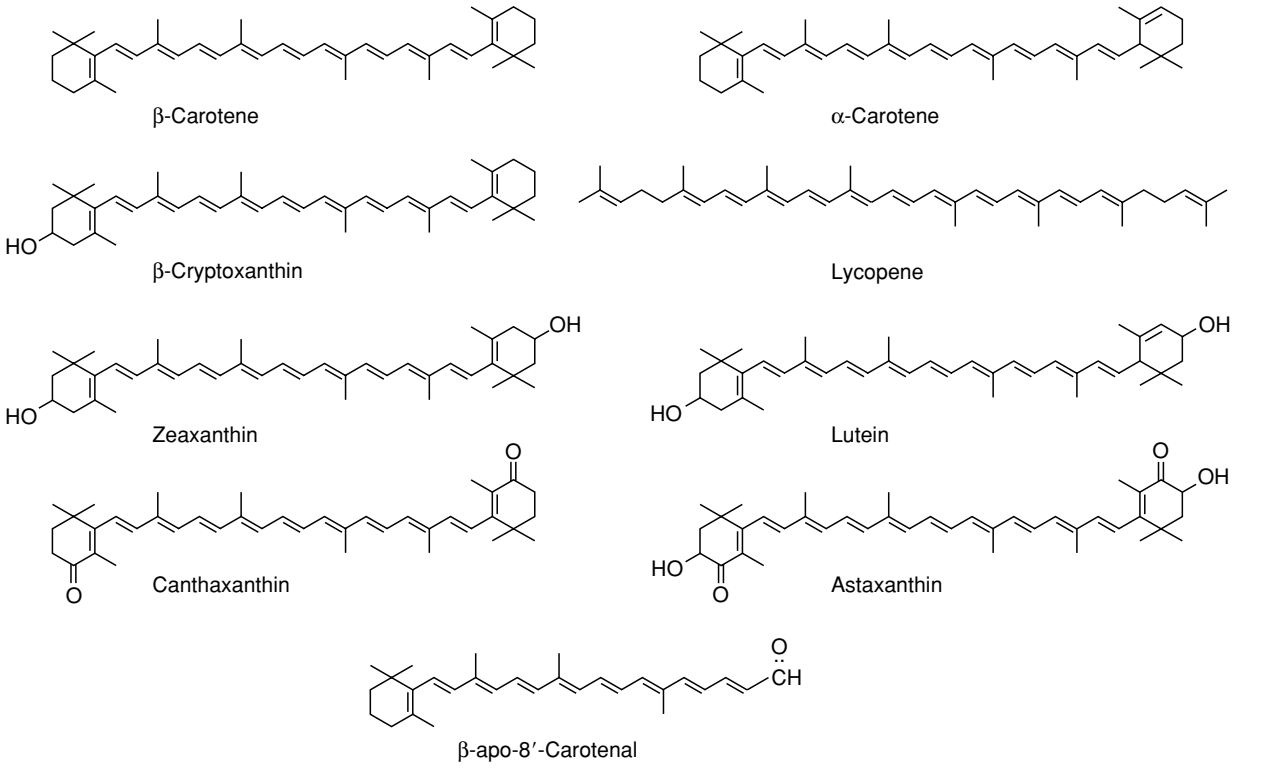

Figure 1 Structures of some representative carotenoids.

carotenoids increase the efficiency of photosynthesis by absorbing light in regions of the visible spectrum where chlorophyls do not absorb efficiently, then transferring the captured energy to other photopigments; carotenoids in photosystems are associated with proteins, and the carotenoid–protein interactions can shift the wavelength of maximum light absorption. Carotenoids are particularly effective in both processes, because their singlet electronic states are higher in energy, and their triplet states are lower in energy than those of chlorophyls, thus allowing both photoprotection and light-harvesting to be energetically favorable.

The total carotenoid production in the biosphere has been estimated at 10^8 tonnes per year; this is mostly due to fucosanthanin (characteristic of many marine algae) and the main carotenoids of green leaves, namely lutein, violaxanthin, and neoxanthin. β-Carotene, although quantitatively less important, occurs widely and is of particular interest as a major precursor of vitamin A for animal and human nutrition.

Absorption and Bioavailability of Carotenoids

There is considerable species variability in the efficiency of absorption and in metabolism of carotenoids. Humans are apparently unusual in absorbing, transporting, and storing both carotenes and xanthophyls well. Rats do not accumulate β-carotene, but instead metabolize almost all dietary β-carotene to vitamin A. In contrast, cattle show serum and milk accumulation of β-carotene but not of xanthophyls. Animals with yellow fat absorb and store carotenoids, whereas animals with white fat do not. Ferrets, gerbils, preruminant calves, and nonhuman primates have been used as animal models for human carotenoid absorption; rats and mice are also useful for studies of noncleavable carotenoids and for studies of pharmacological doses of carotenoids used for cancer prevention or treatment. Some fish (for example, salmonids) and birds absorb xanthophyls particularly well and use them as pigments.

Intestinal absorption of carotenoids in animals requires the presence of bile acids; human subjects with impaired bile flow (biliary atresia) show low levels of liver carotenoids compared with normal subjects. The presence of other dietary lipid promotes expansion of the mixed bile salt micelle and enhances carotenoid absorption. Animal and human feeding studies have shown that the biological matrix of food affects absorption of dietary carotenoids, and dietary carotenoids in plant tissues have a lower bioavailability than those in oil solutions. Hence, the plant source and method of preparation of foods affect bioavailability of β-carotene and other carotenoids: processes that break down the biological matrix (e.g. grinding or chopping, mild cooking) improve carotenoid absorption. Castenmiller and West (1998) have characterized the factors affecting carotenoid absorption as Species of carotene; Molecular linkage (e.g., esterification of xanthophyls); Amount of carotene consumed in a meal; Matrix in which the carotenoid is incorporated; Absorption modifiers (including lipid content of the meal); Nutrient status of host (in particular, vitamin A status); Genetic factors; Host-related factors; and Interactions (e.g., competition among carotenoids for absorption).

Unequivocal estimation of the efficiency of absorption of dietary carotenoids is very difficult because of the ubiquitous presence of carotenoids in the diet (and thus in plasma and other tissues), slow absorption kinetics, partial metabolism of carotenoids, and considerable individual variation in the extent of absorption and metabolism.

Transport, Distribution, and Storage of Carotenoids

As with other lipids, freshly absorbed carotenoids are transported in the lymph via chylomicra. It is believed that the carotenoids, as with other lipid components of the chylomicron remnants, are taken up by the liver and then released into the blood stream as components of very-low-density lipoproteins (VLDL). The VLDL are taken up by extrahepatic tissues, their components processed into low-density lipoproteins (LDL), and eventually into high-density lipoproteins (HDL). Early studies showed that in human plasma, the hydrocarbon carotenoids β-carotene and lycopene are predominantly associated with LDL (75%) and HDL (25%); the xanthophyl lutein is approximately equally distributed between HDL and LDL. In cattle, where the predominant plasma lipoprotein is HDL, more than 80% of total plasma β-carotene is transported in this fraction. The predominant human serum carotenoids in the USA are β-carotene, α-carotene, lycopene, β-cryptoxanthin, lutein, and zeaxanthin, and also the colorless carotenoids phytoene and phytofluene; serum carotenoid profiles and concentrations are highly dependent on dietary intake and so depend on food habits. It is estimated that serum carotenoids represent about 1% of total body carotenoids in the human.

Adipose tissue (80–85% of total body carotenoids) and liver (8–12%) are the major sites of carotenoid deposition in humans when the total mass of tissue carotenoid is considered. Typical total human carotenoid levels of 100–150 mg are reported from

autopsy analyses. Human adipose carotenoid profiles are similar to those of serum. Reported values for total human liver carotenoids range between 0 and 97 μg per gram of liver (i.e., 0–0.18 μmol g^{-1}; total carotenoids were expressed as β-carotene in older studies), and include lutein, lycopene, α-carotene, and β-carotene. Other tissues that are known to contain high concentrations of carotenoids include adrenals (20 μg g^{-1} (37 nmol g^{-1}) tissue, mostly as β-carotene) and human macular pigment (containing predominantly the xanthophyls lutein and zeaxanthin), as well as kidney, ovaries, pituitary, placenta, testes, and thymus in cattle. Chick retinal oil droplets accumulate astaxanthin, which can be formed from dietary zeaxanthin or canthaxanthin. It has been suggested that organs with high numbers of LDL receptors and high rates of LDL uptake show higher tissue levels of carotenoids.

The specific accumulation of certain carotenoids in particular tissues may furnish clues to distinctive physiological roles of carotenoids. The macula of the primate eye accumulates the xanthophyls lutein and zeaxanthin, with lutein being found predominantly in the center of the macula; loss of these xanthophyls is associated with macular degeneration, a disease characteristic of aging. Bovine corpus luteum amasses xanthophyls (as much as 60 μg of total carotenoids per gram, 105 nmol per gram of tissue), and it has been suggested that carotenoids play some important role in bovine reproduction; however, porcine corpus luteum does not accumulate carotenoids. Bovine pineal gland has been found to store β-carotene (as much as 1 μg per gram, 2 nmol per gram of wet tissue), with perhaps small amounts of xanthophyls also present; the absence of other carotenoids was noteworthy. Levels of approximately 1 μg of total carotenoid per gram of bovine pituitary gland have been reported. The physiological importance of these accumulations of carotenoids is, however, not clear.

Carotenoid–protein interactions have been studied in plants, bacteria, and marine invertebrates. The strength of specific protein–carotenoid binding depends, not surprisingly, on carotenoid structure. Distinctive interactions between a binding protein and its carotenoid ligand are evident by the spectral changes of the carotenoid on binding; these spectral changes may reflect physiological functions as well as producing color polymorphism among species. A notable example of these carotenoid–protein interactions is the binding of the xanthophyl astaxanthin (red-colored in solution) to the protein α-crustacyanin in the lobster, giving a pigment that is typically blue–green; on boiling the animal, the carotenoid is released from its binding protein to yield a bright red color.

Retinol Equivalents of Different Carotenoids

Of the more than 600 known carotenoids, only about 60 have been reported to be precursors of vitamin A. In order to serve as a precursor of vitamin A, a carotenoid must have at least one unsubstituted 'β-ionone' ring (2,6,6-trimethyl-1-cyclohexen-1-yl) with a polyene side chain of at least 11 carbon atoms. Thus, α-carotene (with one β-ionone ring) has half the biological activity of β-carotene, and canthaxanthin (with keto substitutions on both rings; **Figure 1**) has no provitamin A activity. Absolute vitamin A activity, however, depends on a number of other factors, not all of which are well understood. In general, it seems that the efficiency of the conversion of carotenoids to vitamin A depends on the vitamin A status: high intakes of preformed vitamin A result in poor efficiency of conversion to vitamin A, perhaps due to metabolic control of the cleavage enzyme(s). Frank vitamin A deficiency is also associated with impaired conversion efficiency, perhaps because of damaged intestinal epithelial function in vitamin A inadequacy. Because conversion of β-carotene to vitamin A is impaired in vitamin A deficiency, vitamin A deficiency disease is more rapidly cured by providing preformed vitamin A than by providing dietary carotenoids. Excessive vitamin E intake may impair carotenoid cleavage (or interferes with intestinal absorption); vitamin E deficiency decreases vitamin A formation, perhaps because adequate vitamin E is needed to protect carotenoids and vitamin A from oxidation. Conversion efficiency of β-carotene and other carotenoids to vitamin A is also decreased at high carotenoid intakes, perhaps due to impaired intestinal absorption or to metabolic control of the cleavage enzyme(s). Protein deficiency impairs carotenoid cleavage, suggesting that protein malnutrition in humans exacerbates vitamin A deficiency.

Common dietary sources of provitamin A carotenoids are carrots, yellow squash, dark-green leafy vegetables, yellow maize, tomatoes, papaya, and oranges. Cereal grains and white maize contain little or no provitamin A. Red palm oil is one of the richest sources of provitamin A carotenoids, containing approximately 0.5 mg of α-carotene + β-carotene per milliliter; as little as 7 ml of palm oil per day may provide adequate vitamin A for the preschool child. On a global basis, β-carotene is the most important vitamin A precursor, both because of its greater provitamin A activity and because of its wide distribution in plant products. The recent incorporation of the enzymatic pathway of carotenoid biosynthesis into rice ('Golden Rice') promises to help alleviate vitamin A deficiency in parts of the world where rice is

Table 1 Vitamin A activity of common carotenoids relative to β-carotene[a]

Carotenoid	*Activity (%)*	*Occurrence (partial list)*
β-Carotene	100	Green plants, vegetables, carrots, yellow sweet potatoes, squash, tomatoes, red and yellow fruits
α-Carotene	50–54	Green plants, carrots, squash, maize, green peppers
γ-Carotene	42–50	Carrots, sweet potatoes, maize, tomatoes, algae, some fruits
β-Carotene 5′,6′-monoepoxide	21	Plants, potatoes, red peppers
β-Carotene 5,6:5′,6′-diepoxide	Active?	Plants
β-Carotene 5′,8′-monofuranoxide (mutatochrome, citroxanthin, flavacin)	50	Orange peel, red peppers, tomatoes, sweet potatoes, cranberries
4-Keto-β-carotene (4-oxo-β-carotene, echinenone, aphanin, myxoxanthin)	44–54	Algae, sea urchins, *Daphnia*, *Hydra*, red sponges, brine shrimp, crustaceans
3-Keto-β-carotene (3-oxo-β-carotene)	52	
3-Hydroxy-β-carotene (β-cryptoxanthin)	50–60	Yellow maize, green peppers, lichens, persimmons, papayas, lemons, oranges
4-Hydroxy-β-carotene (isocryptoxanthin)	48	Brine shrimp
3,4-Dehydro-3′-hydroxy-β-carotene (anhydrolutein, deoxylutein)	Active, *c.* 10	Alfalfa meal, acidulated soybean soapstock
3-Hydroxy-4-keto-β-carotene (hydroxyechinenone)	Probably active	Algae, bacteria, flowers
β-Apo-2′-carotenal	Active	Citrus fruit
β-Apo-8′-carotenal	36–72	Citrus fruit, green plants
β-Apo-10′-carotenal	Active	Citrus fruit, green plants, alfalfa meal
β-Apo-12′-carotenal	120	Alfalfa meal
β-Apo-8′-carotenoic acid	Active	Maize, animal tissue
β-Apo-8′-carotenoic acid ethyl ester	25–78	
Lycopene	Inactive	Tomatoes, carrots, green peppers, pink citrus fruit
3,3′-Dihydroxy-β-carotene (zeaxanthin)	Inactive	Spinach, paprika, yellow maize, green peppers, fruits
3,3′-Dihydroxy-α-carotene (lutein)	Inactive	Green leaves, yellow maize, potatoes, spinach, green peppers, carrots, tomatoes, fruits
3,3′-Dihydroxy-4,4′-diketo-β-carotene (astaxanthin)	Inactive	Oranges, crustaceans, lobster, fish, algae, *Daphnia*, trout, salmon
4,4′-Diketo-β-carotene (canthaxanthin, aphanicin)	Inactive	Mushrooms, trout, *Daphnia*, *Hydra*, microorganisms, algae, crustaceans, brine shrimp
Capsanthin	Inactive	Red peppers, paprika
Capsorubrin	Inactive	Red peppers, paprika
Bixin	Inactive	Annatto seeds

eaten extensively. Other provitamin A carotenoids, such as α-carotene and β-cryptoxanthin and β-apo-carotenals, can be nutritionally important sources of vitamin A from particular foods (Table 1). Other carotenoids, such as lycopene (which has no β-ionone rings) and the dihydroxycarotenoids lutein and zeaxanthin (which are substituted on both ionone rings), may be major carotenoids in particular foods and may have other important physiological functions but have no provitamin A activity.

Estimation of provitamin A content of foods from food composition tables is problematic: carotenoid composition of raw fruits and vegetables varies with species, growth conditions, and mode of storage. Furthermore, older tables often express total carotenoids as 'β-carotene,' ignoring the different provitamin A activity of different carotenoids. Biological activity of carotenoids in foodstuffs may differ from the analyzed content because of the mode of preparation, binding of carotenoids within the foodstuff, and the nature of the meal (presence or absence of fat), as discussed above. Conversion factors, recently revised to account for apparent bioavailability of carotenoids from foods, are given in Table 2.

Enzymatic Conversion to Vitamin A

By comparison of the structure of β-carotene with that of vitamin A, it would appear that β-carotene could be cleaved in its center (between the 15 and 15′ carbon atoms) to give two molecules of vitamin A per molecule of carotenoid. Such a mechanism was first proposed by Karrer. However, in addition to this central (symmetric) cleavage, a random (asymmetric) cleavage has been proposed. Glover first suggested that asymmetric cleavage of the symmetric β-carotene molecule could be followed by stepwise shortening to vitamin A. In support of this hypothesis, small

Table 2 Conversion factors for estimating vitamin A value from carotenoid composition[a]

Factors
1 retinol activity equivalent (RAE)
= 1 μg all-*trans* retinol
= 12 μg all-*trans* β-carotene
= 24 μg other provitamin A carotenoids
= 3.33 IU vitamin A
(Note that 1 RAE = 1.15 μg of retinyl acetate (MW 328) = 1.83 μg of retinyl palmitate (MW 524), i.e., molar equivalence)
1 International Unit of vitamin A (IU_A)
= 0.3 μg all-*trans* retinol

(2) β-Carotene and other provitamin A carotenoids given in μg, RAE = (μg β-carotene/12) + (μg other provitamin A carotenoids/24)

[a]Adapted from Olson JA (1987) Recommended dietary intakes (RDI) of vitamin A in humans: Appendix. *American Journal of Clinical Nutrition* 45: 704–716 and from Panel on Micronutrients, Subcommittees on Upper Reference Levels of Nutrients and of Interpretation and Use of Dietary Reference Intakes, and the Standing Committee on the Scientific Evaluation of Dietary Reference Intakes (2001) *Dietary Reference Intakes for Vitamin A, Vitamin K, Arsenic, Boron, Chromium, Copper, Iodine, Iron, Manganese, Molybdenum, Nickel, Silicon, Vanadium, and Zinc*. Washington, DC: National Academy Press. Available online at http://books.nap.edu/.

amounts of labeled β-apo-8′-, β-apo-10′-, and β-apo-12′-carotenal (and their alcohols and acids) have been found in rat tissues after feeding radioactive β-carotene. These apo-carotenals can be formed by chemical reaction of oxidizing agents (hydrogen peroxide, potassium permanganate) with β-carotene *in vitro*, and they are found in small amounts in plants and in animal-feeding experiments. Enzymatic asymmetric cleavage activity has been demonstrated *in vitro*, but its relative importance has not been established. However, *in vitro* experiments (initially carried out by Olson and Hayaishi and by Goodman and Huang) using partially purified intestinal homogenates (from rat, rabbit, or guinea-pig) have demonstrated symmetric cleavage of β-carotene, with retinal (vitamin A aldehyde) as the only detectable product. This enzymatic activity requires the presence of O_2, and has been named '15,15′-β-carotenoid dioxygenase' (EC 1.13.11.21). The enzyme has recently been cloned from mammalian sources, and its further characterization promises to explain much about the factors affecting provitamin A activity of β-carotene and related carotenoids. This enzymatic activity has been demonstrated in intestine, liver, kidney, and several other tissues *in vitro*. β-Carotene is not a source of vitamin A in the cat, and it has been reported that 15,15′-dioxygenase activity is not present in cat intestine, consistent with the 'central cleavage' hypothesis. The possiblity remains that excentric cleavage is a source of retinoic acid, which is an important modulator of gene expression.

Some fish and birds can also convert the xanthophyls astaxanthin, canthaxanthin, and isozeaxanthin to vitamin A; some freshwater fish can convert lutein to 3,4-didehydroretinol (vitamin A_2). Keto carotenoids can be reduced to the corresponding alcohols and esterified with long-chain fatty acids.

Toxicity of Carotenoids

There is virtually no toxicity associated with high intakes of carotenoids, in marked contrast to vitamin A. Excessive human ingestion of β-carotene can cause high serum carotenoid levels and yellowing of light-colored skin, but such over-intake is very unusual, and no harmful physiological effects from even such high intakes of β-carotene have been reported. The effects disappear when high carotenoid intakes cease. Ingestion of large amounts of carotenoids does not give rise to hypervitaminosis A, probably because of the decreased efficiency of conversion of carotenoids to vitamin A at high intakes. Teratogenicity due to carotenoids has never been suggested. β-Carotene supplementation in humans does not produce elevated serum triacylglycerols or cholesterol. However, prolonged intake of high doses (20 mg per day) of β-carotene has been associated in epidemiologic studies with increased risk of lung cancer in cigarette smokers, perhaps because of the prooxidant effects of β-carotene at relatively higher oxygen concentrations in the lungs. Although ingestion of 3–10 mg of carotenoid per day from foods and dietary supplements appears to be completely safe and advisable, there are concerns that higher doses of β-carotene (20–30 mg per day) may not be safe in smokers.

The only carotenoid that has been clearly associated with adverse effects is canthaxanthin (4,4′-diketo-β-carotene), a carotenoid that has been used in treatment of patients with erythropoietic protoporphyria

and related skin disorders. High daily doses (50–100 mg) have resulted in canthaxanthin retinopathy (crystalline deposits in the retina leading to impaired night vision); the effect is slowly reversible on cessation of intake. Pharmacological doses of canthaxanthin have depressed liver accumulation of dietary vitamin A in rats. Human ingestion of large amounts of canthaxanthin gives a yellowish coloration to light-colored skin; this is the basis of some 'skin tanning' pills.

Therapeutic Role of Carotenoids

In addition to the important role of some carotenoids as vitamin A precursors, there is evidence that carotenoids can quench singlet oxygen and can serve as radical-trapping antioxidants; it has also been shown that carotenoids may have a role (apart from being precursors of retinoids) in enhancing the immune function in animals. Singlet-oxygen trapping and antioxidant capabilities are shown by carotenoids that have no provitamin A activity (such as lycopene and astaxanthin) as well as by provitamin A carotenoids.

Both β-carotene and canthaxanthin have been used in large dose regimens to ameliorate photosensitivity associated with erythropoietic protoporphyria (a genetic disease of porphyrin metabolism). β-Carotene also prevents photosensitivity resulting from quinidine ingestion, but not photosensitivity to ultraviolet light, although it has been reported that human serum carotenoid levels decrease after repeated exposure to ultraviolet light.

Epidemiological evidence strongly suggests a role for carotenoids in human cancer prevention, although such studies may be confounded by other factors. The strongest evidence is for a protective effect of carotenoids against lung cancer; tomato products (which provide lycopene) may be more effective than carrots and squash (sources of β-carotene). In particular, consumption of tomato products (high in lycopene) has been associated epidemiologically with a reduced risk of prostate neoplasms. Protective effects of carotenoids against laryngeal cancer, gastric cancer, invasive bladder cancer, and cervical dysplasia and cervical cancer have been suggested also; these effects are not shown by vitamin A, suggesting a direct role of carotenoids. Neither carotenoids nor vitamin A protect against cancers of the esophagous or gastrointestinal tract, breast, head, or neck. A variety of cancers in animal models are prevented or delayed by carotenoids, including skin tumors and mammary tumors. In studies in cells in culture, carotenoids can prevent malignant transformation, sister chromatid exchange, and mutagenic effects in bacterial systems.

A high consumption of carotenoid-containing foods is associated with a reduced risk of coronary heart disease, although there is a lack of consistency in identifying the responsible compounds.

Carotenoids have been found to enhance both specific and nonspecific immune functions, including proliferation of T- and B-lymphocytes, induction of specific effector cells capable of killing tumor cells, and increased production of tumor necrosis factor, and secretion of factors required for communication between cells (prostaglandins and leukotrienes). It has been suggested that the mechanism(s) may involve quenching singlet oxygen and trapping free radicals (generated by neutrophils to kill invading cells), or maintaining cell-membrane fluidity (important for the function of membrane receptors and for the release of immunomodulating factors). Again, some of the immunologic functions of carotenoids seem to be independent of any provitamin A activity, although retinoids are also important in immune function.

The xanthophyls lutein and zeaxanthin are accumulated specifically in the macula of the primate eye, and high dietary intakes of these two carotenoids (and elevated plasma concentrations) are associated with a reduced risk of age-related macular degeneration.

Elucidation of these biochemical effects of carotenoids and further explanation of the metabolism of conversion of carotenoids to vitamin A remain central issues in the study of carotenoid function.

Methods of Manufacture

C R Southward, Fonterra Research Centre, Palmerston North, New Zealand

This article is reproduced from *Encyclopedia of Dairy Sciences*,

Introduction

The commercial production of casein, the principal protein in cows' milk, has occurred for most of the 20th century. During the period to 1960, the major proportion of casein was used in technical (or non-food) applications. More recently, however, there has been a significant change from technical to edible uses for casein products and this has been reflected in the introduction of requirements for pasteurization of milk intended for casein manufacture (*c*. 1970) and the greater number of specifications for microbial quality and freedom from impurities. At the present time, the major producers of casein include the European Community (in particular, Denmark, France, Germany, the Irish Republic, and The Netherlands) and New Zealand, with Poland, Australia, and India producing smaller quantities. World production of casein products is currently estimated at 220 000–250 000 tonnes. This article describes the manufacture of the main casein products.

General

The proteins that exist in milk can be broadly divided into two groups – casein and whey proteins. Caseins may be considered as those proteins that are precipitated when unheated (raw) milk is acidified to pH 4.6 (the isoelectric point of casein) whereas whey proteins remain in solution. Commercial casein is a mixture of four different caseins – α_{s1}-, α_{s2}-, β- and κ-casein, and may sometimes be referred to as whole casein. As a phosphoprotein, casein belongs to a relatively rare class of proteins. It contains 0.7–0.9% phosphorus, covalently bound to the casein by a serine ester linkage. Casein exists in milk in combination with calcium, inorganic phosphate, and citrate as a colloidal suspension of complex micelles and accounts for 2.6–2.9% by weight of whole milk.

Manufacture

Casein may be precipitated from skimmed milk to produce several products such as acid casein, rennet casein, or coprecipitate. All these products are insoluble in water after precipitation. However, addition of alkali to acid casein yields water-soluble caseinate.

Acid Casein

Acidification

When milk (pH 6.6) is acidified, the calcium and inorganic phosphate are removed from the casein micelles, the net charge on the micelles decreases, and the micelles become less and less stable until the casein precipitates. Complete precipitation of the casein occurs at the isoelectric point, pH 4.6. Acidification of the milk may be carried out by one of the following processes:

1. Inoculation of milk with lactic acid-producing bacteria such as *Lactococcus lactis* subsp. *lactis*

or *cremoris*. These bacteria, commonly known as 'starters,' convert some of the lactose in the milk to lactic acid during the period of incubation (about 16–18 h). This is the most commonly employed method of manufacture in New Zealand (Figure 1).

2. Direct addition of dilute acid to skimmed milk. Hydrochloric acid, sulfuric acid, phosphoric acid, or lactic acid (or, occasionally, other organic acids) may be used for this purpose. The most common method of producing acid casein in countries other than New Zealand is by means of hydrochloric acid.
3. Indirect acidification of skim milk. A number of alternative processes have been patented in which skimmed milk is acidified by one or more of the following:
   - contact by means of ion exchange resins in the acid (cation) form
   - addition of acidified whey
   - electrodialysis

It is believed that these processes have relatively minor commercial significance.

Cooking/Acidulation

In the manufacture of acid casein, acidification of the milk is followed, or occasionally preceded, by heating of the mixture. Heating promotes agglomeration of the casein curd particles which subsequently shrink (syneresis) to expel whey. At the same time, the curds become firmer and are able to withstand the mechanical processing that follows. Heating of the acidified milk is sometimes termed 'cooking' (as used in cheese manufacture) and may be carried out, usually in the temperature range 45–55 °C, by:

1. injection of steam into the pipeline carrying the acidified milk
2. indirect heating by means of a heat exchanger
3. a combination of both – preheating through a heat exchanger with steam injection to complete the heating process (Figure 1)

In each case, the cooked curds and whey are held in a 'cooking pipe' for a period of about 10–20 s before they emerge into an acidulation vat. The curds and whey may remain here for a period varying from 30 s to about 15 min, during which time the curds are agitated gently in the whey until equilibrium between the calcium in the curds and that in the whey is attained.

Alternative processes may use a syneresis tube; the cooked curds and whey are held in a large-diameter tube for a period of several minutes (also undergoing acidulation or equilibration).

Dewheying and Washing

Following acidulation, the curds and whey are discharged by gravity to a dewheying screen above the first washing vat. The whey is removed and the curds fall into the vat. Alternatively, the curds and whey may be separated more completely using a horizontal solid-bowl centrifuge (decanter) or a casein-dewatering press before the curds are transferred to the first wash. A combination of screening and decanter dewheying can be used to reduce the hydraulic load on the decanter. The purpose of washing is to remove whey (containing mainly lactose) from the curds so that the casein produced is relatively pure. The temperature of the wash water may be varied, depending upon particular requirements. Casein is usually subjected to multiple washes and these are operated in a counterflow to the direction of the curds, with the purest curd meeting the cleanest water.

Dewatering

After washing, the curds are mechanically dewatered to remove excess water before drying. As drying is a relatively expensive operation, it is worthwhile removing as much water as possible from the curd before transferring the casein to the drier. The texture of the curd is affected by temperature; as the temperature of the wash water is increased, the curd releases more water during dewatering but becomes firm and more plastic and is consequently harder to break up and dry. Therefore, it is necessary to regulate carefully the temperature of the last wash to optimize the conflicting requirements of minimum water content and maximum friability of the curd.

Equipment for dewatering casein curd consists of roller or belt presses, decanters, and screen-bowl centrifuges. The roller press, used for many years, is designed to reduce the moisture content of curd to about 55%. The belt press will do a similar duty. Solid-bowl decanters or screen-bowl centrifuges are capable of reducing the moisture content of acid casein curd to about 52%.

Drying

Drying of casein curd is most commonly carried out using horizontal vibrating fluid-bed driers. These driers have two or more perforated stainless-steel decks (Figure 1). The combined effect of vibration of the decks and the flow of hot air (typical temperature range 75–115 °C) up through the holes in the decks causes the casein curd to become fluidized and materially helps in the removal of moisture from the particles. Most of the water is removed during the early stages of drying of the casein as it is evaporated from the surface of the particles. The later stages

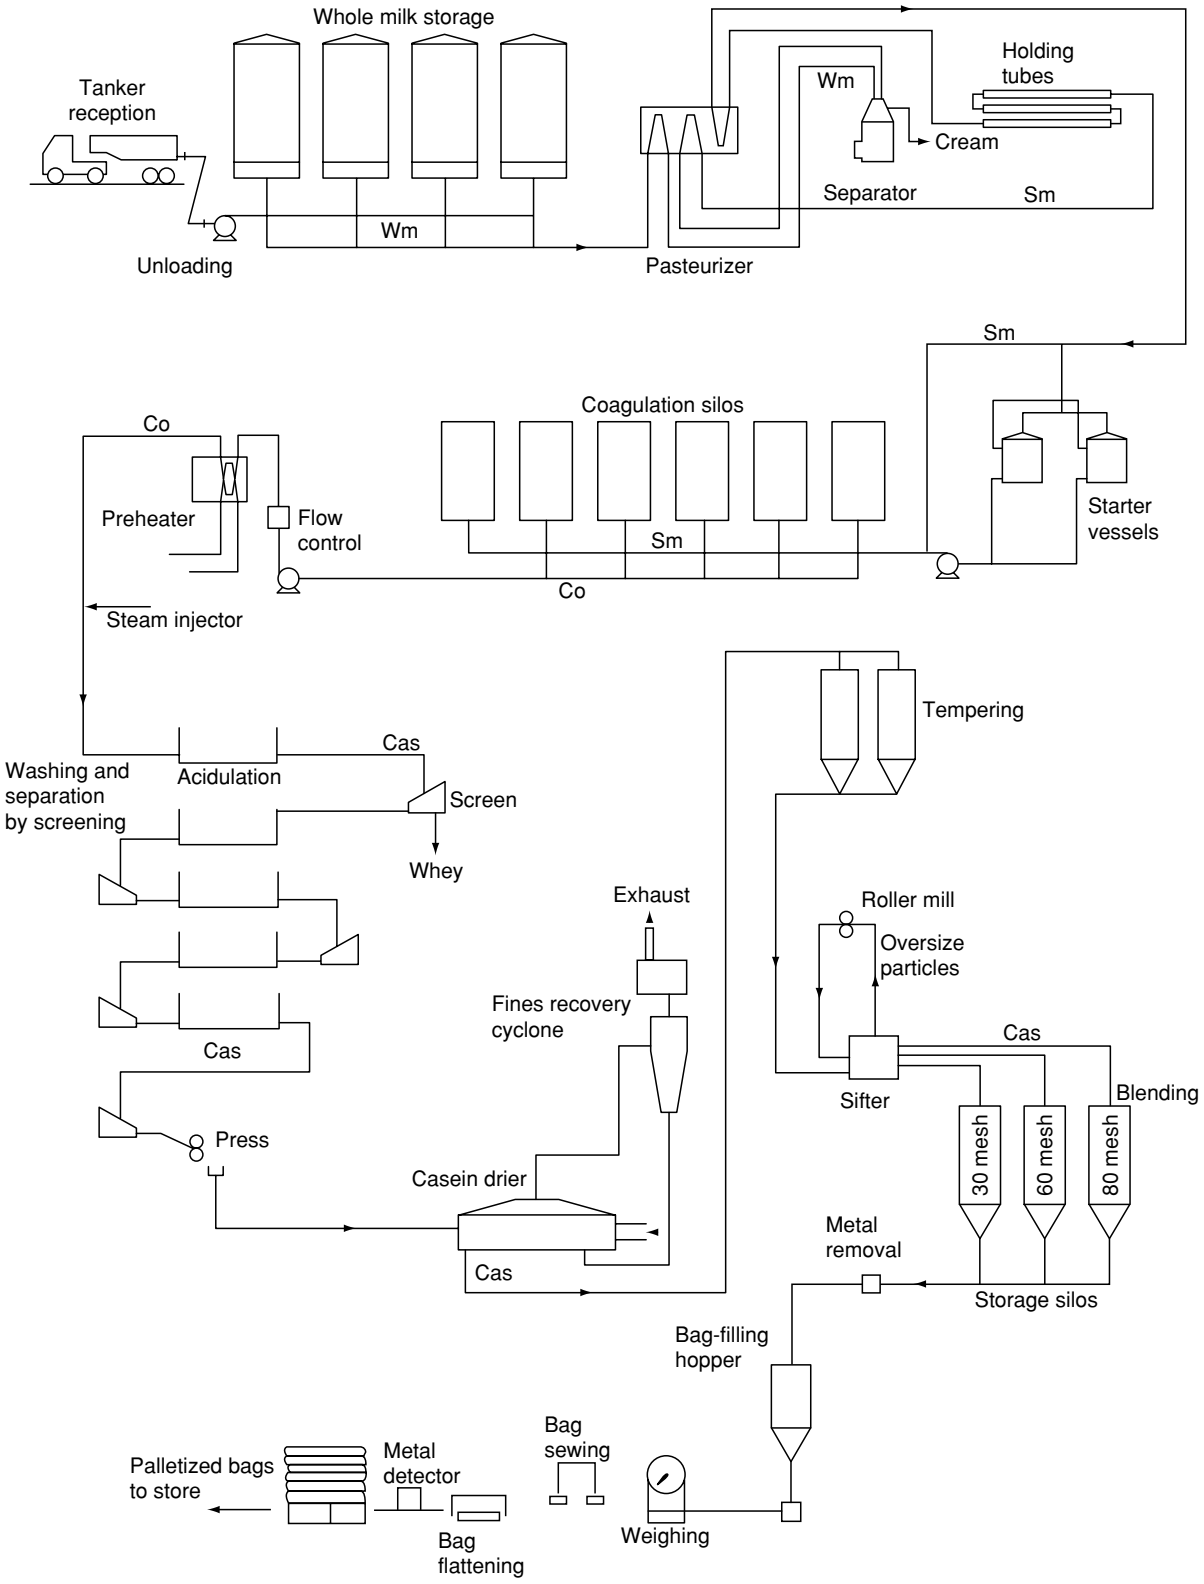

Figure 1 Outline of the manufacturing steps involved in producing lactic acid casein from skim milk. Wm, whole milk; Sm, skimmed milk; Co, coagulum; Cas, casein.

of drying require the transfer of moisture from the center to the surface of the particle, and this is a much slower process.

Pneumatic-conveying ring driers and attrition driers are also used for drying casein. These employ inline milling and tend to produce finer casein products than those dried in fluid-bed driers.

Cooling, Tempering, Milling, Sifting, Blending, Packing

Casein that is produced using fluid-bed driers is warm and soft and unsuitable for grinding immediately in some mills such as roller mills. Consequently, the casein may be cooled and then transferred to tempering bins where equilibration of moisture can occur in and between all the particles during a period of 8–24 h.

The casein may then be ground and sieved, using multideck, gyrating screens, into various particle sizes, usually < 600 μm. Very fine casein (e.g. < 150 μm) is generally produced using pin mills.

Following blending of the ground casein, it is packed into multiwall paper bags equipped with plastic liners and stored. The typical composition of acid casein is shown in Table 1.

Rennet Casein

Action of Chymosin

Casein may also be precipitated from milk by the action of a proteolytic enzyme, such as chymosin, which is present in calf rennet. Chymosin (and other enzymes from animal or microbial sources that cause milk to clot) splits off a portion of the κ-casein (referred to as glycomacropeptide or GMP) from the micelles. As a result, the micelles are no longer stable in the presence of calcium ions and form a three-dimensional gel. This process is essential in the production of most types of cheese.

Clotting of Skimmed Milk

Pasteurized skimmed milk at a temperature of 29 °C (or lower) is mixed with calf rennet (or other milk-clotting enzyme) in the approximate ratio (by volume) of 1:7500 rennet to the milk. If a lower setting temperature is used, renneting time must be correspondingly increased. It is also possible to reduce the quantity of rennet added under these conditions and consequently allow a longer time for rennet action to occur.

Cooking

The usual technique for cooking rennet casein involves the injection of steam into a cooking line of clotted milk pumped from a vat. However, the vat cooking technique (similar to that used in cheese manufacture) is also practiced in some countries. The cooking temperature used in making rennet casein usually varies from about 50 to 60 °C.

Dewheying, washing, dewatering, and drying of the curd then proceed in a manner similar to that used for acid casein, and the dried casein is also treated as outlined previously.

Where indirect cooking of rennet casein is used, a tubular heat exchanger may be used to cook the curds and whey to a temperature similar to that used in the direct cook (steam injection) process. Other processing steps are similar to those described above but no acidulation step is required after cooking of the rennet casein.

The typical composition of rennet casein is shown in Table 1.

Table 1 Typical composition and properties of casein products

Component	*Acid casein*	*Rennet casein*	*Sodium caseinate (spray dried)*
Composition	Amount per 100 g		
Moisture (g)	11.5	11.5	4.5
Fat (g)	1.1	0.4	1.0
Protein (g) (nitrogen × 6.38)	86.2	81.3	92.0
Ash (g)	1.8	8.2	3.6
Lactose (g)	0.1	0.1	0.1
	Amount per 1 kg		
Copper (mg)	2	2	2
Lead (mg)	< 1	< 1	< 1
Iron (mg)	5–20	5	5–10
Physical properties			
Color	Creamy white	Creamy white	White
Flavor	Bland, clean	Bland, clean	Bland, clean
Solubility in water	Insoluble	Insoluble	Soluble

Coprecipitates

Coprecipitates are combinations of casein and whey proteins that are coprecipitated from heated (skimmed) milk. When milk is heated to a temperature greater than 70 °C, some of the whey proteins are heat-denatured and may interact with some of the caseins. When a casein precipitant (such as acid or calcium chloride) is added to the heated milk, the casein and whey proteins coprecipitate together. Depending on the pH of precipitation (which may vary from 6.6 to 4.5), the coprecipitate will contain different quantities of calcium (high-calcium at pH 6.6 to low-calcium at pH 4.5). As whey proteins have a higher nutritional value than casein (as measured by several different biological and chemical techniques), coprecipitates also have an enhanced nutritional value compared with casein. The yield of coprecipitate from skimmed milk is usually 5–20% greater than that of acid casein.

Caseinates

Caseinates are produced by the neutralization of acid casein with alkali. All caseinates are substantially water-soluble and are typically prepared as a solution of about 20% solids prior to spray drying. Roller-dried caseinates may be prepared from more concentrated solutions. It is also possible to prepare granular, partly soluble, or semidispersible forms of caseinate in which the casein and alkali have only partly reacted. Sodium caseinate is the most common form of this class of product and is prepared by mixing a solution of sodium hydroxide, bicarbonate, or carbonate with acid casein curd or dry acid casein that has been suspended in water and then drying the resultant solution (Figure 2). The dried powder dissolves completely in water to produce a viscous, sticky, straw-colored solution.

Calcium caseinate, on the other hand, produces a thin, opaque, white colloidal dispersion in water, similar in appearance to milk. Other caseinates, such as those of potassium and ammonium, are similar in general properties to sodium caseinate. Magnesium caseinate has properties that are intermediate between those of sodium and calcium caseinates. However, relatively insignificant commercial quantities of these products are manufactured at the present time.

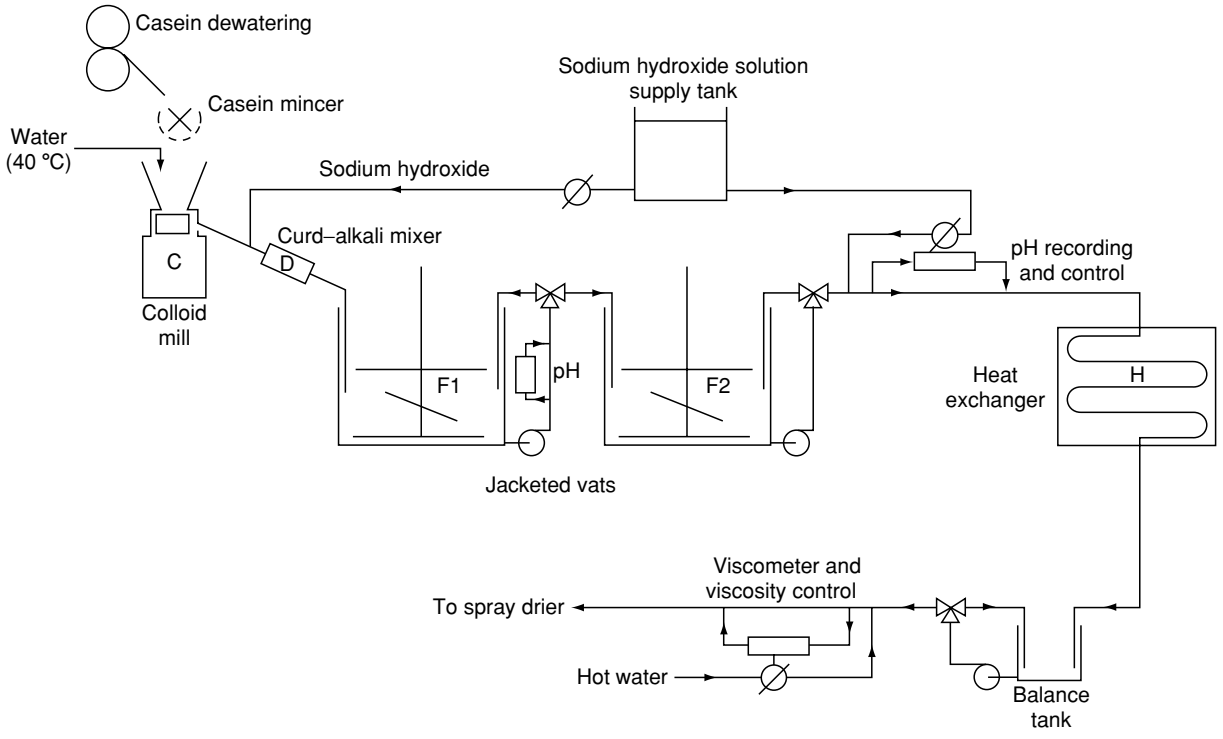

Figure 2 Suggested plant layout for dissolving casein for sodium caseinate manufacture. Dewatered casein curd is minced, mixed with water, and finely milled in a colloid mill (C). The curd–water slurry is then mixed (D) with dilute sodium hydroxide solution and transferred to the first of two jacketed dissolving vats (F_1), each equipped with an agitator. The sodium caseinate solution is subsequently pumped from the second dissolving vat (F_2) and extra alkali is added, if necessary. The solution is heated by means of a tubular heat exchanger (H) and then pumped via a balance tank to the spray (or roller) drier for drying. The viscosity of the solution may be monitored and reduced, if necessary, by addition of hot water. From Southward CR (1985) Manufacture and applications of edible casein products. I. Manufacture and properties. *New Zealand Journal of Dairy Science and Technology* 20: 79–101, with permission.

The typical composition of sodium caseinate is shown in Table 1. Acid (low-calcium) coprecipitates can be dissolved in alkali in a similar manner to that used for acid casein. Both rennet casein and high-calcium coprecipitate (precipitated at a pH of 6 or greater) are usually rendered soluble by means of complex phosphates, such as sodium tripolyphosphate, to produce translucent solutions with a viscosity somewhat higher than that of the corresponding caseinates.

In the great majority of applications, in both edible and technical (nonfood) uses, casein must first be made soluble before it can be used in its final application. Although some users convert the dry casein to caseinate themselves, others tend to purchase the caseinate directly from the producer (often as a 'fresh-curd' caseinate). For applications in foods. Uses in the Food Industry

C R Southward, Fonterra Research Centre, Palmerston North, New Zealand

Introduction

Although casein, as it exists in milk, has been consumed as 'food' for thousands of years, the extracted form of casein had very little application in foods prior to 1960. Instead, from early in the 20th century, and in some cases before then, it was used as an adhesive in wood glues and paper coating, and in paints, fibers, plastics, and leather finishing. The introduction of coffee whiteners and whipped toppings, in particular, by the food industry in the USA during the 1960s played a significant part in the establishment of casein products in foods. These two product groups were based on vegetable fat and contained casein in a water-soluble form (usually sodium caseinate), together with carbohydrate, emulsifiers, and stabilizers. They were promoted as 'non-dairy' foods. (As casein was derived from milk, it was not considered to be a dairy product. Furthermore, it had been classified as a chemical because of its long-established use in nonfood technical applications in adhesives, paints, etc., as described above.) Nondairy coffee whiteners and whipped toppings were thus presented as alternatives to the traditional dairy products of milk, cream, and whipping cream. They offered advantages of lower price (because the (imported) raw materials from which they were made were cheaper than the domestic milk solids they were replacing), convenience, and shelf stability (several of the products were sold in powder form). Other nondairy products followed, many of them containing casein, e.g., so-called imitation milks, imitation cheese, and salad dressings. Food supplements and dietary products were also produced and a number of these were based on casein. This article reviews the use and function of casein products in food.

General

The main applications of casein products in foods, together with their functions in such foods, are shown in Table 1. As a high-quality protein, casein can provide nutrition in foods, although this is often not the main reason for its use. It is frequently incorporated into food products for its ability to impart so-called 'functional' properties of whipping, foaming, fat emulsification, film formation, water binding, and thickening. Consequently, casein can have a significant effect on the texture or consistency of a food.

Animal Feeding and Pet Foods

During the middle of the 20th century, many experiments were undertaken in the USA and, to a lesser extent, in Europe and elsewhere, to determine the effect of feeding cows with iodine and iodinated casein (sometimes referred to as 'thyroprotein') on their nutrition and milk yield. A number of studies suggested that milk yield was increased, but there was sufficient conflicting evidence for the practice not to be widely adopted. Extensive nutritional feeding trials for ruminants were undertaken in the late 1960s and 1970s to determine the effect – on milk production and wool growth, respectively – of feeding 'protected' casein to cows and sheep. The casein was protected by reaction with formaldehyde, which prevented it from being broken down by the rumen microflora. It could pass undigested to the abomasum where the acidic conditions were able to promote the digestion of the casein. These studies were also extended to determine how the feeding of polyunsaturated oils, encapsulated in formalin-treated caseins, to ruminants affects the quantity of polyunsaturated fat in meat and milk. Again, however, this was not adopted commercially.

Casein (generally in the form of sodium caseinate) may be used as a nutritional supplement in pet foods and calf milk replacers, and it has also been reported as an ingredient in fish food. Some recent reports in the literature indicate that casein can be used to produce novel textured pet foods, as well as the more traditional nutritional foods.

Bakery Applications

The water-binding properties of casein (as well as nutrition) are important for bakery applications in which casein products are incorporated. Soluble forms of casein (such as caseinates) tend to bind too much water and may make some foods too sticky or 'doughy.' Accordingly, insoluble or partly soluble casein products are often used, because these have less water binding than the fully soluble caseinates. Some bakery products that have been made with caseins include doughnuts, waffles, cake mixes, and bread. A number of examples of the use of casein products in bakery applications, taken from the recent literature, are shown in Table 2. Figure 1 illustrates the use of casein products in biscotti.

Cheese-like Foods

Casein has been used as an extender and texture modifier in processed cheese, and even to increase the yield of cheese from cheese milk (e.g., in Europe). However, the most significant use of casein in cheese products has probably been in the production of

Table 1 Use and function of casein products in foods

Application	*Principal functions*
Animal and pet foods	Nutrition, binder for moisture and fat
Bakery products	Nutrition, texture, water binding
Beverages, including soups	Emulsifier, stabilizer, nutrition
Coffee whiteners and creamers	Resistance to feathering, emulsifier
Confectionery	Nutrition, texture
Cultured products	Stabilizer, emulsifier, consistency, nutrition
Extruded snack foods	Texture
High-fat powders and shortenings	Emulsifier, whipping
Icecream, mousse, and desserts	Whipping, foaming, emulsifier
Imitation cheese and other cheese-like foods	Texture, emulsifier
Infant foods	Nutrition
Instant breakfasts and dietary preparations	Nutrition
Meat products	Emulsifier, water binding
Pasta	Nutrition, texture
Pharmaceutical products	Nutrition, therapeutic, film formation
Spreads	Texture, stabilizer
Whipped toppings	Stabilizer, emulsifier

Table 2 Use of casein products in bakery applications

Examples	*Casein product used*	*%*	*Use/function of casein product*
Bread	Sodium caseinate	2–30	Emulsification
Glazing agent	Casein, casein salt	5–15	Film formation
Blini (pancake)	Sodium caseinate	2.9–5	Increased storage life, friability
High-protein wafer	Casein	≥ 50	Texture, nutrition

so-called 'imitation' or synthetic cheese (often referred to as cheese analogs). This product, similar in properties to processed cheese, is made from water, casein (e.g., acid casein, rennet casein, or sodium or calcium caseinate, singly or in mixtures), vegetable fat, stabilizers, and emulsifiers. The food industry in the USA was first to develop imitation cheese (at least in name), which could be seen as a similar development in the cheese industry to the much earlier production of margarine as an 'imitation' butter. Just as coffee whiteners and whipped toppings (and artificial milks) were developed in the US food industry in the 1960s as cheaper and/or convenience foods to compete with milk and cream (see elsewhere in this article), so imitation cheese appeared. The commercial production of imitation cheese first occurred in the USA in the early 1970s, and the quantity produced grew, during a period of several years, to a maximum of about 5% of the total cheese sales in the USA. Imitation cheese found its application as a cheaper alternative to natural cheese, particularly in fast-food outlets, in frozen pizza and hamburgers, for instance. Figure 2 illustrates the use of rennet casein in an imitation Mozzarella cheese, used on a pizza. In consideration of its nutritional properties, imitation cheese was also approved for use in the American school lunch program. The main function of the casein product in this application is to provide the required body and texture, with emulsification of fat, as well as the melting properties of the finished cheese in pizza. This last-named function is achieved by careful formulation, using food acids and stabilizing salts to achieve the correct pH and mineral balance in the cheese that will cause it to melt during the cooking of the pizza to provide the expected 'stretch' and 'stringing' properties required for pizza cheese. Although the use of imitation cheese in the UK and Japan has been mentioned in the literature, its main area of commerical significance is in the USA.

Other applications of casein in the cheese food industry include surface coating of whole cheese and cheese granules, using the natural film-forming properties of casein products. Several examples of the use of casein products in cheese-like foods, taken from the recent literature, are shown in Table 3.

Beverages

Imitation Milks

In the USA, so-called 'filled milk', which contains vegetable fat and skimmed milk solids, has been

Table 3 Use of casein products in cheese-like foods

Examples	*Casein product used*	*%*	*Use/function of casein product*
Simulated cheese	Rennet casein	≥25	Texture, nutrition
Coating of cheese pieces	Casein	2	Free-flow agent
Fat-free cheese analogs	Rennet casein	15–35	Texture
Protective protein coating for cheese	Sodium caseinate/ casein	3–14	Film coating
Imitation cheese	Calcium caseinate	12	Texture

sold for many years. In the late 1960s and 1970s, a new class of milk – 'imitation milk' – appeared on the market. This contained vegetable fat and various other ingredients, including protein as sodium or potassium caseinate or from soy beans, and a carbohydrate source such as corn syrup solids. Artificial milks were also reported in the UK and the USSR. The lower cost of the ingredients and the absence of lactose (for which some people show intolerance) were no doubt significant factors in the establishment of such products. However, concerns were voiced over the generally lower nutritional quality (e.g., lack of vitamins and minerals and, sometimes, lower protein content) and often poorer flavor compared with 'normal' cows' milk. Casein products have also been used to fortify fresh milk, though this has occurred in Europe rather than in North America.

Several examples of the use of casein products in beverages, taken from the recent literature, are shown in Table 4.

Cream Liqueurs

Casein, in the form of sodium caseinate, has found application recently in cream liqueurs, especially in the UK and the Irish Republic, where they have been, apparently, one of the fastest-growing markets for cream. Other ingredients include sugar, alcohol, and trisodium citrate. In this application, the sodium caseinate acts mainly as an emulsifier or emulsion stabilizer.

Coffee Whiteners and Creamers

As shown in Table 1, the main functions of casein (as sodium caseinate) in coffee whiteners are to provide emulsification and to promote resistance to 'feathering.' It has been claimed that sodium caseinate (or other protein) also imparts body, provides some whitening (though this is mainly due to the fat) and improves flavor. Although both liquid and dry (powdered) coffee whiteners have been produced, the most popular by far appear to be the latter because, as mentioned in the introduction to this article, they have the advantages of being shelf-stable and convenient to use. In addition, the low price of the major ingredients (vegetable fat and carbohydrate, usually as corn syrup solids) compared with that of (US domestic) milk solids makes coffee whitener an attractive alternative to milk or cream. Figure 3 shows the use of a coffee whitener that contains high-calcium milk protein.

Soups, Gravies, etc.

When casein products are used in soups, their purpose may be for nutrition (e.g., as calcium caseinate) or for increasing the consistency or viscosity of the mixture (possibly in the form of sodium caseinate), as illustrated in Figure 4. Occasionally, hydrolysates of casein products may be used in soups and gravies for flavor enhancement.

Figure 3 Coffee whitener/creamer, representing imitation dairy products that can be made using high-calcium milk protein. Courtesy of NZMP (Wellington) Ltd.

Sour and Cultured Milk Products

In the manufacture of yogurt, casein products have been incorporated for protein enrichment, and improvement in consistency and stability; they give less syneresis than standard yogurt products.

Imitation sour cream products have been produced from vegetable fat, sodium caseinate, and other ingredients. The purposes of adding sodium caseinate to these products are to act as a stabilizer, to increase the consistency, and to emulsify the fat – functions that sodium caseinate performs in mayonnaise as well. Although some publications have claimed nutritional fortification as a reason for incorporating casein/caseinates in cultured milk products, this does not seem to be as significant a reason for their use in this context as the 'functional' properties mentioned earlier. Some examples of the use of casein derivatives in cultured and sour milk products, taken from the recent literature, are shown in Table 5.

Figure 4 Canned creamed soup, representing convenience foods that can be made using sodium caseinate. Courtesy of NZMP (North America) Inc.

Desserts, Icecream, Whipped Toppings, and Confectionery

Sodium caseinate functions in frozen desserts and icecream as a stabilizer (Figure 5), improves the whipping properties of the mix and imparts 'body' (also known as consistency or thickening). Other properties of sodium caseinate that are important in these products include emulsification, foam stability, and film formation.

The incorporation of casein products in icecream has not been commercially extensive, generally because of various legal restrictions. Several icecream substitutes, however, did appear in the USA in the 1960s (e.g., Mellorine) and some of these products incorporated casein (usually as sodium caseinate) into their formulations.

As described in the introduction to this article, whipped toppings which contained vegetable fat, water, and sodium caseinate (together with other ingredients) appeared in the USA in the 1960s as specific competitors for whipping cream. In this application, sodium caseinate is used in forming a film to trap aerating gases. It also functions in fat encapsulation, as a bodying agent and as a stabilizer. Hydrolyzed caseinates, with enhanced whipping and foaming properties, are also produced for food products like these. Such products are now manufactured in other countries, including the UK, Italy, Israel, and

Table 5 Use of casein products in sour and cultured milk products

Examples	*Casein product used*	*%*	*Use/function of casein product*

Japan. A number of examples of the use of casein products in desserts and whipped toppings, taken from the recent literature, are shown in Table 6.

Casein products are used much less in confectionery than are other milk products (e.g., nonfat dry milk, whole milk powder, and sweetened condensed milk). Nevertheless, their use has been described in toffees, caramels, and fudges, where they can form a tough, chewy body, and in marshmallow and nougat to produce heat-stable whips and foams. Casein proteins have also been used to produce high-protein chocolate snacks and confectionery sticks or bars (Figure 6).

Spreads and Fat Replacers

In the wealthier and industrialized countries, in particular, concern over health and nutrition has been focused, at least to some extent, on maintaining a healthy diet and weight. 'Fat,' both in the sense of appearance and in food intake, has taken on a generally undesirable image, and butterfat (with its generally high content of saturated fats), in particular, appears to have been a high-profile target of the health sector of most of these countries. One of the responses to these concerns has been the introduction of lower-fat spreads to complement or replace the traditional fats. In some of these products, casein (usually in the form of sodium caseinate) has been used to stabilize the water phase and to improve the texture of the product. In addition, casein has been used in some (processed) cheese spreads, presumably for similar (functional) reasons.

Table 6 Use of casein products in desserts, icecream and whipped toppings

Examples	*Casein product used*	*%*	*Use/function of casein product*

Acid dessert	Sodium caseinate	0.01–0.3	Stabilizer
Whipping cream	Casein	≤ 5	Stabilizer
Gelling agent	Casein	37.1	Water binding/replacer for gelatin
Chocolate mousse	Calcium caseinate	4–5	Texture, fat replacer

Figure 6 (see color plate 21) Candy bars, representing confectionery products that can be made using modified milk proteins and milk protein isolates. Courtesy of NZMP (North America) Inc.

From a different perspective, the food industry (again starting in the USA) developed some fat-replacer foods that exhibited the mouth feel and other desirable properties of fat-based products, without containing any fat. These fat replacers were based on water-insoluble proteins or carbohydrates, with about half the energy–weight ratio of fat. They were very finely milled to minimize the detection of any individual particles by the tongue but, nevertheless, exhibited the desirable 'creamy' mouth feel found in fat-based foods, such as cream, for example. Products such as Simplesse™ were introduced to the market, and generated considerable interest. A range of alternative products that contained various fat replacers came on to the market with claims for helping weight reduction. A number of foods that are claimed to provide fat replacement are shown in Table 7. These examples have been extracted from the recent literature.

Meat and Fish Products

Comminuted Meats

The reason for using casein products (usually as sodium caseinate) in comminuted meat products such as sausages and mincemeat is to emulsify the fat, bind water, and generally improve consistency. Sometimes, milk protein may be added for nutritional purposes. The use of casein in meat products is strictly controlled by legislation in most countries and the quantity that may be added is generally less than 5% of the weight of the meat. One estimate suggests that the potential world market for the use of high-protein milk products in processed meats is about 100 000 tonnes.

Textured Protein

Meat analogs (with a texture resembling the fibrous nature of meat) have been prepared from casein, either using a spinning technique (similar to methods used for producing textile fibers in the 1930s, in which a protein solution is forced through spinnerets into a coagulating bath) or by production of chewy, meat-like gels. The general disadvantage of using casein in this form is that, when the fibers are heated in a moist environment, they tend to melt together and lose their individual fibrous structure (which is why casein readily forms a smooth plastic or molten mass in the production of processed cheese – or casein plastic for buttons). However, the addition of heat-denaturable proteins (such as egg white or whey protein) can overcome that disadvantage.

Fish Products

Just as casein is used for fat emulsification and water binding in comminuted meat products, so it has found some application in a number of fish products, especially those formed from minced fish and in paste-like forms. The examples in Table 8, which have been taken from the recent literature, show some uses of casein or caseinates in meat and fish products that utilize a number of properties of casein other than those commonly ascribed to casein in this application.

Pasta, Snacks, and Fried Foods

When casein is used in pasta products, it is mainly to enhance their nutritional quality because the high

Powder for fried food in microwave oven	Casein	10–50	Coating
Noodles	Casein	20–80	Oil absorption

lysine content of the casein complements the low lysine- and high sulfur-containing amino acids of wheat and other vegetable proteins present in such products. In some cases, casein plays an important part in forming a suitable texture matrix for the pasta product. Thus, casein products have been reportedly used in macaroni, spaghetti, rice, and noodles.

Casein products are used in extruded (high-protein) snack foods to produce the required texture and for nutritional fortification. In fried foods, it appears that the film-forming properties of casein may also be used, either as coatings or to reduce oil absorption during the cooking/frying stage in preparing the food. A number of examples of the use of casein in pasta and fried foods, taken from the literature, are shown in Table 9.

Edible Films

The film-forming properties of soluble casein products, such as sodium and calcium caseinates, have been referred to earlier in Tables 1 and 3. This specific property of casein products was recognized many years ago, when casein was used in technical, non-food applications such as paper coating, and in paints and leather finishing. Commercially, the film-forming ability of caseinates in foods is seen at the oil–water interface in the formation of emulsions in coffee whiteners, desserts, and whipped toppings, and at the air–water interface in whipping and foaming products (such as whipped toppings). These same properties have been used in the production of sausage skins. More recently, caseinates have been used to coat fruit and vegetable products as a means of maintaining their freshness. As a hydrophilic (water-loving) substance, casein produces films that, on their own, are not very resistant to the passage of moisture vapor. However, they do appear to provide good mechanical strength, and to act as an oxygen barrier. Research has therefore included the study of combined films of casein/caseinate and lipid material in which the lipid repels or resists the passage of moisture vapor and the caseinate provides the matrix and mechanical strength, with resistance to the passage of oxygen. Some examples from the recent literature are shown in Table 10.

Microencapsulation

Encapsulation of oils was practiced in feeding trials for animals in the early 1970s, as referred to earlier in this article. This technique was used as a means of conveying a nutritional supplement, in a protected environment, through a part of the animal's digestive tract (where it would otherwise have been broken down) to the area where the supplement would have the intended benefit. Often referred to as microencapsulation, this principle has been used now for many years as a means of applying drug therapy in humans and in animals, and as a means of preventing undesirable odors and flavors of beneficial compounds from being rejected as having an unacceptable smell or producing a foul taste. Although not as widely used for microencapsulation as gelatin, casein products do find application in these fields, as indicated in the examples from the recent literature that are shown in Table 11.

Pharmaceutical and Medical Applications

Various casein preparations have been used in a range of pharmaceutical applications. These include casein

Table 10 Use of casein products in edible films

Examples	*Casein product used*	*%*	*Use/function of casein product*
General			
Edible film	Lactic acid casein, rennet casein	37.5–59	Strength, moisture and oxygen barrier

hydrolysates and solutions of caseinates, TMP® and/or milk protein hydrolysates for intravenous nutrition in intestinal disorders, veterinary medicine, and disorders involving protein metabolism. Some preparations of casein have been used for feeding patients following surgery, as a therapeutic agent in dressing wounds, in cosmetics, in toothpaste for inhibition of dental caries, and in hair shampoos. The potential for producing specific drugs, such as opiates, from casein has been described, and other extracts from casein have been claimed as being suitable for treatment of arthrosis (pain in a joint) and gastric ulcers, for enhancement of calcium and iron absorption, and to augment immunity. Table 12 illustrates some recent published claims for applications of casein products in this field.

Health and Nutrition

As indicated earlier in this article, a significant proportion of the population in the wealthier and industrialized countries has some concern with regard to their health and nutrition. Such concern has been seen in the great proliferation of nutritional supplements for loss or gain of weight. Other supplements are sold to provide a certain percentage of the recommended dietary allowance of various vitamins and minerals, fiber, protein, etc. Preparations that contain casein

products are among these supplements and a selection of these, taken from the published literature, is included in Table 13. Figure 7 shows a chocolate-flavored health drink that contains calcium sodium caseinate and/or milk protein isolate (consisting of caseins and whey proteins).

Conclusion

In the majority of the applications described above, where casein is used to provide a specific functional or physical effect, it is incorporated in the food in relatively small quantities, i.e., generally below 10% by weight of the product. Unlike other dairy products, such as milk and milk powder, butter and cheese, it is not consumed as a food *per se*. However, when casein is used for nutrition, it may indeed represent a significant proportion of the total weight of the food. In pharmaceutical and medical applications, there are some indications that derivatives of casein may be important therapeutic agents in the future.

CASHEW NUTS AND CASHEW APPLES

J F Morton†, University of Miami, Coral Gables, FL, USA

Introduction

The cashew is one of the two costliest nuts marketed in quantity worldwide. Formerly second to the macadamia nut in retail value, it is now more expensive because of short supply. Few people in the northern hemisphere question why the cashew nut is never sold in the shell as peanuts, pecans, walnuts, and almonds often are. There is a good reason for this. The cashew, by nature, is much more complex than other nuts and a technical explanation of its processing is required.

Description

The cashew tree, *Anacardium occidentale*, of the family Anacardiaceae, is short-trunked, up to 13 m high and normally with a very broad crown, although it is often stunted and bushy on coasts. There is an enormous, very old, wild cashew tree in Natal, Brazil, that covers 0.75 ha and is a great tourist attraction. Its leathery, evergreen leaves are clustered at the branch tips. The small, yellow-and-red flowers are borne in open sprays. The true fruit of the tree is the kidney-shaped, hard-shelled nut that is at first green, later turning an ashy brown; it grows to 3 cm or more in length and develops at the tip of a fleshy stalk. As the 'nut' matures, the stalk inflates to form a showy, pear-shaped, smooth-skinned, succulent, juicy pseudofruit (false fruit), which is bright-red, orange, yellow, or two-tone and is usually viewed, and utilized, as a fruit (**Figure 1**). The weight of the expanded pseudofruit causes the nut to fall to the ground at its peak of maturity. A caustic oil in the honeycomblike cells within the double-layered shell of the 'nut' protects it from being destroyed by foragers that feed on the 'apple.' However, the oil seriously complicates the processing of the 'nut' and extraction of its kernel for food use.

Origin and Distribution

The cashew tree is native from southern Mexico to Peru, Brazil, and the West Indies. Wild stands extend along the coast of Brazil from Pará to Rio de Janeiro, and the nut and apple have always been of importance to the indigenous people. The cashew was one of the first tropical American fruit trees to be introduced by early Portuguese and Spanish voyagers into the tropics of the Old World. In the sixteenth century the Portuguese planted it, especially on the west coast of India and the east coast of Mozambique, in order to halt soil erosion and, in time, it formed extensive forests.

The tree soon became commonly cultivated and naturalized at low altitudes in East, Central, and West Africa, South-east Asia, Sri Lanka, Malaysia, the Philippines, Mauritius, and the Seychelles. In addition, it has been planted around villages in most of the Pacific Islands, including Hawaii, and is occasionally grown in dooryards in southern Florida.

The name 'cashew' is derived from the Brazilian acaju, usually abbreviated to caju. In the Orinoco region, the tree is known as pauji. In all the Spanish-speaking countries of Latin America and the Caribbean area, the common name is marañon, except in Venezuela where it is called merey. In French it is cajou or acajou.

Climate and Soil

The tree requires a tropical or subtropical climate. It is highly sensitive to frost when young, but later is able to withstand brief cold spells. It is well adapted to sandy soil, intolerant of heavy clay, and is drought- and

†Deceased.

Figure 1 The cashew nut, shaped like a boxing glove, develops at the tip of a fleshy, juicy, fruitlike stalk (peduncle), called cashew apple, which enlarges as the nut matures, becomes red, orange, yellow, or two-tone, and is eaten raw or preserved. Reproduced from Cashew Nuts and Cashew Apples, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

salt-tolerant, succeeding on land too poor for most other crops. It thrives from sea level to an altitude of 1000 m.

Commercial Development

India pioneered the domestication and commercialization of the cashew and, for a long time, augmented supply by importing raw nuts from Mozambique. The 1950s saw large-scale planting of cashew trees in Africa, India, and Brazil. In north-eastern Brazil there was first a private plantation of about 1500 ha. Then, in 1957, a programme was begun to plant a million trees in the state of Ceará, the government supplying the seeds and a bonus for each tree set out in plots of 100 or more. From 1957 to 1972, a company in Pacajus set out 2000 ha. Another surge of government-stimulated plantings totalled nearly 136 000 ha by 1972, mostly in Ceará. Later, 18 000 ha were developed in Rio Grande do Norte. By 1986, more than 40 000 ha of cashew had been added in reforestation programs in Ceará, Piaui, Rio Grande do Norte, and Bahia.

There have been sporadic attempts to develop cashew industries in Venezuela, Colombia, Peru, Guatemala, Belize, and Jamaica. Some have been moderately successful. The primary problem is that cashew trees are still mainly grown from seed and there is great variation in yield, and great variability in the form and size of the nuts from seedling trees (Figure 2). The nuts may range from 3 to 32 g in weight and the apples (mostly orange or yellow) from 15 to 650 g. Trees bearing small nuts tend to produce heavily, while trees with large nuts and apples are less productive and may bear in alternate years.

Much research in Mozambique and India has been devoted to techniques of vegetative propagation (by cuttings, grafting, budding, or air layering) to achieve uniformity, but it is still not widely practiced, mainly because of the costs involved. India has accomplished much in rejuvenation of old groves by top-working beheaded, unproductive trees. Side-veneer grafting has been recommended in Venezuela. In Trinidad and India air-layered trees have poor form and tend to blow over in the wind. Once a method of propagation has been adopted, there must be a search for the best types to be grown. An experimental planting of grafted trees was initiated in Ceará but did not prosper because of a prolonged drought. In 1980, a selected clone of a 'dwarf' cashew was grafted on to *Anacardium microcarpum* and the 40 trees set out fruited early and were highly drought-resistant. This trial encouraged experiments with other rootstocks and selection of high-quality clones, but low yields

Figure 2 Cashew nuts range from 2.5 to 5 cm in length and this variability, together with the odd shape, contributes to the difficulties of opening them mechanically. They are never sold in the shell. Reproduced from Cashew Nuts and Cashew Apples, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

have caused such work to languish. There are still no commercial orchards of selected, vegetatively propagated trees.

Varieties

Generally, named varieties have been distinguished merely by color and size of the apple, such as the Vermelho (yellow) and Amarello Gigante (large yellow) of Brazil, and the Marañon Amarillo (yellow) and Marañon Rosado (red) of Colombia. Natural hybrids in Colombia have been named La Gigante (huge) del Rio Magdelena, La Larga (long) de Nazareth, and La Pequeña (small) del Meta. Usually the nut and apple are larger in the yellow forms than in the red, and the apple is less astringent. One name pertaining not to the apple but to the nut is the Jumbo grown by the late Edward B Smith, Crescent Estate, Trinidad, who has supplied air layers to people from South America wishing to establish this large-seeded type in their countries.

In evaluating cashew trees, preference should be given to a cashew tree of slender, compact form because the cashew needs light to flower and fruit and bears only on its outer circumference. The interior of a broad-spreading tree is devoid of foliage and fruit. Likewise, if cashew trees are planted too close together, the branches that overlap or shade each other will be nonbearing and may die back. From an experimental plantation of compact trees, the grower should select those that produce a high yield of large nuts and multiply them vegetatively, rather than increasing labor costs by simply planting more and more seedling trees with yields varying from 5 to 100 kg per tree. There is variation also in the color of the young leaves of cashew trees. On some, the new shoots at the branch tips are purplish-red, while on others they are more or less yellow. The yellow leaves are heavily attacked by leaf-eating insects while the red, being richer in phenolic compounds, are naturally insect-resistant.

Diseases and Pests

In humid atmospheres and in seasons of excessive rainfall, cashew trees are subject to attack by the fungus *Colletotrichum gloeosporioides*, which causes anthracnose, a disease affecting the foliage, especially young shoots, the twigs, flowers, the apple, and the developing nut. A parasitic fungus, *Oidium anarcardii*, appears on the leaves, shoots, and flowers when there are periods of alternating sun and rain. They become coated with a powdery white substance and this is followed by blackening, shrivelling, and shedding. The nut may be ruined by the fungus, *Nematospora* spp., which invades it through minute perforations caused by sucking insects. A large wasp sucks the juice from immature apples, causing them to shrivel and blacken while the nut is still green. Yellow, red-banded thrips (*Selenothrips rubrocinctus* Giard) often infest the foliage. Cashew apples are commonly eaten by birds, bats, monkeys, and squirrels.

Harvesting and Drying

Harvesting of cashew nuts is extremely labor-intensive. The entire crop does not ripen at one time, and harvesting may extend over a period of 40–75 days. Ideally the nuts should be allowed to fall (with the apple attached) when perfectly mature. Some people unwisely shake the branches to bring them down or knock them off with a pole. This results in slightly immature nuts of high moisture content being mixed with partly dried mature nuts

and makes it impossible to assure uniform drying, thereby adversely affecting all subsequent steps in processing. In Brazil, cashews are plucked from the tree only if perfect apples are desired for dessert use. If allowed to fall, the apple will remain in good condition on the ground for 2–3 days. If it is not to be utilized, it is twisted off and left on the ground for cattle or pigs to consume. If it is wanted for preserving, it is salvaged and transported to a packing plant. The nuts are conveyed separately to be spread out in the sun and dried, with constant raking, and then stored if they are not to be immediately shelled. Thoroughly dried nuts can be stored for 1 or 2 years.

Processing

In Latin America and the West Indies there have been crude precracking practices such as boiling the nuts in steel barrels, simply drying them in the sun for 2 or 3 days, or sweating them in cement bins for several months. There was much loss because many nuts were found to be infested with insects or fungi on opening. In some cases the nuts were cut open by machete wielders with their hands wrapped in layers of plastic. The half-kernels were then picked out and sent to local clubs or bars, but these nuts were too contaminated with the cashew nut shell liquid (CNSL) to be fit for consumption (Figure 3).

Figure 3 Cut open with a machete, these cashew nut halves show the caustic, glistening cashew nut shell liquid (CNSL) which is usually expelled by roasting before the nuts are opened and the kernel is extracted, peeled, and reroasted before consumption. Reproduced from Cashew Nuts and Cashew Apples, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Sanitary processing of cashews in the past was best performed in India by roasting the nuts in shallow pans over open fires to expel the caustic CNSL, some of which was caught in jars below for various local uses. Then they rubbed the nuts with sand or ashes before handshelling, at which the Indian female workers were especially adept. But the fumes from the roasting were extremely irritating to eyes, nose, throat, and skin, and the shellers frequently had to dip their hands in lime, ash, or linseed or castor oil to minimize skin inflammation. A merciful improvement was a change to roasting in rotating cylinders over furnaces with chimneys to carry off the toxic fumes. The next advance, brought about by Mortimer Harvey, of New Jersey, who had investigated the chemistry and potential industrial uses of the shell oil, was a method of heating the nuts in baths of the oil kept at 188–194 °C. This method resulted in greater recovery of higher-quality oil.

Semimechanized shelling was initiated in Brazil in 1946. Dried raw nuts were first steamed to moisten the shells and then fed into a device, operated by hand and footpedal simultaneously, which cut the shell into two halves, leaving the kernel whole or cut in half. Facing the cutter, a seated operator pries the kernel loose from the cut shells if it adheres. This system is still used in Ceará for shelling very large nuts.

When East African countries achieved independence from colonial governments, they wanted to cease exporting their raw cashews to India in order to gain more revenue by processing the nuts themselves. A simple, raw-cashew opening-machine was invented by a mining engineer in Tanzania in 1960. The operator protected his hands with barrier cream. There followed the development of complete factory installations of cashew-shelling equipment in Italy, France, and Germany. Mozambique obtained its first full-scale factory in 1964 and 2 years later set a world record in cashew production; most of the crop went to India for shelling, while the rest (26 000 t) of the locally shelled kernels was exported to the USA, West Germany, and South Africa.

The various systems of cracking by pressure, centrifugal cracking, and cutting or sawing were evaluated by the Tropical Products Institute of London (now the Natural Products Institute), and the Sturtevants Engineering Company began producing and exporting the centrifugal shelling equipment in 1970. This system is now used by Brazil Oiticica, and modified versions are used in north-eastern Brazil. An Italian factory installation of a series of machines, designed by the Instituto Agronomico per l'Oltremare, involves 15 steps. The dried nuts are cleaned, roughly sorted according to size, wetted for several

days to the desired moisture content, roasted in CNSL, centrifuged to eliminate any oil residue, cooled, and mechanically calibrated to separate eight sizes. The nuts are then machine-cut, and the shell separated from the kernel and removed by pneumatic tubes for use as a fuel. The kernels are dried for 48 h in the sun or in ovens until the testa wrinkles and is removed mechanically. The kernels are rehumidified to resist breaking; they are then sorted into wholes and pieces. Lastly, kernels that still have clinging testa must be hand-peeled. Japanese processors freeze the nuts instead of roasting them before shelling.

However, none of these or other factory systems have given ideal results, mainly because of the variability of the raw material. There is a great need for a portable, simple cashew sheller that can take dehydrated, raw nuts of any size, splitting them without contamination of the kernel. The shells would be sent to facilities for total extraction of the oil for industrial purposes, and the split kernels of Jumbo cashews should not be inferior to whole kernels from smaller nuts. Such shelling has been achieved experimentally with explosive decompression, but further refinement of the method is needed.

The latest development in India is a cashew kernel drier, electronically controlled, with timer and alarm to avoid scorching, and adjustable dampers for air inflow; the drier turns out higher-quality kernels in 60–90 min.

Economic Status

In the past, the cashew ranked as India's second dollar earner. After mechanization, India found that the total crop of its cashew plantations could not keep its big factories busy as the productivity of the trees declined after they reached 35 years of age. In Kerala, the leading growing area, cashew orchards have been cut down and replaced by more profitable rubber plantations. From 1980 to 1987, the World Bank assisted India in a cashew development project to improve old plantations and establish new ones. In 1990, adverse weather conditions in India and other major cashew areas seriously affected the supply of cashews for export. Indian production was reduced by 20–25%, causing a sharp increase in prices. Nevertheless, the demand for cashew kernels has increased, especially with the opening of markets in eastern Europe. In 1989, world export of cashew kernels from India, Brazil, Mozambique, Kenya, Tanzania, and other areas amounted to 90 000 t. If horticultural improvement could be brought up to the level of cashew engineering, this figure could be doubled or tripled, and cashews would be less expensive and more widely enjoyed.

Inspection, Grading, and Packing

Before export, cashew kernels go through rigid inspection systems, are classified according to grade – wholes, butts, splits, large and small pieces and baby bits, also white, scorched, and dessert – and are carefully vacuum-packed in 11.3-kg capacity metal containers, two to a crate. They are then held in cold storage at temperatures below 9 °C. For retail sale, cashew kernels are usually reroasted in olive, peanut, or other oil, an adhesive and salt are applied and the kernels are packed in glass jars or cans. In recent years, many have been dry-roasted without salt. High grades have a minimum of split or broken kernels. Lower grades are mainly utilized by the bakery or confectionery industries. They are familiar ingredients in cookies, chocolate bars, and other products, and are made into cashew butter.

Cashew Apple

Because of the difficulty of cracking cashew nuts, many Latin Americans have habitually discarded the nut and consumed the cashew apple or, in Spanish, manzana del marañon, large heaps of which are seen on native markets at the height of the season. As it is fibrous, the apple is massaged and the juice is squeezed into the mouth as a thirst-quencher, especially out in the countryside. Inferior types that are still astringent when ripe are eaten with salt so that they will not irritate the throat. In the kitchen, cashew apples may be sliced and stewed or used to make juice, fruit soup, jam, jelly, paste, or chutney. The best cashew apples are preserved whole in syrup in glass jars. The less perfect are candied – cooked thoroughly in heavy syrup until well wrinkled, and then dried and sometimes rolled in granulated sugar. This is an excellent product resembling candied figs but it is, of course, seedless.

In India, the Central Food Technological Research Institute at Mysore has found that the astringency and acridity of cashew apple juice, due to 35% tannin content and 3% of an oily substance, can be eliminated by pressure steaming for 5–15 min and thorough washing. Then the juice is mechanically extracted. In the Philippines, the Bureau of Plant Industry, Manila, designed a cashew-apple-crushing machine for this purpose. To free the juice of some other undesirable elements, casein, gelatin, pectin, or lime juice may be added before straining or centrifuging. After the addition of sugar and citric acid to arrive at 15° Brix and 4% acidity, the juice is boiled for 1 min and then bottled or canned, alone or with other fruit juices.

In Brazil, it is estimated that less than 10% of the total cashew apple crop is processed, though the juice

is locally popular and, with suspended pulp or clear, it is pasteurized, preservatives are added, and it is bottled and exported. The unclarified juice may be concentrated and bottled as nectar, or made available as frozen concentrate. Cashew apple juice is also made into vinegar. In Cuba, Costa Rica, and the Philippines, and formerly in Brazil, it has been

fermented into wine. Cashew apple brandy is subject to government control in East Africa and Goa. In the late nineteenth century, in Mozambique, the cashew was denounced as a source of vice and ruin because of the highly intoxicating liquor distilled from the apple. Cultivation of the tree was banned for a while; later a tax was imposed on plantations as a possible deterrent.

Food Value of Cashew Nut and Cashew Apple

See Tables 1 and 2. Refer to individual nutrients.

Cashew Nut Shell Liquid

This toxic oil is highly heat- and friction-resistant and is valuable for many industrial uses. When it was first used in aircraft paint-stripping products, mechanics suffered skin reactions. Mortimer Harvey promptly patented processes of detoxification and its uses have multiplied. It has been standard material for automobile clutch facings and brake linings and in insulation for electrical tools. It is incorporated into marine paints, water-resistant plywood, resins utilized in laminating, varnishes, floor tiles, cold-setting cements, molding powders for plastics, and many other products. In addition, the testa, which is removed from cashew kernels, has a high level of condensed tannin (as much as 25%) and the extract has been used for tanning leather.

CASSAVA

Contents

The Nature of the Tuber

C C Wheatley, Nelson, New Zealand
G Chuzel and N Zakhia, CIRAD-AMIS, Montpellier, France

Introduction

The cassava plant is a highly efficient producer of carbohydrate, mainly in the form of starch. It is the fourth most important source of calories in the human diet in tropical regions of the world and is consumed in a wide variety of forms. This article will review the origin and current distribution of the crop, the anatomy of the edible root, and its chemical composition. Special emphasis will be placed on the starch component of the root and on the presence of cyanide-containing glucosides.

Cassava Production

Crop Distribution

Cassava originated in the Americas, although the exact center of origin is disputed: northern Brazil,

northern Colombia/Venezuela, Paraguay, and southern Mexico have been suggested. The crop was widely grown in the Amazon basin by 2000 BC and remains a traditional staple of many tribal groups. Cassava was taken by Spanish and Portuguese traders to Africa, India, and South-east Asia in the sixteenth and seventeenth centuries but did not become widespread in Africa until the late nineteenth century. It is currently cultivated in almost all tropical and subtropical countries, the major producers being Thailand, Indonesia, India, Brazil, Zaire, and Nigeria. The total world production in 1998 reached 162×10^6 t, of which the Americas, Africa, and Asia accounted for 17%, 56%, and 27%, respectively.

Cassava has found acceptance over a diverse range of agricultural and food systems due to its tolerance of poor soil and harsh climatic conditions. Yields in excess of 10 t ha^{-1} $year^{-1}$ per year are achieved with minimal inputs under conditions of acid soils (pH< 4), low rainfall (< 1000 mm $year^{-1}$) and nutrient deficiency. Cassava has thus gained a reputation as a food security and famine reserve crop and as such has become especially important to small farmers living in marginal areas of the tropics. In addition, the efficiency of carbohydrate production, owing to cassava's unique combination of C_3 and C_4 photosynthetic pathways, has promoted its agroindustrial use in the last 30 years, especially in Thailand, Indonesia, and southern Brazil, for starch extraction and as a component of dried animal feed.

This short-daylength, perennial crop can be grown from 30° N to 30° S latitude, and up to an altitude of 2000 m at the equator, where the mean annual temperature is at least 17 °C in the high-altitude tropics, or 20 °C in lowland areas. Established plants can withstand over 6 months of drought but cannot tolerate prolonged flooding or saline conditions. In the humid lowland tropics, roots can be harvested after 6–7 months' growth. This increases to 18 months at higher altitudes, and 2 years in the subtropics. Propagation is by woody stem pieces called stakes. When grown in high-fertility soils with good agronomic practices, up to 50 t ha^{-1} can be produced in 12 months. On a world-wide basis, the crops most frequently interplanted with cassava are maize, cowpea, sorghums, and millets.

Traditional varieties tend to be of restricted agroecological range, having been selected by small farmers over many years. Many countries have introduced new varieties over the last decade, especially Thailand, Indonesia, Colombia, and Nigeria. Varietal improvement has focused on yield, adaptation to environmental and biotic stresses, and, recently, root quality.

Morphology and Anatomy of the Storage Root

The cassava root is anatomically a true root, not a tuberous root. The root cannot serve for vegetative propagation. Root size and shape depend on the variety and environmental conditions. The variability in size within a variety is greater than that found in other root crops. Cassava roots are generally 15–100 cm long and 3–15 cm wide. They are cylindrical, conical, or oval, with a coffee, pink, or cream-colored peel that is covered by a thin brown bark. The parenchyma is generally white, cream, or yellow. Plants produce five to 10 roots weighing 0.5–2.5 kg each.

The root is composed of three distinct tissues: bark (periderm), peel, and parenchyma. The parenchyma is the edible portion of the fresh root and comprises approximately 85% of the total weight. The parenchyma consists of xylem vessels radially distributed in a matrix of starch-containing cells. A central fibrous vascular bundle becomes progressively larger as the roots mature. Other fibrous bundles may develop throughout the root. The peel layer comprises sclerenchyma, cortical parenchyma, and phloem and constitutes 12% of the root weight, with the periderm layer comprising another 2%.

Harvesting, Root Deterioration, and Storage

Harvesting

The cassava root has no fixed period of optimum maturity: the woody plant is perennial, and starch deposition will continue for many years in most ecosystems. Harvest time is therefore determined by a combination of factors relating to yield, quality (starch content, etc.), the farmer's need to clear the field, climatic factors, and market prices. Climate affects starch content, fresh root eating quality, and hence market acceptability. Roots left beyond their optimum time for the fresh market are often used for animal feed or industrial processing at a later date, giving the farmer great flexibility of harvest time.

Harvesting is largely manual, although the use of mechanical harvesters is expanding in Brazil and South-east Asia where large-scale production and processing are located. In most countries, cassava is planted in small plots, often on a sloping terrain unsuited to mechanical operations. Manual harvesting represents one of the major production costs, along with weeding, often accounting for 30% of total cost. The ease of harvesting depends on the variety, soil type, and moisture content. The aerial part of the plant is frequently removed before harvesting. At harvest, roots destined for the fresh market are

sorted, based on size, into commercial and noncommercial classes. For industrial processing, all roots are collected.

Deterioration

Freshly harvested cassava roots have the shortest postharvest life of any of the major staple food crops. Roots become inedible within 24–72 h after harvest due to a rapid physiological deterioration process. This deterioration is a major constraint for industrial processing of the fresh roots and for marketing them to distant urban centers. Deterioration is due to the rapid, *de novo*, postharvest synthesis of simple phenolic compounds (catechins, coumarins, leucoanthocyanins) that polymerize to form blue, brown, and black pigments (condensed tannins). The accumulation of the coumarin, scopoletin, is especially rapid, reaching 80 mg hg^{-1} (dry weight) in 24 h. Scopoletin has intense blue fluorescence in UV light and can be confused with aflatoxins B_1 and B_2 which also have blue fluorescence and similar R_f values under some chromatographic systems: many reports of aflatoxins in fresh and processed cassava should therefore be treated with caution. (*See* **Mycotoxins**: Occurrence and Determination; **Phenolic Compounds**.)

Rapid physiological deterioration is an oxidative process. Tissue dehydration, especially at sites of root mechanical damage, encourages the rapid onset of this phenomenon. Care at harvest to reduce mechanical damage is beneficial. Tissue discoloration is initiated at damage sites and rapidly spreads through the entire root, starting in the vascular system, but later spreading to parenchymal cells. Within 3 days after harvest, a ring of discolored tissues arranged around the outer portion of the parenchyma (Figure 1) typically appears. In advanced cases, dehydrated, brown–white parenchyma tissues result. (*See* **Oxidation of Food Components**.)

A secondary deterioration can follow physiological or primary deterioration 5–7 days after harvest. This is due to microbial infection of mechanically damaged tissues, and results in the same tissue discoloration with vascular streaks spreading from the infected tissues. Generalized rotting and fermentation of tissues follow.

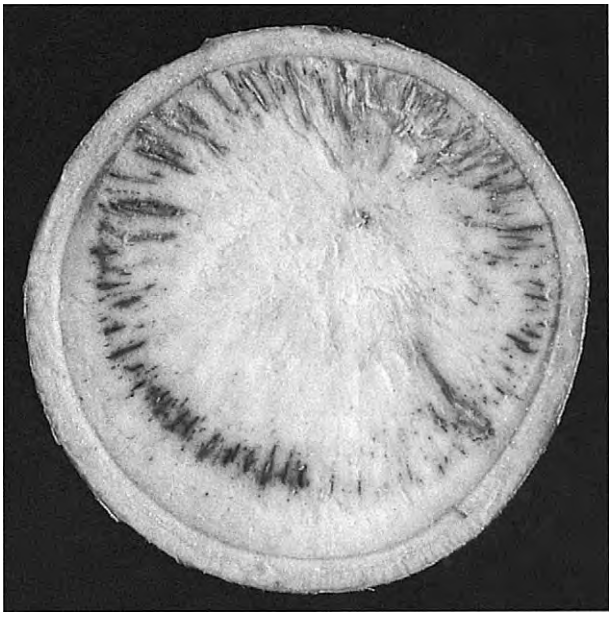

Figure 1 Transverse section through cassava root showing symptoms of physiological deterioration, 3 days after harvest. Reproduced from Cassava: The Nature of the Tuber, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Storage

Conditions of high temperature (30 °C) and high relative humidity (85%) favor the rapid wound healing of mechanically damaged tissues (curing). Under these conditions, the physiological processes described above are localized in the vicinity of the wound itself. The cured tissues represent a barrier to further oxygen entry, thus preventing the oxidative reactions that lead to the formation of condensed tannins. Encouragement of this curing process is the basis for several simple storage methods for fresh cassava.

Traditionally, cassava roots are preserved in the fresh state by reburying them in soil or moist sand. Field clamps, using straw and roots in layers below a soil-covered mound, with adequate ventilation, were developed in the 1970s. Packing roots in boxes with moist sawdust, coconut fiber or other locally available materials has also been successful. Packing roots in perforated polyethylene bags (with optional use of a thiabendazole-based fungicide to protect against microbial deterioration) is effective and has undergone commercial trials in South America and West Africa. With all these storage methods, root quality is maintained for 2–3 weeks. Beyond this time, starch breakdown to free sugars gives roots an unacceptable sweet taste. (*See* **Fungicides**; **Storage Stability**: Mechanisms of Degradation.)

For export markets, paraffin-coating of fresh roots provides an artificial barrier to oxygen entry and hence to deterioration. Costa Rica and the Dominican Republic export paraffin-coated roots to the USA and Europe. Peeled, frozen, or vacuum-packed cassava pieces are also marketed widely in Latin America and exported. No economically viable method for fresh root storage at the plant level prior to industrial processing is available. Fresh roots

should be processed within 2 days of harvest to ensure an acceptable quality and yield: starch extracted from deteriorated roots is light brown in color and of a poor functional quality, and the starch yield decreases by 10% for each day beyond the initial 2 days of storage. Excellent links between processing plant and cassava producers are essential to avoid deliveries of roots of unacceptable quality. The lack of a large-scale storage method for fresh cassava limits processing-plant operations to cassava harvest periods. However, in many areas, cassava can be harvested all year round, especially if irrigation is available. If necessary, fresh roots can be chipped and sun-dried: the dried chips can be used for starch extraction at a later date, although starch yield and quality are lower.

Chemical Composition of the Cassava Root

The chemical composition of cassava roots is shown in Tables 1 and 2. The composition of peel and parenchyma is different: the peel has more protein, fiber, sugars, and cyanogens than the parenchyma, and less dry matter and starch. A wide range of values is reported in the literature for each root component. Reports of whole-root dry-matter contents vary from 20% to 40%, and between 70% and 90% of dry matter is composed of starch, with average values between 80% and 85%. Total carbohydrates, including starch, free sugars, and other cellulose or hemicellulose components, together make up over 90% of parenchyma dry weight. The protein content is uniformly low (below 2% on a fresh-weight basis), as are fats and ash content. The fiber contents are more variable, and increase with plant age. A great variation in total cyanogen content is also found, with parenchyma values of 30–100 mg kg^{-1} common for low-cyanogenic cultivars destined for direct consumption, compared with 1350 mg kg^{-1} in industrial varieties used for processing. (*See* **Carbohydrates**: Classification and Properties; **Starch**: Sources and Processing.)

Table 1 Constituents of cassava root parenchyma and peel

Constituent	*Percentage of dry weight*	
	Parenchyma	*Peel*
Dry matter (%, fresh weight)	23–44	15–34
Starch	70–91	44–59
Total sugars	1.3–5.3	5.2– 7.1
Crude fiber	3.0–5.0	5.0–15.0
Ash	1.0–2.5	2.8–4.2
Protein	1.0–6.0	7.0–14.0
Fat	0.3–1.5	1.5–2.8

Table 2 Vitamin, mineral, and cyanide constituents of cassava root parenchyma and peel

Constituent	*Milligrams per kilogram dry weight*	
	Parenchyma	*Peel*
Total cyanide	30–1350	60–50
Calcium	480–920	
Phosphorus	770–150	
Potassium	6000–10 000	
Iron	5–25	
Vitamin A	0–70	
Vitamin C	380–900	

A variation in chemical composition is found between cassava varieties, and also within varieties at different plant ages, and is due to changing environmental and biotic stress factors. For example, parenchyma dry-matter content may decrease from 35% to 28% after a period of drought followed by the onset of rainfall. Under these conditions, starch is rapidly hydrolyzed to free sugars, especially sucrose, which are used by the plant to initiate regrowth of foliage. These large fluctuations in root quality over relatively short periods must be taken into account in planning harvesting times, both for direct consumption and for processing. (*See* **Starch**: Modified Starches.)

Cyanide in Cassava Roots

All known *Manihot* species contain cyanogens. In cassava, cyanide is synthesized in the leaf and transported to the roots, where it is partitioned between peel and parenchyma. Some 85% of the cyanide occurs as cyanoglucosides, mainly linamarin but also lotaustralin. Linamarin is broken down by the enzyme linamarase, also found in cassava tissues. In intact roots, the compartmentalization of linamarase in cell walls and linamarin in cell vacuoles prevents the formation of free cyanide. On processing, the disruption of tissues ensures that the enzyme comes into contact with its substrate, resulting in rapid production of free cyanide via an unstable cyanhydrin intermediary.

Cassava varieties differ in their total cyanogen content, and although the variation in content is continuous, two distinct types can be discerned in many regions of the world: low- and high-cyanogen varieties. Low-cyanogen varieties are often called sweet, although confusion with elevated free sugar contents in some conditions may occur. These are grown for fresh consumption, or for simple processing. High-cyanogen varieties are called bitter, although the phenolic compounds involved in root physiological deterioration can also produce a bitter taste. These are invariably grown for processing, especially for farinha in Brazil and gari in Africa. It is interesting that low-cyanogen varieties are rarely

used for processing: the reasons for a preference for high-cyanogen varieties are unclear. Contrary to anecdotal evidence, high-cyanogen varieties do not yield more than low-cyanogenic varieties. There is some evidence that cyanide may protect against rodent pests and robbery, and also that there may be a link between end-product quality (e.g., farinha texture) and cyanogen content.

Cyanide is concentrated in the root peel, especially in low-cyanogen varieties where peel:root ratios of 40:1 are found. In high-cyanogen varieties, ratios of 1.6:1 are common. The use of whole or peeled roots for processing may therefore result in great differences in end-product cyanogen content. In root parenchyma tissues, free cyanide – hydrogen cyanide (HCN) plus cyanhydrin – normally accounts for 15% of total cyanide; the remainder is bound as linamarin or lotaustralin. All cassava varieties characterized to date contain these cyanogens. Projects involving genetic manipulation are currently under way to reduce the toxicity problems of cassava, through regulation of cyanide synthesis and increasing the activity of linamarase.

Starch

Cassava starch has many food and industrial uses, which are linked to its functional properties. Although the basic properties of this starch are known, much research is required to complete our knowledge, especially as regards varietal differences in composition and functional properties. Cassava starch granules are round with a truncated end and a well-defined hilum. The granule size is between 5 and 35 μm. The starch has an A-type X-ray diffraction pattern, usually characteristic of cereals, and not the B type found in other root and tuber starches. The C-type spectrum, intermediate between A and B types, has also been reported. The nonglucosidic fraction of cassava starch is very low: the protein and lipid content is below 0.2%. There is thus no formation of an amylose complex with lipids in native starch. Amylose contents of 8–28% have been reported, but most values lie within the range of 16–18%. (*See* **Starch**: Structure, Properties, and Determination.)

Figure 2 shows Brabender amylographs of starch from four cassava varieties. Although a significant varietal variation is present, all curves follow the same general pattern and are similar to all high-amylopectin starches. The starch gelatinizes at relatively low temperatures. Initial and final gelatinization occurs at 60 °C and 80 °C, respectively. The peak viscosity is high and is reached rapidly, within 2 min. At high temperatures starch viscosity decreases greatly. Viscosity increases again on cooling (setback), and then remains stable. Cassava starch has a low retrogradation tendency (i.e., viscosity is stable over time following the cooling episode) and produces a very stable and clear gel. The swelling power of the starch is also very high: 100 g of dry starch will absorb 120 g of water at 100 °C. At this temperature, over 50% of the starch is soluble. (*See* **Starch**: Functional Properties.)

Uses as a Raw Material

C C Wheatley, Nelson, New Zealand
G Chuzel and N Zakhia, CIRAD-AMIS, Montpellier, France

Background

The fresh cassava root is an important staple in many rural areas of the tropics, especially in sub-Saharan Africa, where it is the principal carbohydrate source for 40% of the population. More recently, the crop has been used as a raw material for food and other industries. This article briefly reviews the wide range of products made from cassava roots and then focuses on four of the most important products.

Use as a Staple Food

The fresh, peeled root is commonly boiled for 15–30 min, either alone or with other ingredients in a soup. Raw or boiled root pieces can also be fried. Boiled cassava should have a soft, floury texture, but is sometimes hard and glassy, leading to rejection by consumers. The causes of glassy texture are unknown. The bitter taste is frequently due to residual cyanide remaining after boiling, although the phenolic compounds involved in physiological deterioration can also produce a bitter taste. Cultivars with a low cyanogen content in the parenchyma are invariably used for fresh consumption. Consumption per capita of fresh cassava may reach very high levels (e.g., 405 kg per year in Zaire, and over 200 kg per year in rural areas of Paraguay). A variety of foods made with grated or mashed, boiled cassava are prepared at the household level. Examples of other staple foods based on cassava are gari in Nigeria and farinha in Brazil. These processed products will be considered in the next section. (*See* **Phenolic Compounds**.)

Cassava leaves form an important part of the diet in Zaire and other African countries, and are of minor importance in South-east Asia. In Zaire, cassava leaves comprise nearly 70% by weight of all vegetables consumed. They are normally chopped and boiled, a process that greatly reduces the level of residual cyanogens.

Cyanide Toxicity and Processing

Tissue disruption (chipping, grating or fermentation) is effective in bringing linamarase into contact with the linamarin substrate, thereby liberating hydrogen cyanide (HCN). Processes such as sun-drying of large root pieces or boiling are less effective. Toxicity problems may result when poorly processed cassava products are consumed. Acute cyanide toxicity appears when more than 30 mg is consumed over a 24 h period. The body's natural thiocyanate detoxification mechanism requires a good supply of sulfur-containing amino acids: a protein-deficient diet in combination with cyanide consumption can therefore result in health problems. In addition, thiocyanate interferes with iodine uptake by the thyroid gland, leading to goiter and, in extreme cases, cretinism. Epidemic spastic paraparesis has been reported on several occasions in Africa since 1981, affecting a total of 5000–10 000 people with leg paralysis. The exact metabolic processes involved are unknown, but each outbreak is clearly associated with famine-induced consumption of poorly processed cassava and a lack of protein in the diet. (*See* **Iodine**: Iodine-deficiency Disorders.)

The toxicity of processed cassava products is due to the residual linamarin and cyanhydrin remaining after the action of linamarase ceases. Once consumed, linamarin reaching the gut may be broken down by microbial enzymes or by ingested linamarase. This process is incomplete, since linamarin can also be detected in the urine. The percentage of linamarin

that may be degraded in the gut has received little research attention; however, individual sensitivity to cyanide toxicity seems to vary with nutritional status. Adequate cassava processing (grating, fermentation, slow sundrying), combined with sufficient dietary protein, is necessary for populations at risk in order to take advantage of the food security offered by cultivating high-cyanide cassava varieties. The use of cassava varieties low in cyanogens also has potential.

Overview of Cassava Processing

Processing of cassava has several objectives: to produce a more stable product, capable of being stored in tropical environments for extended periods with no decrease in quality or deterioration; to reduce the content of cyanide to innocuous levels; to reduce bulk and hence lower transport costs; to diversify the food and other uses of cassava, leading to market expansion; and to provide food and other industries with a low-cost raw material for further processing.

Cassava roots may be processed whole, after removal of the peel, or after washing, a process that also removes most of the outer barky layer. The roots can then be grated, chipped, or sliced. Grated roots may be pressed to remove excess water and then toasted to produce the flour called farinha, or a flat bread called cassabe. These are staple foods in several Latin American and Caribbean countries. If a fermentation stage is included, using peeled roots, the product is gari, a staple in West Africa. Alternatively, starch can be extracted from the grated roots, and can be either dried directly or fermented to produce a naturally modified starch (sour starch). Cassava chips are usually sun-dried to produce a dried chip (gaplek), which is used for human consumption in Indonesia, and for animal consumption in Latin America. Larger root pieces are sun-dried in Africa. (*See* **Starch**: Sources and Processing.)

A high-quality cassava flour can be produced from washed or peeled roots, chipped and sun-dried on trays, or artificially dried to avoid microbial contamination. This flour can replace wheat and other imported flours in tropical countries. In Africa, pieces of cassava roots are fermented and dried to produce a flour called lafun. In Indonesia, root pieces are fermented using an innoculum of *Amylomyces* and *Endomycopsis*, to produce a moist product called tape. In Africa, whole roots are retted, grated, and boiled to produce a fermented dough called chickwangwe or fu-fu.

A great diversity of products are prepared from cassava roots in rustic, small-scale facilities, using traditional methods. Over recent decades, medium-scale processing of these traditional products has developed on all continents. This had led to the design of more efficient processing equipment, and to improvements and standardization of quality. In recent years, large-scale operations for starch and farinha have been developed to supply urban and export markets, especially in Brazil, Thailand, and Indonesia. (*See* **Traditional Food Technology**.)

Important Products

Gari

Gari, a fermented, cooked and dehydrated cassava meal, is widely consumed in West Africa. It is a stable, ready-to-use foodstuff, well-suited to urban markets. Gari consumption is increasing, even in countries where it is not a traditional food. Gari is principally consumed in the main meal with vegetable sauces and meat. It can also be eaten as a snack soaked in cold water or milk, with roasted peanuts or coconut. Gari contributes up to 60% of the total calorie intake in West Africa, where an average of 150 g per person per day is consumed. Gari is mainly produced on a small scale and marketed by women; it provides an important source of income in many rural areas. Although many process improvements have been designed, diffusion of equipment has been patchy, especially for the roasting stage, so today, most of the gari consumed is still manufactured using the traditional process.

In traditional preparation of gari (**Figure 1**), the roots are hand-peeled, then grated into a pulp, often using a roughly perforated iron sheet. This pulp or mash is placed in hessian sacks, under heavy weights (logs, rocks) to squeeze out excess water. The mash is left to drain for 1–6 days, during which natural fermentation occurs. The pressed cake is shredded by hand and then rubbed through a woven palm-frond sieve to remove fiber and large lumps. This sieved mash is toasted (garified) in clay or iron vessels over a wood fire until the starch gelatinizes, and the moisture content is reduced to 10–15%. The mash must be stirred constantly to avoid sticking or burning. Palm oil may be added to facilitate this operation and imparts a yellow color to the final product.

Great variability exists in consumer perception of gari quality, and it is difficult to establish optimum values for the different quality parameters. However, in general, consumers prefer a crisp, fine-grained, slightly sour product with good swelling power in water, and a lightly toasted color. Although all the processing steps are important in determining end-product quality, some of them are only mechanical (peeling, grating, sieving, dewatering), whereas others involve some physical and chemical modifications that

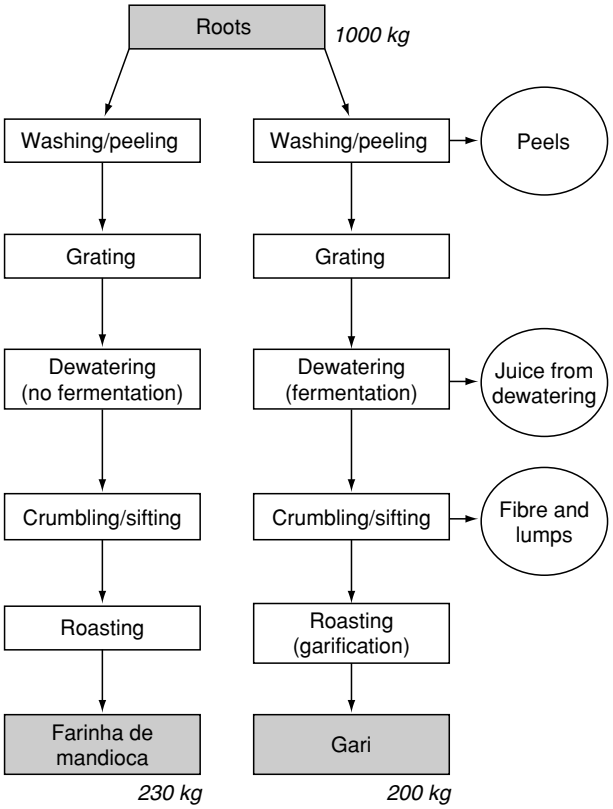

Figure 1 Flow diagram of the traditional processes for production of gari (West Africa) and farinha de mandioca (Brazil). Reproduced from Cassava: Uses as a Raw Material, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

improve the digestibility and reduce the cyanide toxicity (fermentation, garification). The fermentation step is crucial to the development of the characteristic aroma and sour flavor of gari, imparted mainly by lactic acid bacteria, which produce lactic acid and volatiles such as aldehydes, diacetyl esters, and ethanol. Fermentation also helps to detoxify the mash, whereas grating allows linamarase to come into contact with cyanoglucoside substrates. During fermentation, free HCN is released. The pH falls from 6.8 to 4.5 after 24 h of fermentation. Because the cyanohydrin intermediary is quite stable in acidic conditions, and linamarase activity is also reduced, less free cyanide is produced, and cyanhydrins accumulate in the fermented mash. Cyanide detoxification of the mash occurs in three ways: enzymic hydrolysis of cyanoglucosides, solubilization of cyanide in the water lost during dewatering, and volatilization of free cyanide during garification, at temperatures over 26 °C. The combination of these is not enough to completely remove all cyanide from the end product: total cyanogen contents of 15–33 mg kg^{-1}, with a free cyanide content of 5–25 mg kg^{-1}, have been reported. (*See* **Lactic Acid Bacteria**.)

The garification step is essential to obtain good-quality gari, for which 60–80% of starch should be gelatinized. This also improves starch digestibility. The starch is not completely gelatinized during garification because of the low initial moisture content of the dewatered mash (50–55%) and the temperatures used (60–85 °C). Gelatinization proceeds until the moisture content is reduced to about 40%, after which only drying occurs. The efficiency of manual stirring during garification is an additional variable affecting the final quality.

Farinha

Farinha de mandioca is a major dietary staple in Brazil, especially in the northeast region of the country, where the per capita consumption is over 40 kg per year or 1881 J (450 cal) per person per day. This represents 25% of the total calories consumed – more than rice and wheat combined. In Brazil as a whole, farinha contributes an average of 752 J (180 cal) per person per day to the diet. Farinha is a traditional cassava product and is still the major source of dietary energy for many of the indigenous peoples of the Amazon basin; one study of the Colombian Vaupes

region found that cassava provided over 80% of dietary calories and that farinha was the major product consumed.

The process for the production of farinha is similar to that of gari (Figure 1). It is probable that gari is an adaptation of farinha to African tastes, which occurred when cassava was introduced from Brazil to Africa. Unlike gari, however, a typical farinha preparation does not include a fermentation step. The operation proceeds directly from grating through pressing and sieving to toasting. Another difference is the use of washed but unpeeled roots. The end product is thus a cream/yellow-colored meal with no fermented taste. The final moisture content is the same as in gari, but the residual cyanogen content is lower ($10\,mg\,kg^{-1}$). Since no fermentation occurs, acid conditions do not develop, and the cyanhydrin intermediate rapidly breaks down to free cyanide.

Farinha is an integral ingredient in many traditional dishes. Mixed with beans, farinha provides a thicker texture. Farinha is also consumed with meats. Consumption decreased markedly between 1960 and 1980, as government subsidies on wheat reduced the competitiveness of farinha. However, over the last few years, elimination of wheat subsidies has resulted in an increase in the attractiveness of farinha. As a storable, rapidly prepared, and well-accepted food, farinha integrates easily into urban food habits.

Considerable applied research has resulted in the design, testing, commercial construction and use of efficient medium- and large-scale farinha production facilities in Brazil. Plants with a capacity of 50–200 tonnes of cassava roots per day are in operation. Alongside this, many thousands of small-scale traditional 'casas de farinha' exist, especially in the northeast, providing employment over vast areas of this region, the poorest in Brazil. Over 460 000 such plants exist, often run as communal operations at the village level. The range of scales of operation and the regional differences in cassava varieties and the process itself result in large variations in end-product quality. The variation in quality and its effect on consumption patterns need to be studied further. Research aimed at improving and standardizing quality has yet to produce results.

Starch

Although cassava is an efficient starch producer, only 5% of total starch traded worldwide is from cassava, representing about $0.8–1.0 \times 10^6$ tonnes per year. The main industrial-scale producers of cassava starch are Thailand, Brazil, China, and Indonesia. Production of cassava starch has increased dramatically in Thailand: by 1994, 50% of the 19×10^6 tonnes of cassava roots produced were processed into starch. Exports, mainly to East Asia, totaled 1.15×10^6 tonnes, and domestic use comprised 0.9×10^6 tonnes. In Thailand, starch is developing as a feedstock for further processing: in 1994, 31% of starch was modified, 12% was used for sweeteners, and 12% was used for MSG (monosodium glutamate). In addition to large-scale industries, many small-scale starch extraction plants operate in South and South-east Asia and in Latin America. Here, cassava starch is used in the local food industry to make a wide range of traditional food products (tapioca or sago in India; krupuk in Indonesia; chipa in Paraguay; maltose in Vietnam). In Brazil and Colombia, moist starch is fermented before drying, and a naturally modified starch is obtained, which has functional properties distinct from those of native cassava starch, namely a spontaneous expansion capability during baking. This starch is used in several traditional cheese breads (pandebono, pandequeso, bizcocho) and, more recently, in novel snack foods.

Cassava roots are washed and peeled; sometimes, only the outer bark is removed and then grated to release starch granules (Figure 2). The starch is extracted under running water and separated from the fiber and other root components by screening. Solid starch is separated from the starch/water slurry by sedimentation or centrifugation. The resultant starch is dried to a final moisture content of 12–14%. Sun-drying in small-scale operations and flash-drying in large-scale plants are typical. To obtain sour, fermented starch, the sedimented starch is left in tanks for 20–30 days before drying. Whereas a small-scale extraction plant may process only 2–10 tonnes of cassava per day, large-scale operations in Brazil and Thailand can handle 200 tonnes per day. Starch extraction rates are usually 18–22% for small-scale plants and 20–25% in large operations, depending on the process efficiency and initial root starch content. In small-scale plants, operations are manual or partially mechanized, resulting in less efficient starch extraction: in Colombia, 45% of the starch contained in the roots is lost in the waste water from the process, or remains in the peel and fiber byproduct, which is dried and used for animal feed. Waste water from processing plants can present severe environmental contamination problems, owing to significant concentrations of starch and cyanide. More efficient use of water in the process, and simple water treatment systems can reduce pollution. Regulatory pressure, especially on large-scale factories, is increasing.

In India, Brazil, and Malaysia, partially dried native cassava starch is used to make tapioca or sago: the still moist starch is globulated on a vibrating

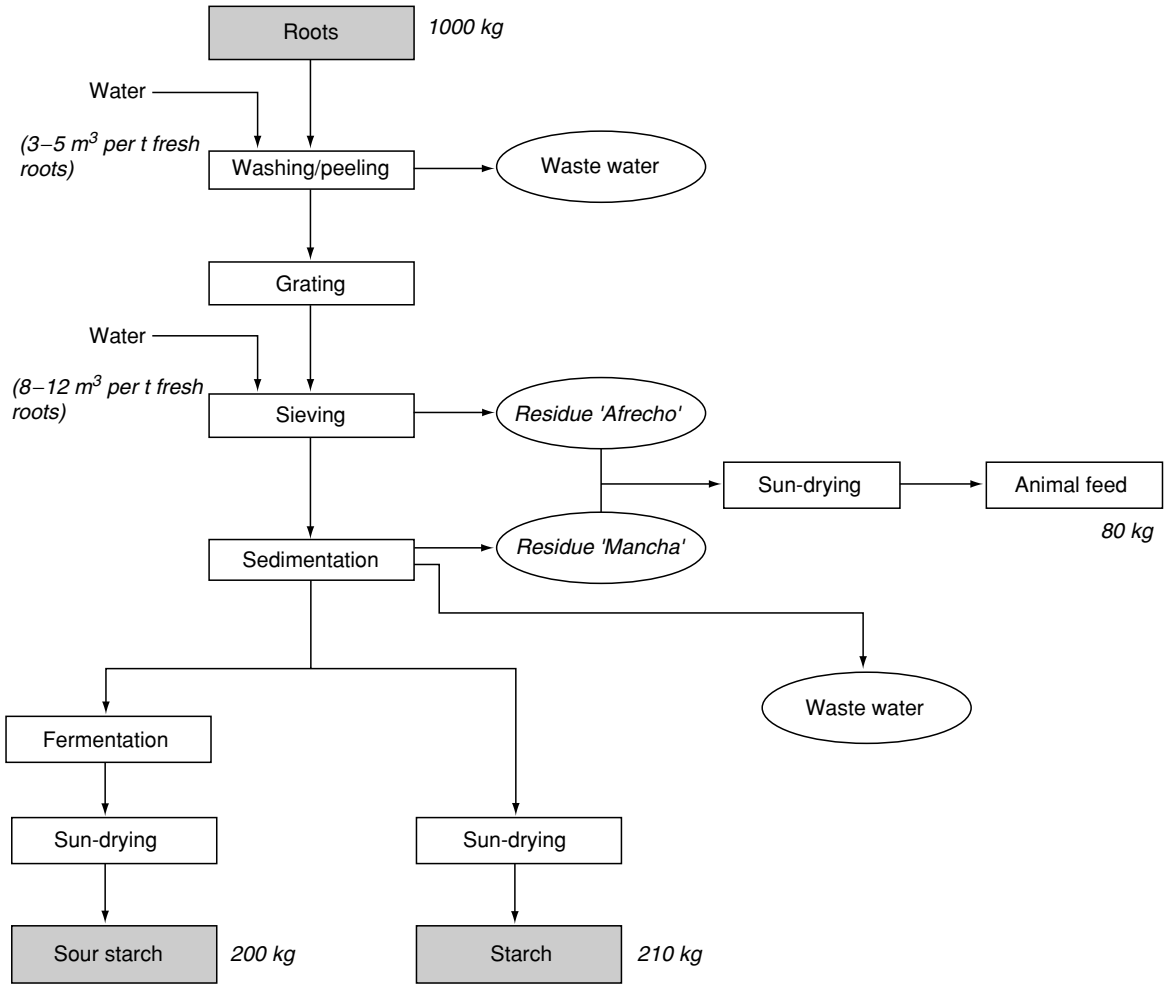

Figure 2 Flow diagram of the process for production of fermented (sour) and nonfermented (sweet, native) cassava starch. Reproduced from Cassava: Use as a Raw Material, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

surface, and the resulting small spheres are then steamed or baked to gelatinize the surface layers of starch. The end product, tapioca pearls, is used to make a variety of desserts. In Indonesia and Malaysia, the native starch is mixed with water, fish, or prawn flavoring and coloring. This dough is steamed, then sun-dried to make krupuk, or prawn crackers. When fried, these expand to several times their original size. They are a major snack food in Java and elsewhere in the region.

Fermented or sour starch has excellent expansion power; thus, the volume of a dough containing this starch increases greatly during baking. Although many factors affect the expansion power of sour starch, including environmental conditions, cassava variety and water quality, the major factors are fermentation and sun drying. During fermentation, amylolytic organisms produce reducing sugars, which are immediately consumed by lactic acid bacteria to produce organic acids (lactic, propionic, butyric, acetic, etc.) and carbon dioxide (CO_2). The high lactic acid content in sour starch correlates with a good expansion power and a good-quality final baked product. The action of the amylolytic enzymes and the acidification of the fermentation medium (pH 3.2) result in a lower viscosity, improved ease of baking, and reduced gelling ability of sour starch compared with native cassava starch. During baking of doughs containing sour starch, the moisture content loss (from 50% to 8–12%) together with volatilization of lactic acid and CO_2 results in an increased expansion power and reduced gelling ability, giving the end product its characteristic texture. A simple method for assessing the expansion power of sour starch is now available and in use with processors in Colombia.

Flour

In several regions of Africa and in Indonesia, cassava roots are chopped into pieces, sun-dried, and then pounded into a coarse meal or flour. This flour serves as a base for the production of many dishes at the household level. More recently, in Thailand, sun-dried cassava chips have been produced on a large scale, over 6×10^6 tonnes per year, for export to Europe as an animal feed. The chips are ground to a meal, which is then converted under steam and pressure to hard pellets. Dried cassava for animal feed expanded in Latin America during the 1980s as an alternative to imported grains for internal use. Globalization and cheap imports of feed grains reduced the feed use of cassava in the early to mid-1990s, but is now becoming increasingly competitive again. Potential also exists to produce high-quality cassava flour to replace imported wheat flour in bakery and other products in many tropical countries. One such program in Brazil was halted during the 1970s by wheat flour subsidies, which made it impossible for cassava flour to compete. The food industry use of root crop flours depends largely on international wheat grain prices: if these continue to decrease, the potential for substitution will be limited to those uses where cassava flour offers some specific functional advantages, or in remote areas where the transport costs for wheat flour are high (e.g., the Peruvian Amazon, where cassava flour is currently a commercial product).

The process for the production of high-quality cassava flour requires the use of cleaned roots with the bark removed. Peel removal is optional. Roots are chipped and sun-dried on trays or artificially dried (60 °C for 8–10 h) to obtain a hygienic product. The dried chips, with 12% moisture content, can be reduced in size (premilled) sufficiently to enable them to be used in standard wheat flour roller mills. Conversion rates in excess of 90% can be obtained in this way, compared with 72% for wheat grains. If roots are not peeled before chipping and drying, the peel and fiber fractions can be removed efficiently during the milling and grading process. A conversion rate of 3:1 is possible with cassava flour, compared with 4.5–5:1 for starch. The approximate composition of the flour is as follows: moisture 12%; carbohydrate 75%; protein 3%; fiber 5%; and lipids 2%. The total cyanogen content should be below 50 mg kg^{-1}.

Industry trials with cassava flour in Colombia have demonstrated that some specific attributes of the flour are especially suited to certain products. A 40–50% substitution of cassava for wheat flour produces biscuits with superior texture and color compared with 100% wheat flour controls. In Indonesia, a wide range of bakery products are being manufactured from cassava flour, at the village level as well as the food-industry level. Nutritional Implications

Catering Systems

A G Smith and A West, The University of Huddersfield, Huddersfield, UK

Background

Catering systems are complex sociotechnical organizations involving both people and machinery in the production and service of food. Such systems have the key purpose of transforming a diverse combination of 'inputs' into desired 'outputs.' Systems need to maximize their interdependence with the environment within which they exist. The objective for the management of any system is to find ways of ensuring its long-term survival and growth, often by seeking gains in efficiency and effectiveness in producing its outputs. Different types of catering systems have evolved in recent years as a result of efforts to achieve these goals. These developments have brought with them further technological challenges related to the provision of safe, nutritious, quality food products.

Emergence of Catering Systems

It has been noted that the 'systems' approach to management involves viewing organizations 'holistically' in order to gain a better insight into these complex situations, rather than merely focusing on individual parts or problems. Systems theory has been applied to a wide range of organizational contexts and has proven valuable in solving problems particularly where the situation is unpredictable and issues causing concern are ill defined or vague.

It has been suggested that 'systems' terminology was first applied to food production and service operations during the 1950s. The terms 'catering systems,' in common use in the UK, and 'food service system,' more frequently used in the USA, can be said to have been coined as a result of the 'systems approach' being applied to those operations that undertook the production of food and its service to consumers.

A simple definition of the term 'catering system' that has been proposed is that it refers to 'a particular method of organizing the production and service of food.' It is contended that the application of a systems approach involves defining and describing food production and service operations using 'systems concepts.' This enables the component parts, or subsystems, of an operation to be identified and the efficiency of their interaction assessed. Undertaking such a 'systems analysis' facilitates the application of 'problem-solving' methodologies, which can generate design solutions for the optimization of system performance. Utilization of these techniques, and awareness of the nature of organizations as being complex groups of 'subsystems' that need to be monitored and modified according to how efficiently they fulfil their specified objectives, can hence be referred to as 'systems management.'

Catering systems may be described as systems that have objectives relating to the production and/or service of food products to specified groups of consumers. Such systems normally receive a combination of inputs, which include:

- fully, part, or unprocessed food items;
- adequate numbers of appropriately skilled people;
- sufficient equipment and machinery;
- any necessary financing.

A simple 'model' of catering systems can be represented diagrammatically, as in Figure 1. The inputs form the components of a complex set of 'subsystems' that act to produce outputs required by the environment within which the system exists. The activity of the subsystems must be 'managed' effectively to ensure that they exhibit unity of purpose and exploit potential synergies within the system. The broad aim of any system is to fulfill demand for its outputs with maximum efficiency on a continuous basis. Through effective management that takes account of feedback from the market and environment, and also of 'feed-forward' from the manager's knowledge and experience of similar operations, the system's continued existence and growth are ensured.

Different views have been put forward by management and systems theorists over the years about the most important focus for managers of sociotechnical

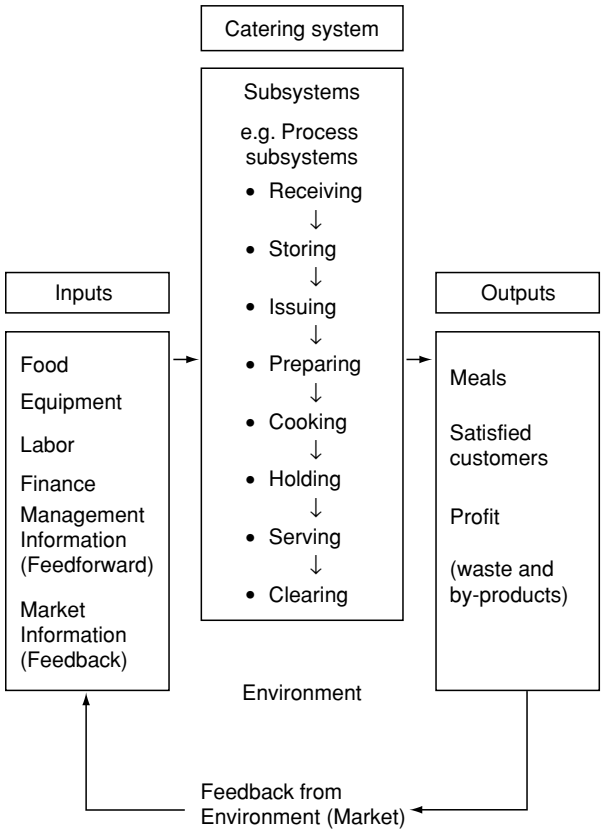

Figure 1 Simple model of a catering system.

systems. In essence, these contentions may be summarized as follows:

- The long-term survival of a system will depend on how well it 'interacts' with its environment, that is to say, how efficiently it acquires appropriate inputs and how ideally the output it produces match the current and potential demands of the environment.
- The efficiency with which a system works, and therefore thrives, will depend on ensuring that its subsystems work harmoniously towards common goals that contribute to, and are congruent with, the objective/s of the organization.

Catering systems, therefore, have been defined either in terms of the markets that they serve, that is against the context of their environment, or in terms of the differentiation in their internal processes or subsystems. There follows a brief summary of the classifications that can be applied to catering systems in relation to these perspectives.

Catering Systems Defined in Terms of Their External Environment

Catering organizations, as with all 'systems,' interact with their environment. In an ideal world, a catering system will produce the exact outputs the 'environment' demands in terms of both quantitative and qualitative requirements. A key task in managing such systems involves matching systems output to the requirements of the environment in such a way as to maximize the systems potential to do work. Thus, catering systems have typically been classified in terms of the sector of the environment they serve.

The two major sectors into which catering systems are divided are the 'Cost Sector,' which, broadly speaking, incorporates all not-for-profit catering activities, and the 'Profit Sector,' which includes all profit-orientated organizations.

The 'Cost Sector' typically includes all catering systems in the following subsectors:

- Healthcare, e.g., hospitals;
- Education, e.g., schools and colleges;
- Business and Industry, e.g., staff-feeding operations;
- Public Services, e.g., the police and armed services.

In 1996, the value of purchases (which equate with sales) in this sector, in the UK, was almost £1.5 billion, 'Healthcare', 'Education,' and 'Business and Industry' sectors each having similar values of £460–475 million.

The 'Profit Sector' includes catering systems in the subsectors listed below:

- Hotels;
- Restaurants;
- Fast Food;
- Cafes and Takeaways;
- Public Houses;
- Travel Organizations (e.g., on-board and in-flight catering);
- Leisure Operations.

In 1996, the value of purchases in the profit sector was over £6 billion, and sales were in excess of £18 billion. The Hotel sector alone accounted for £4.7 billion sales, with Public Houses being the second largest subsector having sales just less than £4 billion.

These figures serve to confirm the economic importance of catering systems to the UK economy, which reflects a global pattern in the developed world.

Catering Systems Defined by Their Subsystemic Differentiation

Catering systems may be defined in terms of the differences in the subsystems they contain. Subsystems can be defined in many ways, depending on the analysis being undertaken. In the example of 'process subsystems' alone, the possible permutations that can be identified mean that there are potentially innumerable variations in operational systems. Attempts have been made to resolve these variations into viable 'generic' groups. There are essentially three major classifications of catering systems into which the minor 'generic' variations may all be fitted. These can be summarized as follows, and their key characteristics are outlined in Figure 2.

- 'Cook–serve'/Integratedfood-servicesystems,where both the preparation of food and its service are an integral function carried out in a single operation, and there is little delay between preparation and food service. The majority of the catering industry still operates conventional systems of this kind.
- Food-manufacturing systems, where the production of food and meals is separated or 'decoupled' from the service of meals. Such systems encompass the use of chilling and freezing methods to preserve the food and in the past have been referred to as 'technological catering systems.'
- Meals-assembly/food-delivery systems, a recent systems development, in which little or no actual food preparation takes place in the system and the operation focuses on the assembly, regeneration, and service of meals.

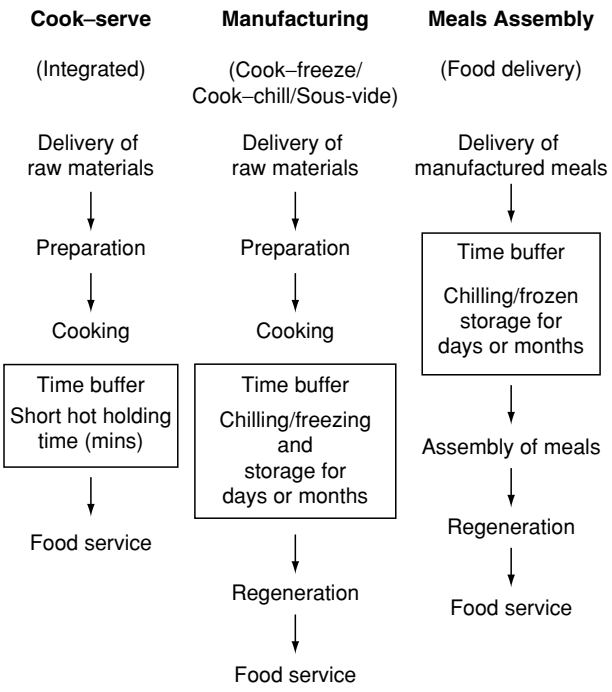

Figure 2 Major types of catering systems.

Cook–Serve Catering Systems

The cook–serve or integrated catering system represents the conventional approach to catering. These systems operate over a short time scale with the minimum feasible period or 'time buffer' between cooking and food service (see Figure 2). Where food is cooked to order, or produced in small batches to suit expected demand, it is quite easy to minimize the 'time buffer,' but this can be more difficult where food is made in bulk quantities for large numbers such as in institutional food services. The period, over which food is held hot, which, according to UK legislation, must be at a temperature above 63 °C, is largely dictated by the logistics of serving individual customers in each situation.

In cook–serve systems, should food need to be held hot for any appreciable period, time- and temperature-dependent changes occur that reduce both the sensory and nutritional properties of food. Adverse sensory changes can affect the color, texture, and flavor of foods. Losses in heat-labile vitamins such as thiamin and vitamin C also occur.

In research, the loss of vitamin C (as measured using the 'Fluorimetric method') has frequently been used as an indicator of food quality, as its destruction is time- and temperature-dependent and is accompanied by losses in sensory qualities. The effect of different cooking periods and hot holding times on the retention of vitamin C in Brussels sprouts is shown

Table 1 Comparison of the percentage overall losses of vitamin C in Brussels sprouts at the end of different periods of hot holding, in four different catering systems

System	*Overall percentage vitamin C loss at end of stages during hot holding (min)*				
	15	*30*	*45*	*60*	*90*
Cook–serve					
'Ideal' cook–serve	17.2	26.9	*	*	*
'Abused' cook–serve	25.3	32.3	*	42.7	51.4
Cook–chill					
2-day storage	34.5	41.0	50.7	*	*
3-day storage	39.8	48.1	54.3	*	*
4-day storage	46.6	53.6	60.0	*	*
5-day storage	55.7	61.9	67.5	*	*
Cook–chill sous vide					
4-day storage	32.9	38.6	45.8	*	*
5-day storage	32.7	41.4	48.3	*	*
Meals assembly	43.8	55.1	63.8	*	*

*no data available.
'Ideal' represents 15-min steaming.
'Abused' represents 30-min steaming.
From West A, Walker A and Lawson JM (1998) The effects of food processing in hospital catering systems. In: Edwards JSA (ed.) *Culinary Arts and Sciences 2. Global and National Perspectives*, pp. 283–289. London: Computational Mechanics Publications.

in Table 1. Extended cooking times and hot holding period cause substantial losses not only in cook–serve systems but also in the other systems discussed.

It can be imputed that cook–serve systems in many areas of catering have their limitations. This is particularly the case in large-scale institutional catering such as in the healthcare sector. Large hospital food-service operations formerly using traditional cook–serve methods and experiencing associated quality problems owing to extended hot holding before service, have been at the forefront of the change to food-manufacturing and delivery systems.

Food-manufacturing Systems

Food-manufacturing systems avoid prolonged hot holding of foods as they incorporate a substantial 'time buffer' between cooking and food service. This is achieved by chilling or freezing the prepared meals followed by appropriate storage. In this case, a 'time buffer' is effectively used to 'decouple' the production subsystems of the operation from food assembly and service (see Figure 2).

In food-manufacturing systems, food items are prepared in quantity in a large kitchen or centralized production unit, then chilled or frozen usually in multiportion packs, in effect preserving food until required. Products can be regenerated in the required amounts in a satellite kitchen, or using specialized reheating equipment close to the point of service (e.g., in large institutional operations) or within individual units (e.g., in an aeroplane's galley kitchen in in-flight catering). This approach minimizes the time food is actually hot-held as it should take only the time required to serve food to customers immediately after regeneration, which will minimize potential deterioration.

Meals-assembly/Food-delivery Systems

Food-delivery systems take the concept of 'decoupling' to a logical conclusion in that the manufacturing subsystems are completely removed. Food products are 'bought in' from specialist manufacturers producing frozen menu items for assembly and regeneration in simple kitchens consisting essentially of reheating equipment, or close to the consumer using specially designed heated trolleys. These catering systems, which do not require the traditional kitchen, may be referred to more aptly as 'meals assembly systems' as they only consist of the storage, assembly, regeneration, and service subsystems (see Figure 2).

The length of the 'time buffer' in these systems is determined by the preservation technique used, being up to 5 days for standard chilled foods and a year for frozen foods. Thus, the time buffer decouples production from service and potentially preserves food quality. This potential can be lost if the food is subjected to another period of hot holding after regeneration. UK guidelines recommend that it should take no longer than 15 min for meals to be served after regeneration is complete. Table 1 shows the damaging effect on vitamin C content if extended periods of hot holding do occur.

Whilst the food-manufacturing approach aims to improve efficiency by decoupling the major subsystems, 'meals assembly' actually simplifies a catering system by removing the preparation and cooking

subsystems completely. This allows the caterer to focus on food service and the monitoring of food safety and quality.

Preservation Methods in Food-manufacturing and Meals-assembly Catering Systems

Cook–Freeze

Freezing is a reliable method of preservation as it includes the barrier of the latent heat plateau seen in any time/temperature graph during the thawing of frozen food. This phase change provides a safety factor against temperature abuse, although any partially thawed foods at the surface could potentially cause food-safety and sensory problems.

A variation of this is the cook–freeze–thaw system introduced because, once thawed, the food can be treated as for cook–chill. However, the system can be potentially hazardous unless the temperatures are tightly controlled.

Cook–Chill

Cook–chill systems have gained acceptance through consumer preference for minimally processed foods. These are, however, more susceptible to temperature abuse in only having a small barrier to temperature change. Precise temperature control is necessary throughout the whole system. The time and temperature requirements currently specified under UK legislation are identified in italics in Figure 3.

Sous Vide

Sous vide is a specialist form of cook–chill system (see Figure 3) in which product shelf-life is extended from the normal 5 days up to as long as 42 days. Sous vide cooking is semicontinuous when operated on a large scale but discontinuous in smaller operations. There are particular concerns that all systems employing this method must have appropriate technical expertise to ensure that all the processing equipment and operating procedures are adequately designed so that products receive sufficient heat treatment.

Questions about food safety and quality in sous vide operations have been raised. Food is cooked in sealed plastic bags under a partial vacuum, which slows the rate of heat transfer and could result in underprocessing. This has led to concerns that psychrotrophic pathogens, such as *Listeria monocytogenes*, *Yersinia enterocolitica*, *Clostridium botulinum*, and the like could survive. The most hazardous of these is *Clostridium botulinum*, some strains of which produce a toxin at temperatures as low as 3.3 °C. Although the vegetative cells of

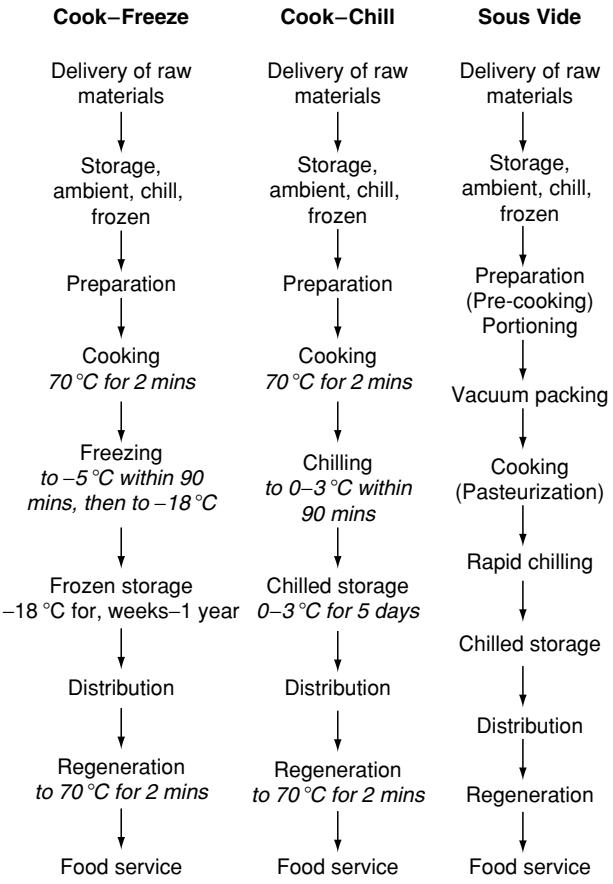

Figure 3 Stages involved in food-manufacturing systems.

Clostridium botulinum are destroyed by heat treatment of not less than 70 °C for 2 min at the coldest spot, foods should be heated to 90 °C for 10 min to ensure destruction of spores.

Concerns about the safety of vacuum-packaged and modified atmosphere-packaged products have led the Advisory Committee on the Microbiological Safety of Food in the UK to issue a Code of Practice that recommends the use of additional hurdles and the application of the HACCP technique in the manufacture of all such products.

The retention of most of the original juices within the package after cooking has led to claims that sous vide processed foods have enhanced sensory qualities. This claim has not been fully supported by research findings to date.

Further Developments in Cook–Chill

As there is doubt that chilled storage alone can assure the safety of sous vide products, recent work has focused on the formulation of products with additional hurdles. This involves the combination of several factors together, which collectively ensure

the microbial safety of food, even though each hurdle on its own might be insufficient to maintain safe food.

Examples of hurdles are low water activity, low pH, use of modified atmospheres (*See* **Chill Foods**: Effect of Modified-atmosphere Packaging on Food Quality) irradiation, added organic acids and protective cultures. The incorporation of such adjuncts provides hurdles to microbial growth and can also impact positively on safety, nutritional, and sensory aspects.

Research indicates that cook–chill produces a product that is inferior in sensory qualities to that produced in cook–serve systems in ideal conditions, but better than that produced in the nonideal or abused situations often found in catering systems.

Meals-assembly Techniques

The main stages in food delivery or meals assembly systems are shown in Figure 2. In this type of system, menu items are prepared and processed by food manufacturers to a specification prepared by a caterer. Typically, these menu items will include main courses, vegetables, and puddings, plus accompaniments such as sauces. The meals are chilled or frozen, and packaged in bulk foil containers suitable for use in commercial catering operations. After delivery to the catering unit, food is stored appropriately until requisitioned. Meals are then assembled, regenerated usually using forced-air convection ovens, and served.

Meals assembly represents a radical change in catering systems. By the year 2000, such systems were being used by almost a fifth of UK NHS hospitals as well being more widely adopted within the profit sector, particularly by pub and fast-food operations. This type of system has proven popular in healthcare catering, because it offers cost savings by reducing the need for skilled labor and expensive plant and equipment.

The meals-assembly system allows the catering manager to concentrate on food-service techniques and monitoring methods, in particular to control time and temperature factors. A quality-management approach is essential for both the manager's own operation and for their suppliers, the food manufacturers.

The final quality of food produced using these new systems is governed by the control of time–temperature parameters throughout the system. Potentially, regeneration is the stage that can affect food quality most adversely, as primary cooking is common to all types of system.

Regeneration

In a meals-assembly system, regeneration usually involves a standard reheat cycle in which a mixed load of chilled or frozen meals is regenerated in a specially designed oven. This means that food can be under- or over-heated as different foods have different thermal characteristics. Owing to food-safety concerns food, is often effectively overheated, with core food temperatures at the end of regeneration in excess of 80 °C being usual. The time spent at this temperature level is particularly detrimental to food quality, causing both heat-labile vitamin losses and sensory losses. There is often potential to reduce the severity of the regeneration process whilst still maintaining safety, yet preserving sensory and nutritional quality, but reliable control and monitoring methods are vital.

Various types of equipment can be used for regenerating assembled meals, the most common currently being forced-air convection ovens. Forced-air convection technology gives a fast regeneration time owing to constant air velocity and even temperature distribution. Hot-air convection currents being forced to circulate the oven cavity by a fan achieve this. These currents remove the steam layer from the surface of the food quickly and enable heat to reach the food directly, thus causing a rapid rise in temperature.

The heating effect can be enhanced further by the incorporation of steam injection into the oven cavity. The latent heating effect of condensing steam on the surface of the food package promotes faster reheating.

The use of microwaves in regeneration is less common but can be successfully combined with forced-air convection technology. Microwaves alone are better for reheating chilled, rather than frozen, foods because of the different absorbency of microwaves by ice and water, which can cause thermal runaway, leading to hot spots and cold spots in the product. This can still occur in chilled products because of different dielectric properties in foods of varying compositions. (*See* **Chill Foods**: Effect of Modified-atmosphere Packaging on Food Quality; **Chilled Storage**: Principles; Attainment of Chilled Conditions; Quality and Economic Considerations; Microbiological Considerations.)

The newer systems of food manufacture and food delivery require strict control throughout heat processing to ensure food safety and maintain consistent quality. New approaches to equipment design include the application of computational fluid dynamics and the use of model-based control design.

Food-safety Issues in Catering Systems (*See* Food Safety)

Temperature control in catering systems is imperative, and monitoring systems have consequently

been developed in recent years. Larger units can have computer-controlled temperature-monitoring devices, whereas smaller operators generally rely on making manual checks and keeping manual records.

Failure to control time and temperature remains a problem responsible for the majority of food-poisoning cases caused by the catering industry. In the UK, there is a mandatory requirement for caterers to identify the steps in the system where hazards can arise and put appropriate control and monitoring measures in place. This relates to the implementation of Hazard Analysis Critical Control Point (HACCP) techniques. Caterers are encouraged to develop modified HACCP approaches based on the Assured Safe Catering methods, but this is expected to be a slow process that will take place over several years. (*See* **Hazard Analysis Critical Control Point**.)

There is a need to address the safety of individual foods as caterers continue to cause outbreaks of food poisoning owing to the use of contaminated fresh shell eggs. The UK Government has recommended that caterers should make use of heat-treated egg products, pasteurized to eliminate *Salmonella enteritidis*. (*See* ***Salmonella***: Properties and Occurrence; Detection; Salmonellosis.)

Systems used in the catering industry can be seen as a continuum of the techniques used in the food-manufacturing industry and therefore can employ similar methods of control. For example, the concept of quality management can be usefully applied. As more food-manufacturing techniques are adopted, and encouraged by regulatory authorities, these techniques should accompany the HACCP approach so that safety and quality issues are both addressed.

Catering Systems in Conclusion

There is a need for further research to confirm claims of improved sensory qualities, safety, and nutritional values in food manufacturing and meals assembly systems. Quality changes can occur rapidly, but many variables affect the end result that is often product-specific. The lack of control and standardization in both the catering industry and experimental methods makes comparisons between studies difficult. The fact that technological innovations in catering systems have not introduced new methods of food production but rather, as some have noted, introduced systems of food preservation has not been proven to have had a positive impact on food quality predicted, as a matter of course.

Generally cook–serve catering systems still predominate throughout the food-service industry. It has been found that increased size, certainly in the healthcare sector, tends to dictate whether or not food-manufacturing systems have been adopted. However, recent surveys have indicated that around three-quarters of hospitals in the USA and almost the same proportion in the UK still operate conventional food-service systems.

In recent years, the emergence of food-delivery/meals-assembly systems has offered the opportunity for many smaller catering operations to adopt this type of system. Whilst this development means that catering systems can provide a wider menu with less skilled staff and reduced equipment needs, it has been observed that quality suffers if regeneration of products is poorly controlled and if the aesthetics of meals assembly and customer service expectations are overlooked.

It is pertinent to recall that the term 'catering system' emerged from the application of systems theory to the management of food-service operations. It should not be forgotten, therefore, that the systems approach is 'holistic,' and that any innovation that affects one or more subsystems will also affect the rest of the system, its inputs, and the efficiency and effectiveness with which it produces its outputs.

Nutritional Implications

A G Smith and C Hunt, University of Huddersfield, Queensgate, Huddersfield, UK

Introduction

The catering or food service industry incorporates a wide range of organizations engaged in the provision of food products for customers within either the commercial or welfare sectors (*See* **Catering**: Catering Systems). Catering operations have been defined as: 'establishments whose main business comes from the sale of meals . . . refreshments . . . alcoholic drinks . . . or the provision of accommodation.' The following article focuses specifically on the aspect of the provision of meals by food service systems. The process subsystems involved in typical catering operations are identified and the consequent nutritional implications, both positive and negative, that these processes might have for the final food products is then considered.

It is the preparation and cooking of raw food ingredients that renders the nutritional benefit of food available to the consumer. In this sense, the food service system may be seen as both positive and necessary for the acquisition of necessary nutrition by human consumers within today's society, where an increasing number of meals are consumed outside the domestic setting. However, there are many opportunities for an inadequately managed food service system to contribute to the avoidable deterioration of the nutritional content of food items.

General Nutritional Considerations

Nutrients can be subdivided into macronutrients (fats, protein, and carbohydrate) and micronutrients (minerals and vitamins).

Macronutrients are relatively stable during storage and heat processing. Commodities such as meats and dairy products provide macronutrients such as proteins and fats. They may also provide fat-soluble vitamins. These nutrients are relatively stable, although they can be broken down by certain activities, such as the natural digestive process, whereby they can be utilized by the body.

Cereal products are key sources of carbohydrate in the diet. Processed cereal products such as pasta and breads hence are also a major provider of this essential energy fuel. Carbohydrates are relatively stable and, if commodities such as those outlined are stored and handled correctly, then little deterioration should occur whilst the products are processed by a food production or service system.

Of the micronutrients, minerals, which occur in a variety of foods, are heat-stable and will not be destroyed by cooking, Nevertheless, some loss can occur by water leaching.

Vitamins vary considerably in terms of stability. The fat-soluble vitamins (A, D, E, and K) found in meats, nuts, and yellow fats, for instance, are relatively stable. The B-complex of vitamins and vitamin C, which are largely supplied by fruit and vegetables, are the nutrients most vulnerable to loss during storage and processing. These water-soluble vitamins are also generally unstable to heat and liable to oxidation.

A Catering System – Defined in Process Terms

Amongst the many ways in which catering systems can be defined (*See* **Catering**: Catering Systems), perhaps the most useful of these, when considering the production elements of catering, is to view a catering system in terms of process subsystems (**Figure 1**).

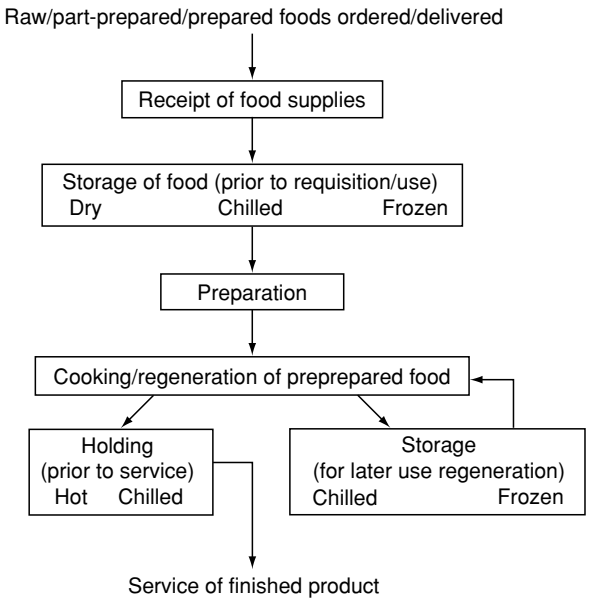

Figure 1 Process subsystems within a typical catering (production) system.

To consider the nutritional impact on food items as they are transformed from raw products into finished dishes for the consumer, each process stage is discussed below.

Ordering and Receipt of Food Supplies – Nutritional Considerations

The first process undertaken by all food service systems is generally that of ordering and receiving the raw materials or part-processed goods that will be used to make finished products. Whilst there are aspects of efficiency in the undertaking of this process that should be considered in order to insure that foods retain their maximum nutritional value, it is apposite to consider initially the nutritional quality of the foodstuffs when received by the caterer.

Many factors affect the incoming nutritional value of food materials, which may ultimately have more impact on the final nutritional profile of manufactured food products than the following preparation activities might have. These influences vary depending on the commodity, so that animal-based raw materials such as meats may display different nutritional values for different reasons to plant-derived foodstuffs such as vegetables.

Key influences on the nutritional content of these major commodity areas are listed in Table 1.

In order to insure that goods received are of appropriate quality, it is important that food production and service systems draw up comprehensive purchase and product specifications. Even so, it will not be possible to avoid the substantial effects on nutrient values that certain natural occurrences or agricultural practices instigate.

Receiving Procedures – Impact on Nutrition

Receiving procedures for food items arriving at a food service operation can have a negative impact on nutritional value if not planned and executed efficiently. All food service systems should have procedures that incorporate staff accountability and immediate checking and transfer to appropriate storage facilities for foodstuffs at the time of delivery.

Accountability is important for retracing the chain of events if there should be any problems with food materials found in storage, hence a responsible member of staff should be appointed to undertake the receipt of deliveries.

If food is held at the point of receipt prior to appropriate storage then time- and temperature-related factors can lead to rapid onset of deterioration. Foods that are not properly stored immediately on receipt may be open to contamination or infestation, leading to hygiene and food safety-related problems and an adverse impact on nutritional value.

Table 1 Factors influencing nutritional value of food comÙmodities prior to processing

Animal origin (e.g., meats)	*Plant origin (e.g., vegetables)*
Breed/strain/genetic make-up of animal	Variety of plant
	Climate variations
Age of animal at slaughter	Seasonal factors
Feedstuffs used during growth	Quality of soil
Quality of grazing pasture	Use and nature of fertilizers
Other seasonal variations	Growing conditions
Use of growth stimulators	Degree of maturity of crop

Nutritional Implications of Storage of Food

There are essentially three key forms of storage of food items that most, if not all, food production and service systems utilize for keeping food prior to preparation into finished products. Items may be held as:

- dry goods
- chilled goods
- frozen goods

Each of these categories of stored goods may be subject to nutritional deterioration whilst being held prior to use. The amount of deterioration that takes place will largely depend on the following factors:

- the food item itself
- the nature of the item's nutritional make-up
- the type of storage
- the length of time it is held in storage

Given that the nutritional content for key commodities can vary on delivery due to many factors whilst stored pending use, in most cases further deterioration will be largely time- and temperature-dependent. The higher the temperature stored and the longer the item is held, the more the nutritional value of some foods will decline. The likelihood that food will exhibit nutritional deterioration depends on the nature of the major nutrients that food contains.

As mentioned earlier, vitamin C is the nutrient which is most susceptible to loss, so measurement of the extent of its retention during storage or processing has come to be used as an indicator of the efficiency of food production systems. If the proportion of vitamin C retained in the food is good, then this indicates that the levels of the less unstable nutrients will be also be good. (*See* **Catering**: Catering Systems.)

The major food commodities that supply vitamin C are fruit and vegetables. Fruit and vegetables should not be stored above 8 °C, with optimal storage temperature within the range 0–3 °C. Many fruit and

vegetable products are stored prior to delivery in a controlled atmosphere where the environmental gas mixture contributes to the lengthening of shelf-life. Products delivered to food service systems are often supplied in modified-atmosphere packaging (MAP). MAP should be retained intact until the stocks are issued, as the gas mixture used in the packing process can increase shelf-life of fruit and vegetables from between 2 and 7 days to up to 35 days, depending on the item. The inhibition of the ripening process and enzyme activity preserves the organoleptic quality and nutritional value of foods held in storage pending use. (*See* **Chill Foods**: Effect of Modified atmosphere Packaging on Food Quality.)

For food items that provide a source of the relatively stable nutrients, the nutritional profile of the foods will be adversely affected if storage is inappropriate such that loss due to spoilage renders the food unfit to eat. This means that the nutrient value of the food would no longer be available for safe consumption. For instance, over time poorly stored foods which contain fats will become rancid. This will occur more rapidly if temperatures are too high, and the product is poorly wrapped, allowing oxidation to occur. Protein-rich foods such as meats quickly become subject to contamination, hence unsafe to eat, if stored at temperatures and in conditions that allow the establishment of bacterial colonies that thrive on the same sources of protein as humans.

In the case of carbohydrate sources, such as cereals, grains, pasta, and flour, it is essential that these items are kept dry and in containers that are impervious to insect pests. The nutrient value *per se* will not deteriorate but poor storage can lead to spoilage or contamination, rendering the food unfit to eat.

Food Preparation Techniques and Impact on Nutrient Content

Many food items delivered to catering systems require preparation before they can be utilized. Fruit and vegetables will need washing and peeling and may be further prepared, by chopping or slicing, for example, prior to cooking. Raw meats may require differing amounts of preparation depending on how much has already been done by the butchers prior to delivery and according to what use is to be made of the item.

Whilst the purpose of preparation of foodstuffs is either to remove any inedible parts or generally to enhance the eating quality of the ingredient, any preparation process can lead to a reduction in overall nutritional value of the food.

The process of peeling fruit and vegetables, whilst enhancing visual appeal and possibly eating quality, will normally result in the reduction of overall nutrient content. If any proportion of the preparation waste would originally have been edible, overall nutrient value will be reduced. It has also been shown that peeling vegetables can lead to increased vitamin loss as a result of leaching during the cooking process.

In the preparation of meat it is increasingly likely that, due to healthy-eating advice, the larger proportion of surface fat will be removed from raw meats during the preparation stages. In effect, the overall potential nutritional value of the meat is reduced by doing this. However this might be viewed as acceptable nutritional loss in the light of the potential contribution this makes towards achieving healthier diets.

It can be argued that the consequent improvement in final eating quality of a product achieved by preparing ingredients appropriately could result in more of the total finished product being consumed than if such preparation had not been undertaken. This implies that good preparation may lead to more efficient consumption of the nutritional potential of foods items made for consumption. However, for the manager of a food-manufacturing or catering operation it is imperative that good staff training emphasizes the importance of minimizing waste during the preparation stages in food production. This will mean that both nutrient contents and potential profits are preserved.

Cooking Processes and Nutritional Implications

In general, cooking has the biggest nutritional implications of any single process undertaken within a typical catering system. The impact of cooking on nutrients varies according to the method of cookery, the length of time food is cooked for, and the temperatures employed.

Broadly, the shorter the cooking time and the more quickly food is consumed after it is prepared, the less the unstable nutrients will have declined. However, the methods of cookery that are used in most systems are dependent upon the nature of the foods themselves. The nutritional implications of the methods of cookery are briefly considered below.

Dry-Heat Cooking

These cooking methods are largely applicable to proteinaceous foods and to certain carbohydrate nutrient sources. Meats, poultry, and fish, as major protein sources, can be baked, roast, or grilled, for instance. Cakes and bread are baked, whereas potatoes are often baked or roasted: all these are important sources of carbohydrates.

These dry-heat cooking methods generally require quite high temperatures (150–400 °C) and the period for which heat is applied is directly related to the size and density of the food being cooked. However, proteins and carbohydrates are quite stable and efficient cooking results in positive changes taking place during cooking that increase the edibility and digestibility of these nutrients.

When carbohydrate-rich foods are dry-cooked, the starches are turned to easily digested sugars called dextrins which darken as they cook. This accounts for the browning of toast and the surface of potatoes, as dextrins caramelize, and which shows when a food is cooked. When such foods are overcooked, the sugars char, which can impart unpleasant visual and flavor characteristics, making foods less palatable and resulting in the destruction of the carbohydrates that have been burnt. B-vitamins can also be lost in the toasting process, e.g., toasting bread results in considerable loss of thiamin.

Moist-Heat Cooking

These methods are generally applied to:

1. Delicate foods such as vegetables that contain a high percentage of water in themselves, and must be kept moist to insure that they are edible and digestible. This also applies to delicate protein foods, such as fish. The final eating quality of these foods can benefit from gentle moist cooking for a relatively short period of time.
2. Tougher protein foods such as stewing meat and boiling fowl, which require moderate temperatures for longer times to retaining moistness and achieve a tender, palatable product.

For vegetables this method of cookery can be problematic because they are often a source of the least stable vitamins, such as vitamin C and B-vitamins such as folate. Vegetables commonly lose around half of their vitamin C content on boiling, mostly due to the vitamin dissolving into the cooking liquor by leaching out of the cut or peeled vegetables. Similarly, almost a third of folate is lost on boiling. In contrast, it has been shown that steaming vegetables considerably reduces such losses (vitamin C 10–20%; folate 0–10%) because it involves a lot less water so there is less opportunity for leaching to occur.

Nutritional analyses have shown that vegetables lose considerably higher proportions of these vulnerable vitamins when they are peeled and when they are chopped up. New potatoes lose only about 5% of vitamin C on boiling when their skins are left on, as opposed to up to 50% loss when peeled. As the skin acts as a natural barrier to vitamin leaching, caterers should consider retaining edible peels whenever possible during cooking. It is also advisable to minimize the chopping of vegetables within reason, as whole items retain vitamins much more successfully because the cellular structure of the vegetables remains intact and cell contents are less likely to leak into the cooking liquor.

Although heat in combination with exposure to oxygen in the air will result in permanent destruction of a proportion of vitamins during the cooking of vegetables, by far the greater amount of 'lost' vitamins will simply be dissolved into the cooking liquor. It is for this reason that caterers should make it common practice to incorporate cooking liquors into stocks, sauces, and gravies wherever possible as this will insure that such 'lost' vitamins are retained for potential consumption.

Many vegetables also provide important carbohydrates and fiber in the diet. Moist cooking methods help to gelatinize carbohydrates, which aids their digestion. Fiber, in the form of cellulose, also needs to be softened by such cooking to make the vegetables more palatable. The more cellulose there is, the longer cooking time is required. Hence carrots need longer cooking than some delicate green vegetables. This has implications for the caterer who wishes to achieve the optimum balance of color, flavor, and digestibility, along with retention of maximum nutritional value.

Delicate protein foods such as fish may be poached or steamed to achieve moist and palatable results. Flavors will not intensify as much as they might during dry cooking, which effectively dehydrates foods and hence concentrates flavor elements. Natural mineral salts are also dissolved into the cooking liquor and these are not only important nutrients but also key to the development of flavor. There may also be some minor loss of proteins into the cooking liquor. Once again, using any resultant stock, after cooking is complete, to make sauces to be served with the dish will recoup the majority of these nutrients.

When moist cooking methods are applied to appropriate cuts of meat in the process of making stews, pie fillings, or casseroles, for example, this helps to turn the tough collagen in the meat to gelatin. Gelatin is more easily digested because it is a soluble protein, hence the cooking process not only improves palatability but also makes the nutrients more readily available to the consumer of the product. Once again, it is imperative that the cooking liquor becomes part of the dish, in the form of sauce or gravy, because flavorsome, nutritionally valuable natural mineral salts as well as some proteins will be dissolved or suspended in it.

Nutritional Impact of Regeneration and Warm-Holding of Foods

Traditionally catering systems either operated on a basis of 'making-to-order,' where there is no delay between cooking and service of food, such as in quality restaurant operations, or bulk production, when food may be held warm for considerable periods prior to service, as in hospital and canteen feeding operations. In relatively recent times interrupted catering systems, such as cook-chill and cook-freeze operations, have been introduced (*See* **Catering**: Catering Systems) where foods are cooked, then rapidly chilled or frozen, to be reheated later just prior to use. These different methods have implications for retention of nutritional value of foods that must be considered by caterers.

Traditional Catering Methods and Warm-Holding Foods

Where food is made-to-order and served, and presuming quality stock has been purchased originally and stored, prepared, and cooked efficiently, then it is likely that consumers will receive food with optimal palatable, digestible, and nutritional characteristics. However, for those large-scale operations where it is necessary to hold food warm for any length of time, the outcome can be significantly different.

Whilst some unstable nutrients are irredeemably destroyed during the cooking process, as discussed, due to the action of heat and oxidation, this may be seen as a necessary trade-off to achieve improved digestibility and hence give access to the vast majority of nutrients remaining in the food, and liquors produced during cooking. Should food have to be held warm for any period after cooking and before consumption, the only nutritional effect is adverse.

Maintaining foods at safe temperatures (above 63 °C, and usually much higher) and further exposure to atmospheric oxygen results in rapid and unrecoverable depletion of unstable nutrients. Warm-holding of cooked vegetables, for instance, which are the key dietary sources of vulnerable nutrients such as vitamin C, can result in typical permanent losses of up to 20% h^{-1} and 10–15% h^{-1} for folic acid. Prolonged warm-holding also results in deteriorating organoleptic (flavor, texture, aroma) and visual properties. This reduction in the palatability of foods may lead to less food being consumed, hence further reducing utilization of remaining nutritional potential.

Cold-Holding and Regeneration of Foods

In interrupted catering systems, food is chilled rapidly immediately upon completion of cooking. The process of chilling itself has no adverse impact on nutritional value of food. However, if foods are only chilled and not frozen, a significant reduction of unstable nutrients continues to occur during chilled storage. Vitamin C levels have been shown to fall by around 10% per day during such holding, although this varies depending on the particular food. If foods are frozen then further vitamin losses are virtually halted, although losses may occur during the thawing process, if foods are not regenerated from frozen, when liquid containing vitamins may run off.

Frozen or chilled foods will need to be regenerated prior to service and brought to a safe temperature in excess of 63 °C. During this second heating, further permanent vitamin losses will occur, as in primary cooking, due to the effects of heat and oxidation. Foods that have been regenerated must then be served and consumed as swiftly as possible, to reduce to a minimum the warm-holding effects previously discussed.

The Importance of Catering in Relation to Nutritional Intakes

Whilst there are many influences that can affect the final nutritional value of a meal or food item before it reaches the consumer, it should be noted that the contribution that catering makes to the overall nutrition of individuals varies greatly.

Catering systems operate either as welfare-related concerns within the cost sector, or as commercial operations within the profit sector (*See* **Catering**: Catering Systems). Where customers are captive, such as in hospitals, schools, or prisons, then the catering provision may be an important contributor to daily nutritional intakes. Just how important this becomes to individuals will depend on the length of time for which they are reliant on catering provisions for all or a major part of their daily diet. Long-stay hospital patients, boarders at schools, and those retained at Her Majesty's Pleasure for prolonged periods will need to acquire satisfactory nutritional benefit from the food provided by the caterers in their respective environments.

In the UK the National Food Survey, conducted by the Ministry of Agriculture, Fisheries and Food (MAFF), indicated that households were spending almost £24 per person per week on average on food and drink in 1999. Of this sum, just over £7 per person per week was spent on meals and beverages eaten out – around 30% of total expenditure. Between 1998 and 1999 expenditure on eating out rose by just over 5%, whereas the total spent on food and drink at home remained almost static. Whilst the economic climate is generally positive it is likely that such a tend will continue, as consumers

may not feel the need to 'tighten their belts.' In terms of nutrition, the implication must be that, as the proportion of expenditure on food and drink eaten outside the home increases, so the relative importance of catering and food service operations to the national diet increases.

The National Food Survey indicated that the pattern of consumption of food away from the home varies considerably between socioeconomic groups in respect of total amount spent and nature of foods consumed. Gender and age differences also influence individuals, food consumption patterns. This means that it is difficult to make any generalizations about the impact of commercial catering on the nutrition of the community at large. However, some observations relating to the nutritional value of food and drink consumed include the fact that fats and alcohol provide a considerably higher proportion of the total energy (caloric value) of food eaten out. Overall, food eaten away from the home accounted for just over 12% of total energy intake for the average person in the UK in 1999.

There are increasing concerns about the increasing prevalence of obesity in developed countries such as the UK. Medical practitioners and nutritionists regularly confirm this growing problem, exemplified by the fact that nearly one in five adults in the UK are classified as clinically obese. Because obesity is recognized as contributing to a range of health problems such as cardiovascular disease, it is suggested that caterers should make any efforts that they can to contribute to the general dietary goals of reducing fats, sugar, and salt by examining and modifying recipes whenever they can.

CELIAC (COELIAC) DISEASE

P D Howdle, St. James's University Hospital, Leeds, UK

Introduction

Celiac disease, or gluten-sensitive enteropathy, is a common condition in which the principal abnormality is in the small intestine. This abnormality is related to the ingestion of a cereal protein, gluten, and leads to a variety of clinical problems. The pathogenesis of the abnormality is thought to be an immune reaction to gluten in a genetically predisposed individual.

The clinical presentation varies from a normal state to a severely malnourished state, and there are a number of associated diseases.

Treatment is with a gluten-free diet and, in the majority of patients, is very effective.

Epidemiology

The most comprehensive data on the prevalence of celiac disease are from Western Europe. The prevalence of clinically apparent disease ranges from one in 300 to one in 1000. The disease has thus been described principally in Caucasian peoples, although cases have been diagnosed in all other ethnic groups. Any variation between ethnic groups may be due to a genetic variation between different populations, the availability of diagnostic facilities, and the consumption of the relevant cereals, since the disease can only present in wheat-eating populations.

In recent years, serological antibody tests have been used to screen for the disease in the general population of several European countries. Such studies suggest that the true prevalence may be as high as one in 140, although the majority of the subjects have no apparent symptoms of the disease.

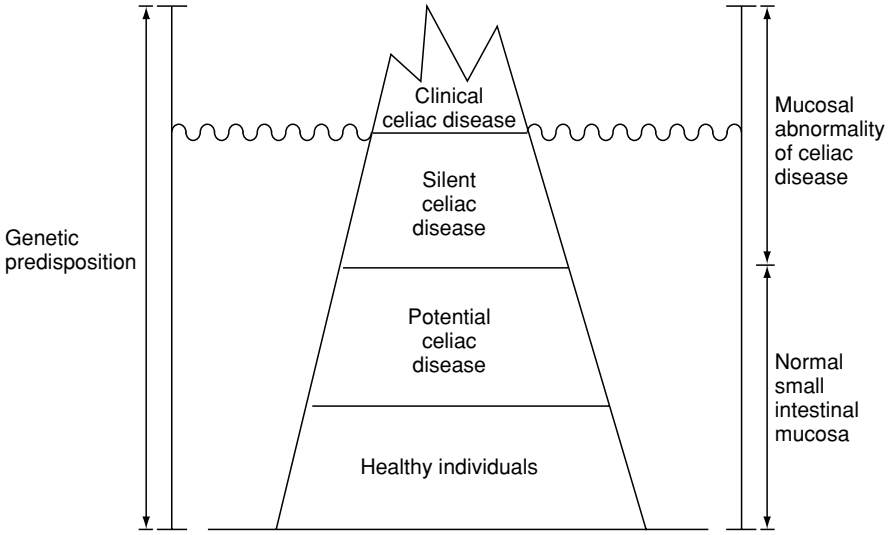

Figure 1 'Celiac iceberg' showing the spectrum of disease and small intestinal abnormality.

Such screening studies have led to the concept of the celiac iceberg (see Figure 1). This suggests that a minority of patients have clinical evidence of the disease, others have the small intestinal abnormality but are asymptomatic (silent disease), and others have the genetic predisposition but have not yet developed the pathological changes that could lead to symptoms (potential disease). There are normal individuals who have the genetic predisposition as described at present, but who never develop the disease. There is presumably an as-yet unidentified factor that distinguishes these normal individuals from the potential celiac patient.

Pathogenesis

Genetics

Celiac disease has been recognized as being a familial condition for many years. Approximately 10% of first degree relatives have the condition. The mode of inheritance is not understood.

It is also known that a particular haplotype in the MHC region of chromosome 6 is necessary in order to develop the disease. The extended haplotype concerned is B8, DR3, DQ2 but it is the DQ2 haplotype that is specifically associated with the disease, being present in 95% of patients. The 5% of patients who are DQ2-negative are DQ8-positive. It should be noted that other genes must be involved, since approximately 30% of the general population carry these genes, and the majority of these do not develop the disease. Hence, DQ2 or DQ8 is necessary, but not sufficient in terms of the genetic constitution of an individual in order to develop the disease. For this reason, other genes are being sought elsewhere in the genome that might predispose to the disease, but to date, no consistent results have been produced.

Gluten

The term 'gluten' is the generic name applied to the storage proteins found in wheat, rye, and barley. Gluten is responsible for the visco-elastic properties of these cereals, which make them good for baking. It is the insoluble material (a complex mixture of proteins, with small amounts of lipids, sugars, and minerals) obtained when flour is washed in tap-water to remove the soluble substances (albumins, globulins, and starch). Gluten is thus an ill-defined mixture that varies between different flours and is even dependent upon the solubilizing properties of the tap-water used. Gliadin is the ethanol-soluble component of wheat flour, usually solubilized in 70% ethanol; the same component can be extracted from wheat gluten. Gliadin, although a complex mixture of proteins, is thus more homogenous than gluten. The comparable ethanol-soluble components from rye and barley are termed secalin and hordein, respectively. Collectively, these proteins are prolamins. All these prolamins are related phylogenetically and are rich in the amino acids proline and glutamine. All are capable of provoking the pathological changes in the small intestine characteristic of celiac disease.

Most is known about wheat gluten or gliadin, and the terms are often used interchangeably when referring to their involvement in celiac disease. Gliadin comprises approximately 50% of wheat proteins, and a single variety of wheat may have 45 different gliadins. Their complexity has made them difficult to

investigate, but some gliadins have been sequenced, and synthetic or chemically derived peptides from gliadin have been tested in *in-vitro* or *in-vivo* experiments in celiac disease. It appears that short peptides, approximately 10–20 amino acids in length, which are particularly rich in glutamine, are capable of producing small-intestinal damage. It is believed, therefore, that ultimately, several peptides from the prolamins of wheat, rye, and barley, with similar amino acid sequences, will be found to be responsible for initiating the disease process in predisposed individuals.

Oats are a major related cereal, but the prolamin in oats (avenin) only accounts for 5–15% of the oats' protein. It is thought that because of this low prolamin content and possible dissimilarities between the amino acid structures of avenins and the other prolamins, oats are nontoxic to the vast majority of celiac patients.

Immunology

There is much evidence of enhanced immunological activity in celiac disease. In the small-intestinal mucosa where the characteristic pathology develops, there is an increase in T-lymphocytes, principally of the helper (CD4) type in the lamina propria, resulting in the production of pro-inflammatory cytokines, and of the cytotoxic-suppressor (CD8) type in the epithelium, the so-called intra-epithelial lymphocytes. Concomitantly, the plasma cell numbers increase, leading to the production of immunoglobulins, particularly antibodies to gliadin and tissue auto-antigens. Recently, tissue transglutaminase (tTG), a ubiquitous enzyme present particularly in the lamina propria, which catalyzes the cross-linking of proteins, has been reported to be an auto-antigen in celiac disease. The antibody against this antigen is termed the 'anti-endomysial antibody' and is very specific for the disease when measured in the serum of untreated patients. Interestingly, gliadin is an excellent substrate for tTG because of its high glutamine content. It is currently hypothesized that in celiac patients, tTG reacts with gliadin, thus forming a deaminated gliadin and a gliadin–tTG complex. This neo-antigen could then be involved in the initiation of an immune reaction in a predisposed individual.

Pathophysiological pathway

A possible pathway leading to the small intestinal mucosal damage in celiac disease is shown in Figure 2. This scheme takes into account the pathogenetic factors discussed above. The products of the

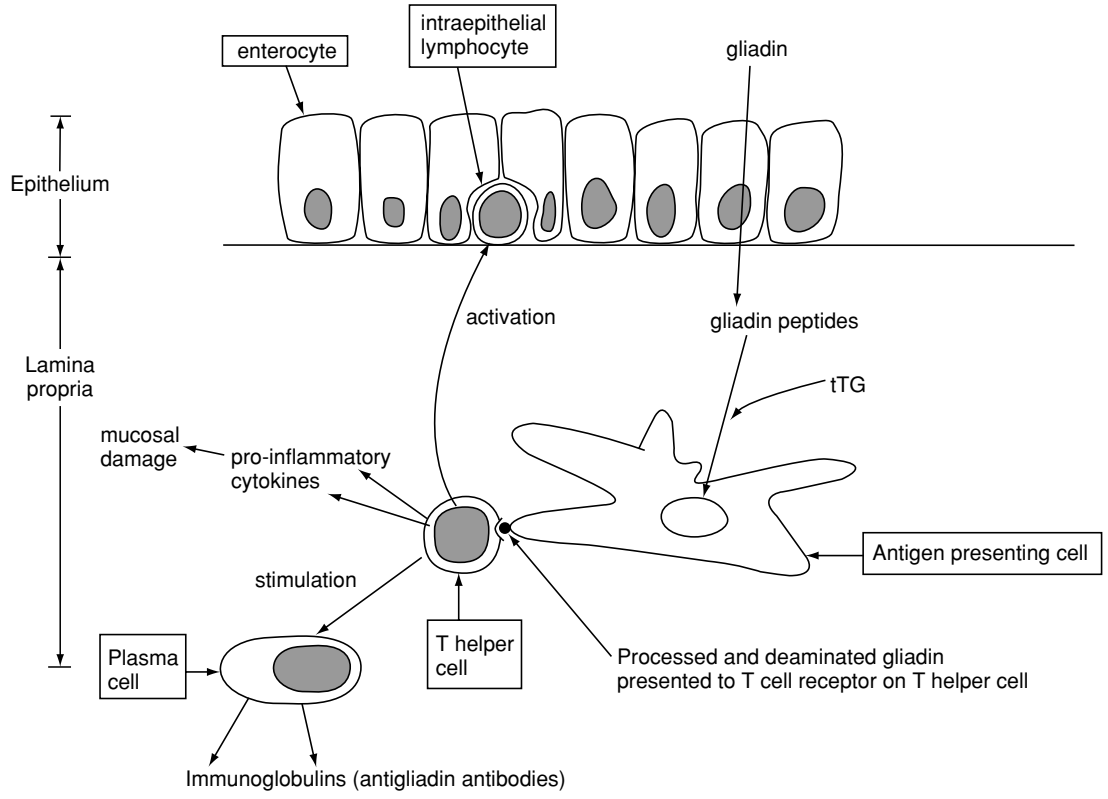

Figure 2 Schematic representation of the immune mechanisms leading to the mucosal abnormalities in celiac disease.

HLA-DQ2 genes are proteins located on the membrane of antigen-presenting cells (e.g., macrophages in the lamina propria). These HLA molecules form a groove in which short peptides (i.e., digested gliadins) can be specifically bound. Deamination by tTG may unmask neo-antigens, which bind more effectively to the HLA-DQ2 molecules. The bound peptides are presented to the T-cell receptor on the CD4 lymphocytes, and the lymphocytes are activated to proliferate and to produce pro-inflammatory cytokines. This promotes the inflammatory cascade and leads to an immune reaction, with resulting tissue damage.

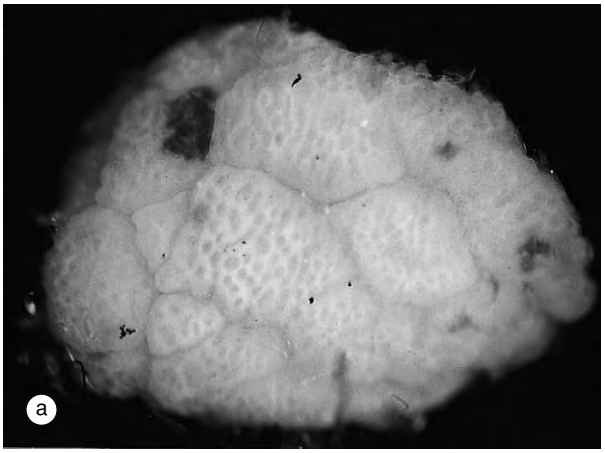
Mucosal pathology

The normal appearance of the small intestinal mucosa has finger-like villi (see Figure 3a), which, on microscopic sections, appear as tall villi covered with a layer of regular epithelial cells supported by a lamina propria (Figure 3b). In untreated celiac disease, the villi are lost, and the surface looks 'flat' (Figure 4a). Microscopically, there are no villi, the crypts between the villi are deeper, and the lamina propria has a vastly increased number of inflammatory cells (Figure 4b). Careful studies of serial biopsies have shown that these changes develop in a sequential fashion related to the amount of gluten in the diet. Hence, in celiac patients, one can see a range of abnormalities from the severe, as can be seen in Figure 4, to the normal, as can be seen in Figure 3 when the patient is well treated, or in potential patients before the mucosal abnormalities develop.

Clinical Features

Celiac disease can present at any age, in both adults and children. The clinical features are protean (see Table 1), although since it is a disease affecting the small intestine, symptoms of gastrointestinal disease predominate in classical descriptions of the disease. Patients may have diarrhoea, anorexia, nausea,

Figure 3 (see color plate 22) (a) Dissecting-microscopic appearance of normal mucosal biopsy showing finger-like villi; (b) light-microscopic appearance of normal mucosal biopsy.



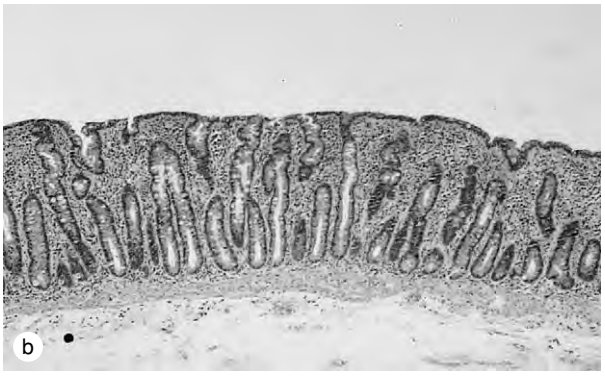


Figure 4 (see color plate 23) (a) Dissecting-microscopic appearance of biopsy from untreated celiac patient with total absence of villi and a 'flat'-looking mucosal surface; (b) light-microscopic appearance of untreated celiac mucosa with absence of villi, deep crypts, and an increase in inflammatory cells.

vomiting, abdominal distention and pain, flatulence, a sore tongue, or mouth ulcers. As well as these gastrointestinal symptoms, patients commonly have constitutional symptoms of lassitude and malaise, weakness, and weight loss. Children may fail to thrive as infants and be underdeveloped, not reaching their expected height. Apart from these general symptoms, there are symptoms that arise as a result of poor absorption of various vitamins and minerals due to the small intestinal mucosal abnormality, which causes 'malabsorption'. Such symptoms include features of anemia (malabsorption of iron and/or folic acid), a bleeding tendency (vitamin K) cramps, paraesthesiae, rickets, and proximal muscle weakness (vitamin D). Finally, there are rare symptoms that may result from the chronicity of the disease or malabsorption of undiscovered factors; these include disorders of the nervous system, reproductive system, and skin.

It is important to stress that many of these symptoms are described in untreated patients with celiac disease, and almost all are reversible with treatment. It is also of note that as physicians have become more aware of the disease, the diagnosis is being made more quickly, and patients nowadays do not present with such gross features. In fact, the majority of patients are diagnosed with mild symptoms and minor biochemical or hematological abnormalities. Recently, it has become apparent that previously unrecognized osteopenia and osteoporosis are present in a significant minority of celiac patients.

When untreated patients are examined, the findings on physical examination reflect the symptoms referred to above. For example, a patient with major symptoms may be thin and wasted, with muscle weakness, bruising of the skin, a sore tongue, and a distended abdomen. Patients diagnosed at an early stage may be apparently normal on physical examination.

Table 1 The presenting symptoms encountered in patients with celiac disease

General	Lassitude, malaise, weakness, weight loss
Gastrointestinal	Diarrhea (± features of steatorrhea)
	Anorexia
	Nausea and vomiting
	Flatulence and abdominal distention
	Abdominal pain
	Constipation
	Glossitis/aphthous ulcers
Metabolic	Features of anemia
	Bleeding tendency
	Edema
	Cramps/tetany
	Paresthesiae
	Nocturnal diuresis
Musculoskeletal	Increased risk of fracture
	Bone pain
	Rickets
	Proximal myopathy
Neuropsychiatric	Peripheral neuropathy
	Cerebrospinal degenerations
	Anxiety/depression
Reproductive	Menstrual irregularities
	Reduced fertility (male and female)
	Relapse associated with pregnancy
Skin	Variety of rashes
	Dermatitis herpetiformis

Associated Disorders

Many disorders have been described to occur in association with celiac disease. The explanation may be that the underlying predisposition to celiac disease enhances the possibility of other disorders occurring, particularly those that have an immunological etiology. The most common of the associated disorders are shown in Table 2.

Diagnostic Tests

Hematological investigations

The majority of untreated patients are anemic. Anemia is caused by iron or folic acid deficiency, or both, and is a result of the malabsorption of these factors. Vitamin B_{12} may be low but rarely causes the features of B_{12} deficiency. Unexplained anemia may therefore alert the physician to the possibility of celiac disease.

Biochemical investigations

Similarly, other nutritional factors are often low in the serum of untreated celiac patients, e.g., the fat-soluble vitamins A, E, D, and K, deficiency of the latter two being responsible for the features of osteomalacia and a bleeding tendency referred to above. Calcium and magnesium, as well as water-soluble vitamins such as Vitamin C, may be low, although scurvy is rare in celiac disease. Albumin is often low, owing to loss into the gastrointestinal tract from the

Osteoporosis
Epilepsy

blood, rather than malabsorption. This can lead to peripheral edema in the patient. Immunoglobulin A (IgA) deficiency may be found since this is 10 times more common in celiac disease than in the general population. None of these measurements is specific for celiac disease, and therefore, they are not used in diagnosis.

Tests of malabsorption

Apart from finding low levels of various nutrients in the serum, as outlined above, absorption can be assessed more formally. For example, the absorption of fat can be assessed by measuring the dietary intake and fecal output over a period of days. A more indirect method measures the serum levels and urinary excretion of D-xylose, a carbohydrate not normally found in the diet. Such tests can indicate malabsorption but are not specific for celiac disease and are rarely used routinely.

Serological screening tests

IgA and immunoglobulin G (IgG)-class antigliadin antibodies are present in the serum of many patients with celiac disease. Their measurement has been used particularly as a screening test. The sensitivity and specificity of these tests approach 90%. False positive results limit their use as a definitive diagnostic test.

IgA-class anti-endomysial antibodies are also found. As outlined above, tTg is the auto-antigen responsible for anti-endomysial antibody positivity. This antibody test has more than 95% sensitivity and specificity in celiac disease and thus is an ideal screening test. It cannot, however, be regarded as definitely diagnostic.

tTg itself has been used as the substrate in an enzyme-linked immunosorbent assay (ELISA) test, and tTg antibodies are now coming into use as another serological screening test for celiac disease, with a similar accuracy to anti-endomysial antibodies.

These serological tests are useful as screening tests in case-finding studies, particularly in at-risk groups such as patients with disorders associated with celiac disease, or first-degree relatives. They are also useful for follow-up of patients to monitor treatment and to indicate the timing of follow-up intestinal biopsies, since the tests usually become negative when treatment is being effective (see below).

Small-intestinal mucosal biopsies

Celiac disease is defined as that disease in which there is an abnormality of the small intestinal mucosa, made manifest by contact with the gluten fraction of wheat and related cereals. The cornerstone of diagnosis must therefore be the examination of a biopsy of this mucosa. Such a biopsy can be obtained using a biopsy tube or fiber-optic endoscope, which the patient swallows, usually under sedation. Careful examination of the biopsy will reveal the typical pathological features, although these can vary in severity. Since there are other, rarer causes of the same abnormality, the diagnosis is only definite when a second biopsy is obtained after a period (usually 6–12 months) on a gluten-free diet, and the abnormality has been shown to improve and return towards normal (**Figures 3** and **4**). If such an improvement in the pathological features is seen, the diagnosis of celiac disease can be firmly made. Such a scheme for diagnosis is suggested in the definition of the disease, since this indicates that the mucosal abnormality must be related to the presence of gluten in the diet.

Management

Treatment: a gluten-free diet

The cornerstone of treatment is a gluten-free diet, which should be taken for life. Patients should omit foods containing wheat, rye, and barley from their diet. In severely symptomatic untreated patients, initial treatment may also include replacement of nutritional deficiencies such as iron, folate, calcium, and Vitamins D and K. Rarely, severely ill patients may require parenteral nutrition.

Once treatment with a gluten-free diet is established, patients begin to respond quickly and usually note a remarkable improvement within weeks. Patients vary in their sensitivity to gluten in the diet. Some can eventually consume some gluten and appear to remain clinically well; others have to adhere strictly to their diet, even to the extent of avoiding Communion wafers. They may need to omit oats from their diet. If patients do consume gluten, they can produce some damage to the small intestinal mucosa, which may take months or years to produce clinical symptoms. There is evidence that the malignancy that can occur in celiac disease can be reduced by strict adherence to a gluten-free diet.

Osteopenia will improve with a gluten-free diet, but patients should have an adequate calcium intake and take regular exercise.

If patients are to adhere to a gluten-free diet, they need help from an experienced dietitian. Some patients have problems once dietary treatment has started. Initially, some put on weight, presumably as a result of improved absorption. These patients need advice about weight reduction. In this situation, diabetes may be unmasked.

Constipation sometimes becomes a problem, reflecting the fact that bran from most cereals is omitted from the diet. Defatted rice bran or soya bran has

been shown to help, and bulking agents such as ispaghula husk or methyl cellulose may also help. The dietitian can help with all these problems and advise about a diet based around fresh meat, vegetables, fish, and fruit, with the gradual introduction of other safe foods as the patient becomes more confident about the gluten-free diet.

Prognosis

The prognosis is good for celiac patients. Nearly all respond clinically and pathologically to treatment with a gluten-free diet, there being an improvement in symptoms and in the small intestinal mucosa. Lifelong treatment with the diet is recommended, as is follow-up in an out-patient clinic with the help of a dietitian. Younger patients, particularly teenagers, need sympathetic follow-up since they often find the restrictions of the diet quite onerous.

Some physicians recommend further intestinal biopsies (after the first two that are necessary for diagnosis) every few years. This provides an objective assessment of the patient's condition and helps to motivate patients to maintain a strict diet.

Occasionally, the mucosa does not respond to a gluten-free diet, and the physician must consider the other, much rarer, causes of an abnormal small intestinal mucosa (see Table 3). However, by far the most common cause of failure to respond to the gluten-free diet is inadequate dietary gluten exclusion. This may be conscious or inadvertent. Dietary compliance needs to be assessed by a well-informed dietitian. Rarely, other foods (e.g., milk, eggs and soya) need to be excluded as well as gluten, either temporarily or permanently. Other causes preventing a mucosal response to gluten exclusion may be pancreatic insufficiency, or contamination of the small intestine by bacterial overgrowth. Such causes should be sought and treated in this situation. Finally, nonresponse may be associated with serious complications of the disease, which, fortunately, occur only rarely. These are the development of ulcers and strictures in the small intestine and also malignancy, particularly small intestinal lymphoma. Such complications may be a cause not only of nonresponse but also of deterioration in a previously well patient who has been adequately treated for some time with a gluten-free diet. As already suggested, there is good evidence that the incidence of malignancy in celiac disease may be reduced in patients who maintain a strict gluten-free diet.

If no underlying cause is found for nonresponse to a gluten-free diet, and the diagnosis has been carefully considered, patients may be treated with oral steroids in order to induce a remission. This should only be done under careful supervision, and there are no long-term studies, but the side-effects of steroid therapy suggest that such a course of treatment has a limited role in celiac disease.

Table 3 Causes of an abnormal small-intestinal mucosa

Celiac disease (CD), including:
Non-responsive CD
Complications of CD (ulceration, malignancy)
Cow's milk protein intolerance
Soya protein intolerance
Immunodeficiency syndromes
Eosinophilic gastroenteropathy
Immunoproliferative small-intestinal disease (IPSID)
Protein-energy malnutrition
Intractable diarrhea of infancy
Gastroenteritis in children
Infections:
Parasites, e.g., giardiasis
Tuberculosis
Human immunodeficiency virus
Contaminated bowel syndrome
Whipple's disease
Tropical sprue
Arterial disease of small intestine
Drug and radiation damage

CELLS

P McGrath, University of Newcastle, Callaghan, Australia

Structure and Function of Human and Animal Cells

The cell is the fundamental functional unit of all living organisms. Cells perform all of the body's vital physiological functions. Cells are ultimately responsible for activities such as breathing, moving, combating infection, digesting food, thinking – in fact, all bodily functions. These activities require energy. It is inside cells that fuels are used to produce the energy needed to drive these activities. This article examines the structure inside the cell and the combined activities of cells that make all of this possible.

Structure and Organization of Human Animal Cells

Structure

Common to nearly all cells are three compartments, namely the cell membrane (also called the plasma membrane), the cytoplasm, and the nucleus (mature, human red blood cells have no nucleus). This basic structure is evident in a wide variety of cells even though they may differ dramatically in size and shape (**Figure 1**). The plasma membrane not only encloses the contents of the cell but performs many vital functions. The cytoplasm is that compartment between the nucleus and the cell membrane. It is composed of a soluble component (the cytosol) in which are immersed various microscopic components called organelles. Among the many important biochemical reactions that take place in the cytosol is glycolysis, an energy-releasing process involving the breakdown of glucose to pyruvic acid. (*See* **Glucose:** Function and Metabolism.)

The cellular organelles are a diverse group of structures that perform many different functions within the cell. The nucleus of the cell is a membrane-bound structure that contains within it the genetic material of the cell. It is here that the genes reside in the form of DNA (deoxyribonucleic acid) molecules grouped into structures called chromosomes.

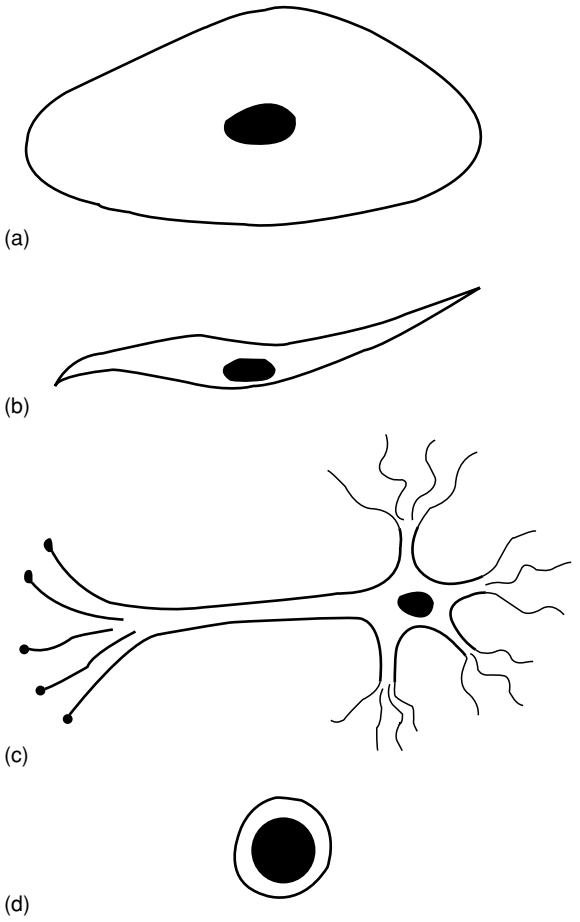

Figure 1 Different shapes of cells. The nucleus is darkly shaded; the plasma membrane is represented by the outline of the cell; the cytoplasm is represented by the clear space between the plasma membrane and the nucleus. Reproduced from Cells, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Organization

In the body, cells often function in combination with other cells of the same type and are held together with varying degrees of tenacity and with varying amounts of extracellular material between them. Clusters of cells of the same type are called tissues. Four different types of tissues are recognized:

1. Epithelial tissue, in which the cells are held very tightly together, and there is very little extracellular material between them. This tissue forms glands and the linings of the body cavities and surfaces.
2. Connective tissue, in which the cells are not bound closely to one another. There is much extracellular material in such tissue, and the cells may be held rigidly in place by this material, as in the case of bone, or they may be freely moving, as in blood.
3. Muscle tissue, in which the cells may be bound to each other, as in cardiac muscle and smooth muscle, or separate from each other but gathered into bundles by connective tissue, as in skeletal muscle. (*See* **Exercise**: Muscle.)
4. Nervous tissue, which is composed of neurons (nerve cells) that conduct electrical impulses from one neuron to another. These cells are not physically coupled but are held in place by specialized connective tissue cells.

The organs of the body are in turn composed of different types of tissues. For example, the heart is composed mainly of muscle tissue but also includes connective tissue, epithelial tissue, and some nervous tissue.

Cellular Components

There are numerous chemical activities occurring simultaneously inside the cell. Eukaryotic cells (cells that have membrane-bound compartments) are able to minimize interference of one chemical reaction with another by confining certain chemical activities to specific membrane-bound components of the cell. This design also facilitates cellular specialization. Prokaryotic cells (cells that lack membrane-bound compartments) such as bacteria are disadvantaged in this regard. These membrane-bound components and other specific structures inside the cell are called organelles. Although some of these (e.g., the nucleus) can be seen under the light microscope, it has been necessary to employ electron microscopy to clearly visualize most of them. Not all of the organelles are found in every cell, and the relative abundance of a particular type of organelle varies from cell to cell, depending on the activity of the cell. Figure 2 is a drawing of a generalized cell with various organelles represented.

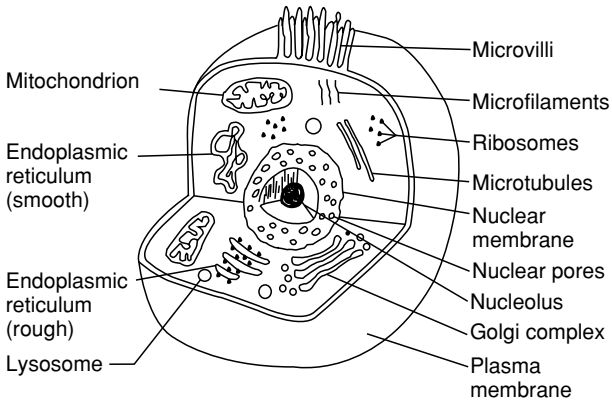

Figure 2 Drawing of a 'generalized' cell showing many of the organelles found in human and animal cells. Reproduced from Cells, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Nuclear Components

The nucleus contains the chromosomes. In humans, there are 46 chromosomes (23 pairs). The number in other animals varies from species to species. The chromosomes are very long, thin strands of DNA. They also contain proteins called histones. They are not easily seen under the light microscope until just prior to cell division, when they shorten and coil up, making them visible following appropriate staining. The nucleus also contains other structures called nucleoli. These are roughly spherical structures containing strands of RNA (ribonucleic acid) molecules, DNA, and proteins. The nucleoli are responsible for manufacturing rRNA (ribosomal RNA) of the ribosome. The nucleus is enclosed by a membrane that is perforated by holes (nuclear pores) that are large enough to allow large molecules, such as RNA, to pass through. There are several different types of RNA, and each type has a distinct role in the manufacture of proteins (protein synthesis). Protein synthesis takes place in the cytoplasm. (*See* **Nucleic Acids**: Physiology.)

Cytoplasmic Components

There are many organelles or structures within the cytoplasm that are involved with specific cell functions. These are listed below with a brief description of the structure and function of each.

Ribosomes Ribosomes are tiny granules (about 25 nm in diameter) composed of rRNA and protein. A ribosome consists of two subunits, one about twice the size of the other. Ribosomes play an integral role in protein synthesis.

Endoplasmic reticulum The endoplasmic reticulum is actually a series of double-membrane channels distributed throughout the cytoplasm. Ribosomes may be attached to the membranes and are then referred to as the rough endoplasmic reticulum. Without ribosomes attached, it is called smooth endoplasmic reticulum. This organelle serves several important functions in the cell, among which are involvement in the synthesis and storage of molecules, providing a system of channels for distribution and transport of materials throughout the cell, release of calcium ions into the cytosol that initiate contraction in muscle cells, and providing some structural support for the cell.

Golgi complex The Golgi complex consists of flattened membranous sacs stacked upon each other with expanded areas at their ends. The main function of this organelle is in the sorting and packaging of various molecules, particularly proteins, for distribution to various parts of the cell. The Golgi complex is particularly extensive in cells with high secretory activities.

Mitochondria Mitochondria are double membrane–bound organelles that may have a variety of shapes. The inner of the two membranes is thrown into folds or plates, called cristae. This arrangement provides a large surface area for chemical reactions to take place. Many enzymes involved in energy-releasing reactions are located on the cristae. These reactions are collectively known as cellular respiration and include the reactions of the tricarboxylic acid cycle and the electron transport chain. Since much of the cell's energy is produced through these reactions, mitochondria are sometimes called the 'powerhouse' of the cell. Cells that have a high energy expenditure, e.g., muscle, liver, and kidney tubule cells, have large numbers of mitochondria. The fact that mitochondria have some structural similarities with bacteria, have their own DNA, and are capable of reproducing themselves has led some scientists to speculate that mitochondria may have evolved from bacteria. According to this idea, the bacteria were incorporated into the cell during evolution.

Lysosomes Lysosomes are membrane-bound, spherical structures containing powerful digestive enzymes and are formed from vesicles budding off the Golgi complex. These enzymes are capable of digesting bacteria and other solid matter that may be engulfed by a cell. Leucocytes, specifically neutrophils and monocytes that engulf bacteria and other foreign particles (a process known as phagocytosis), contain large numbers of lysosomes.

Cytoskeleton Helping to maintain the shape of the cell and supporting various organelles within the cell is a scaffolding-like assembly of filaments and tubules called the cytoskeleton. The filaments and tubules are composed of proteins similar to those found in the contractile machinery of muscle. They are rod-shaped structures and vary in length and thickness. Microtubules average about 24 nm in diameter and may also provide channels for the transport of materials within the cell. Microfilaments are about 6 nm in diameter and may also play a special role in movement of cells, e.g., movement of phagocytes. Intermediate filaments, diameters ranging from 8 to 12 nm, have also been discovered inside cells.

Plasma Membrane

The plasma membrane (Figure 3) is composed mainly of lipid molecules. The lipid is arranged into two layers, the hydrophobic tail regions of the lipid molecules pointing to the inside of the bilipid layer, and the hydrophilic heads of the lipid pointing to the outside. Proteins and carbohydrates float in this lipid membrane. The plasma membrane facilitates contact and communication with other cells, mediates the entry and exit of materials into and out of the cell, and is the site of many important biochemical reactions.

The plasma membrane is selectively permeable: it will allow the transit of some substances, but not of others, and furthermore, some substances are allowed across the membrane more readily than others (differentially permeable). There are very specific 'channels' in the membrane that allow the passage of specific substances. These 'channels' are in fact proteins.

All of these properties of the plasma membrane contribute to the differences that are seen in the composition of the fluid inside the cell (intracellular fluid) compared with that outside (extracellular fluid). A very important difference to note in terms of ion concentrations is that of potassium and sodium ions. Intracellular fluid has a much higher concentration of potassium ions than the extracellular fluid. The reverse is true of sodium ions. It is extremely important to the function of all cells in the body that these concentration differences (or gradients) are maintained. At times, the concentration differences will be disturbed. The role of certain proteins found in the plasma membrane is to act as ion pumps to restore the original concentration gradients. Of particular importance is the so-called sodium/potassium pump. When the concentration gradient of sodium and potassium ions is decreased, these pumps expend energy to pump sodium ions out of the cell and at the same time pump potassium ions into the cell. The importance of this mechanism to normal cell function

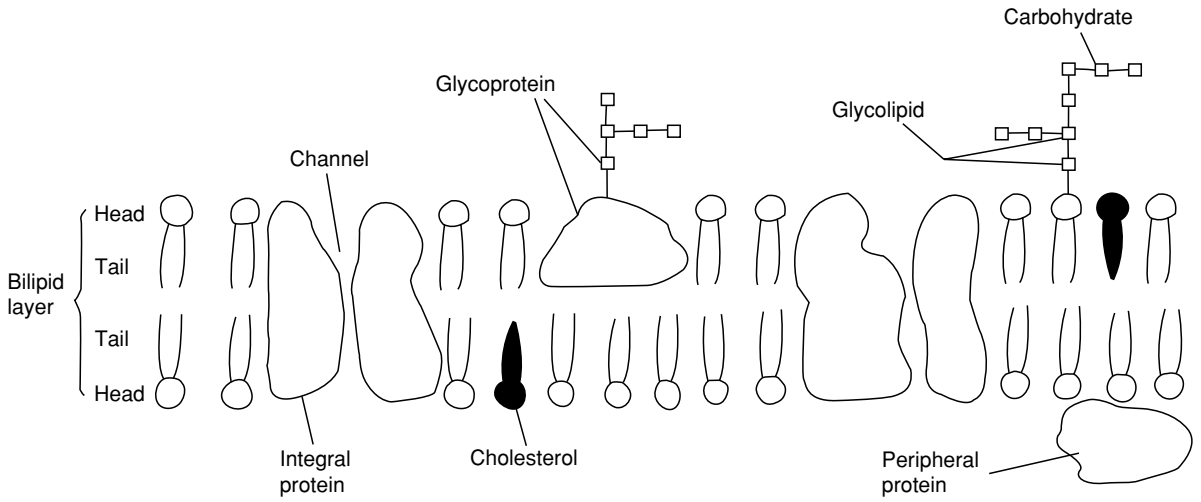

Figure 3 Arrangement of molecules in the plasma membrane. Reproduced from Cells, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

is markedly demonstrated by the nerve cell (the neuron). In order to conduct electrical impulses, sodium ions must enter the cell and potassium ions move out. The sodium/potassium pump works vigorously in the neuron to try to maintain the original gradients. Indeed, the neuron expends 80% of its energy on this pump.

These properties of the plasma membrane contribute not only to chemical differences between the inside and the outside of the cell but also to an electrical difference. A small voltage (of the order of tens of millivolts) can be measured across the plasma membrane. The inside of the cell is electrically negative with respect to the outside. This electrical difference, or membrane potential as it is called, is particularly important when considering the functions of neurons and muscle cells, both of which can conduct electrical impulses.

The cell membrane in some cells is thrown into many small folds that project from the bulk of the cell and are called microvilli. These greatly increase the surface area of the cell and provide a much larger surface for the absorption of materials across the cell membrane. Such specializations are seen in cells lining the small intestine and in tubule cells in the kidneys. In some cells, similar types of projections of the plasma membrane are seen with underlying contractile machinery of the cytoplasm. These form cilia. The cilia move in unison, providing a sweeping motion that moves material over the surface of the cell. Cells bearing cilia line many of the larger respiratory passages, and the mucus produced here traps dust and foreign particles and is swept up to the throat region by this mucociliary escalator.

Requirement of Cells

For cells to carry out their normal functions properly, certain conditions need to apply. For human and most animal cells, environmental conditions such as temperature, pH, and ionic strength of solutions bathing the cell need to be kept fairly constant. Many of the body's mechanisms are geared towards this homeostatic control. Cells also need to be supplied with nutrients. They need the basic building blocks to manufacture complex organic molecules, such as amino acids for the synthesis of proteins. They need fuels to supply the substrates for generating energy, and oxygen to oxidize the fuels and allow energy to be released. The fuel requirements of some cells are very exacting. While several types of fuel molecules may be available to cells, neurons need to use glucose almost exclusively. If the glucose cannot be supplied to these cells, the brain will stop functioning properly. Such is the importance of glucose to neurons that many body mechanisms operate to maintain adequate levels of glucose in the blood at all times. Other fuels used by cells are fatty acids and, to a limited extent, proteins. When glucose is in short supply, many cells turn to a greater utilization of fatty acids to derive energy. (*See* **Fatty Acids**: Metabolism; **Protein**: Synthesis and Turnover.)

Importance of Specialized Cells

While all cells are able to (and need to) carry out certain basic functions, such as protein synthesis and energy metabolism, many cells develop special intracellular machinery to carry out specific functions. The

complex behavior of animals is possible only because of this cellular specialization. All somatic cells (body cells, as opposed to the gametes, or sex cells) contain the full complement of genetic information. With cellular specialization, however, the capacity to develop in a variety of ways (sometimes called cellular plasticity) is sacrificed. In some cases, cells become so constrained and devoted to their special task in the body that they even lose the ability to divide and provide more of the same type. Such is the case with neurons; these cells make up the main controlling and information-transfer system of the body. Neurons detect various environmental stimuli and pass this information on to centers in the nervous system that interpret this information. Having determined the appropriate response, the nervous system sends messages to the muscles and glands of the body to effect this response. All this is achieved by transmitting electrical signals around the body. When neurons are injured and die, they are not replaced. Muscle cells, too, are incapable of dividing. These cells devote their energies to building contractile machinery within them. When these cells are activated, they contract, bringing about movement of various organs, limbs, etc., of the body. Adipocytes, or fat cells, are specialized to store large amounts of fat to such an extent that the nucleus of the cell becomes confined to a small part of the cell squashed against the cell membrane. It is thought that mature adipocytes do not divide. Erythrocytes are packed with the protein, hemoglobin, which is responsible for transporting the blood gases, particularly oxygen. It enhances the oxygen-carrying capacity of the blood about 60-fold. Human erythrocytes are peculiar cells in that they have no nucleus, losing their nucleus during maturation. They have a limited lifespan of about 120 days. Under normal circumstances human erythrocytes are produced in the body at a rate of 2×10^6 per second. Hepatocytes are specialized cells of the liver. These cells contain large amounts of specific enzymes involved in the metabolism and detoxification of many different molecules in the body. These are just some of the many specialized cells in the body; there are numerous others, including osteocytes (bone cells), endocrine cells (hormone-producing cells), and chondrocytes (cartilage cells). CELLULOSE

M T Holtzapple, Texas A & M University, TX, USA

Background

Cellulose is the world's most abundant biological material. An estimated 10^{11} tonnes are produced annually, a daily production of about 45 kg per person. Because of its rigidity, cellulose provides structure to plants. It is almost always associated with other components as a composite material termed 'lignocellulose.' (*See* **Hemicelluloses**; **Lignin**.)

The most-studied celluloses are from cotton, ramie, *Valonia* algae and *Acetobacter xylinum* bacteria.

Structure

Polymer Structure

Cellulose is a polymer of the monomer glucose (see **Figure 1a**). The free-aldehyde glucose conformation is very unstable, so it cyclizes into a six-membered pyranose ring. (In aqueous solutions at 25 °C, only about 0.02% of the glucose is in the free aldehyde form.) The C1 hydroxyl of the cyclic ring can be in the equatorial β

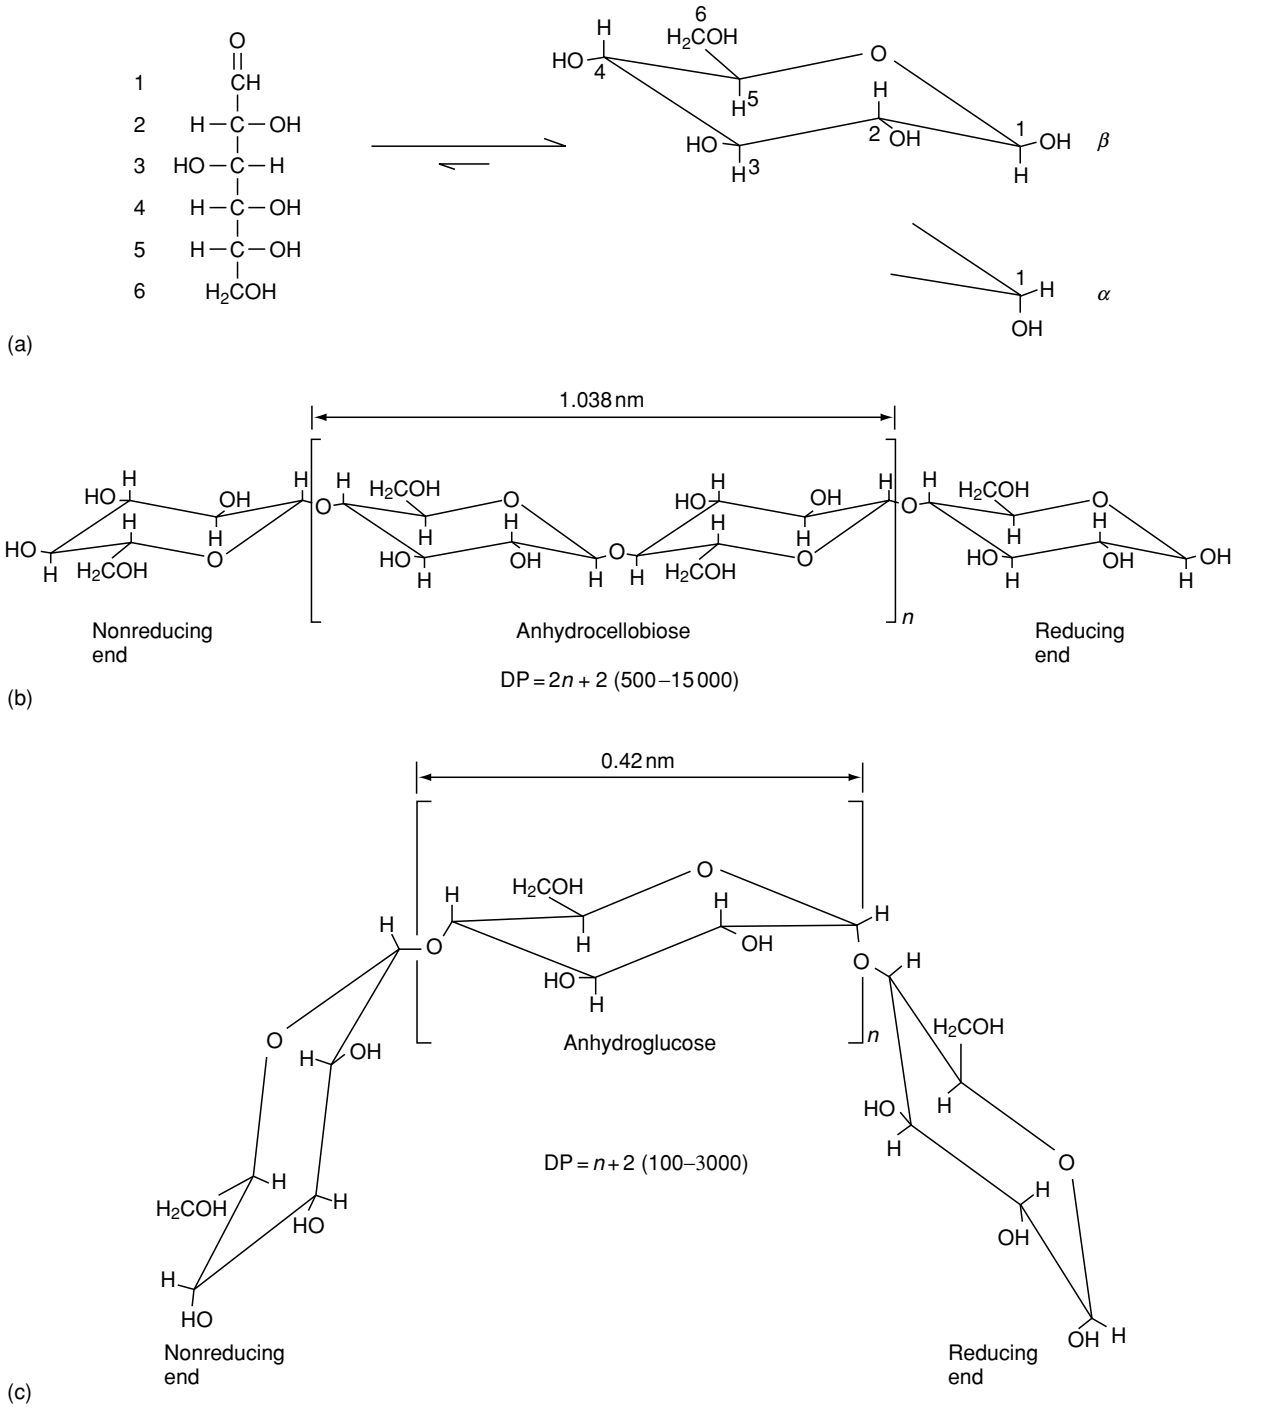

Figure 1 (a) Glucose, (b) cellulose, and (c) amylose starch. Reproduced from Cellulose, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

position or the axial α position. The β position is favored thermodynamically and accounts for 62% of the glucose with the remaining 38% in the α position.

Cellulose is a linear, unbranched polymer of anhydroglucose joined with ether linkages between C1 and C4 (see Figure 1b). Cellulose is polymerized from β-glucose, whereas starch (see Figure 1c) is polymerized from α-glucose. In the rightward anhydroglucose unit, C1 retains its hydroxyl group, so it may potentially form free-aldehyde glucose, which has reducing power. Hence, this terminus is called the 'reducing end.'

β-Linked cellulose has dramatically different properties than α-linked starch. Starch is helical,

water-soluble, and easily hydrolyzed by enzymes, whereas cellulose is planar, water-insoluble, and difficult to hydrolyze. Whereas starch is a widely utilized animal food, cellulose is used only by a select few, ruminants being the most prominent example. In starch, the repeating unit is anhydroglucose. For cellulose, anhydrocellobiose is the repeating unit because adjacent anhydroglucoses are rotated 180° with respect to their neighbors. This rotation causes cellulose to be highly symmetrical, because each side of the chain has an equal number of hydroxyl groups, whereas starch is unsymmetrical. The cellulose degree of polymerization (DP) ranges from 500 to 15 000. When fully stretched, a single cellulose molecule could extend as long as 7 μm. Amylose starch has a lower DP (100–3000) and could extend as long as 1 μm if fully stretched. Cellulose is completely unbranched, whereas amylopectin starch has branches at C6. (*See* **Starch**: Structure, Properties, and Determination.)

Crystalline Structure

The cellulose hydrogen atoms are all in the axial position, whereas the hydroxyl groups are all equatorial. These equatorial hydroxyl groups can hydrogen-bond with their nearest neighbors, allowing cellulose to crystallize. The monoclinic crystalline unit cell for cellulose I (native cellulose) is shown in Figure 2. The hydrogen bonds run in the *a* direction and are medium-strength (15 kcal mol^{-1}). In the *c* direction, the structure is held by weak van der Waals forces (8 kcal mol^{-1}). Covalent bonds run in the *b* direction and give cellulose its strength (50 kcal mol^{-1}). A continuous cellulose strand is about four to

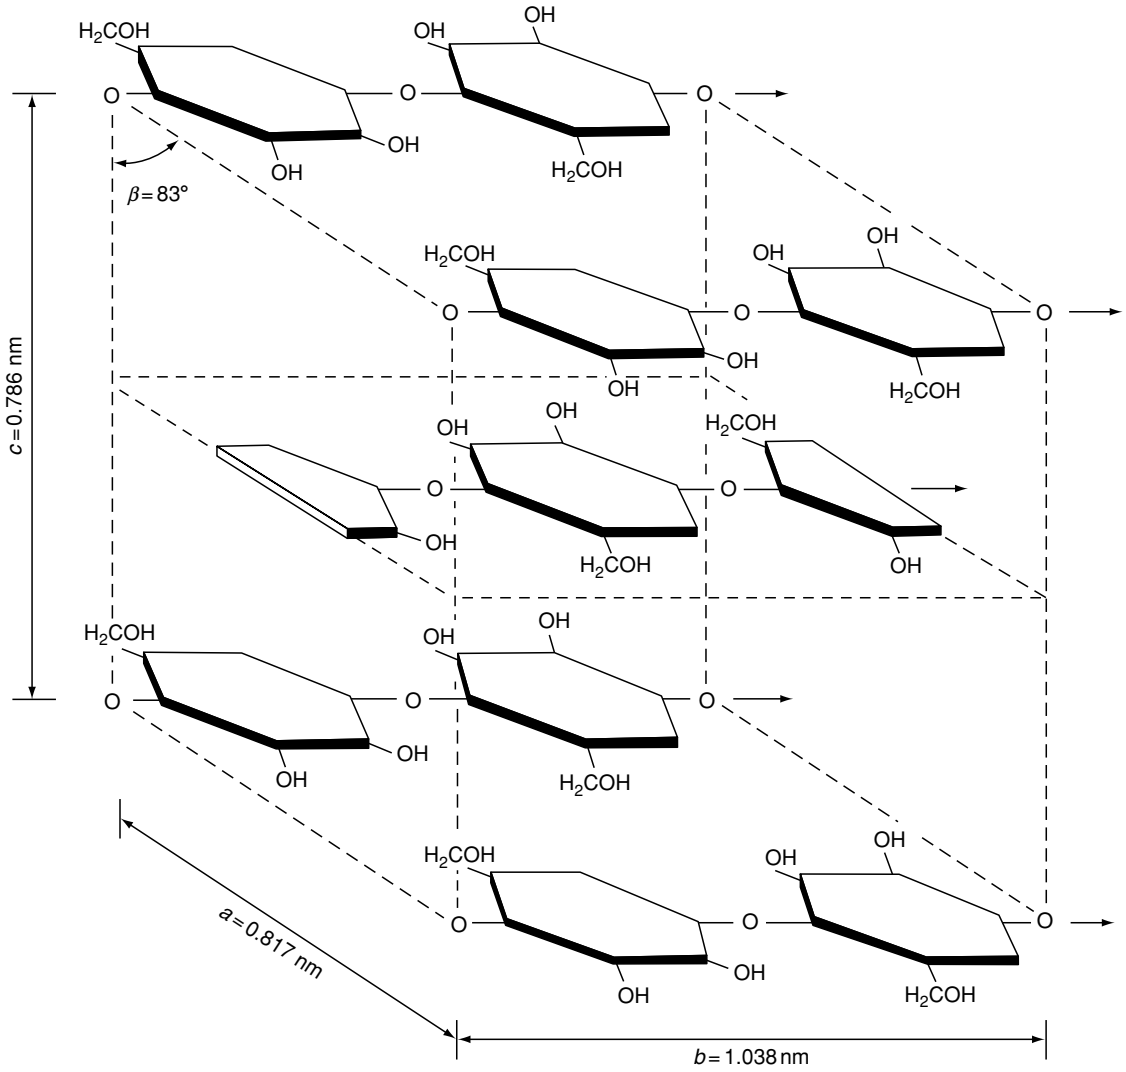

Figure 2 Parallel cellulose I unit cell. Reproduced from Cellulose, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

five times stronger than steel with the same cross-section. Cellulose I is parallel; that is, all the cellulose molecules run in the same direction from nonreducing to reducing ends (see Figure 3a).

Native cellulose (cellulose I) can be converted to other crystalline forms. Cellulose II is formed by (1) treating cellulose with sodium hydroxide (mercerization), (2) precipitating from solutions of alkali/salt (e.g., cuprammonium hydroxide), or (3) removing the added functional groups from cellulose derivatives (i.e., regenerated cellulose). Cellophane and rayon are both forms of cellulose II. Table 1 shows that the unit cell dimensions are slightly expanded in the *c* direction and compressed in the *a* direction. Of course, the *b* direction is essentially the same, because it is the covalent bond. Cellulose II is the most thermodynamically stable form of cellulose because it can always be produced from cellulose I, but not vice versa. The stability may result from hydrogen bonds extending in the *c* direction, which normally has only van der Waals bonds. There is general agreement that cellulose II is antiparallel (see Figure 3b) with three to four anhydroglucose moieties required to make the bend. Precipitation of cellulose II from solution appears to favor the antiparallel conformation, as occurs with many synthetic polymers.

Cellulose III is formed by soaking cellulose in cold (about $-80\,^{\circ}C$) liquid anhydrous ammonia, which is subsequently removed by evaporation. Cellulose I is transformed into cellulose III_1 and cellulose II is transformed into cellulose III_2. When rehydrated, cellulose III reverts back to its original form.

Cellulose IV is formed by soaking cellulose in hot (about $200\,^{\circ}C$) glycerol, with subsequent removal by washing with 2-propanol and water. Cellulose I is transformed to cellulose IV_1, and cellulose II is transformed to cellulose IV_2.

Native cellulose (Figure 3a) forms crystalline regions (40% bacteria, 60% cotton, 70% *Valonia*) interspersed with amorphous regions. The amorphous regions are more porous than the crystalline regions, allowing water or dyes to penetrate and increasing the reactivity to acid or enzymatic hydrolysis. When purified cellulose fibers are subjected to dilute acid hydrolysis, the amorphous regions selectively hydrolyze, leaving the more resistant crystalline regions, which have a 'levelling-off DP' of 100–300 in the case of cotton.

Table 1 Unit cell dimensions of cellulose I and II

Cellulose	*a (nm)*	*b (nm)*	*c (nm)*	β *(°)*
I	0.817	1.038	0.786	83.0
II	0.801	1.036	0.904	62.9

From Blackwell J, Kurz D, Su M-Y and Lee DM (1987) X-ray studies of the structure of cellulose complexes. In: Atalla RH (ed.) *The Structures of Cellulose. ACS Symposium Series*, No. 340, pp. 199–213. Washington, DC: American Chemical Society.

Cellular Structure

Young plant cells have only the primary wall to resist osmotic pressure. This wall is composed principally of hemicellulose and pectin with small amounts of cellulose and protein and is sufficiently flexible to accommodate cell growth. When cell growth ceases, the secondary wall is formed in three layers (S_1, S_2, and S_3) with S_2 the thickest (see Figure 4). (*See* **Protein**: Chemistry.)

All cell wall layers are composed of 7–30-nm-diameter microfibrils, which are visible using an electron microscope. In the primary cell wall, the fibrils are randomly oriented. In the S_1 layer, the microfibrils are oriented helically, with each successive layer alternating between right-handed and left-handed helices. In the S_2 layer, which provides much of the plant strength, the microfibrils are arranged in steep right-handed helices nearly oriented along the cell axis. The S_3 layer is another shallow helix. All higher plants (softwoods, hardwoods, herbaceous) are thought to have cell structures similar to that shown in Figure 4.

The plant cell diameters range from 15 to 80 μm, depending on the species and time of year. Spring cell

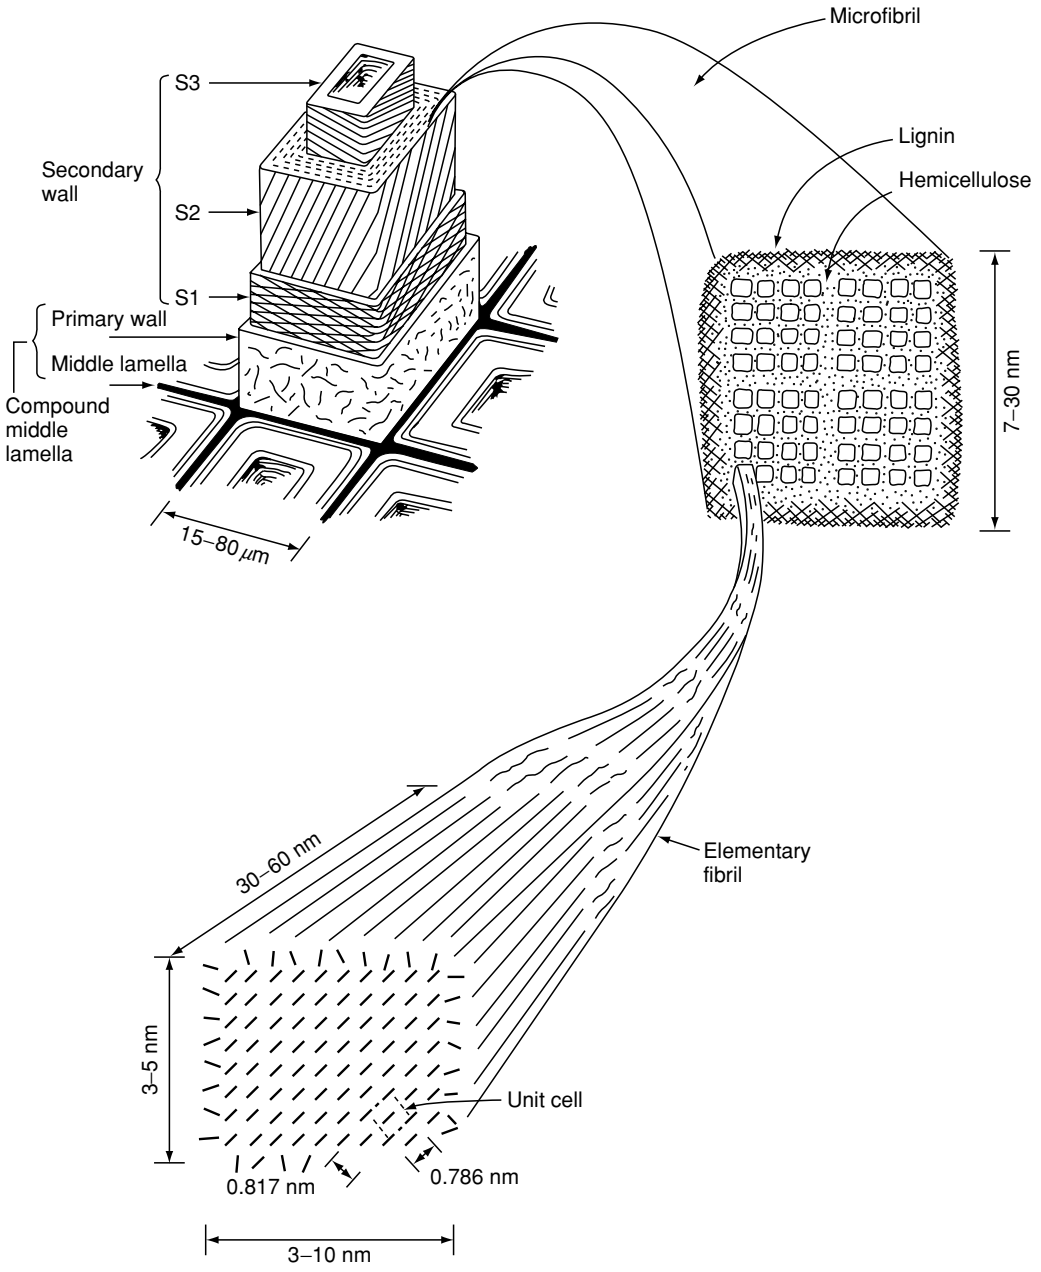

Figure 4 Schematic of plant cell, microfibril, and elementary fibril. Reproduced from Cellulose, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

diameters are larger than summer diameters, giving rise to the familiar growth rings in trees. The wall thickness is typically about 2–5 μm, with thicker walls formed in the summer. Softwood cells are about 3–4 mm long, which makes them particularly useful for paper pulp, whereas hardwood cells tend to be shorter (0.7–2 mm long). Cotton cells suitable for textiles are about 25 mm long.

Microfibrils are composed of elementary fibrils of pure cellulose embedded in a matrix of hemicellulose. The fringes of the elementary fibrils are paracrystalline and intermingle with tightly adsorbed hemicellulose. (An exception to this is cotton in which the fringes contain only cellulose.) In Fengel's model of the microfibril, the elementary fibrils are clustered into four 4×4 arrays. The lignification process occurs late in cell life, so lignin is located primarily on the microfibril exterior, where it covalently bonds to the hemicellulose. Lignification is initiated in the middle lamella where lignin constitutes about 70% of

the wall. The wall interior is less lignified, with only about 15% lignin. The hemicellulose content is fairly constant (20–30%), with cellulose the remaining 10–50% of the wall. The cells in fruit pulp are composed mainly of primary walls containing approximately 34% pectin, 24% hemicellulose, 23% cellulose, and 19% protein.

Properties

Physical

Table 2 shows the physical properties of cellulose and cellulosic materials. The listed heat of combustion is the 'higher heat' (i.e., the combustion water is 25 °C liquid). Cellulose is stable up to 300 °C.

The DP for various types of cellulose is shown in Table 3. For cotton, the DP may be as high as 15 000. Cellulose is insoluble in water because of the strong hydrogen bonding in its crystal lattice. However, it is soluble in a number of solvents, including concentrated acids (e.g., 85% phosphoric, 72% sulfuric, and 40% hydrochloric acids) and inorganic salt solutions (e.g., cuprammonium hydroxide, cadoxen (i.e., cadmium ions and ethylenediamine)). The viscosity of cellulose dissolved in salts is often used for molecular weight determinations.

Chemical

Cellulose may be hydrolyzed to glucose by acids or enzymes. Acid hydrolysis produces a number of degradation products, such as 5-hydroxymethylfurfural, formic acid, levulinic acid, formaldehyde, furfural, and resins. Enzymatic glucose production requires a cellulase system containing *endo*-cellulase (to produce nonreducing ends from the chain interior), *exo*-cellulase (to produce cellobiose generally from the nonreducing end), and cellobiase (to hydrolyze cellobiose to glucose). Up to about 10% of cellulose is enzymatically digested by microbes in the human large intestine, so it is not completely noncaloric.

Cellulose is fairly stable to base, provided that oxygen is excluded. The reaction terminates after approximately 50 anhydroglucose units are 'peeled off' from the cellulose reducing end; D-glucoisosaccharinate is the soluble product. Under severe conditions (e.g., 1 M sodium hydroxide, 170 °C), alkaline hydrolysis readily occurs.

Cellulose is more stable to oxidants than lignin, a property exploited in pulp bleaching and analytical methods, which selectively oxidize lignin. However, oxidants (e.g., chromic acid, permanganate, and hypochlorite) can damage cellulose by cleaving the chain or by inserting carbonyl functional groups.

The three cellulose hydroxyl groups are very reactive, allowing ready formation of the cellulose derivatives described later.

Specialty Celluloses

Microcrystalline cellulose (Avicel, FMC Corporation) is prepared by acid hydrolysis of cellulose using 2 M hydrochloric acid at 105 °C for 15 min. The highly reactive amorphous regions selectively hydrolyze, releasing the crystallites, which are subsequently

Table 3 Cellulose polymer length

Material	*Degree of polymerization*	*Molecular weight*
Native cellulose	3500–10 000	600 000–1 500 000
Chemical cottons	500–3000	80 000–500 000

mechanically dispersed. Aqueous suspensions of microcrystalline cellulose have constant viscosities over a wide temperature range, are heat-stable, and have good mouth-feel properties. Avicel is used to extend starches, stabilize foams, and control ice crystal formation. Avicel has found widespread acceptance in the food industry for meringue, whipped toppings, confections, and ice cream, and is also used as a binder in pharmaceutical tablets and in cosmetics.

Bacterial cellulose (Cellulon, Weyerhaeuser Co.) is produced by selected strains of *Acetobacter xylinum*, which maintain their ability to produce cellulose in agitated submerged fermentors. The cellulose fibers are about 0.1 μm in diameter, which is substantially smaller than softwood pulp fibres (about 30 μm diameter). Cellulon is a potential noncaloric food thickener or texturizer.

Modified Celluloses

Alkali cellulose is prepared by soaking cellulose in concentrated sodium hydroxide (> 14%) in the 'mercerization' process invented by John Mercer in 1844. The sodium ions are incorporated into the cellulose structure according to the following reaction (eqn (1)):

$$\underset{\text{Alkali cellulose}}{R_{cell}ONa} + H_2O. \qquad (1)$$

The cellulose structure swells, allowing easy penetration by dyes or reagents for the manufacture of cellulose derivatives.

Cellulose xanthate is formed by reacting alkali cellulose with carbon disulfide (eqn (2)):

$$\underset{\text{Cellulose xanthate}}{R_{cell}O\overset{\overset{S}{\|}}{C}SNa}. \qquad (2)$$

Regenerated cellulose is made by dissolving cellulose xanthate in 4–7% sodium hydroxide and contacting with aqueous sulfuric acid. These steps convert the cellulose xanthate back into cellulose, which may be spun into viscose rayon or cast into films. The fibers are used in textiles (artificial silk), tyre cords, and V belts. The films are used in packaging (Cellophane) or sausage casings. Weiner casings (70% regenerated cellulose, 12% glycerol, and 18% water) are peeled away after the meat emulsion is cooked. Hemp paper casings (23% paper, 46% regenerated cellulose, 21% glycerol, and 10% water) are used in bologna, salami, pepperoni, summer sausage, and liverwurst.

Cellulose hydroxyl moieties are highly reactive, allowing a variety of esters and ethers to be manufactured. Because each anhydroglucose has three hydroxyl groups, the maximum degree of substitution (DS) is three. Purified wood pulp or cotton linters (short fibers) are the industrial sources of 'chemical cellulose.'

Cellulose Ethers

Sodium carboxymethyl cellulose (CMC) is formed by reacting sodium chloroacetate with alkali cellulose (eqn (3)):

$$R_{cell}ONa + ClCH_2\overset{\overset{O}{\|}}{C}ONa \rightarrow \underset{\text{CMC}}{R_{cell}OCH_2\overset{\overset{O}{\|}}{C}ONa} + NaCl. \qquad (3)$$

Commercially available CMC has a DS range of 0.38–1.4, with 0.65–0.85 more common. The negatively charged carboxyl group makes CMC soluble in both hot and cold water. The solution viscosity decreases as the temperature increases. CMC is 'generally recognized as safe' and is used as a thickener in many foods such as cheese, frozen desserts, and salad dressings. It is not metabolized, so it is used in low-calorie foods.

Methyl cellulose is formed by reacting alkali cellulose with methyl chloride (eqn (4)):

$$R_{cell}ONa + ClCH_3 \rightarrow \underset{\text{Methyl cellulose}}{R_{cell}OCH_3} + NaCl. \qquad (4)$$

Methyl cellulose (DS 1.8) solutions form a firm gel when heated to 50–55 °C and return to solution when cooled. Methyl cellulose is added to salad dressings, jams and preserves, soda water, and meat patties as a binder.

Ethyl cellulose is produced by reacting alkali cellulose with ethyl chloride. In commercial products, the DS ranges from 2.0 to 2.6. It is water-insoluble and may be incorporated into inks used for marking foods and in vitamin tablet binders.

2-Hydroxypropyl methyl cellulose is formed by reacting alkali cellulose with mixtures of methyl chloride and 2-hydroxypropyl chloride. It forms gels like methyl cellulose, but has a higher gelation temperature. It may be used as an emulsifier, film former, stabilizer, or thickener in foods such as salad dressings, sherbet, pie fillings, fried foods, whipped toppings, breading batters, and baked goods.

2-Hydroxyethyl cellulose (HEC) is produced by reacting cellulose with ethylene oxide using a sodium hydroxide catalyst at 30–35 °C for about 4 h (eqn (5)):

$$R_{cell}OH + \underset{\diagup\ \diagdown}{CH_2{-}CH_2}\overset{\overset{O}{}}{} \rightarrow \underset{\text{HEC}}{R_{cell}OCH_2{-}CH_2OH}. \qquad (5)$$

Because the side-chain also has a hydroxyl group, ethylene oxide can continue to react and form a

side-chain with several units. HEC is soluble in both hot and cold water. The solution viscosity decreases as the temperature increases. HEC is not permitted as a direct food additive, but it may be used in food-packaging adhesives and coatings.

2-Hydroxypropyl cellulose is produced using propylene oxide, rather than the ethylene oxide used for HEC. It has a thermal gel point, like methyl cellulose, and is used in food coatings and glazings.

Cellulose Esters

Cellulose acetate is the most important cellulose ester. The cellulose is first 'activated' in aqueous acetic acid to ensure uniform acetylation. It is then dehydrated and reacted with acetic anhydride using a catalyst (e.g., sulfuric acid) in a solvent (e.g., anhydrous acetic acid) (eqn (6)).

$$R_{cell}OH + CH_3\overset{\overset{O}{\|}}{C}O\overset{\overset{O}{\|}}{C}CH_3 \rightarrow R_{cell}O\overset{\overset{O}{\|}}{C}CH_3 + CH_3\overset{\overset{O}{\|}}{C}OH. \quad (6)$$

Cellulose acetate

The resulting cellulose triacetate (DS ~ 3) product may be subsequently acid-hydrolyzed to lower the DS. Cellulose triacetate is water-insoluble and hydrophobic, whereas cellulose monoacetate is water-soluble. Cellulose acetate is used in fibers, plastics, photographic films, lacquers and reverse osmosis or dialysis membranes.

Other esters (e.g., cellulose formate, cellulose propionate, cellulose butyrate) may be formed, but they do not have the widespread commercial applications of cellulose acetate. Also, mixed esters (e.g., cellulose acetate propionate, cellulose acetate butyrate, cellulose acetate phthalate) may be produced.

Cellulose nitrate is made by reacting cellulose with nitric acid/sulfuric acid for 20–30 min. The acids are then removed by washing with water. The water must be removed with great care because dry cellulose nitrate is extremely explosive. It is often shipped wetted with water or alcohol. Highly nitrated (DS 2.4–2.6) forms are used as explosives (gun cotton). Less nitrated forms (DS 2.1–2.3) find applications in plastics, films, and inks.

Composition of Cellulosic Materials

Table 4 shows the composition of many cellulosic materials. The cellulose content in vegetables ranges from 1 to 21%; fruits range from 0.6 to 4.2%; seeds range from about 2 to 12%; agricultural residues range from 31 to 59%; wood ranges from 41 to 53%; flax and hemp have about 70% cellulose; and cotton (the purest natural cellulose) has about 95% cellulose. The free sugars shown in Table 4 are the sum of glucose, fructose, and sucrose. The 'crude fiber' is reported as the sum of cellulose and lignin in the case of the seeds. The indigestible portion of some fruits, called 'dietary fiber,' is reported as the sum of cellulose, lignin and hemicellulose. (*See* **Dietary Fiber**: Properties and Sources; **Fructose**; **Sucrose**: Properties and Determination.)

Cellulose Isolation and Analysis

Gravimetric Methods

Van Soest procedure The raw plant material is contacted with dilute acid and washed with solvents to remove starch, pectin, hemicellulose, fats, oils, protein, free sugars, and soluble minerals. The residue, called 'acid detergent fiber,' contains cellulose, lignin, and insoluble minerals (mainly silica).

Air-dried plant material (1 g), ground to particles of less than 1 mm, is placed in a beaker with 100 ml of acid-detergent solution (49 g l^{-1} H_2SO_4, 20 g l^{-1} cetyl trimethylammonium bromide). Decahydronaphthalene (2 ml) is added, and the contents are slowly boiled for 1 h while the reflux condenser maintains a constant liquid volume in the beaker. Then, the beaker contents are filtered through a tared Gooch crucible, washed with boiling water, acetone, and hexane (optional). The residual acid detergent fiber (ADF) is dried at 100 °C and weighed.

The cellulose content in ADF can be measured by two methods: (1) cellulose removal with acid or (2) lignin removal by oxidation.

Method 1 The ADF prepared above is placed in a tared Gooch crucible containing an equal volume of asbestos as a filter aid. The crucible contents are contacted with room-temperature 72% sulfuric acid for 3 h and then thoroughly washed with hot water. The sample is dried at 100 °C for 8 h and weighed. The weight loss corresponds to the cellulose content.

Method 2 The ADF (0.5–1.0 g) is placed in a tared Gooch crucible. A saturated potassium permanganate solution (50 g l^{-1} $KMnO_4$, 0.05 g l^{-1} $AgSO_4$) and buffer solution (6 g l^{-1} $Fe(NO_3)_3 \cdot 9H_2O$, 0.15 g l^{-1} $AgNO_3$, 500 ml l^{-1} glacial acetic acid, 5 g l^{-1} potassium acetate, 400 ml l^{-1} *t*-butyl alcohol) are mixed in a 2:1 ratio (by volume). This mixture (25 ml) is added to the crucible for 90 min at room temperature to oxidize the lignin in the ADF. The spent reagent is then removed by vacuum filtration. The crucible contents are soaked for 5 min in demineralizing solution

(50 g l^{-1} oxalic acid dihydrate, 700 ml l^{-1} 95% ethanol, 50 ml l^{-1} 12 M HCl), which is then removed by filtration. The filter contents are washed with ethanol and acetone. The crucible is dried at 100 °C for 8 h. The crucible contains cellulose and insoluble ash. The crucible may be placed in a 500 °C oven for 3 h; the weight loss corresponds to the cellulose content.

A simpler approach to removing the lignin from the ADF has been described by C.S. Edwards. The ADF is soaked in activated trigol (i.e. 6.3 ml of 32% hydrochloric acid dissolved in 1 l of pure triethylene glycol) in a 121 °C autoclave for 60 min. The sample is then washed with 95% ethanol and acetone. The residue contains cellulose and insoluble ash.

Other gravimetric methods Cross and Bevan cellulose is the lignocellulose portion remaining after removing hemicellulose with two boilings in NaOH and removing lignin with chlorine and bleach.

Monoethanolamine cellulose is the lignocellulose portion remaining after monoethanolamine treatment, chlorination, and bleaching.

Norman–Jenkins cellulose is the lignocellulose portion remaining after sodium sulfite boiling, bleaching, and acid treatment.

α-Cellulose is the cellulose fraction insoluble in room temperature 17.5% sodium hydroxide wash water (DP > 90).

β-Cellulose is the cellulose fraction in the alkaline wash water that precipitates upon neutralization (15 < DP < 90).

γ-Cellulose is the cellulose fraction soluble in the neutralized alkaline wash water (DP < 15).

Holocellulose is the residue that remains after lignocellulose is defatted with hot, azeotropic benzene/ethanol and delignified with hot chlorous acid ($HClO_2$). Holocellulose contains the cellulose and hemicellulose of the original plant material.

Colorimetric Method

Hexosan assays may be used to measure cellulose, the dominant hexose polymer in starch-free plant materials (other than softwoods). Holtzapple describes an assay in which the hexosan sample is placed in a sealed test tube with 1530 g l^{-1} sulfuric acid and 20 g l^{-1} chromotropic acid, and boiled for 1 h. Hexose C6 degrades to form formaldehyde, which reacts with the chromotropic acid to form a purple compound that is measured spectrophotometrically. There is minor interference by pentosans that may be reduced by lowering the chromotropic acid concentration to 1 g l^{-1} and shortening the reaction time to 20 min. There is also some interference with lignin, so the most accurate results are obtained with holocellulose, rather than the original lignocellulose. (*See* **Spectroscopy**: Visible Spectroscopy and Colorimetry.)

Chromatographic Method

The cellulose content can be estimated from the glucose composition, because cellulose is the main source of glucose in plant materials (assuming free sugars and starch are not present). (*See* **Chromatography**: Principles.)

CEREALS

Contents

Contribution to the Diet

C MacEvilly, Food Safety Promotion Board, Cork, Ireland

Background

Cereals are grown for their highly nutritious edible seeds which are often referred to as grains. They remain the staple food in most diets, even given their decline in importance as a country becomes more affluent. Current nutritional advice highlights the benefits of cereal foods as a source of complex carbohydrates and as foods that should replace some of the energy currently provided by fat in the diet.

Cereals supply a variety of nutrients and other food components like phytochemicals. Although cereals make an important contribution to the diet, they cannot alone support life because they are lacking in vitamins A, D, and C and iodine, for example. Also cereal proteins are deficient in certain amino acids, notably lysine. Refined cereal products and unrefined cereals have certain advantages and disadvantages. With refinement, some nutrients and fiber are removed, but the body is better able to make use of certain nutrients. The role of fortified cereals as a means of increasing levels of specific vitamins has been recognized. This chapter will discuss the role that cereal plays in both in the developed and developing world and the implications that the type of cereal has on the diet.

Cereals as a Global Food Source

The world has over 50 000 edible plants and just three of them – rice, maize, and wheat – supply 60% of the world's food energy intake. Table 1 presents an overview of world cereal production for 1999.

Rice feeds almost half of humanity. Per capita rice consumption has generally remained stable, or risen slightly since the 1960s. However, it has declined in recent years in many of the wealthier rice-consuming countries, such as Japan, the Republic of Korea, and Thailand, because rising incomes have enabled people to eat a more varied diet.

Although there are over 10 000 species in the Gramineae (cereal) family, few have been widely introduced into cultivation over the past 2000 years. Cereals constitute the 'starchy staples' in the human

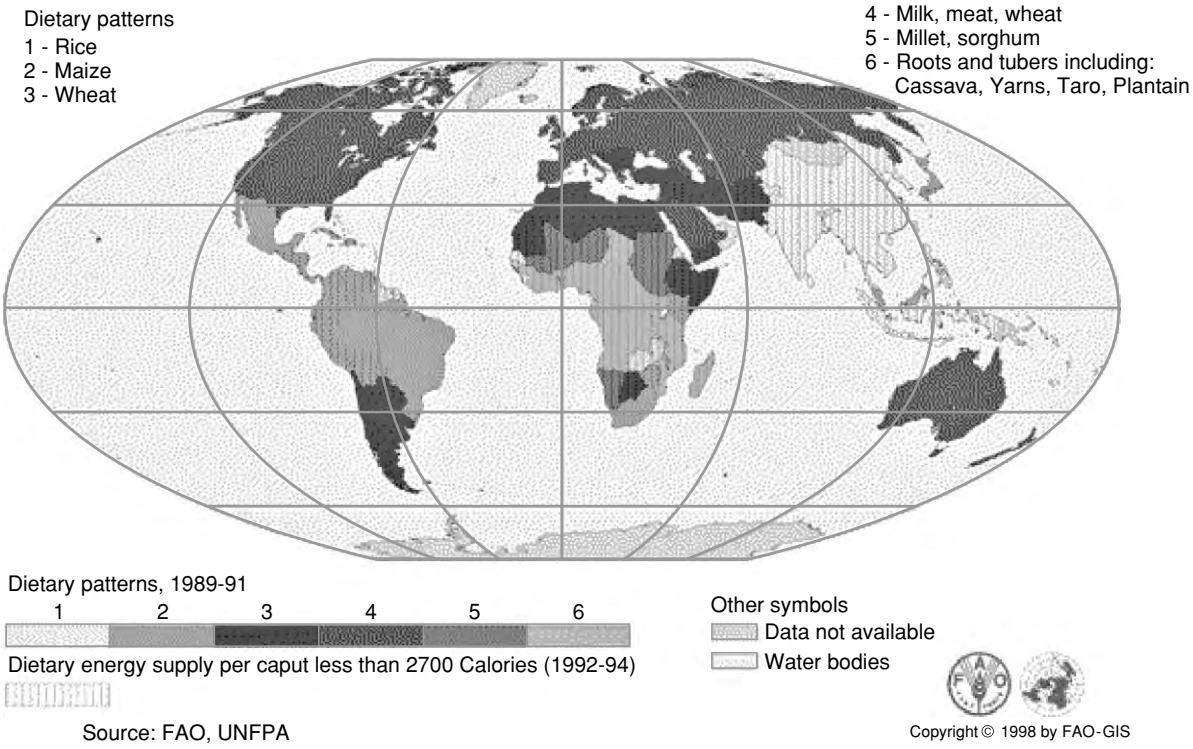

Figure 1 Dietary patterns.

diet and as such are the primary source of dietary carbohydrate throughout the world. The contribution of these crops to the diet varies from continent to continent, and even among countries within continents. The consumption of starchy staples throughout the world has changed over the last three decades. Figure 1 shows the world picture of dietary patterns, with countries highlighted according to the starchy staple providing the highest proportion of energy. As can be seen, large parts of the world depend on wheat and rice, with more selected areas dependent on maize, sorghum, and millet.

The distribution of the production, and to a great extent the importance, of the different cereals is in part due to the climatic constraints on the growth of the different species. Wheat production is limited to temperate zones; rye has a wider northern range and can be grown in the Arctic circle, and rice can be grown in standing water in tropical and subtropical climates and less commonly on dry uplands. Barley and oats have a similar range to wheat, although oats thrive on poorer soils. Maize and millets are major crops in the tropics and subtropics; much is also grown in temperate climates where it is also important as animal feed.

As a food, cereals have many benefits and there are several reasons why cereals have become the staple food of mankind. They do not deteriorate easily if kept dry, they are easily stored and transported, they are cheap to produce, and they have a high nutrient density. (*See* **Wheat**: The Crop; **Rice**; **Barley**; **Oats**; **Maize**; **Rye**; **Millets**.)

The Nutritional Composition

In westernized countries approximately 50% of the food energy available is derived from cereals and in the developing world it provides two-thirds of energy and protein. Cereals provide 1400–1600 kJ per 100 g whole cereal. The nutritional composition of the main types of cereal grains and some products is shown in Table 2. Cereal grains contain, on average, 75% carbohydrate, 10–15% protein, 2% fat, and 10–15% water.

Cereals as an Energy and Protein Source

Cereals are classified as 'carbohydrate foods' and although this is compositionally correct, such a classification does not take into consideration the importance of the proteins present in cereals. They constitute a rich source of both nonstarch polysaccharides (dietary fiber) and starch, which together comprise 70–77% of the grain. Protein accounts for 6–15% and the limiting amino acid is lysine, although maize is additionally low in tryptophan. Protein quality is highest in the outer layers of the endosperm (a starchy

core with a protein matrix) and in the germ (the grain's embryonic root and shoot) because that is where the lysine-rich albumins and globulins (salt-soluble proteins) are located and as a result are more affected by processing.

Gluten is the major protein in wheat and rye. The special properties of this protein make it particularly important in breadmaking; isolated gluten is also used as a method for assessing suitability of cereal proteins in gluten intolerance (celiac disease), which will be discussed later. Oryzenin is the major protein in rice. Table 3 shows the role of cereals in the supply of dietary energy and protein in various countries.

The data are presented as food supply statistics (sometimes referred to as food balance sheets or food disappearance statistics). This type of population level data is relatively easy to collect compared with information based on the dietary records of individuals, which requires meticulous attention to detail. However, there are also important drawbacks: data exist only for basic commodities, they cannot show patterns in different sectors of the population, and they substantially overestimate the amounts of food actually eaten as they do not take into account wastage, for example.

Lipids

In themselves, cereals are low-fat foods, their endogenous fats making only a very minor contribution to total intake and being overshadowed by the amount and composition of the fats used in the cooking and preparation of the cereal foods commonly consumed. Although lipids comprise only about 1.5–7% of cereal grains, some lipid components appear to have special properties that contribute to added health benefits. Most (approximately 80%) of the lipid in cereals is present as triglycerides (fatty acids esterified in a glycerol backbone). Linoleic (C18:2) acid is the major unsaturated fatty acid in cereals except brown rice, which contains more oleic acid (C18:1). Palmitic acid (C16:0) is the major saturated fatty acid in cereals and, except in barley, is present in lower concentrations than linoleic and oleic acids. However, cereals also contain a broad class of unsaponifiable lipid material (about 2–10% of the total) that includes tocols, carotenoids, sterols, and high-molecular-weight alcohol. Tocols and carotenoids have antioxidant properties and sterols have been extensively studied for their role in the reduction of blood cholesterol levels.

Mineral Elements and Vitamins

Whole grains are a good source of thiamin and provide significant amounts of many other B vitamins. However, factors affecting the bioavailability of these vitamins from grain products are still under investigation. The germ is rich in vitamin E; however, vitamin E is not stable to light, heat, and air, so almost all processing methods will adversely affect its concentration. As grains mature, the niacin they contain becomes progressively more bound to indigestible components of the seeds. Cereal grains are deficient in vitamin A, C, and D. The ascorbic acid that is customarily added to white flour to improve its baking properties has no nutritional significance. In addition, low levels of vitamins D and K are found in the lipids of most cereals. Recent results from the National Food Survey in the UK suggest that fortified cereals provide almost 32% of the average intake of folic acid.

Cereals consist of about 1.5–2.5% of minerals. This includes minerals such as potassium, phosphorus, magnesium, iron, and zinc. Selenium enters the food chain via plants, which obtain it from soil. Wide international variations in intakes have been observed, in part because of wide differences in selenium soil content and differences in selenium bioavailability from different foods. In 1997, 12.2% of total selenium intakes in the UK were obtained from breads and 10% from cereals. A wide variability exists in the levels of selenium present in grain and cereal products. Among the cereal grains, rice contains the highest levels (10–13 μg $100\,g^{-1}$) while recent analysis of levels in bread (6–9 μg $100\,g^{-1}$) suggest that levels have decreased over the last 20 years and are significantly lower than selenium levels in US bread samples (32–44 μg $100\,g^{-1}$). This is because wheat is a good source of selenium in North America, as the wheat is grown in soils rich in selenium. In Europe, although bread and cereals make a significant contribution to selenium intake, due to frequency of consumption (22% of total selenium in the UK), European wheat is not a good source of selenium because of the low bioavailability of selenium from European soils. Wheat is not a good natural source of iron in Europe but many cereals are fortified with iron.

The differences in selenium intake between the USA and Europe are reflected in serum and whole-blood selenium concentrations. Although serum values of $100\,\mu g\,l^{-1}$ are the suggested level required for optimal enzyme activity, current levels in the EU appear to be below this level with mean serum selenium levels in seven European countries calculated as $79\,\mu g\,l^{-1}$.

Mineral composition of grains can be affected by genetic factors, as well as environmental ones, such as soil composition, crop fertilization practices, and climatic conditions. The values reported for any grain can vary over a wide range. Refer to individual vitamins and minerals.

Complex Carbohydrates and Dietary Fiber

Cereals are composed of up to 85% (dwb; dry weight basis) of complex carbohydrates. These are defined by their sugar residues and the linkages between them. Cereals also contain cellulose, β-glucans and dietary fiber. Fiber is the sum of the plant polysaccharides plus lignin that is not digested by enzymes in the intestine. Cereals are a unique source of dietary fiber and in countries where whole-grain products, such as wholemeal bread, are popular, cereal products may contribute more than 40% of the average dietary fiber intake (data taken from the UK National Diet and Nutrition Survey).

Fiber has two forms – soluble and insoluble. Although to some extent their function overlaps, they do have different effects on the body and so it is important to eat a variety of high-fiber foods to get both types.

Both types of fiber – soluble and insoluble – can help with weight control. In the stomach, they absorb water and some delay the emptying of the stomach, instigating a feeling of fullness.

Insoluble fibers found in wheat bran, whole-grain breads, and cereals hold water in the colon, thus increasing bulk which stimulates the muscles of the digestive tract so that they retain their health and tone. The toned muscles can move waste product more easily through the colon for excretion. This helps prevent constipation, hemorrhoids, and diverticulosis.

Soluble fibers found in oat bran are credited with reducing the risk of heart and artery disease – atherosclerosis – by lowering the level of cholesterol in the blood. It appears that the products of bacterial digestion of soluble fiber in the colon are absorbed into the body and may inhibit the body's production of cholesterol as well as enhancing the clearance of cholesterol from the blood. Blood cholesterol levels may also decrease if food sources of soluble fiber are used as part of a low-fat, low-cholesterol diet. Certain fibers also bind to cholesterol compounds in the gut and carry them out of the body so that the whole-body content of cholesterol is lowered.

In January 1997, the US Food and Drug Administration (FDA) allowed the first food-specific health claim for a whole-grain cereal, oats. That regulation was amended in February 1998 to include soluble fiber from psyllium seed husks. In the USA, foods containing whole oats or psyllium seed husks as ingredients can now make a health claim linking consumption with a reduced risk of coronary heart disease when they are part of a diet low in saturated fat and cholesterol. The FDA acknowledged that soluble fiber from sources other than oats and psyllium probably also affects blood lipids and reduces the risk of heart disease, but that the sources would need to be considered on a case-by-case basis.

Soluble fibers also improve the body's handling of glucose, even in people with diabetes, perhaps by slowing down the digestion or absorption rate of carbohydrates. Blood glucose levels therefore stay moderate, helping to prevent symptoms of diabetes such as hypoglycemia.

Phytochemicals

During the last decade, data from experimental and epidemiological studies have been accumulated showing that grains contain a large variety of potentially health-promoting substances called 'plant chemicals' or 'phytochemicals.' The explosion of new information related to the exciting approach of

phytochemicals is certainly only a prelude to their inclusion in our daily diet.

Because foods are complex mixtures of various phytochemicals, studying them is a difficult task. A major group of phytochemicals in foods are the phenolic compounds, which include plant flavonoids like catechins. In cereals, flavonoids are present in small quantities only. Barley contains measurable amounts of catechins and some di- and trimer procyanidins. Work mainly in experimental animals and *in vitro* has suggested that flavonoids possess numerous biochemical and pharmacological qualities, including anticarcinogenic, antiinflammatory, and antiallergic properties.

Other phytochemicals found in cereals include phytoestrogens such as lignans, isoflavones, and coumestans. The precursors of these compounds are found in fiber-rich unrefined grain products and cereals. Lignans are potent antioxidants and exert anticancer effects in experimental studies. Lignan contents vary greatly between cereals. The amounts in cereals are low compared to that in linseed and high compared to those in vegetables. However, since the consumption of cereals is considerable, high amounts of lignans and other bioactive phytochemicals are provided in the daily diet.

Further nutritive antioxidants present in cereals are small amounts of carotenoids, tocopherols, and tocotrienols, especially in the lipid-rich germ. Grains are a unique group in that they contain more tocotrienols than other food products. Tocotrienols possess vitamin E activity.

Fortification

No one cereal can provide adequate amounts of all nutrients to meet the nutritional requirements of a child or adult. Because of the stable nature of cereal products, their contributions to the diet of the populations of the world's nations are frequently perceived by governments as an important means of insuring adequate nutritive standards, not only through their natural composition but also through the addition of nutrients from other sources. Various terms are applied to such additions, including restoration, fortification, and enrichment.

The nutritional quality of sorghum and millets, especially the former, is poor. Therefore attempts have been made to fortify these cereals to make nutritionally superior and acceptable products. Cost, availability of ingredients, and marketability must be taken into consideration if fortification is to be implemented successfully on a sustained basis. In the UK, bread and breakfast cereals are currently voluntarily fortified with folic acid and this in part may explain the importance of cereal sources to the folic acid intake of populations. Other vitamins and minerals that are currently fortified include thiamin, iron, riboflavin, niacin, and calcium. In the USA, mandatory fortification was enforced on 1 January 1998.

Wheat flour and other common cereal products are very suitable vehicles for fortification because there are virtually no major population subgroups which would not be able to use cereal grains and because cereals are consumed by all socioeconomic subgroups. In the UK and Canada, the addition of nutrients to flour, where addition is required, is made at the flour mill. In the USA enrichment is permitted either at the mill or at the bakery. In most developing countries refined cereal products are not vitamin-enriched, but 10 nations are currently adding iron to wheat or maize flours and many other countries are considering doing so.

For any supplementation initative to succeed it is necessary that the added nutrient is physiologically available; it does not create an imbalance of essential nutrients, e.g., by competing for absorption with another nutrient; it does not adversely affect the acceptability of the product; and there is reasonable assurance that intakes will not become excessive. (*See* **Food Fortification**.)

Effects of Processing and Cooking

Changes resulting from cooking are complex: in only a few cases, such as boiled rice and pasta, are cereal products cooked substantially on their own. More frequently they are included in a recipe, so that differences between the raw cereal ingredient and the final product reflect not only changes due to cooking but also to dilution and interaction with other ingredients.

In general, fiber, protein, vitamin, and mineral concentrations in cereals decrease from the outer layer to the inner part of the seed, with the decline being steeper in some cereals than others. For that reason, and because of the removal of the aleurone (outer) fraction of the cereal, milling results in large losses of many nutrients. When wheat is milled to white flour, the niacin content drops to about 20% of its original level, thiamin to 27%, and riboflavin to 19%. After milling of wheat to white flour and then bleaching, almost 98% of vitamin E is lost.

Many cereal-based foods are subjected to heat processing in baking, frying, and extrusion cooking, and these have effects on more labile vitamins. In processes involving boiling the losses are of the order of 40% for most of the B-group vitamins; losses of folates are slightly higher at around 50%. In baking the losses are generally lower except for the folates. The losses during the more vigorous conditions of

extrusion cooking are still of the same order, primarily because the cooking times are generally shorter than with more conventional cooking procedures.

Probably the most significant enzymic changes that occur during processing are those involved in the conversion of starch into sugars and the subsequent fermentation mediated by microorganisms, converting sugars to alcohol or lactic acid. Another important example is the reduction in phytate content during fermentation and the proving of bread doughs.

Negative Attributes

In spite of the fact that cereals are among the safest and most important foodstuffs, there are some antinutritious aspects of their composition (some of these affect only a small proportion of consumers). There are hazards associated with their storage and handling also.

The negative nutritional attributes of phytate derive from the fact that it forms insoluble complexes with minerals such as calcium and iron, possibly reducing their bioavailability and leading to failure of their absorption in the gut of animals and humans and thus to mineral deficiencies. The reduced bioavailability of minerals depends upon several factors, including the nutritional status of the consumer, concentration of minerals and phytate in the foodstuff (and the diet as a whole), ability of endogeneous carriers in the intestinal mucosa to absorb essential minerals bound to phytate and other dietary substances, and the digestion or hydrolysis of phytate by phytase during processing and in the intestine.

Tannins are phenolic compounds of the flavonoid group and are also considered to have negative attributes. It is alleged that they reduce protein digestibility through phenol–protein complexing. There is also no doubt that they and their derivatives can adversely affect flavor and color, thus reducing palatability. Tannins in seeds are concentrated in their outer layers, therefore milling to remove the bran and testa is an effective means of reducing the tannin content. However, because nutrient content and protein quality tend to decrease from the outer to the inner regions of cereal grains, tannin reduction by milling is achieved at the expense of nutrient loss.

Adverse effects on health can arise from the consumption of cereals contaminated by toxic substances. At least 25% of the world's crops may be affected by mycotoxins, even small quantities of which can potentially harm humans. These are toxic secondary metabolites produced by fungi. Aflatoxins, often found in wheat and rice, as well as corn, are some of the most potent naturally occurring carcinogens. (*See* **Mycotoxins**: Classifications.)

Celiac disease is a permanent condition, requiring a lifelong strict gluten-free diet, and is the main form of wheat intolerance. Older literature suggests that celiac disease has a prevalence of around one case in 1500 people in the UK. However, the advent of sensitive serological screening tests has allowed studies which suggest that the true prevalence may be higher, both in the UK (although a population-based study has yet to be conducted) and abroad. Studies in Italy, the USA, and The Netherlands have suggested that one in 300 of the general population in these countries may be gluten-sensitive. Classically, celiac disease inflicts many "negative attributes" on its sufferers, including diarrhea, weight loss, and anemia. However, these may be absent and many individuals may suffer from mild or nonspecific symptoms, which may be ignored for many years. Delayed diagnosis can result in osteoporosis, infertility, or even cancer. The condition is triggered by the ingestion of wheat, rye, and barley. Oats are probably safe for consumption by gluten-sensitive individuals. (*See* **Food Intolerance**: Types; Food Allergies.)

In conclusion, cereals are important sources of many nutrients, but they are limited in others. In the past few years, a steady stream of exciting new developments in cereal nutrition has flowed from scientists to consumers. Sometimes data seem contradictory but gradually the physiological benefits of cereal-rich diets are becoming clearer and indications are good that more health benefits of grains and grain components will soon be revealed.

Bulk Storage of Grain

D Richard-Molard, INRA, Nantes, France

Introduction

At the beginning of the 21st century, world production of cereal grains is about 1600 million tonnes. This represents by far the greatest production of staple food material, the second most important source, i.e., tuber-producing crops, being far behind, with a total production of less than 100 million tonnes of edible dry matter. A simple arithmetic calculation shows that cereal crops will be able to provide more than the 1.3 kg of bread or rice per day for all of the 6000 million world population, provided that postharvest losses are minimized.

Whatever the political problems and ethnic questions, two essential facts must be taken into account: cereals (mainly wheat and maize) are produced in excess in only a limited number of countries, and only during limited periods in the year. Good and safe storage would allow consumption to be delayed and grain to be exported anywhere throughout the year and is, therefore, of primary economic, political, and social importance.

Existing Losses of Cereal Crops

It is difficult, if not impossible, to calculate accurately the postharvest losses resulting from poor storage conditions and inadequate practices. However, in 1976 it was estimated that losses of grain could represent a commercial value up to US$4000 million.

Food and Agriculture Organization (FAO) reports generally indicate that percentage losses remain at rather low levels in industrialized countries, probably never more than 1 or 2%, whereas they can reach very high levels, maybe 50% or even more, in countries where climatic conditions are unfavorable and modern storage equipment is lacking. It is important, however, to realize that, in developed countries, low percentage levels of loss involve enormous quantities of grain, leading to problems of significant economical importance. By contrast, high levels of losses in developing areas apply in most cases to only limited quantities of stored cereals, raising questions of vital importance only for the populations concerned.

It must also be emphasized that losses in grain quality can occur without significant losses of dry matter, e.g., decreases of nutritional value, losses of vitamins or essential fatty acids, appearance of toxicity, off-flavors or discolorations due to microbiological activity and insect pest infestation. The assessment of such hidden losses remains impossible at the present time.

In every situation it is of primary importance to have the best understanding of local environmental, economic, climatic, and ethnic conditions, and appreciation of possible causes of grain deterioration during storage, in order to minimize losses.

Some basic questions still lack satisfactory technical or economic answers but, usually, it can be said that postharvest losses are mostly due to lack of adequate training of the people who handle and store the grain. Most significant losses generally result from insect infestation or from the growth of microorganisms. To a lesser extent, biochemical changes in the grain itself can also be important.

The causes and extent of grain losses may differ widely from one place to another. They depend on many parameters but three major environmental factors determine the extent of damage in a given situation: the water content of the grain, the mean temperature of the bulk, and the duration of storage. Of these factors, water is by far the most important and also the most interesting because it can be managed; whereas it is very difficult to control temperature in practice. (*See* **Storage Stability**: Mechanisms of Degradation; Parameters Affecting Storage Stability.)

Main Biological Causes of Losses

Unless cereal grains are sufficiently dry at harvest, they must be considered as perishable biological products that will be damaged by microorganisms or insects, depending on the environmental conditions. Surprisingly, the major role played by microorganisms, and particularly by molds, has only been recognized recently, but it is now understood that artificial drying of moist grains after harvest is essential for the avoidance of mold growth during storage, rather than for the prevention of development of insects or biochemical changes in the kernel itself. (*See* **Spoilage**: Molds in Spoilage.)

Respiration of the grain itself is a secondary phenomenon in most situations, when germination is not taking place. Respiration of the germ seems to remain more or less constant and at a very low level, compatible with seed conservation, whatever the hydration or the gaseous environmental conditions.

To initiate germination of the grain, very large moisture contents, higher than 70–80% (wet basis), i.e., sufficient for the full hydration of the grain, are necessary. When much moisture migration occurs in metallic bins, intense condensation is produced, generally on the roof of silos, and grain sprouting at the top of farm silos or in railway wagons frequently occurs. (*See* **Water Activity**: Effect on Food Stability.)

Role of Microorganisms in Grains

The microorganisms which make up the microflora of cereal grain and their products are now well known in regard to their ecological requirements and the damages they are able to produce during storage.

As soon as the relative humidity in equilibrium with the grain is sufficient for the growth of microorganisms (with freely available oxygen), the greater the humidity and temperature, the more intense and rapid the activity of microorganisms (Table 1). Fortunately, there exists an absolute hydration limit below which microbial activity cannot take place. Expressed in terms of relative humidity of the air in equilibrium with the stored grain, this absolute limit is about 65% for all cereal species of interest for humans. It corresponds to a moisture content of about 13% (wet basis) for wheat at 25 °C. Below this limit, nothing of importance can occur in the kernel for many years, with the exception of possible weak evolution of the lipids, as explained below. Above this hydration limit, which is in fact very low, some mold species belonging to the genera *Aspergillus, Eurotium* (Figure 1) and *Monascus*, among others, can develop. With the extraordinary physiological ability to grow in extremely dry conditions, these molds invariably do develop unless additional barriers such as cooling, antifungal agents, or modified atmospheres are utilized. Such molds contaminate cereal grains all over the world, but it must be emphasized that the growth of these so-called xerotolerant or xerophilic species is very slow, and usually not accompanied by mycotoxin formation or significant deterioration of nutritional value. For their growth, molds utilize lipids and carbohydrates from the grain (as do humans) and produce carbon dioxide, water, and heat in exchange, following the simplified scheme shown in eqn (1).

$$\text{Grain components} + \text{oxygen from air} \quad \text{I} \quad \text{CO}_2 + \text{H}_2\text{O} + \text{energy} + \text{heat} \qquad (1)$$

The main consequence is a local increase in relative humidity and temperature and it is generally accepted, but not easily demonstrated, that this progressively allows the growth of molds with greater water requirements, such as *Penicillium* spp., other *Aspergillus* spp., or even *Fusarium* spp. These kinds of molds are able to destroy the grains and to produce extremely dangerous mycotoxins, such as the hepatotoxic aflatoxin B_1 or the immunosuppressive T_2 toxin. (*See* **Mycotoxins**: Occurrence and Determination.)

In practice, chiefly for economic reasons, grains are most often stored at moisture contents around 15–16% (wet basis); this allows storage without visible molding for some months, as shown in Table 1,

Table 1 Microorganisms able to grow and approximate safe storage periods for various moisture contents of wheat

Moisture (% wet basis)	*ERH (%)*	*Microorganisms*	*Safe storage period*
12	50	None	Indefinite
14	65	*Aspergillus glaucus*	Years
15	68	*A. candidus, Penicillium* spp.	Years
16	75	*A. ochraceus*, most penicillia	Year
17	77	Most storage fungi	Months
18	80	Some yeasts, some lactic bacteria	Month
20	85	Most yeasts, most fungi (*Fusarium* spp.)	Week
30	95	Most fermentative bacteria	Days

ERH, Equilibrium relative humidity. Data mainly from the cited literature.

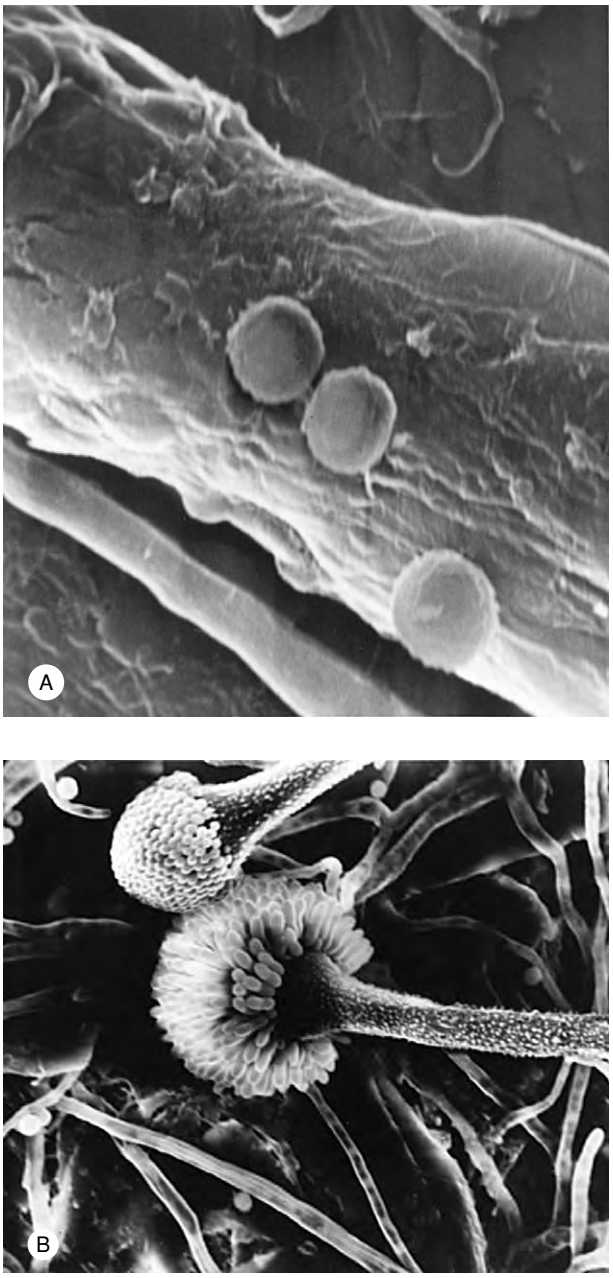

Figure 1 Scanning electron micrographs of *Eurotium chevalieri*, a xerophilic species common on stored grains: (A) × 1400, round conidia on the surface of the kernel; (B) × 280, conidial heads, responsible for vegetative multiplication and dissemination). Courtesy of INRA, LMTC, Nantes.

but also allows xerophilic species to develop slowly. At such hydration levels, a slight increase in water content, due for example to water vapor migration or to insect respiration in a limited pocket, can be sufficient to cause a significant acceleration in microbiological activity, leading to the formation of 'hot spots' in the bulk.

In hot spots, molds grow actively, producing further heat and water, leading to moisture content which is eventually sufficient to permit the growth of yeasts and bacteria. Grain dust and small particles accumulate at the center of the pile of grain in bulk silos, because grain tends to separate into heavier and lighter components when poured into a bin. Such accumulations of dust and broken kernels greatly increase the risk of hot spot formation by molds and insects, because they reduce the circulation of dry or cool air through the grain and promote the accumulation of heat and moisture. In such situations, it becomes urgent to cool and dry the grain by forced ventilation in order to avoid further problems throughout the bulk of the silo. (*See* **Spoilage**: Bacterial Spoilage; Yeasts in Spoilage.)

Role of Insects in Stored Grains

Among animal pests (i.e., mites, insects, rodents, and birds), insects cause by far the most damage to stored cereal. They are also the most feared because, even if they do not produce clearly toxic substances or strong off-flavors as do molds, their presence depreciates the value of grain even in cases of light infestations. Insects secrete some metabolic residues like quinones or uric acid that sometimes produce objectionable smells and tastes. They may also transmit pathogenic bacteria to the grain or leave fragments (including feces) in flours and other cereal products. Most consumers are strongly repelled by this filth, and one can say that, due to their contamination, insects ruin much more grain than they consume. (*See* **Insect Pests**: Insects and Related Pests; Problems Caused by Insects and Mites.)

Infestation of grain by insects is a constant phenomenon and several species are particularly well adapted to the grain ecosystem. They exist permanently in machines and buildings for crop reception and must always be regarded as a permanent, potential pest danger, leading to sytematic grain treatments by chemical contact insecticides or by fumigation.

Storage insects belong mainly to the orders Coleoptera and Lepidoptera. Most are adapted forms of crop-destroying species. The most injurious species belong to genera *Sitophilus, Rhyzopertha, Trogoderma, Sitotroga, Cryptolestes*, and *Tribolium*, and are very flexible and adaptable with only minimal nutritive requirements: for example, they tolerate movements of grain during intersilo transfer or temperature fluctuations induced by heating and ventilation. Most important species have a classical development cycle: the females lay fertilized eggs which lead to worm-like larvae, and then to adults through successive stages and a final metamorphosis via a pupal stage.

Adults usually live for several months, sometimes more than a year, depending on storage conditions.

Insects do not like low temperatures and cannot survive subzero temperatures for more than weeks. For this reason, damage caused by insects is generally only a secondary problem in cold or temperate climates.

Like molds, insects are aerobic organisms, only able to 'burn' with oxygen the dry matter they eat, producing carbon dioxide, heat, and water. They can initiate hot spots in dry grains, but such dry heating generally remains below 40 °C, which is the lethal temperature for most grain-infesting insects. By contrast, heating due to aerobic microorganisms can exceed 65–70 °C and can even lead to autocombustion of the bulk, when the moisture content becomes sufficient for the development of thermophilic fermentative bacteria and, subsequently, the occurrence of exothermic chemical reactions.

Despite their absolute requirement for oxygen, insects are able to stop breathing for several hours, days, and even weeks, depending on the development stage. However, they are also very sensitive to high concentrations of carbon dioxide and this is why it is possible to control insect infestations with efficiency by the use of modified atmospheres. (*See* **Controlled-atmosphere Storage**: Applications for Bulk Storage of Foodstuffs.)

They are remarkably tolerant to dryness, and commonly develop in grains with 11–14% water content (wet basis) but cereal weevils cannot multiply below 9% moisture content and adults cannot survive long in such dry grains. On the other hand, flour beetles seem to be able to develop in completely dry flour. At least some storage insects seem capable of reutilizing their own metabolic water (produced by respiration, as with molds) when surviving in extremely dry grains (below 6% moisture content).

Moisture Migration in Silos

In silos, elevators, and other installations for storage and transportation, the temperature fluctuates as a consequence of solar heating and daily or seasonal fluctuations in ambient temperature. The outermost layers of grain are most affected by such temperature variations. In a dark-green metallic silo, the wall temperature on the sunny side can frequently change from 15 to 80 °C on a sunny summer day in northern Europe. This produces measurable temperature changes in the outermost 30–40 cm of grain, and large oscillations occurring in the first 5–10 cm. Such fluctuations are less pronounced in concrete silos.

When heated, grain loses water vapor and dehydrates. Due to convective movements of the intergranular atmosphere, the lost water vapor is transported to the coldest zones in the bulk where it condenses, increasing the water content of the cold grain. The main consequence is always an increase in microbial activity.

In nonhermetic silos, when the intergranular atmosphere is not controlled, oxygen is always available, at least in the outer layers, for respiration of molds, which in turn produce heat and moisture and an acceleration of microbial activity, which may cause carbon dioxide to accumulate deeper in the bulk. This chain reaction always occurs, everywhere in the world, under all climatic conditions. The main difference from one place to another is the speed and intensity of this general phenomenon but, whatever the initial moisture content of the grain, sunshine will more or less rapidly destroy the stored cereals it previously allowed to produce. (*See* **Oxidation of Food Components**.)

The only way this process can be slowed is by removing heat and moisture using forced ventilation of the bulk, or by transfer of the grain from one bin to another to mix the hot and dry grain with cold and moist grain from other parts of the silo. Underground storage under airtight conditions, where temperature fluctuations and moisture migration are minimized, provides an interesting alternative to bin storage, especially when germinative capacity is not the main characteristic to be preserved.

Losses Due to Rodents

Many species of small rodents cause grain losses throughout the world. Rats and mice, which are found everywhere, are probably the most important, causing damage mainly at farms where grain is stored in loose structures. Control measures against rats and mice include traps, baits containing rodenticides, and fumigation similar to that used against insects. In many cases, it is important to know which kind of rodent is concerned in order to take its feeding preferences into account for poisoning, or to find the best way to trap it. Rodent control in larger grain stores requires a sound concrete construction that is able to resist rat gnawing, and the silo must be maintained in good condition. (*See* **Fumigants**.)

Biochemical Changes During Storage

For dry grains, i.e., with moisture contents permitting only very slow development of molds, slight changes in biochemical composition can be observed over several months. The lipid fraction of the grain deteriorates most rapidly during open-air storage under the influence of microbial enzymes, leading to the accumulation of fatty acids. Unsaturated acids can be further oxidized by the oxygen in air to produce volatile compounds with rancid odors and off-

flavors. When moisture contents exceed 15–16% (wet basis), amylases from both grain and microorganisms start to hydrolyze starch into dextrins and maltose, resulting in losses of dry matter and a deterioration in quality. Very small changes seem to occur in the protein fraction of stored grains when molds cannot develop significantly in a few months, i.e., below 15% moisture content. However, the aggregative properties of some proteins may be modified after several years of storage, leading to a decrease in the water-soluble fraction. This may result in slightly lowered digestibility or, for wheat, in losses in bread-making value.

In order to verify good storage of cereal grains, several simple laboratory examinations can be performed. Arguably the most sensitive is the germinative capacity of the grain, which clearly indicates the presence or absence of mold growth during storage in the open air. Fat acidity is another good criterion which correlates well with the metabolic activity of storage fungi and the quality of the grain after a long period of storage.

In practice, in business transactions, the most important criterion is to insure the absence of any live insect. In most cases, it is too often still necessary to fumigate the grain or treat it with insecticide before dispatching from the elevator. Modern consumers are more and more suspicious of chemical residues in food and the coming years will probably see a revision of the risk assessment of chemical residues and of the real benefit of insect destruction in grains.

Handling of Grain for Storage

D Richard-Molard, INRA, Nantes, France

Background

The conservation of cereal grains is of utmost importance for the survival of human populations.

Different technologies have been used to conserve grain, such as storage in waterproof or airtight buried silos.

In the sixteenth century, in Europe, the first texts explaining the importance of drying, ventilation, or modified atmospheres for the good conservation of grains appeared, but the scientific bases explaining the reasons for these practices were absent.

Today, with the development of scientific knowledge on the grain ecosystem, and progress in the fields of building materials, sensors, and measurement techniques, grain storage technologies have been mastered.

However, with continuous, and increasing, requirements of technological and sanitary quality, particularly at the present time, increasing world trade of grains, and the resulting increased commercial competition mean that this area of industry is very dynamic and responsive to new innovative technologies.

Storage Facilities

Storage facilities may take many forms, from a simple pile of unprotected grain on the ground in a farm building to the most sophisticated terminal elevator designed to handle grain for long-distance exportation. At the farm level, grain may be stored temporarily in small concrete or round steel bins of small capacity (25–100 tonnes), which receive the crop immediately after harvest and before transport to a better long-term storage facility or in order to wait for the best market situation.

Grain may also be taken from the farm directly to a collecting center, a small storage installation with several small bins providing an average capacity of about 1000 tonnes. This does not generally have machinery for grain cleaning or drying, since the grain is usually transferred soon after to an elevator (**Figure 1**).

Country elevators (5000–50 000 tonnes), so called because they are filled with grain elevated into them by rolling belts with buckets, receive grain from the individual producer or from small collecting centers. Their capacity is adapted to the seasonal production of the area, and their main role is to keep crops in good condition before and during storage, and to

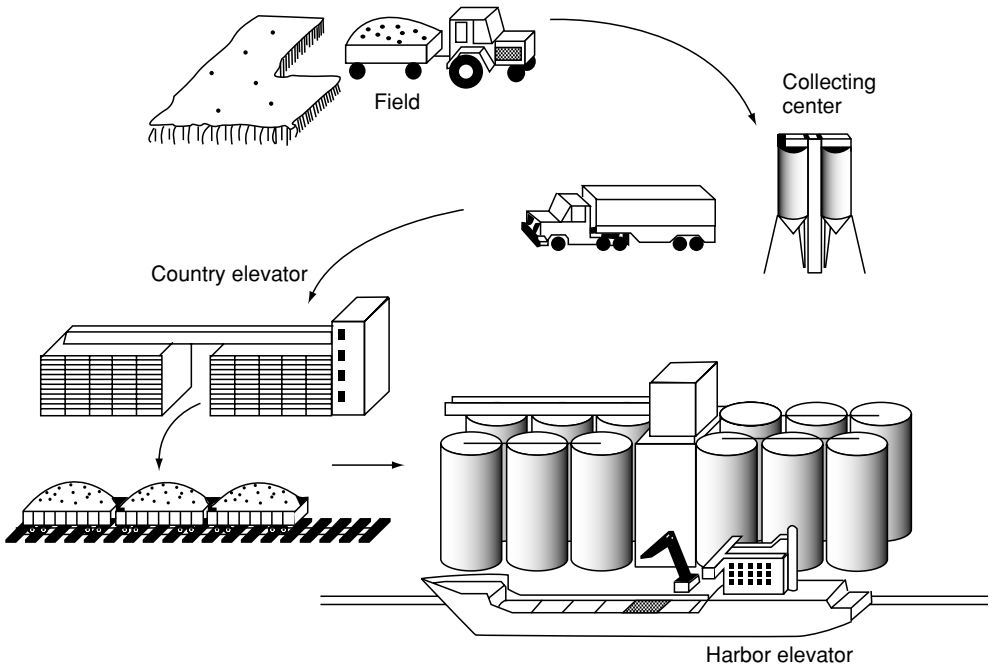

Figure 1 Grain collection, from field to terminal elevator, a long trip for the grain.

reload it into trucks or rail cars for transportation to terminal silos, export elevators, or industrial users.

There is no general rule for determining the best dimensions of a farm bin or a country elevator. Usually, the cost of storage increases sharply as the size of the silo decreases, so there is a tendency to build large structures. However, the grains are managed in multiple silos, where grains of different grades or water contents can be separated easily.

The terminal elevators are generally located close to trade centers and/or transportation terminals, such as harbors (Figure 2). Terminal elevators commonly offer storage capacities of 5000–500 000 tonnes in the USA or northern Europe.

Equipment for grain handling and control is often basic at the farm level, with only very simple devices for grain elevation and ventilation. By contrast, country and terminal elevators have handling capacities adapted to their transportation facilities and usually have sufficient capacity for peak load handling during the short period just following harvest. Today, most are fully equipped with remote control and automation, so that grain can be automatically transferred from one silo to another or to ships and railway cars. Weighing, cleaning, sampling, and even several grain sample tests are now electronically controlled.

When possible, gravity discharge from grain bins is ideal, but the cost of the corresponding structures and equipment is high. Consequently, flat storage of cereals is also commonly carried out in many situations, both at the farm level and in terminal elevators, to provide additional storage capacities when necessary. Such flat-bottomed silos are emptied through a central outlet, where a rotating screw-conveyor draws the grain away beneath the floor. Many other sophisticated devices have been developed for moving the grain using air blown through metallic networks of ducts below the bins, or with suction blowers as back-up devices.

Quality Maintenance During Storage

When the farmer brings freshly harvested cereals to the elevator, several tests are performed to determine the appropriate treatment for safe storage, such as cleaning, dust removal to avoid very dangerous dust explosions, drying, cooling, chemical treatments against insects, etc.

As previously emphasized, the major parameter to be controlled is water content. Even with mature dry grain harvested at about 12–13% moisture content, serious problems will be encountered within a few months if moisture cannot be properly managed to prevent the heat and moisture transfer that can occur in bulk during storage and transportation. It is, therefore, important to store grains with a sufficiently low initial moisture content to prevent mold development and biochemical changes, and to maintain this low temperature as constant as possible everywhere in the silo throughout the storage period. This can be achieved by artificially drying grains with excessive humidity at harvest, like maize in Europe, and by periodic forced ventilation during storage to remove

excess water where condensation has occurred. (*See* **Storage Stability**: Mechanisms of Degradation; Parameters Affecting Storage Stability.)

Moisture Levels for Safe Storage

Determination of the correct moisture level for safe storage of a given crop in a given situation and for a given storage time is difficult. Very general and theoretical rules can be given, but one should bear in mind that a large mass of cereal grain is never homogeneous in temperature, moisture, apparent density, thermal conductivity, etc., and so continuous monitoring with modern techniques, such as silothermometry, and periodical sample examination is highly recommended in every situation.

The thermodynamic activity of water, which represents the availability of water in the grain, is the most important physical parameter governing grain stability during storage, determining both biochemical changes and microbial growth. The availability can be estimated (and measured) by the equilibrium relative humidity (ERH) of the intergranular air in equilibrium with the grain. A nonlinear relation relates ERH to moisture content, as shown in Figure 3 for wheat and maize. This curve is named a 'sorption isotherm' and depends on both the average temperature and the biochemical composition of the grain. It differs from one cereal to another, but its relationship to the level of deterioration by different causes, such as microorganisms or enzymes, remains constant to a first approximation. Wheat stored at 16% moisture content is in equilibrium with an ERH of about 80% and will undergo the same kind of degradation at the same rate as maize with 15% moisture content, which also has an ERH of 80% at the same temperature. As the temperature increases, the sorption isotherm is shifted to the left, i.e., at the same water content, there is a higher ERH, and spoilage is faster. (*See* **Water Activity**: Effect on Food Stability.)

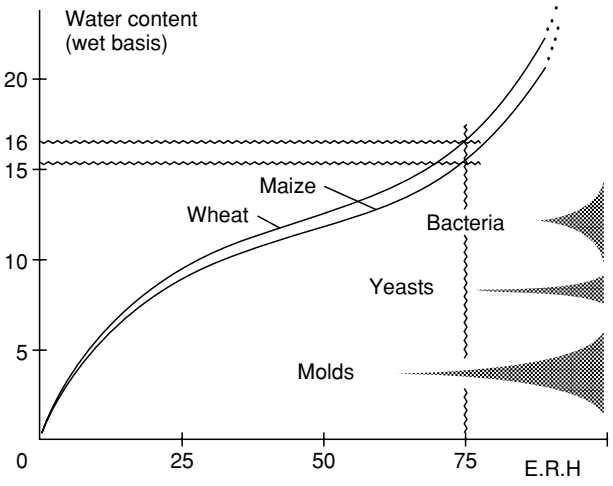

Figure 3 Sorption isotherms for wheat and maize at 20 °C and zones of activity for the main causes of grain degradation during storage (the wider the zone representing a cause of spoilage, the more intense and rapid the spoilage).

Silothermometry is a sophisticated technique, utilizing thermocouples placed in the silo able to detect slight variations in grain temperature, which indicate the beginning of deterioration through an aerobic process, resulting from a localized increase in humidity. Modern sensors can detect temperature changes

of less than 0.5 °C. In most situations, this gives sufficient sensitivity and overcomes the problem of the very low thermal conductivity of cereal grains, which allows temperature differences to be transmitted only over short distances in the bulk. With this method it is also possible to determine the best moment for drying and ensure the completion of grain cooling by nocturnal ventilation.

Drying Methods and Alternatives

The use of adequately dried grains for storage in silos is a mandatory condition (Figure 3). Many types of driers, such as full-bin driers, layer driers, continnous-flow driers, etc., are presently used on farms or in country elevators, but all utilize the same basic principle: heated dry air is blown through the grain to remove excess water. Figure 4 represents a farm bin equipped with a low-heat drier capable of drying grains with moisture contents of less than 20% (wet basis). (*See* **Drying**: Theory of Air-drying.)

When large quantities of moist grain are to be dried rapidly, high-temperature drying is necessary. This gives a higher extractive capacity but also can cause thermal degradation of the grain, if used improperly, as often happens with maize, which is sometimes harvested with a water content as high as 35% (wet basis) in Europe. If the air for drying is too hot, the functional proteins are denatured, and the value of the crop is decreased. However, high drying temperatures destroy all forms of insects in the bulk. (*See* **Drying**: Hygiene.)

When possible, a combination of different drying and cooling practices often gives the best technical and economic results. The essential principle is to decrease the moisture content rapidly to a level, thus decreasing the rate of mold development, i.e., to about 18% moisture in a first step, then to decrease the residual humidity to 15–16% by forced aeration when the ambient air is cool and dry enough to be efficient.

Natural Drying Methods

Alternative natural methods for grain drying have often been used, and at least two must be mentioned. The first, used mostly for maize, uses gentle drying by the wind of cobs stored outside in cribs or other forms of mesh silos. This is satisfactory, provided that the temperature remains sufficiently low to inhibit the growth of such toxinogenic fungi as *Fusarium* species.

The second type of natural drying method uses solar driers. These have been tested in efforts to save energy, but their use can be recommended only in regions where sufficient energy is provided by the sun to achieve drying in a time short enough to avoid spoilage by microorganisms. Unless drying to 80–82% ERH can be achieved in less than 7–10 days, the grain will certainly be damaged. (*See* **Drying**: Drying Using Natural Radiation.)

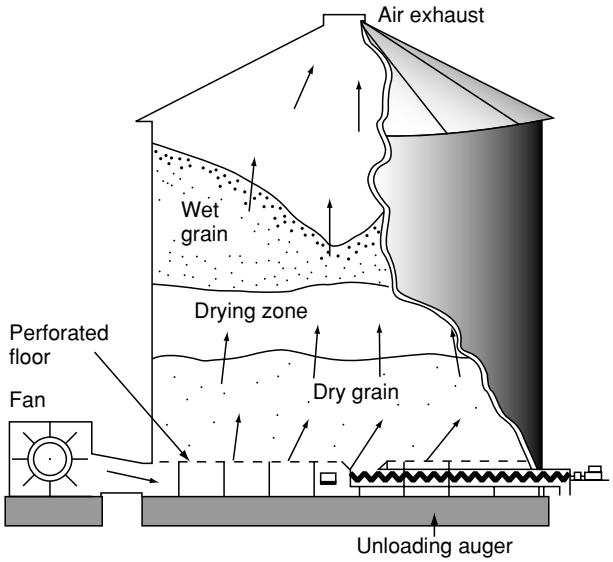

Figure 4 Farm bin for low-temperature drying.

Modified-atmosphere Storage

When cereals are not intended for uses requiring particular properties, such as a high germination ability for malt production or functional properties of proteins for breadmaking, it is possible to store them with a higher water content than usual, provided the oxygen is removed from the system.

Underground storage and storage in anoxic atmospheres in hermetically sealed silos, or silos continuously flushed with nitrogen, for example, are quite possible. For example, it was recently shown that the nutritional value of wheat for animal feeding could be successfully maintained over several months by storing it, after grinding, in airtight conditions at 21% water content and 15–20 °C. Storage of wet (35% water content or more) maize for pig feed in hermetic silos is now popular in several countries. Because of the important demand for intergranular oxygen at such a high humidity, especially through respiration of yeasts and lactic acid bacteria, the concentration of available oxygen remains extremely low in the silo. The growth of molds is inhibited and, at least until the silos are nearly empty, that is to say when free oxygen again appears and concentrations of carbon dioxide are decreasing, no mycotoxins can be produced. With such hermetic silos, it is not necessary to grind the humid grain in order to produce silage, and the commodity can be handled more easily than with traditional practices. (*See* **Controlled-atmosphere Storage**: Applications for Bulk Storage of Foodstuffs; **Spoilage**: Molds in Spoilage.)

Control of Insects

Storage of dry or wet grains under modified atmospheres is an excellent way to kill insects, and modern techniques for storage of dry wheat under high concentrations of carbon dioxide have yielded very good results in Australia in recent years. Most often, if all living insects are to be killed, chemicals need to be used when infestations are detected in a silo or a ship. (*See* **Insect Pests**: Insects and Related Pests; Problems Caused by Insects and Mites.)

Insecticides can be divided into two main classes: contact insecticides, which kill insects and prevent reinfestation owing to their remanent effect, and fumigants, which destroy insects without leaving any significant residues. Organochlorine insecticides, which belong to the first class, were extensively used in the past but are now forbidden because the toxicity of their residues is very high for humans.

Pyrethroids like deltamethrin, permethrin bifenthrin, and organophospates like malathion, dichlorvos or methyl pirimifos, are also contact insecticides, used at concentrations of about 4–8 g of active substance per tonne of grain. They are very fast-acting and highly toxic by contact and ingestion, but their residues necessitate careful consideration of the number and timing of treatments. Their relative inefficiency against the hidden forms of insect (eggs, larvae) that live within the kernels should also be mentioned. (*See* **Pesticides and Herbicides**: Residue Determination.)

The only current fumigant is hydrogen phosphide, which is used to rapidly kill all live insect stages, including adults. It is used in airtight structures equipped with systems that allow the gas to be introduced and removed safely. (*See* **Fumigants**.)

Apart from modified-atmosphere storage under nitrogen or carbon dioxide, only persistent insecticides can provide good long-term protection for grain. It is then of primary importance to ensure that there is no residue in byproducts like flour and brans used for human and animal food. At the present time, there is a general tendency to decrease the concentrations of toxic substances used against insect infestations. A possible approach would be to combine the use of carbon dioxide with an active substance, such as methyl bromide or hydrogen phosphide, which would permit a considerable reduction in the dose of fumigant used because of synergism with carbon dioxide, which increases the penetration of the active substance in the respiring stages.

The Future

All over the world, safe storage of cereal grains is a vital but expensive activity. Too many cereal grains are still used in the food industry despite the poor quality resulting from inappropriate storage conditions. Current scientific and technical knowledge in this domain is sufficient to answer the main questions about handling and storage of grain, but new trends are appearing: consumer demand for safe products, i.e., free of chemical residues, is growing fast. This probably means that the use of contact insecticides and even fumigants should be replaced by more acceptable techniques like physical techniques in the coming years.

Another trend seems to be a clear demand for identified grains, nongenetically modified grains, and grains from a precise geographic origin or a well-specified technological quality, for example. Such an evolution would certainly introduce very important changes in the way in which the grains are harvested, collected, stored, and distributed. Loading speeds as high as 5000 tonnes per hour are often reached today in harbor elevators, but this is not the most convenient technology if small bulks of 50–100 tonnes of well-certified grains are to be prepared.

Breakfast Cereals

R S Kadan, United States Department of Agriculture, New Orleans, LA, USA
E F Caldwell, American Association of Cereal Chemists, St Paul, MN, USA

Introduction

The US breakfast cereals (BC) industry, in its history of over 110 years, has emerged as an important segment of the food industry, with annual sales of about \$9.5 billion (9.5×10^9). This remarkable progress has been achieved through a combination of knowledge gained in human nutrition, innovative progress in cereal processing technology, and imaginative marketing. The chief driving force has been the continued market for new, convenient, nutritious, and fun foods for a discriminating, affluent, and mobile society. Any large grocery store in the USA, Canada, or the UK is likely to stock 100 or more different BC. In the UK, annual sales are about £1 billion (1×10^9). The relatively lower penetration of BC into other European and other developing countries increased significantly during the 1990s, and this is forecast to continue over the next decades.

BC have been defined as processed grains for human consumption. The major grains used in the manufacturing of BC are corn, rice, wheat, oats, and barley. Cereals can be divided into those that are ready-to-eat (RTE) or ready-to-cook, also known as hot cereals (HC). Alternative breakfast products based on cereal grains include cereal bars, toaster pastries, waffles, French toast, and bagels. RTE cereals are frequently made from mixtures of one or several grain components with other ingredients; they require extensive processing, are usually fortified with vitamins and minerals, and are specially packaged to protect their flavor, texture, and nutrition during storage. On the other hand, HC are typically made from a single grain component by using relatively simple processing and packaging technologies. The difference between the RTE and HC products is reflected in the price at the consumer level. The typical single serving (28–35 g or 1 oz) of RTE cereal costs about \$0.20 (\$0.08–0.40) in the USA and represents about 90% of the business. A typical 28–35-g or 1-oz serving of HC costs from about \$0.06 to \$0.24, for bulk-packaged product to instant single-serving pouches, respectively or up to \$0.30 for instant farina.

Annual sales in the USA of alternative breakfast products amounted to over \$2 billion (2×10^9) by 1999, but the per capita annual consumption of RTE cereals had still increased from 3.8 to 5.0 kg (8.3–11.0 lb) since 1970. On the other hand, HC per capita annual consumption had declined from 1.1 to less than 0.6 kg (2.4–1.2 lb) over the same period. The latest per capita annual consumption in UK was 5.9 kg (13.0 lb) and 0.6 kg (1.4 lb) for RTE and HC respectively. (*See* **Barley; Oats; Rice; Wheat:** The Crop.)

Methods of Manufacture

Ready-to-eat Cereals

RTE breakfast cereals are primarily grain formulations, suitable for human consumption without further cooking. Manufacturing technology varies according to type of cereal.

Flaked cereals Flaked RTE breakfast cereals can be divided into two groups: flakes made from whole grains or parts of the whole grains, and flakes made from more finely ground materials that must be first extruded into pellets that can then be rolled into appropriate-size flakes.

The whole grains (wheat and rice) or major components (such as grits from degermed yellow maize or corn) are cooked with flavorings such as sugar, salt, and malt; they are then dried and tempered to a firm but slightly plastic state, flaked by passing between rolls, and toasted or dried to a final specified moisture content. Cooking of grits or whole grains for traditional flakes is usually done in batches. The moisture content of the cooked mass at the end of cooking is usually about 28%. The cooked material should not be mushy, soft, or sticky. After cooking, the mass of material is cooled, dried at about 120 °C, and tempered (held) for several hours at a final equilibrated moisture content of 10–18%, depending upon the grains. The tempering process is important, not only to allow equilibration of moisture within the cooked grains or pellets, but also to allow sufficient starch recrystallization or retrogradation to provide a suitable texture for flaking (or for shredding, as discussed next).

Flaked RTE cereals can also be made from extruded pellets rather than cooked grits or whole grains. A variety of floury or finely ground grain products such as whole wheat or oat flour can be mixed with sugar, salt, and malt syrup or other flavoring and coloring ingredients to form a dough. This is then extruded to form pellets about the same size as cooked grits or whole grains, the cooking having taken place in the extruder. Pellet moisture is in the range of 18–24%. Conditioning or tempering prior to flaking may or may not be required.

Whether consisting of cooked grits or whole grains or of extruded pellets, the tempered material is then

flaked. Tremendous pressures are necessary to flatten the prepared material into thin flakes, which traditionally have been toasted by keeping them suspended in hot air between 270 °C and 330 °C for about 90 s. Some properties of the finished flakes can be modified by a heating or steaming step immediately before flaking (e.g., infrared heating immediately before flaking will increase the tendency of flakes to crinkle rather than remain flat), while other properties, such as blistering, color, crispness, tenderness, and flavor of the final product, are influenced by toasting conditions. The moisture content of the finished product is about 1–3%.

Puffed cereals The predominant grains used for making puffed cereals are wheat and rice. The milled rice used for puffing is either short- or medium-grain white rice. Such rice usually requires no pretreatment other than the hull and bran removal that occurs during milling or pearling. Wheat, on the other hand, is usually decorticated (bran removed), either by pretreatment with concentrated brine solution or by pearling. In the pearling operation, the grain is passed through a revolving cylinder inside which are mounted silicon carbide or carborundum stones.

Usually hard wheat, preferably durum, is used for puffing. A grain flour mixture can also be formed into desired shapes by an appropriate extrusion process and dried to a moisture content of 9–12% for subsequent gun-puffing.

Puffing guns are vessels capable of holding very high temperature and high-pressure steam. The critical feature of any puffing gun vessel or barrel is a quick opening lid that seals the vessel. Operation of a simple single-shot gun consists of placing the grain in the vessel, closing the lid and raising the pressure and temperature in the vessel to about 1380 kPa (200 psi). The quick-opening lid is then activated, causing rapid pressure drop, which in turn instantaneously causes moisture in the grain to 'flash off' as steam, and the kernels of grain or preformed pellets to expand to as much as 16 times their original volume. The guns can also be multiple-shot automatic or continuous in operation.

Another group of BC is made by oven puffing. Specially prepared rice or corn grains or their mixtures are oven-heated to 290–340 °C in order to puff them. Puffed rice cereal sold in the USA can be either oven-puffed (e.g., Rice Krispies, prepared from short-grain rice) or gun-puffed (e.g., Puffed Rice). Whether gun- or oven-puffed, the grains are then screened to remove any unpuffed kernels, loosened bran, fine dust and broken kernels, and the product is heated to lower the final moisture to 1–3%. Processes such as coating or vitamin enrichment can be carried out during this drying operation.

Shredded cereals Shredded wheat, one of the oldest mass-produced breakfast cereals, is still an important product. Soft white wheat is the primary grain used. Other varieties of wheat, as well as other cereals such as rice, corn, and oats or mixtures thereof, can also be used to make shredded products. The grains are cleaned, cooked in boiling water, partially dried, and tempered. The shredding operation consists of passing the tempered grain between two rolls. One roll is grooved and the other is smooth. Strong forces in the range of 7000 kPa (1000 psi) along the roll length are often required to maintain the rolls in tight contact. The tempered kernels are squeezed into the grooves of the roll and emerge as strands roughly 1 mm in diameter. These strands are accumulated in multiple layers below multiple pairs of rolls, and formed into biscuits or bite-sized pieces. A refinement of the shredding process is the use of a roll with added cross-grooves to provide lateral strands that can tie the shreds together in a coherent sheet. Mixtures of ground cereal products with sugar, salt, malt, and flavoring can be cooked by extrusion, formed into pellets, tempered, and then shredded in the same way as cooked whole grain kernels.

The formed pieces are oven-dried and baked to the desired color, texture, and moisture. The baking procedure is done in a specialized manner to impart fluffy texture, particularly for products containing rice or corn. Other minor ingredients, such as flavorings, nutrients, or antioxidants, can also be added prior to drying and baking.

Granola cereals The main grain used to make granola cereals is either regular or quick-cooking rolled oats. The cereal products are mixed with other desired ingredients such as nut pieces, coconut, corn syrup, brown sugar, honey, malt extract, dried milk, dried fruits, and/or vegetable oil. Liquid and dry ingredients are prepared separately, then mixed together and spread in a uniform layer on the band of a continuous oven. Baking temperatures are in the range of 150–220 °C, until the product is uniformly toasted to a light brown color and the moisture is reduced to about 3%. After baking, the product is broken into small pieces and packaged.

Extruded expanded cereals Successful application of extrusion technology for producing cereal products from grain flours or meal mixtures by formulating, continuous preconditioning, extrusion cooking, and forming has been an important achievement of the BC processing industry. The extruders can be single-screw, twin-screw, low-shear, high-shear, and combinations of these or other features. Extrusion technology was developed to produce flaked, puffed,

shredded, and expanded breakfast cereals. For extruded expanded cereals, cereal flour mixtures having about 25–30% moisture are preconditioned, cooked, and extruded. Perforations in the die and design of the cut-off knives at the end of the extruder, as well as temperature, pressure, time, and shear in the extruder barrel, all influence the shape, size, and texture of the final product. The sudden change from high pressure and temperature to ambient conditions as the product exits the extruder imparts the necessary expansion, texture, and other characteristics. The extruded products may be coated with solutions of vitamins and minerals, and with sweetening and flavoring materials, and are then oven-dried to desired moisture levels.

Hot Cereals

HC are products of a single grain or a simple mixture that require cooking or heating in water before consumption. The main such products are rolled oats and related oat products, farina and other wheat fractions, and corn grits.

After cleaning, oat kernels are dehulled by an impact process. The resulting groats are steamed, primarily to deactivate lipolytic enzymes, then rolled, dried, and packaged. Quick-cooking rolled oats are made by steel-cutting groats into four or five pieces before the steaming and flaking process. Instant oatmeal is made by subjecting groats to a special process that results in rapid cooking of the flakes. Incorporation of 0.1–1.0% of an edible gum during processing helps to achieve this objective. Distribution of the gum and necessary salt without damaging the extra thin flakes is accomplished by portion-control packaging. Such instant products require only the addition of boiling water, stirring, and a short standing time to make the product ready for consumption. The industry has successfully incorporated dried fruits, nuts, and other flavorings to make instant oatmeal products more attractive to consumers.

Wheat farina is another important HC. In the USA, farina and enriched farina have to meet respective legal standards of identity. Farina is basically wheat endosperm, preferably obtained from hard red spring or winter wheat, the granules of which stay intact during cooking at home. Farina is normally obtained by drawing off chunks of endosperm during milling of wheat into bread flour. In the UK it can also be called semolina, but in the USA that term is reserved for a similar product from durum wheat intended for macaroni and other pasta products. Farina is heated at around 60 °C for 15 min before packaging, for flavor and to head off infestation. Quick and instant farina products are prepared by the use of disodium phosphate, enzymes, and other treatments. Similarly, wheat germ, bran, malted barley, cocoa, and other flavorings can be mixed into farina to enhance the consumer appeal.

Other important HC products include wheat products such as cracked wheat and bulgur, and corn grits. Grits and bulgur are generally used as cereal accompaniment to other meal menu components such as eggs, sausage, meat and related preparations, whereas cracked wheat products are cooked for breakfast. Grits usage is mostly in southern parts of the USA, garnished with butter and salt rather than with sugar and milk as in traditional breakfast cereals. Grits are produced by dry milling of white degermed corn and can be fortified with vitamins and minerals. Bulgur or parboiled wheat is one of the oldest cereal-based foods and has been consumed for centuries in Turkey, Syria, Jordan, Lebanon, and Egypt. To prepare it, common hard or soft wheat varieties are soaked in water and heated to about 90 °C for 2–3 h. The cooked wheat is then cooled, dried, moistened, peeled (optional), redried, cleaned and sized. Bulgur has a good shelf-life because cooking destroys insects present in harvested crops.

Significance in the Diet and Fortification

BC are one of the most highly fortified foods in both vitamins and minerals. One serving typically can supply 25% of the daily values of most vitamins and trace minerals as these are defined in the USA for labeling purposes. A few BC supply 100% of all established daily values, making them as much nutritional supplements as breakfast foods. The cereal industry justifies these practices on the basis that they fulfill a genuine need to improve the overall nutritional needs of consumers. Food consumption surveys have shown that some of the US population had inadequate intakes of several vitamins and minerals, particularly vitamin A, folic acid, calcium, and iron, and possibly vitamin B_6, zinc, and magnesium. (*See* **Calcium**: Physiology; **Food Fortification**; **Iron**: Physiology; **Magnesium**; **Retinol**: Physiology; **Vitamin B6**: Properties and Determination; **Zinc**: Physiology.)

The practice of fortification of cereal foods started in 1941, when the US Food and Drug Administration (FDA) established a standard of identity for enriched flour to include the addition of thiamin, niacin, and iron. Riboflavin was subsequently included, and addition of calcium and vitamin D was optional. Such recommendations developed after extensive discussions by the various committees of the American Medical Association, hearings sponsored by the FDA, and the Food and Nutrition Board. As a result of these meetings, criteria for fortification of foods were developed:

1. The intake of nutrient is below the desirable level in the diet of a significant number of people.
2. The food used to supply the nutrient is likely to be consumed in quantities that will make a significant contribution to the diet of the population in need.
3. The addition of nutrient is not likely to create an imbalance of essential nutrients.
4. The nutrient added is stable under proper conditions of storage.
5. The nutrient is physiologically available from the food.
6. There is reasonable assurance against excessive intake to a level of toxicity.

Various studies have confirmed that fortification of BC foods is appropriate and has contributed significantly to improving overall nutrition. Fortification of flour and other grain-based foods with folic acid became a requirement in the USA in 1998 because of evidence that it may help prevent neural tube defects.

Many nutritionists consider eating breakfast regularly as one of the important health habits associated with subsequent favorable health status and reduced mortality. Breakfast consumers were found to do significantly more work in the morning than those who did not. Children and the elderly (above 65 years old) are the largest consumers of BC. Half of the school-age children in the USA prepare their own breakfast because most of their mothers work outside their homes. These groups are more likely to skip breakfast. Studies have indeed confirmed that BC consumers are likely to skip fewer breakfasts and that they obtain higher levels of vitamins and minerals than others. Most BC also contain up to 5 g of dietary fiber per serving. Some high-fiber products can provide 10 g or more of fiber and thus help consumers to improve their dietary fiber intake and to meet recommendations of 25–30 g daily dietary fiber intake. Oat-based BC containing sufficient beta-glucan soluble fiber to provide 3 g or more of that substance daily, or other BC containing sufficient psyllium to provide 7 g of soluble fiber from that source daily, have been shown to decrease blood cholesterol by a small but significant amount and in the USA may carry label health claims to that effect.

BC, with few exceptions, are not high in protein. The protein in some cereals, such as gun-puffed or flaked products, may have little or no biological value, due to excessive Maillard browning. Some RTE cereals may also be high in sugar and/or salt (sodium) and may contain added saturated fat. Nevertheless, BC with milk and fruit make an inexpensive, nutritious, and easy-to-prepare breakfast. (*See* **Browning**: Nonenzymatic; **Dietary Fiber**: Properties and Sources.)

Packaging, Storage, and Spoilage

The BC industry, over the years, has developed efficient processing, packaging, storage, and shipping technologies to supply consumers with cereal foods that routinely have 6 months' or longer shelf-life. It is indeed quite a feat to have such an array of vitamins and minerals, which often interact with each other, in a highly processed food and yet end up with a wholesome product with a desirable flavor and texture. In the process, the industry has developed novel techniques for vitamin preservation and for the incorporation of antioxidants directly or via the packaging material. BC packages not only protect the product against moisture, oxygen, and insects during shipping and storage, but also provide attractive consumer appeal at the point of purchase. The industry has accomplished this by following good manufacturing practices and other quality control measures, and by instituting Hazard Analysis and Critical Control Point (HACCP) systems for food safety purposes. Computer control of processing and attention to environmental issues also characterize most BC manufacturing operations, and certainly the newer ones.

Future Developments

The Nutritional Labeling and Education Act of 1990 and subsequent amendments in the USA undoubtedly contributed to the reevaluation of product development, marketing, and advertising strategies by the BC industry as a result of stricter control of nutrient claims, ingredient listing, and other label data. Among other moves, the BC industry has endeavored to develop new products made from whole grains that are also low in fat, sugar, and salt (sodium). Encouragement was provided by FDA approval of a health claim being made for products containing one or more whole grains as a majority constituent. Other product developments or modifications of BC in the USA or elsewhere are likely to be influenced by such regulatory developments as well as by advances in technology or nutritional knowledge.

Dietary Importance

S O Serna Saldivar, Instituto Tecnologico y de Estudios Superiores de Monterrey, Monterrey N.L., Mexico

Introduction

Cereal-based foods are by far the major source of energy, protein, B vitamins, and minerals for the world population. In most countries, diets have a single cereal as the primary staple. The most widely used cereals are rice, wheat, and maize, which provide 93% of the total cereal calories. These grains constitute the main staple for Asia, Europe, and America, respectively. In Africa and India, sorghum and millets are widely grown and consumed. (*See* **Maize**; **Rice**; **Sorghum**; **Wheat**: The Crop.)

According to the Food and Agriculture Organization (FAO), the amount and proportion of food energy and protein provided by cereals in human diets in 1997 were 1384 kcal (5796 kJ), nearly 50% of the average per capita caloric intake. Likewise, cereals provided 33.8 g of protein of the total estimated daily intake of 73.9 g of protein. Cereal grains are considered primarily as caloric or starchy foods and, more recently, as an important source of dietary fiber. However, their protein quality, especially for infants, is marginal. In developing countries, cereals are usually consumed with legumes and pulses, thus significantly increasing protein intake and, more importantly, complementing their essential amino acid composition. Protein and/or calorie malnutrition (i.e., marasmus, kwashiorkor) is prevalent among groups of people who have inadequate food intake or rely solely upon cereals and/or starchy roots as their source of protein. (*See* **Energy**: Measurement of Food Energy; **Kwashiorkor**; **Malnutrition**: The Problem of Malnutrition; **Marasmus**.)

Plant breeders have developed maize, sorghum, and barley genotypes with high lysine, which results in an improved protein quality and nutritional value. A high lysine and tryptophan corn, called quality protein maize, with satisfactory grain yield and structure is being commercially grown in different places around the world (Brazil, China, Ghana, and other African countries). (*See* **Maize**.)

Carbohydrates

Starch is the most abundant carbohydrate in cereals and the main contributor of calories (**Table 1**). It is composed of molecules of branched amylopectin and linear amylose. Most cereals contain 70–75%-amylopectin. Waxy maize, rice, and sorghum contain more than 95% amylopectin. Most food processes partially or totally gelatinize the starch granules, making the molecules more prone to amylase hydrolysis. (*See* **Starch**: Structure, Properties, and Determination.)

Starch is highly digestible by the human digestive system. Practically all starch disappears in the gastrointestinal tract. A small portion of the starch (1–5%) resists enzymatic hydrolysis when cereal foods are thermally abused. This residual starch can be quantified in the soluble dietary fiber residue and is highly susceptible to fermentation in the large intestine. (*See* **Starch**: Resistant Starch.)

Other factors that can decrease starch digestibility are excessive amounts of fiber and enzyme inhibitors (i.e., tannins). The digestible energy of cereals is negatively and positively related to the grain's fiber and lipid contents, respectively. Refined grains contain more digestible energy than whole products (**Table 1**). As a result of its high fat and low fiber content, maize contains high quantities of digestible energy.

Cereals contain small quantities of soluble carbohydrates (i.e., glucose, fructose, maltose, sucrose); they are therefore suitable foods for diabetics. Highly refined cereals have a higher glycemic index than whole-grain products. (*See* **Glucose**: Glucose Tolerance and the Glycemic (Glycaemic) Index.)

Whole cereal grains are considered a rich source of fiber (**Table 1**). However, foods from grains have marked differences in the amount and type of dietary fiber. Fiber components are concentrated in the outer tissue of the kernel (pericarp). The dietary fiber content in cereal-based food varies greatly, depending on the extent of milling. Refined flours lose most of their fiber during decortication and milling. All cereals are

considered a rich source of insoluble dietary fiber (i.e., cellulose, insoluble hemicellulose). Insoluble fiber binds water, speeds up intestinal transit and binds some carcinogens. Epidemiological evidence has related a high-fiber diets to a lower incidence of diabetes, obesity, and diverticular disease. A high dietary fiber consumption benefits diabetics because of the reduced diffusion of glucose in the intestinal mucosa and the diminished insulin secretion rate. (*See* **Dietary Fiber**: Properties and Sources; Determination; Effects of Fiber on Absorption.)

Oats, barley, and rye are considered goods sources of soluble dietary fiber (i.e., pentosans, β-glucans, soluble hemicellulose), which has been associated with increased excretion of bile salts and dietary cholesterol, thus lowering blood cholesterol levels.

Protein

Cereal grains provided 45% of our total protein intake in 1997. Genotype, environment, and growing conditions affect the amount of protein in the kernel. In general, brown rice and oats contain the lowest and highest protein content, respectively (Table 1). Protein quality is mostly dictated by the amino acid profile and digestibility (Table 2). The apparent protein digestibilities in cereals range from 80% to 90%. Sorghum (especially kernels with condensed tannins), whole barley, rye, and oats are consistently lower in digestibility than other cereals. Milling, decortication, fermentation, and germination all increase protein digestibilities because of the removal of fiber and the enzymatic breakdown of proteins. (*See* **Protein**: Chemistry; Quality.)

The storage protein in cereals (prolamines) contains small amounts of essential amino acids, especially lysine. The albumin and globulin proteins, mainly located in the germ, contain the best essential amino acid profile. High-lysine cultivars of maize, sorghum, and barley are genetically modified to contain lower amounts of prolamines and higher amounts of the other protein fractions. Thus, they have a more balanced protein. (*See* **Amino Acids**: Metabolism; **Protein**: Quality.)

For all cereals, the most limiting amino acid is lysine. Oats, rice, rye, barley, and the high-lysine cultivars contain a more favorable essential amino acid composition or amino acid score than the rest of the cereals (Table 2). Lysine deficiency is observed particularly in postweaned infants who suffer from kwashiorkor and rely on cereals and/or starchy tubers as the only food source. The supplementation of cereal-based foods with small quantities of legumes or animal foods improves protein intake and protein quality. The next most limiting amino acids for maize and the rest of the cereals are tryptophan and threonine, respectively.

Decortication or milling partially or totally removes the pericarp and germ tissues, therefore improving the digestibility and reducing the lysine level. Malting improves protein quality due to enzymatic degradation of proteins. Fermentation improves protein quality via improved digestibility and *de-novo* synthesis of lysine by the fermenting biomass.

Lipids

Lipids are relatively minor constituents in cereal grains (Table 1). However, cereal lipids are rich in the essential fatty acid, linoleic acid (18:2 Δ 9, 12; 30–60% of total fatty acids), and practically devoid of saturated fatty acids. Cereals contain trace quantities of phytosterols; they do not have any cholesterol. Cereals with yellow endosperm (i.e., yellow corn, yellow sorghum, durum wheat) contain some provitamin A activity (β-carotenes). Various types of tocopherols are responsible for the vitamin E activity of cereal grains. Degermination of cereal grains greatly reduces the content of lipids and tocopherols.

Minerals and Vitamins

The pericarp, germ, and aleurone layer are rich in vitamins and minerals. Refined cereal products therefore lose part of these important nutrients. The enrichment of cereal-based foods is aimed toward the replacement of minerals (Fe and recently Zn) and vitamins (thiamin, riboflavin, niacin, and recently folic acid) lost during milling. In some countries, the enrichment of cereal-based foods is required by law. (*See* **Anemia (Anaemia)**: Iron-deficiency Anemia; **Folic Acid**: Properties and Determination; **Iron**: Properties and Determination; **Niacin**: Properties and Determination; **Riboflavin**: Properties and Determination; **Thiamin**: Properties and Determination; **Zinc**: Properties and Determination; .)

In general, cereals are a very poor source of calcium, except for finger millet and teff (Table 3). Some food processes, such as nixtamalization of maize for tortilla production, greatly increase calcium. The bioavailability of this mineral in tortillas is high. (*See* **Tortillas**.)

Phosphorus is the most abundant mineral (Table 3). Unfortunately, its availability is questionable because it is complexed with phytic acid. The phytic acid has the property of binding strongly with cations, thus decreasing their bioavailability. Phytic acid decreases significantly during fermentation, due to activation of phytases. These processes considerably improve the

bioavailability of minerals. (*See* **Phytic Acid**: Properties and Determination.)

Cereals are considered a good source of potassium and are practically devoid of sodium. Whole grains provide a significant amount of magnesium, iron, zinc, and copper, which is reduced by degermination, decortication, and milling.

Cereals are also considered an important source of B vitamins (except B_{12} or cobalamin), but dried-matured grains do not contain vitamin C. The B vitamins are concentrated in the aleurone layer. Beriberi (a thiamin-deficiency disease), endemic in eastern and southern Asia, is prevalent among people who consume milled rice. Milled rice contains about 10% of the thiamin of brown rice (Table 3). (*See* **Beriberi**.)

Niacin is found in a free and bound form and can be synthesized from tryptophan. The alkali treatment of maize for tortilla production considerably improves niacin bioavailability because the glucosidic bond that renders it unavailable is alkali-labile. Niacin deficiency produces pellagra, which causes dermatitis, diarrhea, and dementia and has been prevalent in regions of Southern Africa where people rely on maize as the main food source. (*See* **Niacin**: Properties and Determination; **Pellagra**.)

Toxins and Contaminants

Naturally Occurring Antinutritional Compounds

All cereals contain relatively high levels of phytic acid, which binds minerals (cations). Germination and/or fermentation improves mineral bioavailability due to the enzymatic activity of phytases and bacteria.

Brown sorghums contain condensed tannins in their testa. The brown sorghums are grown to avoid bird damage and grain deterioration due to sprouting and weathering. The tannins bind hydrophobically with, and precipitate, proteins in food systems, thus lowering digestibility. Germination and the treatment of grain with calcium oxide (CaO), potassium carbonate (K_2CO_3), ammonium bicarbonate (NH_4HCO_3), or sodium bicarbonate ($NaHCO_3$) detoxifies the grain and consequently improves its nutritional value. In Tanzania, Magadi soda is used to detoxify brown sorghum in small villages. (*See* **Sorghum**; **Tannins and Polyphenols**.)

A higher incidence of goiter among pearl millet eaters in West Africa (Sudan) has been attributed to a goitrogenic compound. The goitrogen has been identified as a thioamide, mainly found in the bran and endosperm. Heat treatment (autoclaving) apparently detoxifies the grain. Trypsin inhibitors and saponins have been isolated in pearl millet. (*See* **Goitrogens and Antithyroid Compounds**.)

Contaminants

Cereal grains are susceptible to mold attack, especially when storage conditions are inappropriate. Some molds produce many toxic compounds that can severely affect human health or even cause death. The most important mycotoxin is that produced by *Aspergillus flavus*. Aflatoxins have been found in most cereal grains, but they are most prevalent in maize. The toxin is a potent hepatocarcinogen at concentrations in parts per billion. The most prevalent aflatoxins in cereal grains are B_1 and B_2. For optimum growth and aflatoxin production, the mold requires a relative humidity of 85% and a temperature range of 27–30 °C and at least 17.5% moisture content in the cereal grain. The alkali treatment of maize for tortilla production significantly reduces the amount of aflatoxins. Most of the aflatoxins end up in the steep and wash waters. (*See* **Mycotoxins**: Occurrence and Determination; **Spoilage**: Molds in Spoilage; **Tortillas**.)

Ochratoxins are produced predominantly by the storage fungus, *Aspergillus ochraceus*. Toxicity is characterized by nephropathy, mild degeneration of the liver, and enteritis in swine, poultry, and humans. Endemic ochratoxicosis has been observed in the Balkans (Bulgaria, Yugoslavia, Romania) since 1950.

Species of *Fusarium* produce toxins that affect humans and animals. An example is scab wheat and barley contaminated with *F. graminearum*. The preparation of bakery products with contaminated grain causes vomiting and inebriation in humans. Zeralenone, another *Fusarium* toxin, is the most frequent mycotoxin in cereal grains. It is mainly found in maize. Zeralenone produces vomiting in monogastrics, and diarrhea, hemorrhage, swelling of genitals, and infertility in swine. The fumonisins are the most recently discovered family of *Fusarium* toxins. Their isolation was prompted by the death of horses from encephalomalacia and esophageal cancer. Recent epidemiological data have related consumption of fumonisin-contaminated maize with esophageal cancer in humans.

Ergot (*Claviceps purpurea*) is a fungus that infects rye and, less often, wheat, barley, and oats. Honey disease of millet and sorghum is caused by ergot. The toxicity of ergot has been documented for several centuries. Epidemics of poisonings have occurred in North America, the UK, Europe, Russia, and other places. Ergot toxicity produces a disease commonly called *Saint Anthony's Fire*, which produces gangrenous necrosis, hallucinations, and convulsions. The fungi produce toxicity via the formation of alkaloids (ergotamine, ergotoxine, and ergometrine). Growth of the fungus is promoted by moist, warm climatic conditions.

CHAPATIS AND RELATED PRODUCTS

P Haridas Rao and R Sai Manohar, Central Food Technological Research Institute, Mysore, India

Introduction

The chapati, also known as the roti, is a flat unleavened baked product that forms the staple food of the majority of the population in the Indian subcontinent. The consumption of this traditional product is increasing and has become popular even in areas where, traditionally, rice has been the staple diet. Chapatis are normally made and served hot at breakfast, lunch, or dinner, and are eaten along with other adjuncts in households, restaurants, and industrial canteens. There are several culinary variations of the chapati – the important ones being the parotha, stuffed parotha, tandoori roti, phulka and puri. The other culinary variations include nan, South Indian parotha and roomali roti.

Either whole-wheat flour – generally known as atta and obtained by grinding wheat in a plate/disc mill – or 'resultant atta', a byproduct of the roller flour-milling industry, simulating whole-wheat flour, is used for the preparation of chapatis. Sometimes, whole-wheat flour is first sieved to remove 3–5% of the coarse bran, and then used for chapati-making. The flour, after having been mixed with water to form the dough, is sheeted to a circular shape, and baked on a heated iron plate or on an electric hotplate. The major differences between chapatis and similar products arise mainly from differences in processing conditions. Puri is prepared similar to chapati, but it is deep-fat-fried instead of being baked. The nan is a lactic fermented flat product. South Indian parotha is a nonfermented, laminated product. Roomali roti is a very thin product baked in an inverted heated convex iron plate. The nan, South Indian parotha, and roomali roti are basically made from refined wheat flour obtained from roller flour-milling operations. (*See* **Flour**: Roller Milling Operations; **Wheat**: The Crop.)

Characteristics of Products

The chapati and its culinary variations come under the category of unfermented flat breads; consequently, they are dense in texture, comprising mostly crust with little or no crumb (**Figure 1**). But, in a few products, viz., nan, south Indian parotha, and tandoori roti, the crumb-to-crust ratio is higher. They are

usually round, but may occasionally be made triangular or rectangular in shape. The diameter varies from 10 to 20 cm, and the thickness from 3 to 10 mm. The desirable characteristics for these products are a soft, smooth, and pliable texture, light creamish brown color, slight chewiness, and wheaty aroma. However, there are very few distinct differences in the product characteristics of the various forms of chapatis.

Chapati

The chapati is circular with a diameter of 10–15 cm and a thickness of 2–3 mm. The dough sheet is baked on a heated iron plate and puffed on a live coal fire or flame. The thinner chapati, with a thickness of 1–2 mm, is known as 'phulka'.

Complete and full puffing is one of the important quality attributes of a chapati, as it results in a soft and pliable texture. The chapati should have an attractive appearance without any cracks on the surface. The surface should have uniformly distributed lightbrown spots. The texture should be soft, smooth, and pliable, and these characteristics should be retained for at least 2–3 h of storage.

The chapati should have a sweetish, wheat taste, and a baked wheaty aroma, and it should not be perceived as being tough and leathery when chewed.

Parotha

Like the chapati, the parotha is also made from whole-wheat flour or resultant atta. Parotha dough contains salt and fat. The dough is sheeted and laminated at least three times; oil is applied during lamination as well as during baking.

The major difference between the chapati and the parotha is that the latter contains four to eight discrete layers, and has a more pronounced taste and flavor of oil. In view of the presence of oil, its keeping quality is better than that of chapatis. The parotha is slightly thicker (4–6 mm) than the chapati and is normally triangular in shape. Its color is creamish brown and it is slightly brittle on chewing. The parotha can be stuffed with cooked vegetables, e.g., potato. Other types of parotha can be made from a dough containing leafy spices, like methi. They are either baked or fried.

Tandoori Roti

The tandoori roti is similar to the chapati in composition, but it is somewhat thicker and larger. It is made in restaurants and other roadside eating places known as 'dhabas'. It is rarely made at home as it requires a special type of oven, called a tandoor, which is essentially an enclosed cavity dug out in a layer of clayey soil, and heated by live coal. In some urban areas, ovens of this type can be seen in centralized places; customers normally bring the dough sheet and get the rotis made and baked in the tandoor for a nominal charge. The thickness of a tandoori roti is greater than that of a chapati; it may be 8–10 mm thick, and its diameter may range between 15 and 20 cm. The crumb-to-crust ratio is greater than that of a chapati. A tandoori roti is less pliable than a chapati; its surface is rough and exhibits several large blisters. The moisture content of a tandoori roti is also lower.

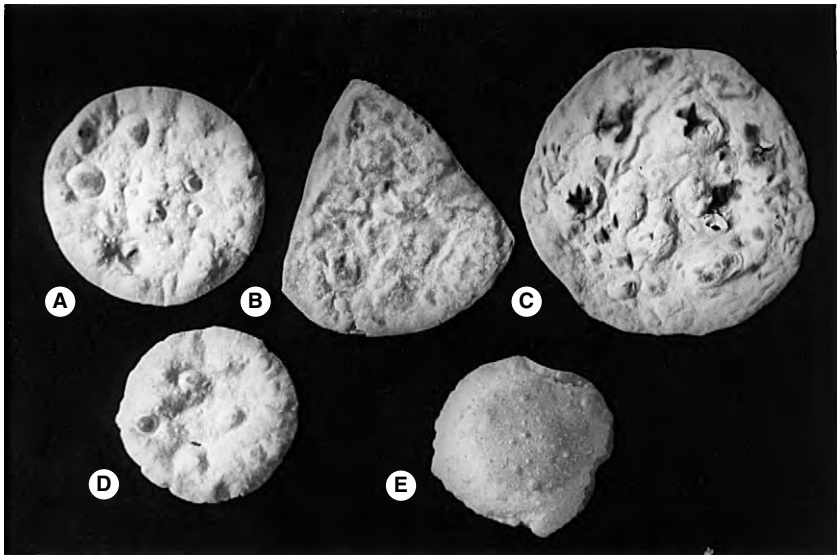

Figure 1 Chapati and its culinary variations. (A) Chapati, (B) parotha, (C) tandoori roti, (D) phulka, and (E) puri.

A typical baked aroma and slightly brittle and chewy texture are considered desirable.

Puri

Puri is also made from whole wheat flour but of 85–90% extraction. Like chapati, it has a thickness of 1.5–2.0 mm and a diameter of 10–12 cm. It is a deep-fat-fried product. The puri should completely puff on frying. A light golden brown color with full puffing, as well as a soft and pliable texture, are considered desirable.

Phulka

Phulka is very similar to chapati, except that it is very thin, with a thickness of only 0.80–1.2 mm and a diameter of 10–12 cm. The product is very light and fully puffed. It is made from whole-wheat flour and water, with fat and salt as optional ingredients. In some places, *phulka* made with fat is preferred, as it can be made into a very thin sheet and yields a highly pliable product. The sheeted dough is baked on a hotplate and puffed on live coals or on a fire.

The following products (Figure 2) are prepared from wheat flour obtained from a roller flour mill.

South Indian Parotha

South Indian parotha is made from refined wheat flour. This type of parotha is thick, with a thickness ranging from 5.0 to 7.5 mm and has a diameter of 15–20 cm. It is a laminated product. Since oil is applied during lamination, discrete layers are seen in the product. It is a soft and chewy product, creamish white in color, and slightly pliable.

Roomali Roti

Roomali roti is a very thin product made from wheat flour, milk powder, oil, and water. It is a very thin product with a thickness of 0.5–0.8 mm but has a large diameter of 60–90 cm. It is served after folding and is eaten along with other side dishes.

Nan

Nan is made using flour, salt, milk, milk powder, curd, baking soda, etc. Egg is an optional ingredient used to improve the color and texture of the product. The nan is circular or ellipsoidal, with a thickness of 4–6 mm, and is baked in a special tandoor oven similar to that used for tandoori roti. The product is creamish in color with dark spots on the surface with a typical baked flavor. Unlike chapati, crumb-to-crust ratio is higher. A soft texture is desired in the product.

Choice of Ingredients

Whole-wheat flour and water are the major ingredients used in the preparation of chapatis and other similar products. Salt and oil form the optional ingredients in products like chapatis and tandoori rotis and phulka, while they are essential in the preparation of parothas and stuffed parotha. Wheat flour, water, and oil are the major ingredients of South Indian parotha and roomali roti. In addition to wheat flour, milk and curd are also essential ingredients in the preparation of nan. Curd is used as a source of lactic acid bacteria.

Whole-wheat Flour

Whole-wheat flour, obtained by grinding wheat in a plate/disk mill, is preferred for the preparation of chapatis. The mill consists of two chilled-case corrugated iron plates placed vertically. One of the plates is stationary, while the other rotates. The wheat entering from the hopper is ground between the plates due to the shearing action as well as the friction. The particle size of the flour is adjusted by varying the clearance between the plates. It is desirable to grind wheat to a fine particle size, so that 80–90% can pass through a 60-mesh sieve. It is normal practice in households to remove 3–5% of the coarse bran from whole-wheat flour by sieving through a 30-mesh sieve. The resultant atta is also used for chapati making, as it is available at a lower price, being the byproduct of the roller flour-milling industry. There is little difference in the composition of resultant atta and whole-wheat flour, except that the former has lower contents of ash and damaged starch, while its water absorption capacity is appreciably less (see Table 1).

The higher water absorption capacity of whole-wheat flour is attributed to its greater damaged starch content. The resultant atta has 1.5 times as much thiamin and riboflavin and twice as much niacin as that of whole-wheat flour. (*See* **Niacin**: Properties and Determination; **Riboflavin**: Properties and Determination; **Starch** Structure, Properties, and Determination; **Thiamin**: Properties and Determination.)

Whole-wheat flour, obtained from medium-hard aestivum wheat, and with the quality characteristics listed in Table 2, is suitable for chapati-making. The dough should show an alveograph stability value of 100–200 mm, a strength of 15–20 $\times$ 10^{-4} m^2, and an extensibility of 0.20–0.27 m.

In the case of phulka, a very fine ground wheat is required, and normally, 100% will pass through a 60-mesh sieve. The grinding is normally done in a stone mill, which is similar to a plate mill, except that it has a pair of emery stones. The damaged starch content in such flour is very high, ranging from 18 to 20%. The

Figure 2 Wheat flour-based culinary variations of chapati. (A) South Indian parotha, (B) nan, and (C) roomali roti.

quality of the flour used for tandoori roti is similar to that used for chapati. The flour used for puri, however, has a lower ash content because 10–15% of coarse branny materials are removed by sieving; alternatively, whole-wheat flour can be blended with 20–25% of refined wheat flour.

Wheat Flour

Products such as roomali roti, nan, and South Indian parotha make use of wheat flour obtained by roller flour-milling of medium-hard wheat. The flour should have 9.5–10.5% protein and 0.5–0.7% ash.

Composite Flour

Part of the whole-wheat flour can also be replaced by other (i.e., non-wheat) cereal flours and flours obtained from legumes or millets, either to improve the taste and texture, or to improve the nutritional quality. Among the legume products used in this way, the most common is bengal gram flour, which is normally added at the 20–30% level; the chapati so made is locally known as a mesi roti. Other flours that are used, or could be used, in chapati making at levels ranging from 10 to 20% are defatted soya, groundnut, or cottonseed flours or refined flours from barley, bajra, sorghum, maize, cassava, and sweet potato. Triticale, a man-made cereal, was found to be unsuitable for chapati-making, but it can be used after blending with wheat flour in a ratio of 1:1. Soft wheat, which is also not suitable for chapati-making, can be improved by blending with hard wheat, or extra-hard durum wheat. (*See* **Barley**; **Cassava**: Uses as a Raw Material; **Sorghum**; **Soy(Soya) Beans**: The Crop; **Vegetables of Tropical Climates**: Root Crops of Uplands.)

Salt

Salt is generally dispersed in water and added to the dough. Hence, edible common salt of any particle size can be used.

Oil

Refined oil is used during dough preparation and during rolling and lamination of the dough sheet for the preparation of parotha and South Indian parotha. Solid fat (hydrogenated oil) can also be used, after it has been melted to make it easier to use during lamination. Solid or plastic fat can also be used in the preparation of the dough.

Egg

Egg is used as an optional ingredient in the preparation of nan. Fresh egg is normally used in the preparation. It is used to improve the color, texture, and flavor of nan.

Skimmed Milk Powder (SMP)

SMP is an optional ingredient used in the preparation of nan, while milk or SMP is an essential ingredient in the preparation of roomali roti. It is added to improve the texture, flavor, and color.

Table 1 Characteristics of resultant atta and whole-wheat flour

Characteristics[a] *(%)*	*Resultant atta*	*Whole-wheat flour*

Damaged starch (%)	16–18
Water-absorption capacity (%)[a]	72–78

[a]Required to prepare dough of optimum consistency.

Water

There is no information on the type of water suitable for chapati-making. Generally, any potable water, with a medium hardness and a pH value close to neutrality, is suitable. This is also true for other variants of chapati.

Influence of Ingredients

Whole-wheat Flour

Since whole-wheat flour is the major ingredient in the preparation of chapati and other products, its quality has a considerable influence on the quality of the end products. Whole-wheat flour obtained from medium-hard aestivum wheat is preferred, as it yields a chapati with the desired quality characteristics. The use of a strong wheat flour, with a protein content of more than 11.0%, results in a chapati with a tough and leathery texture, whereas a soft wheat, with less than 9% protein, yields a chapati with a stiff and brittle texture. Such chapatis also tend to become hard and brittle within an hour of storage. A wheat flour of a similar quality is also well suited for making tandoori roti, puri, and phulka.

The quality of a chapati also depends on the relative amounts of gliadin, glutenin, and residue protein present in the flour. A flour with equal amounts of the above proteins gives fully puffed chapatis with a soft texture, whereas a flour that has more residue proteins, or gliadin, gives a stiff and leathery chapati. A flour with a high content of total glutenin has been found to yield tandoori roti of a highly acceptable quality. The higher levels of polar lipids in flour result in chapatis with a soft texture.

In addition to the type of wheat, the content of damaged starch, the diastatic activity, and the sugars present in the flour affect the quality of a chapati. The higher the damaged starch content, the higher will be the water absorption capacity and hence, the softer the texture of the chapati. A significant direct correlation exists between damaged starch content and water absorption ($r = 0.89$, $P < 0.001$) and texture of chapatis ($r = 0.56$, $P < 0.001$). A flour with a high diastatic activity and sugar content yields a chapati with a sweetish taste.

The characteristics of chapati dough, which are influenced by the quality of the flour, affect the sensory qualities of the chapati. The sensory texture of a chapati is related significantly to farinograph consistency ($r = 0.47$, $P < 0.01$), extensograph extensibility ($r = -0.51$, $p < 0.01$) and resistance to extension ($r = 0.52$, $P < 0.01$), and textureometer cohesiveness ($r = -0.57$, $P < 0.01$).

Wheat with a low polyphenolase activity is desirable to avoid an excessive brownish color in the chapati. These enzymes are found to be low in Indian wheat varieties, whereas Mexican hybrid wheat varieties, now grown in India, have a high content of this enzyme. The adverse effect of enzymatic browning is greater when the chapati dough is rested for a longer period, or when the baked chapati is stored for a few hours.

Among the different *Triticum* species, the wheat, *T. aestivum*, which yields a nonsticky dough with good machinability, and a fully puffed chapati with soft and pliable texture, is most suitable for chapati preparation. When the species *T. durum* and *T. dicoccum* are used for chapati making, dry and hard-textured products result, which are perceived to be leathery when chewed. They are also sweeter due to the higher damaged starch content. In addition to the type and species of wheat, the severity of grinding and particle size of the flour play important roles in influencing the quality of chapatis and other similar products. Among the different types of mills (plate mill, hammer mill, pin mill, roller mill, etc.), the flour obtained from plate mills has been found to be the best for making chapati, tandoori roti, phulka, and puri. This is because of the greater severity of

grinding, which results in a flour with a desirable high damaged starch content, and hence a higher water absorption, resulting in a soft and pliable chapati. The soft and pliable characteristics are retained in products over a long storage period. The heat developed in such a mill during grinding tends to yield a chapati with a better flavor. Among the plate mills, the power- or water-driven mills are found to be better than hand-driven mills, as the latter yield flour with a low maltose figure of 1.72–1.99%, and a water-absorption capacity of just 66–69%, in contrast to the desired higher values of 2.6–4.65% for maltose content and 72–78% for water absorption.

A finely ground flour is desirable for chapati and tandoori roti-making. However, for phulka, the grinding should be much finer. The coarse flour, with more than 70–80% overtailing on a 10XX sieve (130 μm), yields a chapati with a poor appearance and tough texture. The shear force required to cut such chapatis, which is related to the sensory texture ($r = 0.67$, $P < 0.001$), is as high as 18–20 kg, compared with the force of 5–6 kg required for chapatis made from normal flour (20–30% overtailing). The quantity of water required to prepare the chapati dough of desired consistency is significantly related to the fraction passing through a 10XX sieve ($r = 0.89$, $P < 0.01$) and the protein content of the flour ($r = 0.53$, $P < 0.05$).

The extraction rate of flour has a considerable influence on the chapati quality. The quality of chapati is not affected by removing 4–6% of the coarse bran by sieving (extraction rate 94–96%), as is the practice in households. However, removing higher amounts of bran particles by sieving, or using a flour of a lower extraction rate, makes the chapati tough and leathery. Hence, to make good chapatis, a considerable amount of bran needs to be present in flour.

The chapati made from resultant atta is slightly tough and has a bland flavor; the latter is attributed to a lower damaged starch content, as well as to the negligible heat developed during grinding. The temperature reached while grinding in a roller flour mill can be as low as 30–40 °C, as against 90–95 °C in a plate mill. The high temperature reached during the milling operation seems to favor impartment of a wheaty aroma in chapatis. This is true for other products like tandoori roti, parotha, and puri.

If wheat is infected by kernel bunt, at infection levels above 3%, chapatis will have a dark color and an undesirable flavor. However, these adverse affects can be minimized by soaking or washing the infected grains before grinding. Storing whole-wheat flour for more than 3 months at a high temperature adversely affects the quality of chapatis.

Wheat flour

Roller-milled flour obtained from medium-hard wheat is used for the preparation of South Indian parotha, nan, and roomali roti. The protein content and the damaged starch in flour are related to the quality of South Indian parotha. The protein content of 9.5–10.5% and damaged starch of 10–12% are desirable (Table 3). The dough used for roomali roti and South Indian parotha should be quite extensible, but, at the same time, it should have sufficient strength. The optimum extensograph *R/E* value ranges between 4 and 5 for flours used in the above products. In nan, the optimum *R/E* value is 3–4.

Salt

Incorporation of salt in the dough reduces the stickiness and, hence, improves the sheeting characteristics of chapati dough and other similar products (doughs). The texture of the products is also improved considerably.

Oil

Incorporation of oil in the chapati dough improves the texture and pliability. It also keeps the chapati soft and pliable during storage. Puffing characteristics are also slightly improved on incorporation of very small amounts of oil in the dough. Higher levels of fat or shortening in the dough reduce the puffing quality of chapatis.

Discrete layers in a parotha are due to the application of oil during lamination. Oil is also used during the dough preparation to improve the rolling property. Oil is used extensively during stretching and rolling in the preparation of South Indian parotta, while it is used in dough as well as stretching in the preparation of roomali roti. Application of oil during lamination helps to produce discrete laminations in South Indian parotha. However, in the case of roomali roti, the oil helps to produce a very thin sheet of dough.

Water

The amount of water required to prepare a dough of optimum consistency for chapati preparation ranges from 70 to 80%. The amount depends on several factors, such as the type of wheat, grinding method, extraction rate, particle size distribution, severity of grinding, etc. The higher the water requirement, the softer will be the texture of the chapati and the sweeter the taste. Such chapatis keep well on storage. The amount of water required for phulka is higher and ranges from 75 to 80%. The dough for the prep-

aration of tandoori roti requires slightly higher levels of water as the dough is made slightly loose to enable sheeting between two palms. The South Indian parotha and roomali roti require less water since they are made from wheat flour milled in a roller flour mill with a low damaged starch content; moreover, oil in dough reduces the water absorption capacity.

Additives

The incorporation of yeast (0.5%) or yogurt (10%) softens the texture, which is also retained during storage. Emulsifiers or surfactants, such as glycerol monostearate, sucrose esters, and sodium stearoyl lactylate (SSL), and the enzyme, amylase, also improve the texture of a chapati as well as its keeping quality. The use of glycerol monostearate (GMS) in nan improves its texture. Incorporation of SSL and DATEM (diacetyl tartaric acid esters of monoglycerides) improves the softness of South Indian parotha. Cysteine, HCl at a level of 50 ppm further improves the machinability of the dough and texture of South Indian parotha. (*See* **Emulsifiers**: Organic Emulsifiers; **Enzymes**: Uses in Food Processing.)

Methods of Production

Chapatis and their culinary variations are generally freshly made and served, while still hot, in households, restaurants, and industrial canteens. Fresh, hot chapatis are preferred, as they have a better flavor and soft texture. Consequently, chapatis produced on a large scale and marketed in unit packs have not become popular among consumers.

Chapati

The method of preparation of chapatis involves three important steps, *viz*. preparation of the dough, sheeting, and baking-cum-puffing (Figure 3).

The main ingredients used in chapatis are whole-wheat flour, or resultant atta, and water. The water level varies from 65 to 75%, depending on the type of wheat and the milling method. In households, and even in restaurants, the dough is kneaded by hand to a consistency that is stiffer than bread dough, but enables easy sheeting without sticking to the base of the rolling pin. In large industrial canteens, however, either a planetary vertical mixer with a U-shaped blade, or a horizontal mixer similar to that used for bread dough, is used. The dough is mixed for 10–15 min, for complete development of the gluten, rested for a period ranging from 30 to 120 min depending on the convenience. Normally, dough is rested for proper hydration and for stress relaxation, which enables easy sheeting with minimal stickiness. The optimum resting time required is shorter (15–20 min) for a dough mixed in a mixer but longer for hand-mixed dough (30–120 min).

The dough is divided into 35–40 g pieces and then rounded between the palms. The rounded dough is sheeted (using a rolling pin) to a circular shape of about 15 cm in diameter and 1.5–2.0 mm in thickness. Dusting with flour is normally done to reduce the stickiness. The rolled circular dough sheet is then baked on each side on a heated shallow iron plate (200–220 °C), for a total time of 1–2 min. At the final stages of baking on the second side, the surface of the chapati is gently pressed with a clean dry cloth for puffing. Alternatively, puffing can also be done by placing the chapati immediately after baking on a gas flame or live, glowing coals for a few seconds. The hot chapati is served either as such, or after smearing the surface with fat, preferably ghee or butter.

As yet, little work has been carried out on the mechanization of chapati production, particularly with respect to sheeting or baking. However, in some countries, the equipment generally used for the manufacture of tortillas is also used for chapati sheeting

Table 3 Quality characteristics of flour suitable for chapati and its variants

Characteristics	*Whole-wheat flour*				*Wheat flour*	
	Chapati	*Phulka*	*Tandoori roti*	*Puri*	*South Indian parotha*	*Nan*
Ash (%)	1.2–1.5	1.2–1.5	1.2–1.5	1.0–1.2	0.5–1.0	0.5–1.0

and baking. A few mechanized chapati-sheeting units have been developed, and are being used in restaurants and industrial canteens. (*See* **Tortillas**.)

Sheeting of dough using a rolling pin is time-consuming and requires experienced persons to produce chapatis with a circular shape as well as uniform size and thickness.

Shaping by Pressing

Simple machines are now available to shape chapati dough. A 'Hillif' chapati press with a capacity to produce 100–200 chapatis per hour is used in some households and restaurants for sheeting. It consists of two circular cast iron disks connected by a hinge. The contacting surfaces are covered with Teflon sheets. A lever-type handle is attached to the bottom disk. About 30–40 g of dough are placed at the center of the bottom disk and covered by the top disk, and pressure is applied to the top disk for a few seconds with the help of the lever.

The pressed chapati is removed carefully and baked. Oil is applied to the surface of the disk to avoid sticking.

Another mechanical device available for flattening chapati dough is based on the principle of the can flanker, and consists of two disks, one fixed, the other movable. A toggle mechanism is used to press the dough, which is placed in between the disks, as it develops a high pressure with little effort. The thickness of the chapati can be varied by adjusting the clearance between the disks. The bottom plate, on which 40–50 g of dough have been placed, is made to press onto the top disk, with the help of a pedal connected to the toggle. This machine has the capacity to produce 200–300 chapatis per hour. This device is either hand- or foot-operated.

Shaping by Sheeting

All the equipment described above is of the batch type. Hence, little effort has been made to develop continuous shaping machines for shaping by sheeting, which is accomplished by feeding the dough through a hopper and passing it through four sets of roller to attain the desired thickness. The sheet then passes under a rubber-lined drum, and is cut (or stumped) with a Teflon-coated cutter of 18 cm diameter. The scrap dough is fed back to the hopper. The machine has the capacity to produce 1200–1800 chapatis per hour. Some machines, based on continuous sheeting and rotary cutting, are now available for the shaping of chapati dough.

Shaping and Baking

A new device, known as a 'roti maker', is now on the market. It can be used for shaping, baking, and puffing. The device is similar to the 'Hillif' chapati press, but the two disks are heated through the electric coil attached to the disk. About 30–40 g of dough are placed at the center of the bottom disk. The pressure is applied at the top disk for a few seconds

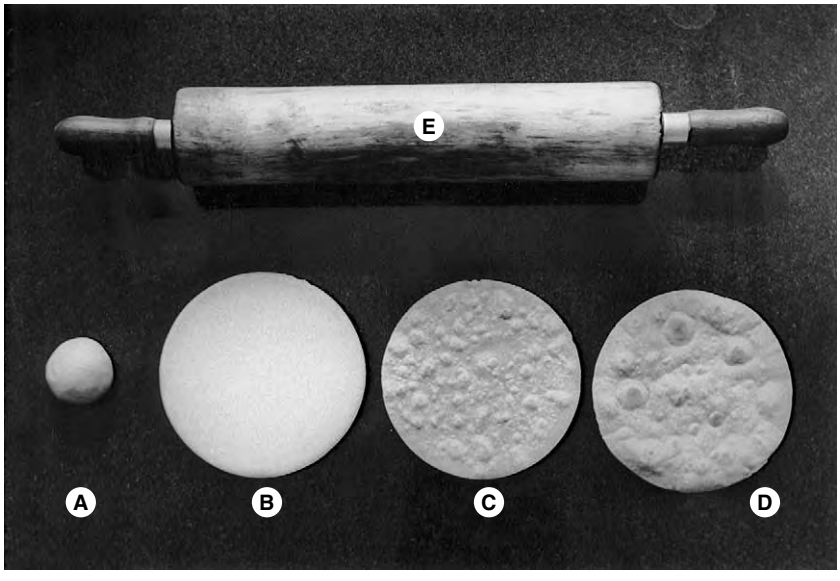

Figure 3 Method of preparation of chapati. (A) Dough ball, (B) sheeted dough, (C) partially baked chapati, (D) puffed chapati, and (E) rolling pin.

and allowed to bake. The chapati gets baked and lifts the top disk while puffing, and the puffed chapati is removed and served.

Continuous Shaping, Baking, and Puffing Units

A continuous chapati-making machine, designed and developed by Central Food Technological Research Institute, Mysore, India, is being fabricated by different machine manufacturers, and is now on the market (Figure 4). The machine has the capacity to produce 600–800 chapatis per hour. The process involves preparation of the dough in a planetary mixer. The dough is continuously conveyed to the extruder. A fish tile die moves the dough sheet to the endless belt conveyor. The sheet travels on the conveyor and passes through a rotary cutter and gets uniformly cut into a circular shape. These chapati sheets enter the baking chamber, while the remaining/cut portions of the sheet are trapped and returned to the extruder. The fuel used for baking is liquid propane gas. The baking chamber consists of a three-tier endless conveyor system. The conveyors are heated by ribbon burners at the bottom. At the third stage, the chapatis are exposed to a direct flame to yield a puffed product, which is collected in a tray.

Phulka

The preparation method, ingredients, and consistency of the dough are similar to those of chapatis. However, the flour requires higher amounts of water (75–80%) to form the dough. About 20–25 g dough are sheeted using a rolling pin to a very thin circular sheet (0.8–1.0 mm) of about 8–12 cm in diameter. The dough sheet is baked on each side on a shallow heated iron plate or hot plate maintained at 200–220 °C for 1–1.5 min and puffed on glowing coal or a live fire. In view of the lighter weight, puffing of phulka is complete. Hot phulka is consumed after smearing with oil, ghee, or butter before serving.

Phulka is also prepared using salt (0.5%) and oil (4–6%) in the dough. This helps in sheeting the dough very thinly, and the resulting phulka will have a softer texture. Phulka, particularly that made with salt and oil, can remain mold-free for about 5–6 days.

Puri

Puri is a deep-fat-fried product made from a whole-wheat flour of low extraction rate 85–90%. The dough made by kneading flour and water is sheeted to a thickness of 1.5–2 mm and a diameter of 10–12 cm using a rolling pin. The sheeted dough is deep-fat-fried in oil maintained at 180–200 °C for about 1 min with intermittent turning. The frying is continued till the puri puffs fully and results in a light golden brown color. Intermittent pressing of puri while frying with perforated ladle helps in puffing. Puri is then removed from the oil bath with a perforated ladle. It is normally consumed hot, along with boiled and spiced vegetables.

Parotha

The dough made by kneading whole-wheat flour, salt (1.0–2%), fat (2–5%) and water (65–70%) is divided into pieces of 35–45 g and sheeted, using a rolling pin, to a circular shape of 10 cm diameter. Then, oil is applied to the top surface (1–2 g) and spread uniformly. The sheet is folded into a semicircle, and oil is again uniformly applied over the surface (0.5–1.0 g); the semicircle is then folded into a quarter circle. This laminated piece of dough is then sheeted (by rolling) into the shape of a triangle with a thickness of 2–3 mm, and sides of 15–18 cm in length. The sheeted dough is baked on an electric hotplate or heated shallow iron plate, for about 1–2 min until the color becomes light brown. Oil is applied to both sides (1–2 g) while baking (Figure 5).

No attempt has been made so far to mechanize the sheeting and lamination processes in parotha-making.

Stuffed Parotha

A parotha stuffed with vegetables and spices, so that it may be eaten as such, without any side dishes, is known as ‘stuffed parotha’. The dough for stuffed parothas is made in the same manner as that for parothas. A filling is prepared by adding chopped onion (25 g), salt (1 g) and chilli powder (0.5 g) to

Figure 4 Chapati-making machine.

boiled, peeled, and mashed potato (100 g), and mixing the ingredients well. A small portion of filling (about 20 g) is placed on the center of the sheeted dough (5 cm diameter). The dough is folded over the filling to make a ball again. The dough is then rolled into a circular shape (12–15 cm) and baked on a hotplate by applying oil or butter to both sides.

The ingredients of the filling may be changed, depending on the availability of vegetables and preferences of consumers. Stuffed parothas can be prepared using radish, cauliflower, fenugreek leaves, etc. Sometimes, vegetables are mashed and mixed along with dough and parothas prepared in the normal manner.

Tandoori Roti

The ingredients used are the same as those used for a chapati, except that salt (1.25–1.5%) is sometimes added. The quantity of dough used for a tandoori roti is higher (40–60 g) than for a chapati (35–40 g). The dough is flattened by beating and pressing between the hands to a thickness of 4–6 mm and a diameter of 15–18 cm. The sheeted dough is baked in an oval-shaped oven, the walls of which are plastered with clay (a tandoor, Figure 6). The oven is heated by burning wood or coal in the bottom. The sheeted dough is placed on a cloth pad, and pasted to the heated walls of the tandoor. Depending on the temperature of the tandoor, the roti is baked in 60–90 s. When the roti has been baked properly, it falls from the side of the wall to the bottom surface. The baked roti is then taken out, using a long L-shaped iron rod. The major heat transfer in a tandoor oven is mainly by radiation, though some heating also occurs through conduction and convection.

South Indian Parotha

The dough is prepared by mixing wheat flour (100%), salt (1.0%), sugar (0.5%), egg (0.1%) and water (55–58%). It is then rested for 30 min, divided into 75 g portions, rounded and again rested for 10 min. Next, the dough is sheeted with a rolling pin, and oil is applied while sheeting. The thin dough sheet thus obtained is folded to form multiple layers and then coiled (Figure 7). The coiled dough is rested for 10 min, then sheeted again to a final thickness of 5 mm using a rolling pin. The dough sheet is then baked at 230–240 °C for 2 min on a hotplate, or on a shallow iron plate heated by gas or coal, and turned every 15 s. Oil is applied during baking, and the parotha is served hot and consumed along with spiced boiled vegetables.

Nan

Nan is prepared from refined wheat flour. The dough is made from wheat flour (100%), milk (6%), curd (12%), salt (1%), baking soda (0.5%), fat (4%), and egg (3%). The dough is fermented for 4 h; thereafter, 80 g of dough are sheeted to a thickness of 2.5 mm, using a rolling pin, and baked in a tandoor oven maintained at 350–365 °C for 60 s. Nan is served hot, and it is normally made in restaurants or

Figure 6 Tandoor oven.

small shops known as 'Dhabas', using a tandoor oven similar to that used for the preparation of tandoor roti.

Roomali Roti

Roomali roti is prepared using refined wheat flour, milk powder, fat, salt, and water. The dough made by mixing these ingredients is rested for about 30 min. About 100–200 g of the dough are stretched through fingers to a very thin transparent sheet, to a thickness of 0.5–0.8 mm and a diameter of 60–90 cm. The dough sheet is then placed on a heated (350–360 °C), inverted shallow iron plate and baked for 60–90 s. The baked roomali roti is semi-folded, quarter-folded, and served hot.

Handling, Storage, and Distribution

As already mentioned, chapatis and other similar products are normally consumed fresh and hot. On storage, they stale, becoming brittle, and hard, and lose their typical flavor; hence, they are not liked by consumers. The very short keeping quality of chapatis poses serious problems when they have to be served to a large number of consumers at one time, as in industrial canteens or in restaurants. A good chapati would be expected to retain its soft, pliable texture for at least 2–3 h. No serious mechanization attempts have been made to enable large-scale preparation and distribution of such products. Persistent research and development efforts are also being made in different parts of the world to improve upon the storage and distribution of chapatis. However, in some parts of the world, the baked chapati is now being marketed in unit packs. These chapatis need to be stored in a refrigerated condition. They are heated or warmed in a microwave oven before consumption.

The chapati, being a high-moisture product, containing 28–30% moisture, stales like bread or cake, becoming less acceptable on storage. Compared with other bakery products, a perceptible staling is observed on cooling. Further storage tends to make chapatis hard and brittle. In addition to these changes, mold growth also occurs after 3–4 days of storage.

Sorbic acid is normally used as an antifungal agent for preserving chapatis/parothas. The maximum level that could be incorporated without affecting the taste is 0.1%. The mold growth is delayed by 2–3 days at this level. However, the use of a higher level of sorbic acid (0.3%) along with 1.5% salt, and packing in polythene (200 gauge), or in an aluminum foil/polythene laminate, can delay mold growth for as long as 180 days. Sorbic acid is found to be a better preservative than its potassium salt. The level of sorbic acid could be reduced further either by including 0.4% citric acid, 3% sugar, and 2.5% salt in the recipe, or by heating the packed chapatis for 2 h at 90 °C. The chapatis made for defense personnel are preserved by in-pack heat sterilization after being packed in paper/foil/polylaminate. Such chapatis can be preserved for 180 days. Subjecting packed chapatis/parothas to γ radiation of 1 Mrad also delays the mold growth for 180 days. Parothas can be preserved well for 10 months by using 0.19% sorbic acid and 1.6% salt; the inner pack, made of MST (moisture-proof sealable and transparent) cellophane, is repacked in paper/foil/polythene pouches. (*See* **Spoilage**: Molds in Spoilage.)

A shelf-life of one year can be obtained for products such as chapatis/parothas/stuffed parothas by packing under a moderate vacuum of about 560 mmHg in sanitary cans, and heating in an oven at 115–120 °C for 1 h.

For civilian consumption, polypropylene or polythene metallized polyester laminate pouches are

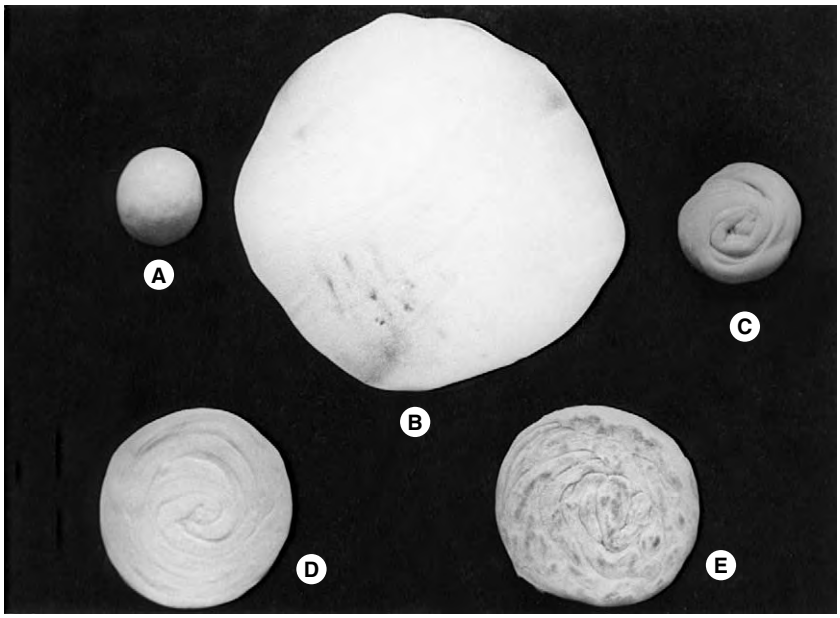

Figure 7 Method of preparation of South Indian parotha. (A) Dough ball, (B) circular dough sheet, (C) coiled dough sheet, (D) sheeted South Indian parotha, and (F) baked South Indian parotha.

found to be quite adequate. Four chapatis are packed and sealed in each pouch. The individual packets are then packed in fiberboard boxes for transportation.

The puri can be stored for a slightly longer period of 4–5 days, but it becomes hard and brittle within 2–3 days. South Indian parotha remains mold-free only for 3–4 days. Its life could be extended using sorbic acid at 0.15% level, but the parotha can become hard and brittle. The tandoor roti and nan also can be stored for the same period as a chapati. No serious efforts have been made to market these products in unit packs.

CHEESES

Contents

Types of Cheese

N F Olson, University of Wisconsin, Madison, WI, USA

Definition of Cheese

Like many fermentation-derived food products, cheese cannot be easily and succinctly defined. Early versions of cheese were likely a soft gel/curd formed through acidification of milk from a mammal by contaminating lactic acid bacteria. A general definition of cheese has recently been accepted by international food regulatory bodies, which illustrates the complexity of defining this complex food. It is defined as the ripened or unripened soft or semi-hard, hard or extra-hard product, which may be coated, and in which the whey protein:casein ratio does not exceed that of milk, obtained by: (1) coagulating wholly or partly the protein of milk, skimmed milk, partly skimmed milk, cream, whey cream or buttermilk, or any combination of these materials, through the action of rennet or other suitable coagulating agents, and by partially draining the whey resulting from such coagulation; and/or (2) processing techniques involving coagulation of the protein of milk and/or products obtained from milk which give an end product with similar physical, chemical and organoleptic characteristics defined under the Codex Committee entry in the Further Reading section.

History of Cheese

The large number of different names (varieties) of cheeses resulted from the long history of cheese manufacturing, the use of milk from various animals, and development of unique technologies usually by accident but also dictated by environmental conditions. These differences were further compounded by the isolation of cheese manufacturing regions and differences in languages that resulted in cheeses that were similar but were given different names. Regional and nationalistic pride institutionalized the plethora of names of cheeses, which is estimated to exceed 1000. Subsequent trade between regions spread the notoriety and consumption of certain cheese varieties, presumably based upon their acceptable characteristics but also their ability to retain desirability during transport.

It is generally accepted that cheese as a distinct product evolved in the Middle East, specifically in the Fertile Crescent between the Tigris and Euphrates rivers. Domestication of animals such as goats and sheep led to their use as sources of meat, milk, and hides. These early herdsmen must have deduced that suckling animals derived satisfaction and growth promoting factors from the mothers' milk. Gaining sustenance from a product without sacrificing the animal for meat would likely have led to taking a portion of the mothers' milk for human consumption. The highly nutritious blend of components in milk promoted the growth of various microorganisms, including lactic acid-producing bacteria that

would be common contaminants from the environment. The soured milk was too precious to be disposed, leading to an acquired taste for this product. Handling of the clotted milk caused separation of a serum (whey) and yielded the first acid coagulated cheeses (*See* **Cheeses**: Soft and Special Varieties; Quarg and Fromage Frais). The practice of storing and transporting milk in animal skins, including stomachs, also clotted the milk by enzymes such as chymosin and pepsin that leached from the stomach lining, which yielded a gel that differed in characteristics from the acid-coagulated curd (*See* **Cheeses**: Chemistry of Gel Formation). Jostling in the bag caused separation of whey that yielded curd, the precursor of a wide range of enzyme (rennet)-clotted cheeses.

The release of the whey from the curd and the hardening of the cheese probably prompted the existing artisans to further dehydrate the curd by techniques similar to the primitive practices used for air-drying of meats. Curds produced by the action of the stomach enzymes were more conducive to dehydration, which greatly extended the storage and transportation of these cheese types.

The evolution of using sodium chloride and heat to preserve various foods was applied to the acid- and rennet-coagulated curds and created more diversity in the characteristics of cheeses that were given unique names. Modern cheese varieties such as highly salted Feta and Domiati cheeses (*See* **Cheeses**: White Brined Varieties) and the heat-plasticized Provolone and Mozzarella cheeses are examples of this evolution.

Travel and trade introduced cheeses with other valued goods to widespread regions and cultures. Introduction of cheeses into different climatic conditions altered the type of microorganisms and their rate of growth in the cheese curd and, consequently, the characteristics of the resulting cheeses. Lower temperatures minimized the need for high sodium chloride levels and use of higher heat treatments as means of preservation. The requirement for low moisture contents was also lessened. Artisans in Central Europe undoubtedly recognized that cooler temperatures in the spring and autumn yielded cheeses of better quality. They also would have known about cool caves in their localities and started the practice of storing cheese in caves or in cooler areas of their dwellings. Under these conditions that imposed fairly consistent temperature and humidity, various proportions of fungal and bacterial growth occurred that imparted unique and desired characteristics. Surface-ripened cheeses such as Camembert, Roquefort, and Munster are current varieties that evolved from such conditions (*See* **Cheeses**: Surface Mold-Ripened Cheese Varieties). Artisans in the mountainous areas of Europe, bordering on Mediterranean regions, would have been familar with cheese varieties that were subjected to a higher temperature during manufacturing. Storing such cheeses or derivatives of such cheeses at lower mountainous temperatures and with an accidental or deliberate reduction of the sodium chloride content would promote the growth of eye-forming bacteria, resulting in present-day Swiss-type cheeses (*See* **Cheeses**: Cheeses with 'Eyes').

The evolution of varietal cheese development has been, and still is, a continuous process. Varieties introduced within the past century have generally been variants of recognized cheese varieties. None of the existing major cheese varieties was the result of deliberate responses to consumer demands and by technologies developed specifically to achieve the consumer-driven demand. All were the results of accidental geneses and subsequent derivations. Science and technology have been vital in optimizing the quality, uniformity, and ability to modify defined characteristics either within the variety or to produce derivatives of the original variety (*See* Chemistry of Gel Formation; **Cheeses**: Chemistry and Microbiology of Maturation). Science and technology will become increasingly important in controlling the functional characteristics of cheeses in the future. Traditional cheese varieties will be altered to attain unique flavors and physical properties that will differ substantially from the original variety. These derived types are used as food ingredients to enhance and modify the food, to which the cheeses are added, a trend that will increase in the future.

Classification of Cheese

Cheese technologists and merchandizers of cheese have attempted to categorize cheeses based upon various criteria. Segregating cheeses by national origins may be useful for marketing purposes, but this approach has few technological bases for categorization, and the production of a given variety may be globally dispersed. A good example is Cheddar cheese, which originated in England, but now, more is produced in North America and in Oceania than the country of origin. Similarly, production of Swiss cheese and surface-ripened French cheeses occurs throughout the world.

Scientists and technologists have generally categorized cheeses based upon composition, manufacturing methods, and systems for maturing or aging cheese. One scheme differentiates varieties by the type of microbial primary and secondary starters (*See*

Cheeses: Starter Cultures Employed in Cheese-making) used in manufacturing and maturation of cheeses and by the moisture content or, more specifically, the ratio of moisture to protein in cheeses. This scheme would differentiate cheeses on the basis of flavor and physical characteristics but would include only natural cheeses, which are generally defined as those varieties derived from milk or milk components. A similar approach suggested that there were only 18 distinct types of natural cheeses that could be categorized into eight families based on firmness of the varieties and the method of maturation (Table 1).

Slightly more comprehensive classifications differentiated varieties by composition, firmness, and maturation/flavoring agents (Table 2) or by manufacturing and maturation processes (Table 3). The system used in Table 2 expands the differentiation of natural cheeses, includes cheeses made from whey and introduces a new category of cheeses that attribute their dominant flavor to added spices or ingredients. Cheese types are divided into two major categories, natural and process cheeses, and the natural cheeses are divided into those in which the curd is formed either by acid or by enzymes in Table 3. This classification introduces the category of process cheeses, which are produced by heating and melting natural cheeses with the aid of calcium-chelating emulsifying salts (*See* **Cheeses:** Processed Cheese).

The previous classification systems were integrated into a comprehensive categorization shown in Figure 1. Although process cheeses are not included, a detailed differentiation of natural cheeses based upon methods of clotting milk, maturation agents, and composition gives a good overview of the diversity of cheeses. There is also merit in the initial division into four 'superfamilies' based upon differences in curd formation. The method of coagulating milk or milk components (curd formation) yields distinctly different end products because of the chemistry of the coagulum (*See* **Cheeses:** Chemistry of Gel Formation). Although there is heterogeneity within the families of cheeses formed by acid coagulation, heat/acid coagulation, and concentration/crystallization, these differences are less than those between families. The most diverse family contains cheeses formed by rennet coagulation. Dividing this family into classes based on the location and major types of microorganisms that distinguish the classes is useful from technological and marketing standpoints. The most diverse category is the surface-ripened cheeses that have a heterogeneous surface flora that can include molds. However, these cheeses are distinct from the surface mold-ripened cheeses. The major cheese varieties, in terms of breadth of type and of amounts produced, are included in the internal bacterially ripened cheese category. The extra-hard, hard, and semihard cheeses vary in moisture contents (moisture:protein ratios) but are similar in containing a mixture of bacteria within the cheese to create the flavors and desired maturity of the particular type (*See* **Cheeses:** Manufacture of Extra-hard Cheeses; Manufacture of Hard and Semi-hard Varieties of Cheese). The extra-hard types are generally distinguished by high numbers of heat-tolerant lactic acid-producing bacteria that evolved from the practice of heating the curd and whey to high temperatures during manufacturing. The severe heat treatments were not used in the manufacturing of the hard and semihard types, resulting in higher moisture contents; different types of lactic-acid producing bacteria dominating the flora of such cheeses during manufacturing and early stages of maturation (*See* **Cheeses:** Starter Cultures Employed in Cheese-making). These same effects of heat treatments resulted in two classes of cheese with eyes. Higher temperatures and lower concentrations of salt promoted the heat-tolerant lactic bacteria plus the eye-forming propionibacteria in Swiss-type cheeses. Lower temperatures during manufacturing and early maturation of Dutch-type cheeses created the environment for the mesophilic lactic bacteria and lactic bacteria that form eyes through metabolism of citrate in the cheese. The flavor and physical properties of the types with eyes usually differ, but variants of these types can be quite similar, as exemplified by the recently developed Maasdam cheese and highly aged Gouda cheese. The classification in Figure 1 also segregates varieties that evolved from the early practices of preservation by using high levels of sodium

Table 1 Classification of cheeses based on firmness and maturation processes

Very hard (grating)
Ripened by bacteria (e.g., Parmesan)
Hard
Ripened by bacteria that form eyes in cheese (e.g., Swiss)
Ripened by bacteria without eye formation (e.g., Cheddar)
Semisoft
Ripened principally by bacteria (e.g., Gouda)
Ripened by bacteria and surface microorganisms (e.g., Limburger)
Ripened principally by blue mold in the interior of the cheese (e.g., Roquefort)
Soft
Ripened (e.g., Brie)
Unripened (e.g., cottage)

Fox PF, Guinee TP, Cogan TM and McSweeney PL (2000) *Fundamentals of Cheese Science*, pp. 1–18, 388–428. Gaithersburg, MD: Aspen.

Table 2 Classification of cheeses according to composition, firmness, and maturation agents

Soft Cheese (50–80% moisture)
- *Unripened – low-fat*
  - Cottage
  - Quark
  - Baker's
- *Unripened – high-fat*
  - Cream
  - Neufchâtel
- *Unripened stretched curd or pasta filata cheese*
  - Mozzarella
  - Scamorze
- *Ripened by external mold growth*
  - Camembert
  - Brie
- *Ripened by bacterial fermentation*
  - Kochkse
  - Handkse
  - Caciotta (ewe or goat)
- *Salt-cured or pickled*
  - Feta – Greek
  - Domiati – Egyptian
- *Surface-ripened*
  - Liederkranz

Semisoft Cheese (39–50% moisture)
- *Ripened by internal mold growth*
  - Blue
  - Gorgonzola
  - Roquefort (sheep's milk)
- *Surface-ripened by bacteria and yeast (surface smear)*
  - Limburger
  - Brick
  - Trappist
  - Port du Salut, St. Paulin
  - Oka
- *Ripened primarily by internal bacterial fermentation but may also have some surface growth*
  - Mnster
  - Bel Paese
  - Tilsiter
- *Ripened by internal bacterial fermentation*
  - Pasta Filata
  - Provolone
  - Low-moisture Mozzarella
- *Internally ripened by bacterial fermentation plus CO_2 production resulting in holes or 'eyes'*
  - Gouda
  - Edam
  - Samsoe

Hard Cheese (maximum 39–40% moisture)
- *Internally ripened by bacterial fermentation*
  - Cheddar
  - Colby
  - Caciocavallo
- *Internally ripened by bacterial fermentation plus CO_2 production resulting in holes or 'eyes'*
  - Swiss (Emmental)
  - Gruyere
- *Internally ripened by mold growth*
  - Stilton

Very hard cheese (maximum 34% moisture)
- Asiago Old
- Parmesan, Parmigiano, Grana
- Romano
- Sardo

Whey cheese
- *Heat and acid denaturation of whey protein*
  - Ricotta (60% moisture)
- *Condensing of whey by heat and water evaporation*
  - Gjetost (goat milk whey, 13% moisture)
  - Myost, Primost (13–18% moisture)

Spiced cheese
- Caraway – caraway seeds
- Noekkelost – cumin, cloves
- Kuminost – cumin, caraway seeds
- Pepper – peppers
- Sapsago – hard grating, clover

Table 3 Classification of cheeses by manufacturing and maturation processes

Natural cheeses
- Cheese varieties in which milk is clotted by acid:
  - Cottage cheese
  - Baker's cheese
  - Cream cheese
  - Neufchâtel cheese
- Cheese varieties in which milk is clotted by proteases:
  - Cheddar cheese
  - Colby and stirred curd (granular) cheese
  - Surface-ripened cheeses – Brick cheese, Limburger cheese, Port du Salut, Bel Paese, Tilsit cheeses
  - Other semisoft cheeses – Edam, Gouda, Monterey, Mnster cheeses
  - Cheeses with eyes – Swiss, Gruyère, Samsoe
  - Italian type
    - Very hard (grating) – Parmesan, Romano
    - Other hard – Asiago, Fontina
    - Pasta Filata – Provolone, Mozzarella
  - Mold-ripened
    - Blue, Roquefort
    - Cheese with surface mold – Camembert, Brie, Coulommiers

Process cheese
- Processed Swiss, processed Cheddar, etc.
- Cold-pack cheese

chloride or high heat treatments of the curd (*pasta-filata* varieties). The need for preservation has lessened so that modern versions of the high salt cheeses may contain salt concentrations sufficient to satisfy tastes of consumers. The *pasta-filata* types, especially Mozzarella cheese, have become global favorites as ingredients in a variety of foods, especially pizza. It is unlikely that the originators of Mozzarella cheese envisioned that heat preservation would yield a product that possessed the functional stability and melt properties that fit the requirements as an ingredient in pizza. Acute perception of

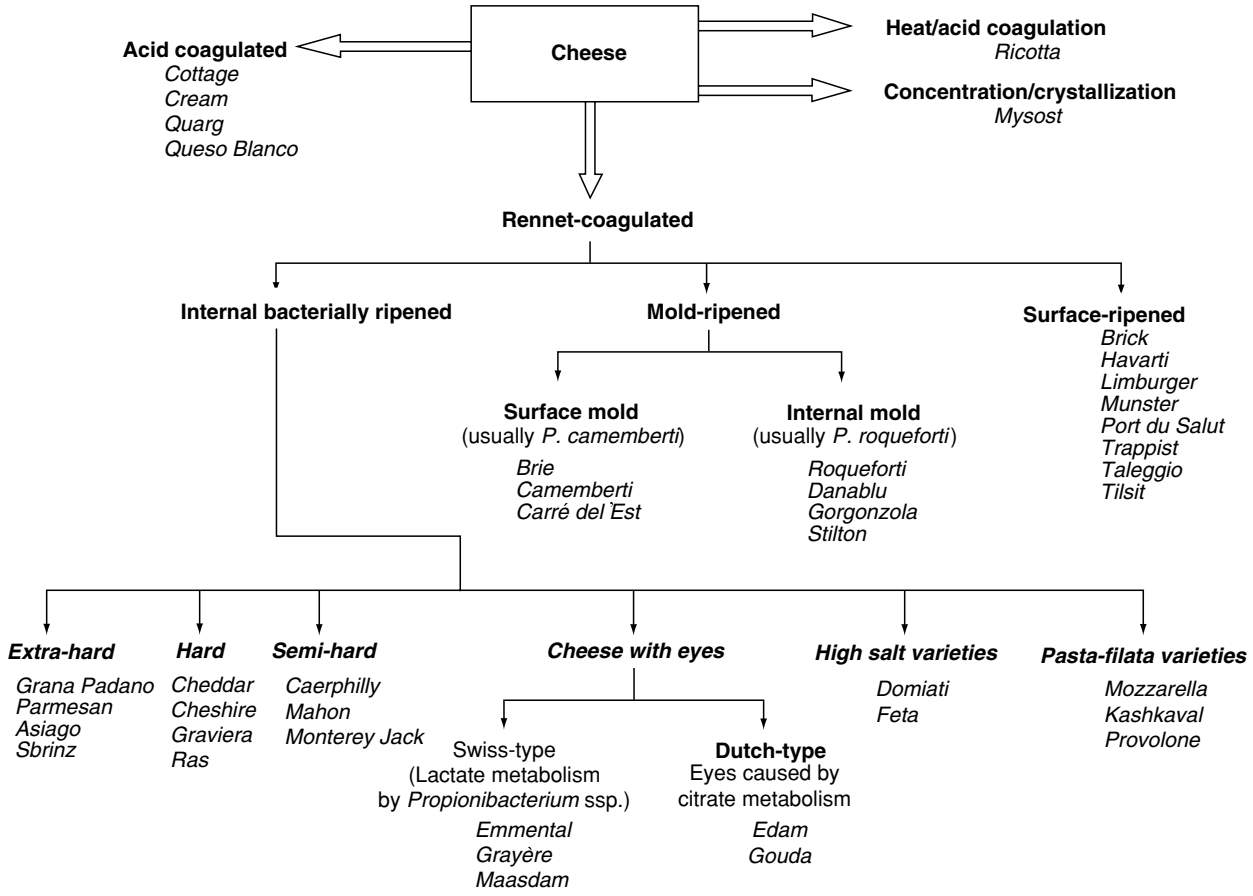

Figure 1 Classification of cheese into superfamilies based on the method of coagulation of milk or milk components with further subdivision based on the principal ripening agents and/or characteristic technology. accidents in food preparation and subsequent science and technology created this unexpected and widespread usage.

Homogeneity and Diversity

In spite of the great number of cheese types, there are common elements in the manufacture of all varieties of cheese. These are clotting of milk to yield a curd, expulsion of serum/whey from the curd, forming the grains of curd into a final shape, and storage either for very limited periods for unaged cheeses or for varying lengths of time to attain the desired flavor and physical characteristics (*See* **Cheeses:** Chemistry and Microbiology of Maturation). The organization of these elements and the flow of the cheesemaking process are illustrated in Figure 2. The bases for diversity in cheeses are also evident in Figure 2 starting with the type, composition, chemistry, and biology of the milk. Agents and conditions at each of the steps in cheese manufacturing impart specific effects that create further diversity to create a cheese type with unique flavor, texture, and functional properties. Additional discussion of the microbiology, chemistry, and technologies of important cheese types are given in the succeeding articles.

Starter Cultures Employed in Cheese-making

G Stanley, Rhodia Food UK Ltd, Woodley, Stockport, UK

Background

The bacteria used in cheesemaking are commonly referred to as 'lactic acid bacteria' (LAB), having lactic acid as their main end product of lactose and other sugar fermentations. It is this acid that plays a major role in the preservation of cheese. Cheesemaking LAB have a 'Generally Regarded As Safe' (GRAS) status and are roughly divided into mesophilic and thermophilic types. Commercial cheese cultures are used for the production of the majority of the developed world's cheeses and for the most part are balanced blends of selected single strain cultures. Such preparations are offered in either a direct vat inoculation (DVI) or a bulk starter (BS) format.

Development of Starter Cultures

LAB occur naturally in raw milk, and initially, cheesemaking relied on these indigenous bacteria to promote acid production; however, this must have resulted in very variable fermentations. Cheesemakers soon developed the technique of inoculating fresh milk with whey from the previous day's cheesemaking – a crude form of starter inoculation, but a technique that is still used in some cheesemaking operations today. The first commercial cultures were prepared as powdered starters by Chr. Hansen Laboratories (Denmark) just before the end of the nineteenth century. These were likely to have been mixtures of strains of unknown composition, commercial undefined starters, and for the first half of the twentieth century, such commercial mixtures supplied to creameries in liquid, frozen, or dried form were the dominant starter types. The discovery of the bacterial nature of starters owes much to the work of Pasteur (mid 1800s), Lister, who isolated *Bacterium lactis* (now called *Lactococcus lactis*) in 1873, and Orla-Jensen, who published his thesis on the nature of starter cultures in 1919. Whitehead (New Zealand), in the 1930/40s, pioneered the concept of single strains, while identifying bacteriophage (phage) as an important causative agent in slow cheese fermentations. This use of (blended) single strains, well characterized for phage resistance, acid production, and flavor delivery has now been widely adopted.

Concentrated starter cultures, developed in the 1960s and 1970s, were prepared in freeze-dried or deep-frozen form, which required simple inoculation into a bulk starter vessel (containing, traditionally, milk, or reconstituted milk powder or a phage-inhibitory whey-based phosphated medium). Improvements to this concentration process have led, in the last 10–20 years, to the development and commercial acceptance of DVI cultures that require no subculture or activation prior to use. In the UK in 2000, more than 50% of all cheese was made using DVI systems.

Microbiology of Starter Cultures

LAB can be divided broadly into mesophiles and thermophiles, which have an optimum growth temperature of approximately 32 or 45 °C, respectively.

Mesophilic Starters

Lactococcus lactis (*Lc. lactis*) is the dominant acidifying mesophile species used, with *Leuconostoc mesenteroides* ssp. *cremoris*, a weakly acidifying culture, being used to impart flavor in certain (fresh) dairy fermentation. *Lc. lactis* has two subspecies, namely *cremoris* and *lactis*, and also a biovariant *diacetylactis*, now referred to as *Lc. lactis* citrate+, which is able to catabolize citrate (found in milk at approximately 0.2%) to carbon dioxide and the flavor compound, diacetyl – both of these are technologically important products. Traditionally, strains of *Lc. lactis cremoris* have been regarded as producing the best flavors in cheese, whereas some strains of *Lc. Lactis* ssp. *lactis* are noted for promoting certain off-flavors (bitter, malty, fruity). However, better selection techniques have identified many *Lc. Lactis* ssp. *lactis* strains suitable for delivering good flavors and,

because of their faster rates of lactic acid production and better yields in concentrated culture preparation, are now regularly used in commercial starters, usually blended with *Lc. lactis* ssp. *cremoris* strains.

Thermophilic Starters

The most important thermophilic LAB are *Streptococcus salivarius* ssp. *thermophilus* (*Sc. thermophilus*) and species of *Lactobacillus* (Lb): *bulgaricus*, *helveticus* and *lactis*. They are used in those technologies where a temperature >40 °C is used, such as yogurt, Mozzarella, Emmenthal, and Gruyere. Generally, these fermentations use blends of strains of *Sc. thermophilus* and a *Lactobacillus* (particulary *Lb. bulgaricus*), there being an associative growth relationship between them: *Sc. thermophilus* produces formate that stimulates *Lb. bulgaricus*, and *Lb. bulgaricus* produces amino acids that stimulate *Sc. thermophilus*.

Some differentiating characteristics of mesophilic and thermophilic acidifying starter cultures are given in Table 1.

Function of Starter Cultures

Three main technological functions can be attributed to LAB starter cultures, namely acidification, texture enhancement, and flavor development. Acidification, the metabolism of lactose to lactic acid, is the major attribute of LAB; the method of this metabolism differs in the various species.

Lactococci actively transport the lactose across the cell wall membrane as lactose-phosphate, which is hydrolyzed to glucose and galactose-6-phosphate; the glucose molecule is then metabolised to L(+) lactate by the glycolytic pathway, and the galactose is metabolized *via* the tagatose-6-phosphate pathway. The thermophilic LAB also use the glycolytic pathway, but they differ from lactococci in several respects, namely the lactose uptake mechanism, and that *St. thermophilus* and *Lb. bulgaricus* are not able to metabolize galactose, whereas *Lb. helveticus* metabolizes it *via* the Leloir pathway. The isomeric form of lactate produced also varies between the different species (see Table 1). It should be noted that for starters, the fermentation of lactose is their energy-producing mechanism, and lactate is merely a waste product. The LAB starters are referred to as 'homofermentative cultures,' i.e. they produce one main end product (lactate); in contrast, *Leuconostocs* can ferment lactose to lactate, ethanol, and carbon dioxide *via* the phosphoketolase pathway, and are regarded as heterofermentative bacteria.

The process of acidification enhances the expulsion of whey from the curd during the cheesemaking process and promotes the development of the texture of the cheese. The final pH obtained in the cheese will dictate to a large extent the texture of the curd: in very acid curds, e.g., Stilton, Cheshire (pH 4.6–4.8), the texture is described as short, noncohesive and crumbly due to the low level of calcium and the small size of the casein aggregates, whereas high pH cheeses (e.g., Edam/Gouda, pH 5.3–5.5) have a springy or plastic texture with a high level of calcium and larger casein aggregates.

Some LAB are able to polymerize galactose and glucose to give polysaccharide molecules, these can be important in modifying the texture of fermented dairy products – they are particularly useful in yogurts, and in low and reduced fat products, as they can improve texture and act as a fat replacer. Strains of *Sc. thermophilus* have been particularly useful in this respect. Eye formation is important in certain cheese (e.g., Dutch varieties), and occurs as a result of carbon dioxide produced by the fermentation of citrate by citrate+ *Lc. lactis* ssp. *diacetylactis* and *Leuconostoc* strains in the starter.

LAB are important in flavor development due to both the end products of fermentation (particularly diacetyl from citrate fermentation) and the slow proteolysis of the milk proteins to peptides and amino acids by the protinases and peptidases of the LAB that are released into the curd matrix as the cells die and autolyze during the cheese maturation.

A fourth function often attributed to LAB is that of the health benefits, which are further discussed under the probiotic section of secondary cheese cultures.

Selection, Production, and Use of LAB

With the increasing use of LAB cultures in a concentrated form, emphasis has been placed on the selection process for isolating strains, the functions of which match the cheesemaking requirements. Raw milk, traditional mixed starters, and dairy products, in general, are a valuable source of natural LAB; selection tests that are conducted on strain isolates from these sources include:

1. flavor promotion, absence of off-flavors;
2. acidification rates at different temperatures;
3. phage insensitivity;
4. compatability with other strains (absence of bacteriocin/inhibitor production);
5. temperature sensitivity;
6. salt sensitivity;
7. proteolytic activity;
8. special attributes, e.g., polysaccharide production;
9. cell yield in industrial fermentation;

Table 1 Some differentiating characteristics of starter lactic acid bacteria

Type	*Species*	*Shape*	*Growth at*			*Lactate isomer*	*Citrate metabolism*	*Galactose metabolism*	*Ammonia from arginine*	*Percentage lactic acid produced in milk*	*Percentage salt inhibition*	*Important metabolic products*
			10 °C	*40 °C*	*45 °C*							
Mesophilic	*Lactococcus lactis* ssp. *lactis*	Cocci	+	+	−	L (+)	−	+	+	0.8	4.0–6.5	Lactate
	Lactococcus lactis ssp. *lactis* (−cit+)	Cocci	+	+	−	L (+)	+	+	+	0.8	4.0–6.5	Lactate, diacetyl, CO_2
	Lactococcus lactis ssp. *cremoris*	Cocci	+	−	−	L (+)	−	+	−	0.8	2.0–4.0	Lactate
	Leuconostoc mesenteroides ssp. *cremoris*	Cocci	+	−	−	D (−)	+	+	−	0.2	2.0–4.0	Lactate, diacetyl, CO_2
Thermophilic	*Streptococcus thermophilus*	Cocci	−	+	+	L (+)	−	−	−	1.2	< 2.0	Lactate, acetaldehyde
	Lactobacillus bulgaricus	Rods	−	+	+	D (−)	−	−	−	1.8	< 2.0	Lactate, acetaldehyde
	Lactobacillus helveticus	Rods	−	+	+	DL	−	+	−	2.0	< 2.0	Lactate
	Lactococcus lactis	Rods	−	+	+	D (−)	−	−	+/−	1.8	2.0–4.0	Lactate

10. stability during cell concentration;
11. stability in freeze-dried or frozen format;
12. acid-producing activity as in DVI cultures.

Genetic techniques developed for bacteria have allowed the further modification of selected cultures to improve their functionality for cheesemaking purposes. Initial studies in this area concentrated on improving the phage resistance of cultures, with the knowledge that certain plasmids in LAB coded for functions relating to the phage infection process. Other areas that have been targeted for such development include food safety (ability of LAB to inhibit pathogen growth), and flavor (transfer of the genes of protein/peptide degrading enzymes, transfer of the citrate fermentation genes coded on plasmids). Although much research has been conducted on the genetics of LAB, its transference into commercial applications has received a setback, particularly in Europe, with the strength of the antigenetic modification lobby.

Once a strain has been selected as a suitable commercial culture, it will be stored as seed cultures in a culture bank (freeze-dried or deep-frozen) in multiple copies in an easy to use form ready for future commercial productions. The seed cultures are activated and grown in a small volume of a selected sterile nutritive medium, then inoculated into an industrial fermenter and grown under strict time, temperature, and pH conditions. The use of pH control (usually at pH 6.2–6.5 for mesophilic and pH 6.0–5.5 for thermophilic LAB) to neutralize the lactic acid produced allows the culture to attain a level of 10e10 bacteria per milliliter. Following concentration by either centrifugation or membrane techniques, the final cell numbers achieved are between 10e11 and 10e12. The cultures are then standardized for their acid-producing activity or cell numbers and frozen (in pellet form for DVI cultures) or freeze-dried; often, cryoprotective agents (e.g., sugars such as sucrose and lactose) are added at this stage to enhance culture stability. Finally, the cultures are blended in predetermined ratios and packaged in sachets or cartons and enter commercial stock once they have passed the appropriate bacteriological/activity quality control tests. Culture blends usually contain between two and six strains and are prepared on the basis of activity, flavor promotion, and phage relationships of the individual components. Mesophilic LAB are used for the majority of cheese fermentations (Dutch, Cheddar, French mold-ripened, cottage, soft cheeses), with thermophilic cultures being used mainly for Italian (Parmasan, Mozzarella, and Pizza) cheeses, Swiss cheese varieties, and yogurt. However, there is an increasing trend to blend mesophilic and thermophilic LAB for certain technologies such as Cheddar and Brie cheeses. The inclusion of *Sc. thermophilus* in mesophilic cultures, together with an increase in the vat milk temperature, produces a 'stabilized' Brie that has a more uniform texture and longer shelf-life than traditional products. In Cheddar DVI cultures, the inclusion of *Sc. thermophilus* enhances culture activity, reduces bitter notes, and increases phage durability; DVI cultures containing *Sc. thermophilus* now account for at least 30% of UK Cheddar. *Lb. helveticus* strains are also being used commercially for Cheddar to enhance and modify flavor profiles, and these strains are being offered either as adjunct cultures or preblended with the DVI culture.

The preparation of bulk starter in the cheese plant involves inoculating the bulk starter culture (usually freeze-dried, in a sachet, or deep-frozen, in a ring-pull can – in the latter case, partial thawing of the culture is required prior to inoculation) into the precleaned and sterilized bulk starter vessel. The growth medium normally used is either skim milk/reconstituted skim milk powder (10–12%) or a blended powder (6%), containing a protein source (whey/milk powder), a sugar source (whey powder/lactose), a bacterial growth stimulant (yeast extract), and a buffering/phage inhibitory agent (phosphate salts). The inoculated culture is grown for a predetermined time at a constant temperature (e.g., 18 h at 22–24 °C for mesophilic cultures, and 5–6 h at 40–42 °C for thermophilic cultures). During incubation, the pH evolution may be monitored, and also pH control may be used, whereby alkali (ammonia) is automatically dosed into the vessel to maintain the pH at the optimum level for the culture (approximately pH 6.2–6.5 for mesophilic cultures and pH 6.0–5.5 for thermophilic cultures). Once the required end point has been reached (as determined by the pH/acidity level, or quantity/rate of alkali addition), the bulk starter is ready for use, ideally after rapid cooling.

Secondary Cheese Cultures

In addition to the mesophilic and thermophilic starters described above, other microbial cultures are used in cheese to produce the flavors, textures, and appearance typical for that cheese type.

Molds

For Coulommier and Camembert type cheese, the white mold, *Penicillium camemberti*, is used to give a white felt on the surface of the cheese. Strains have been isolated that exhibit different mycelial growth characteristics, and in general, four types have been identified:

1. Neufchâtel form (rapid growth that produces a thick mat of yellow–white mycelia);
2. short, flat mycelial form (rapid growth and tight flat thallus);
3. long, tall mycelial form (slow growth, loose high thallus);
4. fluffy woolly mycelial form (white thallus that turns gray on aging, originally called *Penicillium album*);

The mold is added to the cheese as a spore suspension either in the vat or sprayed on at the end of cheesemaking (or both).

Geotrichum candidum is another surface mold, which produces a very short, fine mycelium. It is generally used together with *P. camemberti* and exerts a synergistic effect on its growth. Some strains of *G. candidum* produce a yeast-like appearance on the surface of the cheese, often referred to as 'toad-skin.'

Penicillium roqueforti is the mold culture used for blue-veined cheeses, such as Roquefort, Stilton, Gorgonzola, and Danish Blue. Unlike *P. camemberti*, it generally grows inside the cheese, but like *P. camemberti*, it requires oxygen to grow; therefore, after cheesemaking, the cheese must be pierced to allow sufficient oxygen to penetrate for spore germination and for the carbon dioxide to be expelled.

Yeasts

These form an important part of the microflora of many surface ripened cheeses, such as blue cheeses, soft mold-ripened cheeses, and washed-rind cheeses, e.g., St. Nectaire, St. Paulin, Cantal. *Kluyveromyces lactis*, *Saccharomyces cerevisiae*, *Candida utilis*, *Debaryomyces hansenii*, and *Rodosporidium infirmominiatum* are the most common yeasts used. They colonize the surface of the cheese at an early age, are able to grow in 4% NaCl, and have a strong neutralizing activity by virtue of their ability to metabolize lactate. They are both proteolytic and lipolytic and produce a range of volatile and peptide/amino acid flavor components.

Bacteria

Groups of bacteria that are important in the secondary flora of cheese are *Micrococcus*, *Lactobacillus*, *Corynebacterium*, and *Propionibacterium*.

Brevibacterium linens (*Corynebacteria*) is responsible for the red–orange color and characteristic aroma (originating from the catabolism of sulfur-containing amino acids) of surface-smear and washed-rind cheeses, such as Munster, Maroilles, Pont L'Eveque and St. Paulin.

Micrococci cultures are facultative anaerobes and are used to promote texture and flavor in both hard, semihard and mold-ripened cheeses.

Mesophilic *Lactobacillus* species are used in washed-rind cheeses and in some hard and semi-hard cheeses; they are of value because of their aminopeptidase activity, which promotes flavor and can reduce bitterness during cheese maturation.

The microbiology of the surface smear and washed rind cheeses is complex; combinations of Corynebacteria, Micrococci, molds, and yeasts are present. The Corynebacteria grow once the pH has increased due to the degradation of lactate by the yeasts and molds.

Propionibacteria, principally the species *Proprionibacterium freudenreichii* and *Shermanii*, are used in Swiss cheese technology (Emmenthal, Gruyere, Appenzell). They convert the lactate produced by the *Sc. thermophilus* and *Lb. helveticus* starters to the flavor components, propionic and acetic acids, and carbon dioxide, which is responsible for eye formation.

Probiotic bacteria form an addition group that are used for their potential health-giving properties. The main cultures used are certain *Lactobacillus* species (particularly *Lb. acidophilus*) and *Bifidobacterium* species, and are generally considered to be natural inhabitants of the gut. They are usually added with starter LAB, particularly the thermophilic LAB, since they do not themselves normally produce sufficient lactic acid for standard fermentations. They are used mainly in the production of fresh fermented dairy products (e.g., yogurts). Health benefits associated with them include improved digestion, stimulation of the immune system, reduction of tumor incidence, and reduction of serum cholesterol. However, it has proved difficult to obtain medical evidence in this respect that is acceptable to health authorities.

Factors that Affect Culture Growth

The growth of LAB in milk can be affected by many parameters. For example, variations in milk composition, either seasonal or cattle feed-influenced, can have a stimulatory or inhibitory effect on LAB. Excessive entrainment of oxygen in the milk, as a result of agitation, can cause inhibition due to the bacterial conversion of oxygen into the inhibitory substance hydrogen peroxide. LAB generally do not have the enzyme catalase to degrade this. Milk may contain antibiotic residues following the administration of antibiotics for cow mastitis; however, strict quality-control measures have significantly reduced this problem of recent times. Residues of cleaning and sterilizing chemicals may be present in the cheesemaking vats

and could inhibit starters if present at sufficiently high concentrations.

Nonadherence to the time/temperature regimes of the cheesemaking process can also affect acidification, e.g., overscalding by 1–2 °C in Cheddar cheesemaking would cause significant slowing of the rate of acidification for a culture containing predominantly *Lc. lactis* ssp. *cremoris* strains.

Phage is probably the most important destructive agent in cheesemaking. Phage is found in milk and can lie dormant (lysogenic state) within some wild type and starter LABs. These are viruses with a hollow protein head containing DNA and a hollow protein tail with a plate assembly at the end. Phage attack LAB by attaching themselves to the bacterial surface by means of the plate assembly, injecting their DNA through the tail and into the host cell; once inside, their DNA directs the host to produce more phage particles, and, when mature (30–50 min), lysin is produced to dissolve the bacterial cell wall and release the new phage; up to 200 particles can be produced in one such cycle (in the same time span, one LAB cell would have divided to give two cells). Phage are present in most, if not all, cheesemaking plants, and it is only through the use of good manufacturing practices and hygiene control, together with the selection of suitable LAB, that phage is maintained at low, noninvasive levels. Culture techniques aimed at reducing/eliminating phage problems, which have already been touched on in this article, include:

1. selection of naturally resistant strains;
2. genetic modification (e.g., plasmid transfer), where legally permitted;
3. blending several phage resistant/unrelated strains;
4. use of culture rotation, three or four blends (a different blend used on different days);
5. inclusion of *Sc. thermophilus* in mesophilic blends (used in Cheddar technology).

Chemistry of Gel Formation

J M Banks and D S Horne, Hannah Research Institute, Ayr, UK

Background

The basic ingredient for cheese is milk, usually from cows, sheep, or goats, although the milk of yak, reindeer, camels, mares, and buffaloes is also used in local, indigenous products in some regions of the world. In nature, milk is produced by the mother mammal to feed her newborn offspring; milk, therefore, has to provide all elements essential for their growth and nourishment, namely protein, fat, carbohydrate, minerals, and water, but in proportions relevant to the needs of the animal species. Recognizing the nutritional benefits, man initially sought to preserve this fundamental food for the lean times of low milk availability. Cheese manufacture, which retains the majority of the protein, fat, and some of the minerals, provides one such outcome of this exercise of his ingenuity, with a wide range of products to suit all tastes and desires in the modern portfolio of the cheesemaker's art.

Cheesemaking capitalizes on the curdling of milk. Curds can be produced by either acidification of milk to pH 4.6 or the use of a protease in conjunction with acidification to pH 6.4. The former method is used to produce fresh high-moisture cheeses, e.g., cottage cheese, and the curd is formed by the isoelectric precipitation of milk casein. The latter approach is the basis for producing hard ripened cheeses, such as Cheddar, Emmental, or Parmesan, which have a low moisture content. Gel formation is initiated by proteolysis of casein, and the destabilized casein aggregates to form a gel. The gel produced at the higher pH using a protease differs markedly from that produced by acid alone. The gel is more elastic, and in the presence of increasing acidity and the application of heat, the gel shrinks and expels moisture by a process termed syneresis. To understand the process of curd formation, we must look more closely at the individual components of milk to discern their role,

particularly the fat and protein, and also the agents used in proteolysis.

Fat

Fat in milk exists as small globules surrounded by me mbrane proteins and in a size range dependent on breed, lactational status, and diet of the cow. The fat in milk contributes to flavor development in mold-ripened cheeses with a strong lipolytic flavor, e.g., blue cheeses. In cheeses such as Cheddar or Gouda, in which proteolysis is dominant during maturation, the fat acts as a solvent for flavor compounds. The fat globules are trapped in the protein network created during curd formation; hence, their size and the network mesh size interact in determining overall yield of cheese. Otherwise, the fat globules play no active role in determining curd properties.

Protein

Two types of protein are found in milk: the globular whey proteins, which are soluble in the serum phase, and the caseins, which exist in a stable colloidal suspension of aggregates known as casein micelles. Cheesemaking exploits the destabilization mechanisms nature has built into this colloidal system by using the natural enzyme, chymosin, originally extracted from the stomach of the calf, to hydrolyze the κ-casein and induce the destabilization of the micelle to form the gel, which goes forward through to the finished cheese. Nowadays, a number of alternatives to the calf stomach extract of chymosin are commercially available for cheese manufacture. These include microbial rennets and cloned chymosin produced using yeast or fungi as the host organism.

Casein Micelle Structure

The physicochemical properties of the different casein proteins dictate how the casein micelle is assembled, and they govern the response of the micelle to destabilizing influences. The caseins and casein micelles have been studied extensively over a long period. Several different models of micelle assembly have emerged. Criticisms have been leveled at most of these models, though a more recent dual-binding model answers most of these points and plausibly explains micellar assembly and stability.

In bovine milk, the casein micelles have an average molecular weight of $\sim 10^8$ Da and a mean diameter of ~ 100 nm (range 50–600 nm). The micelles are very open, highly hydrated structures with a typical hydration value of 2–3 g of H_2O per gram of protein, depending on the method of measurement. They contain almost all of the casein protein and a large fraction of the mineral calcium phosphate found in milk. The casein proteins are four distinct gene products, designated α_{s1}-, β-, α_{s2}-, and κ-casein, and are present in a ratio of approximately 40:35:10:12 in cows' milk. Two posttranslational modifications of the proteins newly synthesized in the mammary gland, have a major impact on their physicochemical, functional, and assembly properties. These reactions are glycosylation and phosphorylation. In bovine milk, only κ-casein is found glycosylated, with several threonine and occasionally serine residues in the hydrophilic C-terminal end of the κ-casein molecule carrying relatively short sugar chains. These chains increase the hydrodynamic bulk and hydrophilic character of this end of the κ-casein molecule.

The second posttranslational reaction is phosphorylation. All of the caseins are phosphorylated at serine, or rarely threonine, to varying extents. The phosphorylation reaction requires a particular sequence template, —Ser —X —A —, where X is any amino acid, and A is Glu, SerP, or rarely Asp. The pattern of serine residues along the molecular sequences of α_{s1}-, α_{s2}-, and β-casein ensures that most of the phosphorylated residues are found in clusters in these molecules. κ-Casein is unique amongst the caseins in the absence of phosphoseryl clusters. Most κ-casein molecules carry only one phosphoseryl residue. Some have two or three, but all are singlets and, again, are located in the hydrophilic C-terminal region. The presence or absence of these phosphoseryl clusters has important consequences for micellar assembly and structure.

The caseins are not globular proteins locked into a secondary conformational structure and are not truly random coil polymers. They have been described as rheomorphic proteins, indicating that the conformational structure adopted is dictated by, and responsive to, the molecular environment. The caseins have little α-helical structure, no denaturation temperature, and a high hydrodynamic volume.

When categorized as nonpolar hydrophobic or polar/charged hydrophilic groups, the amino acids of the caseins show distinct segregation into different regions of the molecular chains. Each casein possesses its own pattern (Figure 1), and this helps rationalize their selfassociation behavior and the conformations adopted at a hydrophobic interface. Together with the phosphoseryl clusters in the hydrophilic loops/tails of α_{s1}-, α_{s2}-, and β-caseins, these sequence patterns allow modeling of the micellar assembly as the polymerization process described below.

In the dual-binding model, two distinct forms of bonding take part in micellar assembly and growth. These are cross-linking through hydrophobic regions

of the caseins or through phosphoseryl cluster bridging across calcium phosphate nanoclusters, small mineral crystallites the precipitation of which is regulated by the presence of the caseins. These cross-linking mechanisms are depicted in Figure 2. Each casein molecule effectively functions as a block copolymer, as detailed in Figure 1, with each block possessing different and possibly multiple functionality for the two distinct cross-linked paths, which can be traced through the model micellar network. Thus, α_{s1}-casein can chain-polymerize through the hydrophobic blocks, B, giving a worm-like chain appearance, as highlighted in Figure 2. Further hydrophobic blocks can also link to these duplexes to create branches, but limitations on growth are likely because of electrostatic repulsion from the neighboring contiguous hydrophilic regions of these molecules. That is unless, as postulated for the casein micelle, the chains also polymerize through the negatively charged phosphoseryl cluster cross-linking to a positively charged calcium phosphate nanocluster, with the potential for multiple protein binding to each nanocluster allowing the second different pathway to be extended. β-Casein, with only two blocks, the phosphoseryl cluster (P) and the hydrophobic region (B), can form links into the network through both and thus facilitate chain growth through these. α_{s2}-Casein is envisaged in this model as having two of each block (Figure 1), two phosphate clusters, and two hydrophobic regions. It is only a small fraction of total casein, but by being able to sustain growth through all its blocks, it is likely to be bound tightly into the network. κ-Casein is the most important of the caseins in this dual-binding model of micellar assembly. It can link into the growing chains through its hydrophobic N-terminal block, but its carboxy-terminal block, denoted C in Figure 1, has no phosphoserine cluster and therefore cannot extend the polymer chain through a nanocluster link. Chain and network growth are therefore terminated here. The occurrence of this event on all the growing chains leaves the casein micelle network with a surface layer of κ-casein molecules, limiting micellar growth and ensuring the stability and integrity of the system.

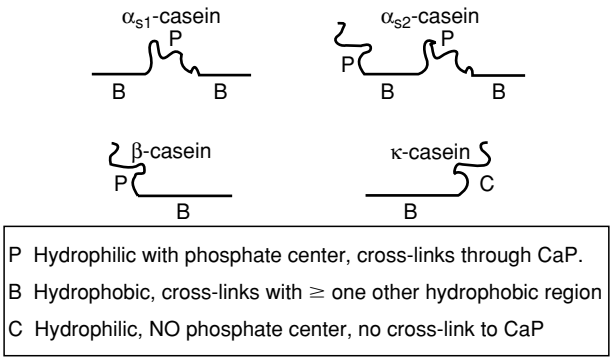

Figure 1 Schematic description of segregation of hydrophobic/hydrophilic residues in the caseins. Hydrophobic regions (B) are represented by the bar structures, which do not imply any form of rigidity; hydrophilic loop regions containing phosphoserine clusters are denoted P and the hydrophilic carboxy peptide of κ-casein by the letter C.

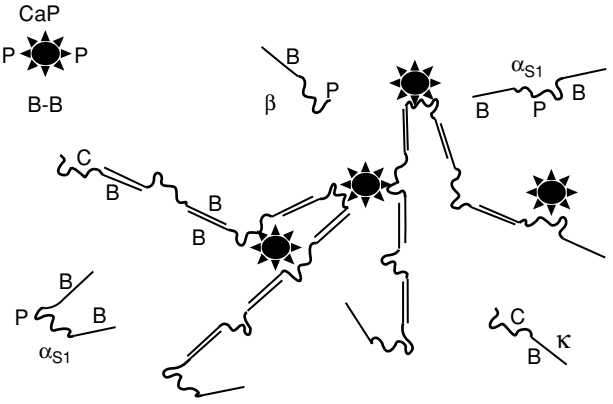

Figure 2 Part of the polymer network built up in the casein micelle according to the dual-binding model. Bridging of casein molecules across calcium phosphate nanoclusters, cross-linking of caseins via hydrophobic interactions, and chain termination by κ-casein are all illustrated. The hydrophobic pathway follows along the straight bars; the nanocluster cross-link points are indicated by the starred circles. Other chains can attach at these points to extend the network or terminate it in the case of κ-casein attaching to a hydrophobic region.

Such a surface location for κ-casein is demanded by experimental evidence linking micellar size and casein composition. Casein micelles can be fractionated from the initial wide size distribution found in milk by subjecting the milk to successive centrifugation steps of increasing speed and duration. A short, low-speed centrifugation sediments the largest micelles. Subjecting the supernatant to a higher-speed, longer-duration stage produces a second pellet of slightly smaller micelles and a supernatant for the next stage, and so on until a clear supernatant is obtained. The end result is a series of pellets, containing largely monodisperse slices of the micellar size distribution. The pellets can be analyzed for protein and mineral composition. Their resuspension in milk ultrafiltrate allows measurement of their size by dynamic light scattering. Such experiments demonstrate that the proportion of α_{s1}- and α_{s2}-caseins is constant with micelle size and that κ-casein is inversely proportional to size. For an object such as a sphere, the surface-to-volume ratio is inversely proportional to the radius,

so such results imply that the κ-casein component resides predominantly on the micellar surface where it controls micellar surface area and hence micellar size. Model and experiment are fully consistent in the role and location of κ-casein, which also readily explains the destabilization of the micelle system on proteolysis of the κ-casein by chymosin. This proteolysis of the κ-casein is termed the primary enzymatic phase of gel formation, and it is followed by a secondary nonenzymic aggregation stage.

Primary Enzymatic Phase of Curd Formation

The κ-casein molecules provide a steric stabilizing layer with their hydrophilic C-terminal peptides protruding into the aqueous phase. Gel formation is a direct consequence of the proteolysis of the κ-casein molecules, the casein being cleaved specifically at the Phe_{105} — Met_{106} bond, releasing the hydrophilic peptide, termed the caseinomacropeptide, into the serum phase, leaving the N-terminal region bound into the micelle network, and thus destabilizing the micelle.

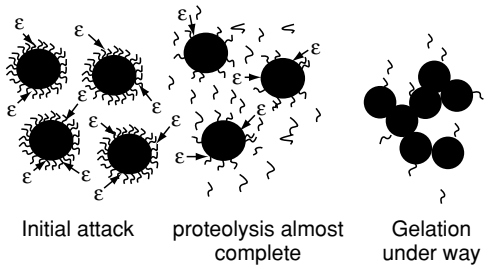

Figure 3 Depiction of the various stages involved in curd formation following proteolysis of κ-casein by chymosin.

Secondary Aggregation Stage of Gel Formation

The gradual loss of the caseinomacropeptide is accompanied by a decrease in the micellar zeta potential from ~−20 to ~−10 mV. The overall process of destabilization and aggregation to a gel network is depicted schematically in Figure 3. Approximately 80% of the κ-casein hairs need to be cut before significant aggregation to define a coagulation time becomes detectable. During this lag phase, the lower levels of κ-casein proteolysis are accompanied by a measurable decrease in micellar hydrodynamic size, as the hairs are lost.

During the development of the gel, the micelle continues to behave as if it were a hard sphere that had become sticky or adhesive with the loss of the stabilizing κ-casein hairs. The gel is therefore initially a network of aggregated particles. As such, it can be predicted that the gel stiffness should be inversely proportional to the cube of the micelle size and directly proportional to protein concentration. Such behavior has been observed experimentally in gels made from micellar fractions, pelleted as described above.

This mechanistic model also helps to explain the influence of the genetic variant of κ-casein on the cheesemaking properties of milk. The C-terminal sequences of the major genetic variants, denoted A and B, of κ-casein are listed in Figure 4. κ-Casein B differs from κ-casein A only at two residues with an isoleucine substituted for a threonine, a potential glycosylation site, at position 136 and an alanine substituted for an aspartic acid residue at position 148. Milk from cows which are homozygous for the κ-B variant have a shorter coagulation time, show a faster rate of gel firming and give a stiffer gel than that from κ-AA cows. All of these changes mean that higher cheese yields are recorded for κ-BB milks. The genetic modifications reduce the net charge of the hydrophilic

C-terminal peptide, making it a less efficient steric stabilizer, leading to a shorter coagulation time and a faster rate of gel firming. The firmer gels are more difficult to explain because the modified hydrophilic peptide is lost to the serum phase and plays no further role in curd network formation and growth. Even more remarkable is that the increase in cheese yield is due to a greater efficiency in fat retention in these curds. The explanation is that κ-BB milk also has a higher content of κ-casein. This means they have smaller micelles on average, and the increased gel firmness results from this difference, in line with the predictions of the particle gel model, and not from the genetic modifications themselves.

Coagulants and their Activities in Curd Manufacture

Proteases capable of initiating the required proteolysis of κ-casein, which is the first step in gel formation, are aspartic proteinases (EC 3.4.23) and originate from a number of sources. Milk-clotting enzymes were historically derived by extraction from the stomach of ruminants, and calf rennet is used widely in commercial cheese manufacture today. Rennets can be extracted from other species such as sheep, goat, and pig, and generally, the clotting activity of these rennets is best suited to milk of the species from which the rennet is derived. The active clotting enzyme in these rennets is chymosin, and the proportion of chymosin in rennet extracts varies with the age of the animal at slaughter. Calf rennet extract contains approximately 90% chymosin with a small amount of pepsin, whereas adult bovine rennet may contain only 10% chymosin and 90% pepsin. Alternative sources of rennet have been sought to sustain the growth in commercial cheese manufacture worldwide. This has led to the development of milk-clotting agents from microbial sources. While the term rennet is applied to clotting extracts derived from ruminants, clotting enzymes from nonruminant sources are termed coagulants.

Commercially produced microbial coagulants for cheese manufacture are produced by fungal fermentation. The most widely used microbial coagulants on the market today are produced from *Rhizomucor miehei*, but *Rhizomucor pusillus* and *Cryphonectria parasitica* are also used.

Since 1991, pure chymosin coagulants produced by fermentation of a genetically modified organism have been available for commercial use. These are termed fermentation-produced chymosins and are produced from either of two genetically modified host organisms, the yeast, *Kluyveromyces lactis* or the fungus *Aspergillus niger*. Following fermentation, the chymosin extract is treated with acid which destroys any residual DNA or RNA from the host organism.

Gel Formation with Rennets and Coagulants

The formation of a rennet coagulum in curd manufacture takes place in two stages as described above. The primary phase is enzyme-mediated and involves the hydrolysis of micellar κ-casein at the Phe_{105}—Met_{106}. This bond is also hydrolyzed by the aspartic proteases of the microbial coagulants produced by *Rhizomucor miehei* and *Rhizomucor pusillus*. However, with *Cryphonectria parasitica*, the Leu_{104}—Phe_{105} is hydrolyzed preferentially.

Approximately 6% of the chymosin added during cheese manufacture is retained in curd. For the microbial coagulants, retention levels are approximately 2–3%. The level of retention of chymosin is influenced by the pH of the curd at cut, and the greater the acidity at cut, the greater the retention of chymosin in curd. Retention of microbial coagulants is not pH-dependent. The temperature profile during cheese manufacture also affects chymosin activity in curd during ripening. The high scald temperature used in the manufacture of Swiss-type cheeses inactivates residual chymosin activity in curd.

The rennet used in cheese manufacture should have a high ratio of milk clotting to nonspecific proteolytic activity to maximize cheese yield. While hydrolysis of the Phe_{105}—Met_{106} is essential for clotting, other nonspecific proteolysis processes in the cheese vat would result in reduced cheese yield owing to a weak coagulum and high losses of fat and protein in the whey. Fermentation-produced chymosin and calf rennet have the lowest level of nonspecific protease activity, whereas increasing levels of nonspecific protease are seen in bovine rennet, *Rhizomucor miehei*, *Rhizomucor pusillus*, and *C. parasitica* coagulants.

Differences in the specificity of proteases in coagulants and their overall proteolytic activity may impact on cheese flavor development, and in producing particular types of cheese, there may have to be a compromise between yield and flavor potential of the coagulant. Residual chymosin activity in Cheddar has been researched extensively and characterized. Chymosin retained in curd rapidly hydrolyzes α_{s1}-casein at the Phe_{23}—Phe_{24} bond producing α_{s1}-casein (f1–23) and α_{s1}-casein (f24–199). This results in softening of the cheese texture in the early stages of ripening. In mature Cheddar (>6 months), this hydrolysis is complete. During the early stages of ripening, the concentration of α_{s1}-casein (f24–199) increases initially, but as ripening progresses, it is

further hydrolyzed by chymosin, predominantly at the Leu_{101}—Lys_{102} and, to a lesser extent, at the Phe_{32}—Gly_{33} and Leu_{109}—Glu_{110}. Peptides resulting from these activities including the α_{s1}-casein (f24–199), α_{s1}-casein (f33–199), α_{s1}-casein (f102–199), and α_{s1}-casein (110–199) have been identified in Cheddar. Further hydrolysis of the α_{s1}-casein peptides is achieved by action of the indigenous milk protease, plasmin, and the lactococcal cell envelope-associated proteinase from the starter culture, and these activities result in the formation of small peptides and amino acids, which may be further catabolized to generate flavor components. The specificity of rennet substitutes on the caseins during maturation has not been characterized but is known to differ from that resulting from chymosin action.

Factors Influencing Curd Formation with Rennet

Factors influencing curd formation include rennet concentration, pH, temperature, and ionic calcium. Each has the potential to influence either the primary enzymatic phase or the secondary phase of aggregation, but some influence both.

Increasing rennet concentration results in an increase in the rate of the primary enzymatic phase. The secondary aggregation phase of renneting also proceeds more rapidly at higher rennet concentrations. Generally, the quantity of rennet is selected to ensure adequate gel formation within 20–40 min during commercial cheese manufacture.

Rennet coagulation of milk is pH-dependent, with optimum activity for hydrolysis of the Phe_{105}—Met_{106} in κ-casein at pH 6.0. Decreasing the natural pH of milk from 6.7 to 6.0 results in solubilization of calcium phosphate and a decrease in the charge on the casein micelles, which also encourages gel formation. The net effect of a decrease in pH is therefore an increase in both the primary enzymatic and secondary aggregation phase of coagulation.

The higher the temperature at renneting, the greater is the rate of aggregation. At a temperature of less than 15 °C, the primary enzymatic phase proceeds normally, whereas the aggregation phase does not proceed at a low temperature. Also, research studies indicate that gel firmness falls off above 40 °C.

Natural seasonal deficiencies in the calcium levels in milk can be overcome by the addition of calcium chloride, which causes a slight decrease in pH, which will promote the primary enzymic phase of renneting, while the secondary stage of aggregation is enhanced by calcium addition. Processing treatments applied to milk, e.g., excessive cold storage or high heat treatment of milk, can inhibit gel formation. These effects can be overcome by the addition of calcium chloride or reduction of the pH of milk.

Although a great deal of research effort has been directed into methods for the determination of optimum gel strength during cheese manufacture, in normal circumstances, there is a window extending to 10 min during which time the coagulum can be cut without any detrimental effects on cheese yield. However, the manufacture of cheese from abnormally weak gels, produced for example from milk deficient in calcium or with a high proportion of the κ-AA casein variant, results in reduced yield. The appropriate time for cutting the curd is dependent on the manufacturing plant, and the time of cutting must be adjusted to allow for seasonal variations in milk composition.

Chemistry and Microbiology of Maturation

N Y Farkye, California Polytechnic State University, San Luis Obispo, CA, USA

Cheese Maturation (Ripening)

Most rennet-coagulated cheeses are ripened for at least 4 weeks before consumption. When manufactured from raw (unpasteurized milk), the cheese must be ripened for at least 60 days at not less than 1.7° C before consumption. Cheese ripening involves several complex and dynamic biochemical processes that result in textural and flavor changes, unique for each variety. Notably, a 'green,' rubbery, tough cheese with a bland taste is converted into a 'mature,' firm, elastic or soft-body cheese with a characteristic flavor.

The major biochemical processes that occur during ripening include metabolism of lactose/lactate, proteolysis, and lipolysis. The biochemical changes are results of the activities of residual rennet, enzymes from starter, starter adjuncts and nonstarter microorganisms, indigenous milk enzymes, and exogenous enzymes added to the milk or cheese for specific functions. The composition of cheese curd (especially moisture, salt, and pH) and ripening conditions (temperature and humidity) affect enzyme activity and, consequently, the rate and extent of ripening.

Rennets

The term 'rennet' was originally used to describe the milk-clotting enzyme preparation from calf stomach, which contains the active digestive enzyme called chymosin (rennin). At present, the term 'rennet' is used broadly to describe milk-clotting enzymes. Commercial milk-clotting enzymes currently available are listed in **Table 1**.

Chicken pepsin and papain are used in some countries for cheese-making. Also, rennets from kid and lamb stomachs are available. Rennet action during cheese-making results in the conversion of milk to cheese curd. The principal reaction that causes coagulation of milk is the cleavage of Phe_{105}–Met_{106} bond in the milk protein, κ-casein. A portion (0–30%) of the rennet used in cheese-making is retained in the cheese, depending on the type. The amount of rennet retained depends on the pH of the milk at setting, the type and amount used, and its ability to survive cooking temperatures used in cheese-making. The retention of chymosin, bovine pepsin, or porcine pepsin in cheese increases as the pH of milk is reduced at the time of rennet addition (setting). However, the pH of milk at setting does not affect the amount of *Mucor miehei*, *Mucor pusillus*, or *Cryophonectria parasitica* proteinases retained in the cheese curd.

Table 1 Commercial milk-clotting enzymes and their sources

Commercial name	*Systematic name*	*Source*
Calf rennet	Chymosin	Calf stomach

Fermentation-produced rennet	Chymosin	*Escherichia coli* K12 *Kluyveromyces lactis* *Aspergillus niger*

Starter and Nonstarter Microorganisms

The term, 'starter' refers to a culture of lactic acid bacteria used for acid production, through the fermentation of lactose, during cheese-making. **Table 2** contains a list of starter and nonstarter microorganisms important in the ripening of major cheeses.

Mesophilic starters (*Lactococcus lactis* ssp. *cremoris* (formerly *Streptococcus cremoris*) or *Lc. lactis* ssp. *lactis* (formerly *S. lactis*)) are important in the ripening of Cheddar and Dutch-type (Gouda, Edam) cheeses. Thermophilic starters (*Streptococcus thermophilus* (formerly *S. salivarius* ssp. *thermophilus*) or *Lactobacillus delbruekii* ssp. *bulgaricus* (formerly *Lb. bulgaricus*)) are important in the ripening of Emmental-type (Swiss, Gruyère) and Italian-type (Romano, Parmesan, and Provolone) cheeses.

Other lactic acid bacteria (*Leuconostoc* spp., citrate$^+$ *Lc. lactis* ssp. *lactis* (formerly *Lc. lactis* ssp. *lactis* biovar. *diacetylactis* or *S. diacetylactis*) or *Lb. helveticus*) play a role in the ripening of Dutch- and Emmental-type cheeses. Microorganisms, other than lactic acid bacteria, significant to cheese ripening include *Propionibacterium shermanii* for Emmental-type cheese, molds (*Penicillium roqueforti*, *P. glaucum*) for blue-veined varieties, *P. camemberti* for

Brie		*Lc. lactis* ssp. *cremoris*	*P. camemberti*, *P. caseicolum*, *P. candidum*, *B. linens*
Camembert		*Lc. lactis* ssp. *lactis*	

Camembert and Brie, and *Brevibacterium linens* for cheeses such as Limburger, Brick, and Port Salut.

Probably all cheese varieties contain nonstarter lactic acid bacteria (NSLAB), such as lactobacilli (*Lb. casei*, *Lb. plantarum*, *Lb. brevis*), pediococci (*P. pentosaceus*), and micrococci. Some of the biochemical processes that occur during cheese ripening are due to the activities of NSLAB.

Microbiological Changes

Starter bacteria multiply from about 10^6–10^7 colony-forming units (cfu) per milliliter milk to 10^9 cfu per gram of fresh cheese curd. There is a decline in starter population as ripening progresses. The rate of decline varies among cheeses and is dependent on the elimination of lactose (the primary source of energy), inhibition by salt, and/or autolysis. Starter activity is inhibited when the salt-in-the-moisture (S/M) of cheese exceeds 5%.

In Cheddar and Gouda cheese, the starter population declines to $< 10^3$ cfu g^{-1} within the first few weeks, whereas in varieties like Provolone and Parmesan, cell densities remain high ($> 10^4$ cfu g^{-1}), even after 12 months of ripening.

In Emmental cheese, the maximum cell density of the lactic streptococci (10^9 cfu g^{-1}) at the periphery and 10^8 cfu g^{-1} in the center) is reached after about 3 h of pressing. The lactic acid produced by the streptococci stimulates the growth of lactobacilli, which reach cell densities of about 10^9 cfu g^{-1} after 10–20 h of pressing. The populations of both streptococci and lactobacilli decline after pressing and brining. When cheese is placed in a warm room (20–25 °C and 80–85% relative humidity, RH), the propionibacteria multiply rapidly, reaching cell densities of about 10^9 cfu g^{-1} in the center of the cheese in 3 weeks.

The growth of starter bacteria is inhibited in blue-veined cheeses because of the high salt content (10% S/M). However, growth of *P. roqueforti* is induced after the cheese is pierced with needles to allow air into its interior, causing blue veining. Ripening of blue-veined cheeses occurs at 10 °C and 96% RH, and growth of *P. roqueforti* reaches a maximum in 90 days.

In many varieties, growth during NSLAB occurs of ripening. The cell densities of nonstarter lactobacilli reach 10^7 cfu g^{-1} in 10 weeks. Also, there is growth of *Pediococcus*, sp. and cell densities of *Micrococcus* sp. reach about 100 cfu g^{-1} during the same period.

Biochemical Changes

Metabolism of Lactose, Lactate, and Citrate

Lactic acid bacteria use either the phosphoenolpyruvate-dependent phosphotransferase or the lactose permease system to transport lactose into the cell. In lactococci, lactose is phosphorylated to lactose-P and transported into the cell, where it is hydrolyzed by phospho-β-galactosidase to glucose and galactose-6-phosphate. The glucose is fermented via the Embden–Meyerhof–Parnas (glycolytic) pathway to produce lactic acid. The galactose-6-phosphate is fermented via the tagatose phosphate pathway to lactic acid. In *S. thermophilus* and *Lb. bulgaricus*, lactose is not phosphorylated before it is transported into the cell. In the cell, it is hydrolyzed by β-galactosidase (or lactase) to glucose and galactose. The glucose moiety is converted to glucose-6-phosphate and fermented via the glycolytic pathway. The galactose moiety is converted to glucose-6-phosphate via the Leloir pathway.

Citrate is metabolized by citrate$^+$ *L. lactis* ssp. *lactis* and *Leuconostoc* species. Both organisms have specific pH-dependent permeases to transport citrate across the cell membrane into the cell, where it is converted into acetate, pyruvate, and CO_2. Pyruvate is converted into other products such as diacetyl, which is an important aroma compound in dairy products.

The concentration of lactose in fresh cheese (1 day old) ranges from < 0.1% in Dutch- and Emmental-type cheeses to about 1% in Cheddar. At S/M levels < 5%, starter and NSLAB metabolize residual lactose to lactate, which may be produced in the L(+) or D(−) isomeric form, depending on the organism (Table 3).

Lactic acid (1.5%, in Cheddar) reduces the initial pH of cheese to < 5.3, and is a source of energy for some microorganisms, thereby serving as a precursor of flavor compounds. L(+)-Lactate is metabolized by propionibacteria, in the pH range 5.0–5.3, to propionic acid, acetic acid, and CO_2 (eqn. (1)) in Emmental-type cheese. Some of the CO_2 produced accumulates in the cheese and forms holes, which are commonly called 'eyes.'

$$3CH_3\text{-}CHOH\text{-}COOH \longrightarrow 2CH_3\text{-}CH_2\text{-}COOH + CH_3\text{-}COOH + CO_2 + H_2O. \quad (1)$$

Lactic acid — Propionic acid — Acetic acid

In Cheddar cheese, NSLAB are capable of metabolizing lactose to produce ethanol and formic acid, both of which are undesirable in large quantities. The NSLAB may also oxidize lactate to acetate and CO_2. Pediococci and lactobacilli convert L(+)-lactate to D(−)-lactate, resulting in a racemic mixture of both isomers after 6 months of ripening. D(−)-Lactate forms an insoluble calcium salt that may crystallize in cheese and appear as undesirable white specks on cut surfaces. The ingestion of high levels of D(−)-lactate by humans causes metabolic disturbances. *Lb. casei* and *Lb. plantarum* oxidize citrate to acetate and CO_2, resulting in a gradual increase in acetic acid during Cheddar cheese ripening.

In Dutch-type cheeses, pyruvate, produced from citrate metabolism, is oxidized to diacetyl and CO_2 (eqn. (2)) by citrate$^+$ *L. lactis* ssp. *lactis* and *Leuconostoc* species.

$$2CH_3\text{-}CO\text{-}COOH + O_2 \longrightarrow CH_3\text{-}CO\text{-}CO\text{-}CH_3 + 2CO_2 + H_2O. \quad (2)$$

Pyruvic acid — Diacetyl

The catabolism of lactate and the formation of alkaline N-compounds (due to proteolysis) result in an overall increase in the pH of some varieties during ripening. After 6 months of ripening, the pH of Emmental-type cheese increases from ~5.3 to ~5.9, and that of Camembert and Blue increases from ~4.8 to ~7. The pH of Cheddar cheese, however, increases only slightly (0.1 pH unit), because the concentration of lactic acid remains high (1.2–1.9%), even after 12 months of ripening.

Proteolysis

Of the major milk proteins, α_{s1}-, α_{s2}-, and β-caseins predominate in cheese. Proteolysis involves the breakdown of these proteins and polypeptides by residual rennet, indigenous milk proteases, and/or proteinases/peptidases of starter and nonstarter microorganisms. Figure 1 shows the effects of different rennets on the release of water-soluble nitrogen in cheese. In general, the lowest level of proteolysis

occurs in cheese made with porcine pepsin, whereas the most extensive proteolysis occurs in cheese made with microbial rennets.

Chymosin hydrolyzes the Phe_{23}–Phe_{24} (and Phe_{24}–Val_{25}) bond of α_{s1}-casein to produce α_{s1}–I [α_{s1}–CN (f24/25–199)] peptide. The hydrolysis of this bond is probably the most important reaction responsible for the initial softening of cheese. Subsequent degradation of the α_{s1}–I casein by rennet occurs during ripening. The peptide, α_{s1}–CN(f1–24/25), is rapidly hydrolyzed by starter cell wall-associated proteinases.

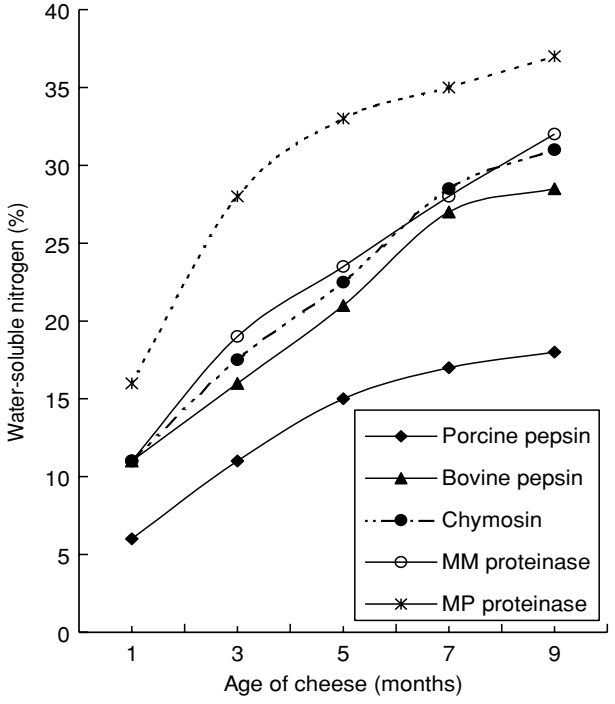

Figure 1 Water-soluble nitrogen (percentage of total nitrogen) during ripening of Cheddar cheese made with identical milk-clotting activities of different enzymes. MM, *Mucor miehei*; MP, *Mucor pusillus*.

Proteolysis of β-casein is less extensive than that of α_{s1}-casein in cheeses made with chymosin, bovine pepsin, or porcine pepsin, but more extensive breakdown of β-casein occurs in cheeses made with proteases from *M. miehei*, *M. pusillus*, and *C. parasitica*.

Plasmin, an indigenous milk proteinase, hydrolyzes all the caseins except κ-casein. Specifically, plasmin hydrolyzes β-casein to γ-caseins [β-CN(f29–209, 106–209, and 108–209)] and proteose peptones. The activity of plasmin is high in cheeses like Romano and Emmental, for which high cooking temperatures are used during manufacture, and in which the coagulant is denatured.

Starter and nonstarter bacteria have very limited proteolytic abilities towards whole caseins in cheese, although proteinase-positive strains of lactococci have cell envelop associated serine proteinases that hydrolyze caseins. Starter lactococci also contain a variety of peptidases (Table 4) that hydrolyze oligopeptides and di- and tripeptides resulting from the action of rennet and/or indigenous milk proteinases on caseins to amino acids essential for the development of flavor. The most common free amino acids in cheese include glutamic acid, methionine, asparagine, histidine, alanine, valine, phenylalanine, leucine, and lysine. In Emmental-type cheese, proline is also present.

Proteolytic enzymes from *Penicillium* species and *Brevibacterium* species are major contributors to proteolysis in mold-ripened cheeses. Depending on the

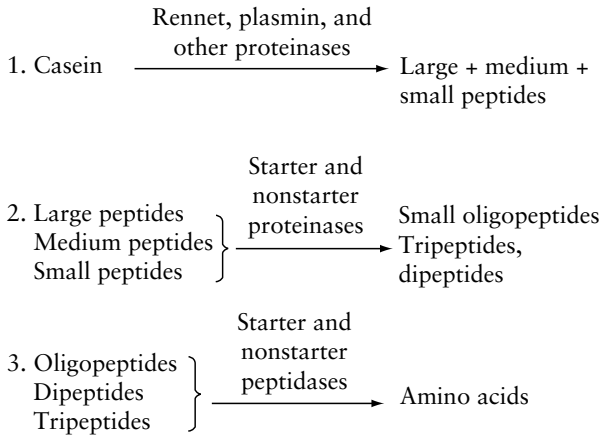
Table 4 Peptidases in Lactococci

Enzyme	*Other name/abbreviation*[a]	*Specificity*
Endopeptidases	PepO	Hydrolyzes glucagon
	LEPI	Hydrolyzes α_{s1}-CN(f1–23)
General aminopeptidases	AMP	Broad specificity. Hydrolyze several di-, tri-, and tetrapeptides
Aminopeptidase A	PepA	Hydrolyzes N-terminal Glu- and Asp residues
Glutamyl aminopeptidase A	GAP	N-terminal Glu- and Asp-containing peptides
Aminopeptidase C	PepC	Active on Lys, Phe, His, Glu, and Leu
Aminopeptidase N	PepN	Substrates with N-terminal Lys, Arg and Leu
X-prolyl-dipeptidyl aminopeptidase	PepX (PepXP)	Hydrolyzes with N-terminal X–Pro in X–Pro–Y-containing peptides
Pyrrolidonyl carboxyl peptidase	PCP	Removes N-terminal pyroglutamate residues from peptides
Aminopeptidase	PepP	Hydrolyzes N-terminal residues from X–Pro–Pro–Y
General aminopeptidase	PepT	Hydrolyzes Pro–Gly–Gly
Dipeptidase	DIP	Hydrolyzes dipeptides
Prolidase	PRD	Hydrolyzes dipeptides containing C-terminal proline (X–Pro)
Tripeptidases	TRP	Cleaves N-terminal amino acids. Do not hydrolyze tripeptides containing Pro as second amino acid
Proline iminopeptidase	PIP	Hydrolyzes di- and tripeptides containing N-terminal Pro residues

[a]The abbreviation 'Pep' is used for peptidases that have been genetically characterized. Others denote peptidases that have not been genetically characterized.

strain of *P. roqueforti* used, water-soluble N in Blue cheese may be as high as 50% of the total N after 3 months of ripening.

A summary of the sequence of proteolytic events that occurs in cheese during ripening is shown below.



Breakdown of Amino Acids

Amino acids can be converted into various products during the ripening of cheese. Amino acids can be decarboxylated to CO_2 and an amine; the resulting amine undergoes oxidative deamination to give NH_3 and an aldehyde from which a primary alcohol or acid is formed. An aldehyde can also be formed by oxidative deamination of an amino acid. For example, deamination of glycine and alanine produces methanol and ethanol, respectively; decarboxylation of tyrosine and histidine results in tyramine and histamine, respectively. Amino acids can be converted to other amino acids by transamination. Sulfur-containing amino acids such as methionine can be converted to products such as methanethiol (CH_3SH), dimethysulfide, etc. Methanethiol and H_2S contribute to Cheddar cheese flavor. Trytophan can be degraded to indole, pyruvic acid, and NH_3. Tyrosine can be degraded to phenol.

Lipolysis

The action of lipase on triglycerides produces fatty acid(s), monoglycerides, and diglycerides. Lipolysis in cheese is due to the activities of milk lipoprotein lipase, exogenous lipases (from rennet pastes), or lipases from microflora in cheese milk. In pasteurized milk cheeses, the activity of milk lipoprotein lipase is small, as under normal pasteurization conditions, 10–15% of the activity in raw milk is left. Some starter and nonstarter bacteria contain lipases that hydrolyze mono- and diglycerides but have a weak lipolytic activity towards unhydrolyzed milk fat (triglycerides). Therefore, the concentration of free (C_4 to C_{18}) fatty acids (FFA) in bacteria-ripened cheeses like Cheddar, Emmental-type, and Dutch-type cheeses is low (0.1% in 3-month-old Cheddar, increasing to < 0.2% after 12 months of ripening). Cheddar cheese containing > 0.2% FFA usually has a rancid flavor.

In some Italian cheese varieties (e.g., Romano, Parmesan and Provolone) lipolysis is more than threefold greater than that in Cheddar as exogenous lipases are added during cheese making. The level of lipolysis in blue-veined cheeses (e.g., Blue, Roquefort, Gorgonzola, and Stilton) is high and is due to the activity of one (the acid enzyme) of the two (acid or neutral) types of lipases produced by *P. roqueforti*.

The sequential process of catabolism of fat during cheese ripening is as follows:

1. Liberation of FFA, mono- and diglycerides from milk fat by lipase.
2. Oxidation of FFA to β-keto acids (β-oxidation).
3. Decarboxylation of β-keto acids to produce methyl ketones (e.g., acetone from butyric acid).
4. Reduction of methyl ketones to secondary alcohols (e.g., reduction of acetone to 2-propanol).

Other lipolytic reactions include formations of esters by esterases (e.g., esters of alcohol, methional, and phenol), formation of lactones from unsaturated fatty acids, and the formation of oct-1-en-3-ol from esters of linoleic acid or arachidonic acid. The short-chain (C_4–C_{10}) fatty acids, methyl ketones (mostly 2-heptanone, followed by 2-nonanone and 2-pentanone), and secondary alcohols contribute to the characteristic flavor and aroma of cheese.

Manufacture of Extra-hard Cheeses

V Bottazzi, Universita Cattolica del Sacro Cuore, Piacenza, Italy

Classification, Definition, and Examples

The extra-hard (or very hard) cheeses are a group of varieties characterized by a long ripening time, and by the production in large pieces weighing from 18 kg to more than 100 kg per whole cheese; they are produced principally in Mediterranean Europe with sheeps' or cows,' milk. Grana cheese produced in the Po Valley can have the mark 'Parmigiano Reggiano' or 'Gran Padano,' depending on the areas of production. The technology of production is thousands of years old, and the hard cheeses are characterized by having a low moisture content. (*See* **Sheep**: Milk.)

Once they are ripe, their taste can be harsh and strong or delicate and fragrant, their structure is compact and friable, and they are used mainly for grating as a condiment. They play an important role in the Mediterranean diet.

The following cheeses are included in the group of extra-hard (or very hard) cheeses: Grana, Pecorino Romano, Provolone Piccante and Caciocavallo, Sapsagno, and Spalen.

Each grana (whole cheese) weighs 34–38 kg, and it is produced only in northern Italy (Po Valley) using partially skimmed cows' milk. It is the best known cheese among those used for grating as a condiment and, in order to maintain all its fragrance, it should be grated just before use. Annual production is 190 000 tonnes, which means using more than 35% of the Italian whole-milk production.

Pecorino Romano cheese is one of the most ancient cheeses: a description of the cheese-making process dating back to before Christ is available. It is produced in Sardinia and in the area around Rome, using only sheeps' milk coagulated by means of rennet paste from lambs; whole cheeses range between 16 and 22 kg in weight, and its taste is typically strong.

Provolone Piccante cheese and the Caciocavallo cheese are typical stirred-curd cheeses, originating in, and very widespread in, the Mediterranean area. The large Provolone Piccante cheese is cylindrical and can weigh up to 100 kg: it is produced with raw milk and rennet paste from kids, and once ripe, its taste is sharp, strong, and very pleasant.

As far as the description of the manufacturing technology, both traditional and modern, of extra-hard cheeses is concerned, we are going to describe only that of the grana cheese, as it is the most well known.

Traditional Methods of Manufacture

The traditional method is not very different from methods used today, for it is a feature of hard cheeses to apply technological rules that do not vary very much with the passing of time.

Up to about 100 years ago, grana cheese was very often manufactured in cheese factories designed following particular rules aimed at obtaining well-defined goals. Such a factory was a single, isolated building with an octagonal base, and walls free from windows. The height of the building was about 3 m, and the roof was supported by a wooden structure. Architecturally, such buildings are pleasant in appearance.

Inside, all the cheese-making operations were carried out using direct-fire heating of the milk, and the typical structure allowed natural aeration.

According to tradition, raw milk obtained the evening before manufacture was poured into shallow vats with a large surface area, so as to facilitate separation of the cream; this process was necessary since grana cheese is produced with partially skimmed milk. The vats were made of either wood or tin-plated copper of sufficient volume to hold half of the milk necessary to produce a whole grana cheese, i.e., 250 l. The creaming took place overnight, and in the morning, after the skimming operation, the milk was mixed with fresh milk, and cheese manufacture in a large copper vat commenced.

Until the end of the nineteenth century, no starter cultures were added, and in order to reach the desired acidity, the contaminating microflora acquired during milking and in the cheesemaking operation was exploited; the vat was then left for a prolonged period, which allowed a remarkable bacterial flora to develop. (*See* **Starter Cultures**.)

Rennet prepared from the stomach of sucking calves was always used to coagulate the milk. After breaking the coagulum, very small curd granules, which had a very low moisture content, were obtained. The granules were smaller in dimension than rice grains, and the expulsion of whey was through the high 'cooking' temperature (53–54 °C).

Originally, the cheese vat had a capacity of 500 l (so as to produce one cheese at a time), had a truncated cone shape (inverted bell), was made of copper, and had direct-fire heating.

Salting, using brine, was started 2 or 3 days after production and continued for 25–28 days in separate brining rooms.

The ripened cheeses were carried out in stores at the prevailing temperature, i.e., under the influence of the seasons, temperatures varied from about 5 to 28 °C, for at least 18 months. During this long period, and especially during the first months, many manual operations were necessary in order to avoid the development of molds on the cheese surfaces, and to obtain a smooth, even rind. Towards the end of the ripening period, the cheese was covered with a mixture of carbon black, umber, and grape seed oil, so as to produce a black color and a characteristic shiny, bright appearance.

Modern Systems of Production

The current manufacturing technology of grana cheese shows, in comparison with the traditional technology, several differences.

The current procedure uses raw milk, natural creaming and a high cook temperature, but nowadays, the technology also includes the addition of a starter culture, 'double cheese-making,' a rapid cheese-making time, 'twins' production, controlled ripening as well as other changes, which will be described later.

The whey starter culture was introduced at the end of the nineteenth century, and has a very complex microflora composition. The prevailing bacteria are *Lactobacillus helveticus* together with *Lb. delbrueckii* ssp. *lactis* and ssp. *bulgaricus* and *Lb. fermentum*; thermophilic streptococci are generally absent. The culture is phage-resistant, has a high acidifying capacity, is thermophilic, has a very good viability, and is very easy to prepare. It is affected by the microbial characteristics of the milk and the environment where manufacture takes place, and it is the result of the action of several technological factors typical of each environment; because of its characteristics, it turns out to be an unrepeatable culture that cannot be replaced by the association of different strains in the laboratory. The activity of the natural whey culture is very important: primarily to produce an acid environment in the cheese (thereby inhibiting gas-producing bacteria), to take part in the hydrolysis of proteins, as well as to take part in the hydrolysis of proteins, as well as to take part in taste and fragrance formation. (*See* **Lactic Acid Bacteria**; **Whey and Whey Powders**: Production and Uses.)

The 'double cheese-making' process involves the transformation of milk from two milkings, and brings about the creaming of all the milk employed. From a practical point of view, this is a very important change, because by creaming at a temperature of 12–15 °C, not only is the milk skimmed, but also many bacteria are carried out with the cream; an effect similar to that obtained through pasteurization.

This cold reduction in bacterial numbers leaves the cheese-making properties of raw milk unchanged, a point of primary importance in grana cheese production.

This system is widespread in the whole production zone of grana Padano; the grana Parmigiano Reggiano cheese-makers keep to the traditional method of manufacture.

The 'rapid cheesemaking time' used today in grana cheese production refers to the time between the addition of rennet to the milk and the end of the curd cooking. At the end of the nineteenth century, the time was rather long – sometimes even 50–60 min – but today, it is just 18–22 min.

The reasons for these changes include both the different conditions of milk production, and the introduction of thermophilic cultures of lactic acid bacteria. From a practical point of view, it allows better work organization and more regular cheese-quality standards.

The 'twins' production started with the replacement of the 500-l vats with 1000-l vats; the shape of the copper vat is unchanged and is typical for this kind of cheese; the maximum capacity is 1000 l of milk. As a consequence, two whole cheeses can be obtained each time, and these are called twins, since they are the result of the division into two even parts of the curd obtained from 1000 l of milk.

The number of grana cheese factories is still more than 1100 today, but a progressive transformation towards medium-to-large factories is taking place. Several copper vats may be found in one factory, but because the manufacture involves separate batches of milk, each of 1000 l, there is neither real mechanization nor automation (not even cheese pressing is carried out mechanically). None the less, the whole cheese-making process in the vat is carried out in a short time, with a regular and precise sequence, even in the case of large factories. Today, the coagulum is broken first manually, but further breaking up and stirring of the curds/whey to complete cooking are carried out using simple mechanical means.

Ripening is carried out in stores with controlled temperature (16–18 °C), humidity (85%), and continuous air change without creating currents of air.

The cheese is ripened for 14–24 months (the grana Padano needs a shorter time than Parmigiano Reggiano), and during this period, the whole cheeses are often turned upside down once a week during the first months, and less frequently thereafter. Maintenance of the cheeses (inverting and brushing) is carried out mechanically by means of automatic systems.

The modern system for Grana cheese production provides for milk cooling at 8 °C for 12 h in sheds, then mixing with warm milk from the subsequent milking, thus allowing a single collection per day. If necessary, and in particular in areas where there is a high consumption of ensiled fodder, irregular fermentations can be avoided through the partial elimination of bacteria by centrifugation. The main steps in Grana cheese production can be described briefly as follows:

1. Milk is poured into 1000-l vats, with dimensions of $4.50 \times 1.90 \times 0.25$ m, for creaming, so that the milk reaches the copper, truncated cone-shaped cheese vats with a fat content ranging, depending on the region, from 2.00 to 2.30%.
2. After transfer of the partially skimmed milk to the 1000-l copper vats, about 3% of natural whey culture is added to give an acidity (in lactic acid) in the mixture (milk + whey culture) of 0.19–0.20%; the milk is heated to 33 °C and rennet (titer 1 : 100 000) at a level of 2 g per 100 l.
3. Coagulation occurs in 9–10 min, and the coagulum is broken for 3 min to obtain curd granules having the dimensions of rice grains.
4. The curds/whey are heated to reach the cook temperature of 54 °C in 7–8 min.
5. The curd is allowed to settle and form a compact layer at the bottom of the vat, and the curd is then kept in the hot whey for about 45 min.
6. The bed of curds is divided into two portions, each of which is scooped from the mold using a coarse cloth, and placed in the unfixed wooden molds; at the start of the pressing operation, the cheeses are pressed by loading each cheese with 20-kg weights.
7. During the first 10 h, the cheeses are turned three or four times, with cloth changes; after 15–20 h, the cloths are removed, and the wooden mold is replaced by a metal mold.
8. On the third day, the cheeses are brine-salted (density 22 °Bé and temperature 16–17 °C) for 24–28 days.
9. At the end of the salting and once the whole cheeses are dry, they are transferred to the ripening store and kept at a temperature of 16–18 °C and a humidity of 85%.

Maturation and Storage

Grana cheese, after ripening, has the following average composition (%):

- protein: 33.20
- fat: 27.50
- ash: 4.80
- moisture: 32.00
- sodium chloride: 1.60
- lactic acid: 1.30

Owing to the high content of protein and low fat content, grana cheese can be defined as a 'half-fat' cheese having a high protein content.

During the first hours of pressing, an intense fermentation process occurs in grana cheese, transforming the lactose into lactic acid. After 6 h, the pH is about 5.50 and after 16 h, 5.0; the lactic acid is distributed as indicated in Table 1.

After 5 h of fermentation, the lactose has decreased to about 1.6%, the accumulated galactose is slightly higher than 1%, and the concentration of glucose is about 0.30%.

During the long ripening period, even the casein undergoes extensive proteolysis. β-Casein is hydrolyzed rapidly during the first part of the ripening cycle, and its enzymatic degradation finishes within the first 12 months of ripening. However, α_{sl}-casein is degraded much more slowly. With reference to the total amount of hydrolysis products, about 30% are from β-casein, while those from α_{sl} casein form about 18%.

The release of amino acids increases progressively until about the 15th month of ripening and then becomes stable. When the cheese is ready to use, the amino acids form, on average, 22% of the total crude nitrogen value and 7% of the cheese; as a consequence, grana cheese is one of the cheeses having a high content of free amino acids. In cheeses of first-class quality, serine increases progressively throughout the ripening time and finally reaches about 1.5% of free amino acids; glutamine reaches 1% in the first 12 months and disappears once the ripening is finished, and arginine, released during the ripening period, is degraded into ornithine. The presence of γ-aminobutyric acid indicates that anomalous fermentation processes have taken place. (*See* **Amino Acids**: Properties and Occurrence.)

The hydrolysis of fat in grana cheese does not play an important role, in spite of the long ripening period. There is also a slight loss of vitamin A, a greater remarkable loss of vitamin E, and a serious reduction of β-carotene from 640 to 100 μg per 100 g of cheese. (*See* **Carotenoids**: Occurrence, Properties, and

Determination; **Retinol**: Properties and Determination; **Tocopherols**: Properties and Determination.)

The mineral component, composed of macro- and microelements, takes on a very precise character: calcium, phosphorus, and magnesium are the elements present at the highest levels: 1150, 680, and 430 mg per 100 g respectively. The calcium:phosphorus ratio is high (1.70), i.e., much higher than that found in many other cheeses. (*See* **Calcium**: Properties and Determination; **Magnesium**.)

The average content of sodium in grana cheese is 650 mg per 100 g. Among the microelements, the content of zinc is very high. (*See* **Sodium**: Properties and Determination; **Zinc**: Properties and Determination.)

The microbiological composition of grana cheese is characterized by two separate steps. The first concerns the very young cheese (first hours), and the second covers the first months, and continues even until the end of ripening.

The lactic acid bacteria are numerous during the first period, and the flora is that of the starter, mainly composed of *L. helveticus*, usually reaching, after 12–14 h, $0.8–1 \times 10^9$ cells per gram, and *L. fermentum*, which reaches a maximum in about 24–28 h with $120–140 \times 10^6$ cells per gram. In this first period, even *L. delbrueckii* ssp. *bulgaricus* and ssp. *lactis* are active. The development of this homo- and heterofermentative thermophilic lactic acid flora plays a very important role in the commercial success of the final product, since it:

- ensures a rapid acidification of the fresh cheese;
- regulates whey drainage;
- accumulates enzymes of the proteolytic system;
- causes the formation of small holes;
- produces volatile compounds;
- contributes to the formation of the cheese structure.

During the second period, a nonstarter lactic acid flora develops, consisting of coccoid lactic acid bacteria, e.g., *Pediococcus acidilactici* and rod-shaped bacteria, e.g., *L. casei* ssp. *casei*, ssp. *pseudoplantarum* and ssp. *rhamnosus*.

During the period of maximum development, i.e., 25–40 days after production, this lactic acid flora reaches $60–80 \times 10^6$ cells per gram, but, for the remaining ripening period, the number decreases progressively. Pediococci are the most resistant forms and are still present in the cheese at the time of consumption.

The metabolic activity of the mesophylic lactic acid bacteria contributes to the ripening process, and its contribution to casein hydrolysis is very important.

Finally, there are the propionic bacteria, which are useful for the development of the organoleptic characteristics of the cheese, so long as their development is limited to a few million cells per gram.

Formation of Micro- and Macrocrystals

The formation of individual or grouped crystals occurs during ripening of the cheese (Figures 1–3). In grana cheese, the first type of microcrystals appears at the end of the lactic fermentation driven by a thermophilic lactic microflora, during the first hours of ripening. The crystals are spherical. The external side is porous, showing an irregular surface, with a diameter of 8–20 μm. The internal portion, as shown in Figure 1A, is well defined, with a compact peripherical ring and laminar structure converging in the centre. Crystal formation is limited to the first 48 h

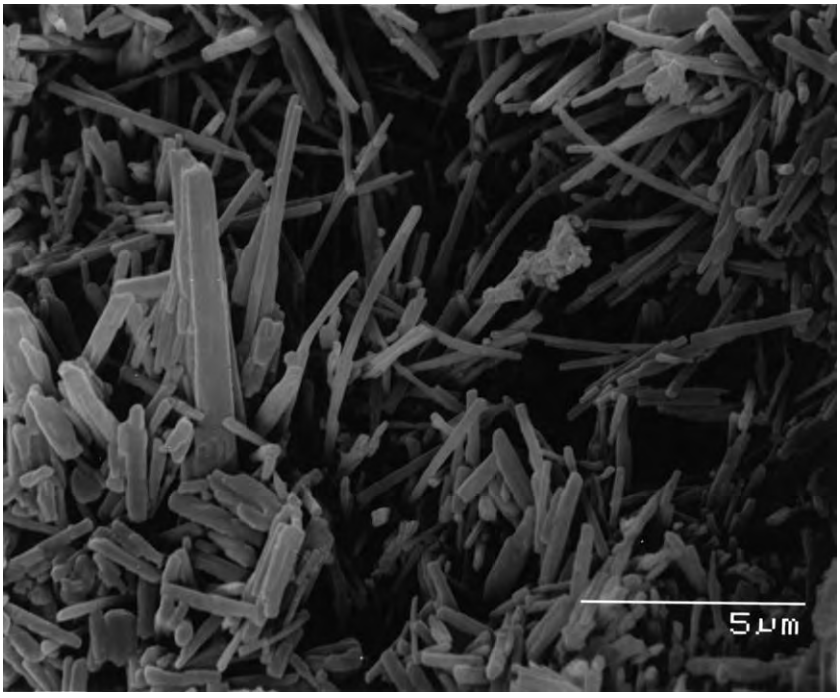

Figure 2 Needle-shaped calcium lactate crystal aggregates in ripened grana cheese.

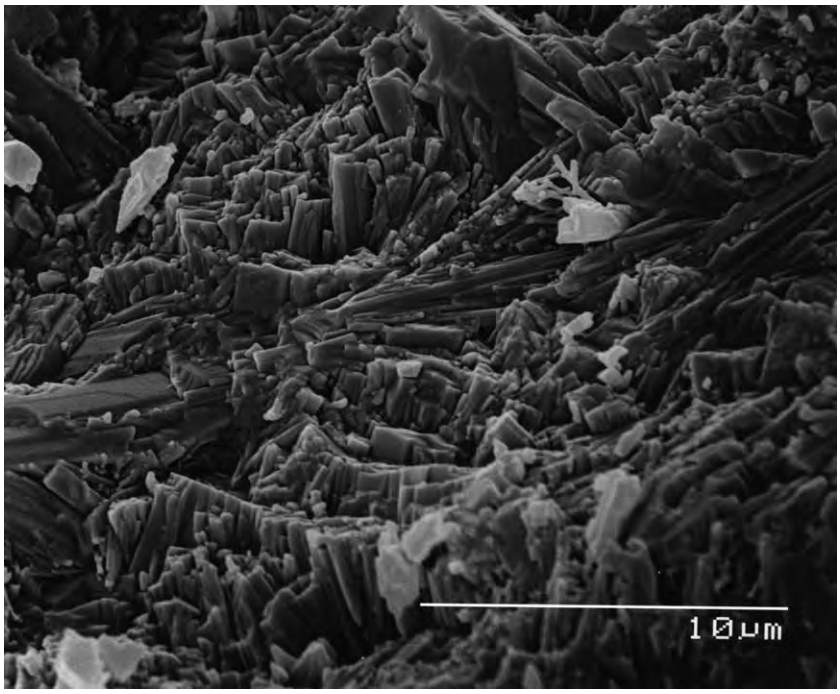

Figure 3 Internal structure of a tyrosine macrocrystal in ripened grana cheese.

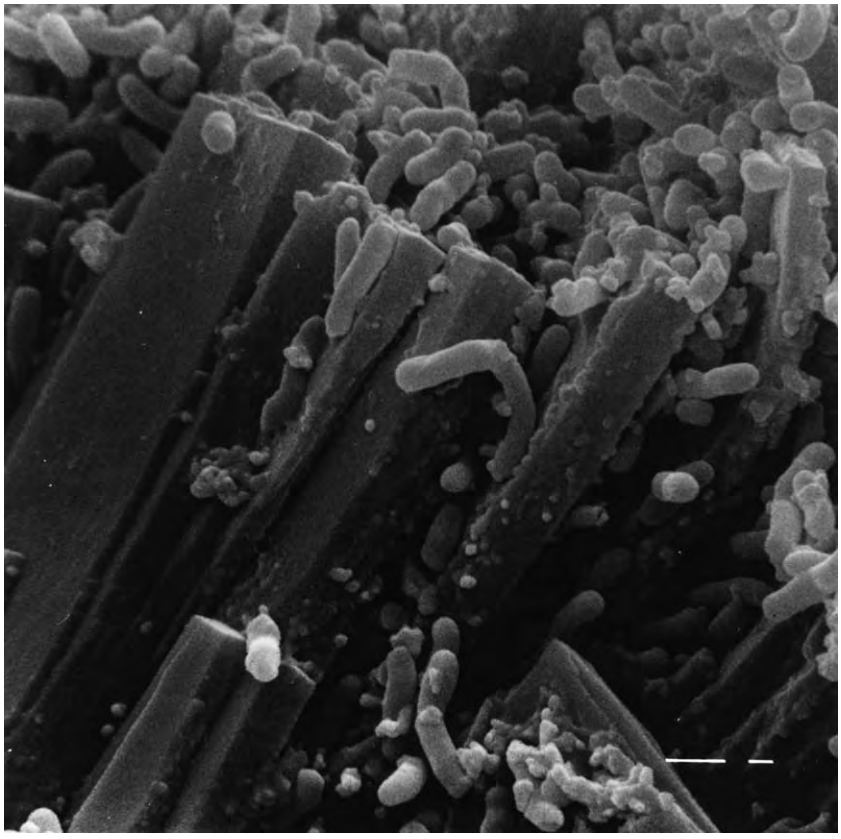

Figure 4 Sodium chloride microcrystals in ripened grana cheese.

in grana cheese. During further cheese ripening, no further increase in volume or number of crystals can be seen. These crystals are composed of calcium phosphate.

Figure 2 shows a second type of crystal: needle-shaped and generally grouped. At the end of ripening, these can be observed in the cheese paste as white, friable, sandy granules. These crystals are typical of grana Padano cheese and are generally associated with a high-quality product (if not too numerous) and are composed of calcium lactate.

At the end of ripening, a gray crystalline formation becomes evident (0.3–0.5 mm in diameter). These crystals are formed by tyrosine and impart a bitter taste. Their internal part is shown in Figure 3. Aggregates of NaCl rarely appear in cheese at the end of the ripening process. Figure 4 shows these aggregates observed under a scanning electronic microscope.

Specification and Standards

Grana cheese is a half-fat hard cheese, cooked and slowly ripened, with a light straw color yellow and a compact, granular and friable structure with flake-shaped radial fractures and a fragrant and delicate aroma. For its production, raw milk, half-skimmed through natural creaming, is used. To the milk is added a natural starter culture of thermophilic lactic acid bacteria developed in whey, and the mixture is coagulated by means of rennet from sucking calves. The ripening lasts 18–24 months for Parmigiano Reggiano and 13–15 months for grana Padano.

The ripe product, ready to eat, has:

- a cylindrical form with convex (lateral) sides, and slightly convex flat sides;
- dimensions varying between 35 and 45 cm in diameter, and between 18 and 24 cm in height on the lateral side;
- a whole-cheese weight between 32 and 34 kg;
- a hard, smooth, bright surface, with a natural uniform color.

Manufacture of Hard and Semi-hard Varieties of Cheese

P F Fox and P L H McSweeney, University College, Cork, Ireland

Background

Approximately 500 varieties of cheese are recognized by the International Dairy Federation; in addition, numerous minor cheese varieties are manufactured locally. For various reasons, a number of attempts have been made to classify cheese varieties into meaningful groups. Traditional classification schemes have been based principally on moisture content, i.e., extra-hard, hard, semihard/semisoft, or soft. Although used widely, this scheme suffers from serious limitations, since it groups cheeses with widely different characteristics, e.g., Cheddar and Emmental are classified as hard cheeses, although they have quite different textures and flavors, they are manufactured by very different technologies, and their microbiology and biochemistry are very different. This composition-based scheme is made more discriminating by including information on the source of the milk, coagulant, principal ripening microorganisms, and cook temperature. Based on the method of milk coagulation, cheeses may be divided into four super-families:

- rennet-coagulated cheeses: most major cheese varieties;
- acid-coagulated cheeses, e.g., Cottage, Quarg, Cream;
- heat/acid-coagulated, e.g., Ricotta;
- concentration/crystallization, e.g., Mysost.

Rennet-coagulated cheeses represent ~ 75% of the total world production and include all ripened varieties; owing to the great diversity of these cheeses, further classification is desirable, e.g., based on the characteristic ripening agent(s), e.g., internal bacteria, internal mold, surface mold or surface smear (bacteria), or manufacturing technology. The most diverse family of rennet-coagulated cheeses is that containing the internal bacterially ripened varieties, which include most hard and semihard cheeses. The composition of these cheeses is not defined precisely, and for the present purpose, cheese containing about 35–45% moisture will be included. Traditionally, cheeses develop a rind through which moisture evaporates; hence, the composition of cheese changes as it ages, and there is a moisture gradient from the surface to the center. The moisture content of long-ripened cheese may decrease by 5–10% during ripening. Obviously, the differentiation between hard and semihard is arbitrary.

Hard Varieties

Several subgroups of hard/semihard cheeses are discussed in other articles, i.e., Swiss-type, Dutch-type, pasta filata, and ripened-in-brine varieties. This article will focus on Cheddar-type cheese with brief descriptions of British Territorial cheeses and several other varieties which are generally similar to the above.

Cheddar-type Cheese

Hard cheeses have a moisture content of 35–40% and are manufactured by a generally similar technology, including renneting at ~ 30 °C, cutting the coagulum into small pieces, cooking to ~ 40 °C, drainage of the whey and pressing the curd. In some cases, e.g., Cheddar and other British varieties, the curds are textured in the vat ('cheddared'), and the blocks of curd are milled and dry-salted when sufficient acidity has developed. The salted curds are molded, pressed for 12–16 h, and matured for 3–12 months, or longer. Hard cheeses include Cheddar, Cheshire, Derby, Gloucester, and Leicester (British), Cantal (French), Friesian and Leiden (Netherlands), Graviera and Kefalotiri (Greece), Manchego, Idiazabal, Roncal, and Serena (Spain), Sâo Jorge (Azores, Portugal), and Ras (Egypt).

Cheddar cheese, which originated around the village of Cheddar, Somerset, England, is one of the most important cheese varieties worldwide, representing ~ 30% of total cheese production; it is produced on a large scale in the USA, the UK, Australia, New Zealand, Canada, and Ireland. Although small amounts of Cheddar cheese are made from raw milk, mainly at the farmhouse level, the vast majority is produced from pasteurized cows' milk standardized to a casein:fat ratio of ~ 0.7:1, intended to give a fat-in-dry matter (FDM) of at least 48%. With the objective of reducing the intake of dietary fat, reduced-fat Cheddar is produced commercially, but because its flavor and especially its texture (which is hard and crumbly) are inferior to those of full-fat Cheddar, it has only a minor share, perhaps 5%, of the market. However, research is continuing on ways of improving the flavor and texture of reduced-fat Cheddar and related varieties.

Some consumers prefer an intensely colored cheese, and the orange pigment, annatto (E160b), is sometimes added to the milk for Cheddar and other British cheeses. Annato is produced from the berries of the tropical plant, *Bixa orellana*, and contains two apocarotenoid pigments, bixin and norbixin.

A key feature of the manufacture of all cheeses is a decrease in pH to ~ 5, usually through the production of lactic acid in the curd. Traditionally, the lactic acid was produced by the adventitious microflora, especially lactic acid bacteria (LAB), but this was very variable and unpredictable, and hence the rate of acidification varied, with adverse effects on the quality of the cheese. The practice of adding a culture of selected LAB, referred to as a starter, was introduced at the end of the nineteenth century, and it is now standard practise to inoculate milk for Cheddar-type cheese with a culture of mesophilic LAB, i.e., *Lactococcus lactis* ssp. *cremoris* and/or *Lc. lactis* ssp. *lactis*. Initially, these cultures were undefined and contained a mixture of strains. Defined-strain starters were introduced in New Zealand in the 1930s, initially as a component of a phage-control program, and are now used widely in large Cheddar factories; their main attraction is that, if properly managed, they give a very reproducible rate of acid production and hence cheese quality, although the flavor of the cheese may be rather mild, due to the lack of microbial enzyme diversity. Today, the thermophilic organism, *Streptococcus thermophilus*, is fairly widely used as a component of starters for Cheddar cheese, mainly to increase stability to phage, to permit a higher cook temperature, and to intensify and modify the flavor of the cheese.

Sufficient rennet is added to the milk at ~ 30 °C to give a firm coagulum after about 35 min. Traditionally,

rennet prepared by extracting the stomachs of young, milk-fed calves with NaCl brine was used for Cheddar, but owing to increased production of cheese and a dwindling supply of young calves, several rennet substitutes have been introduced over the past 40 years, especially bovine and porcine pepsins, acid proteinases from *Rhizomucor meihei, R. pusillus*, and *Cryphonectria parasitica* and chymosin from genetically engineered microorganisms. An aqueous extract of the flowers of the cardoon thistle, *Cynara cardunculus* L., which is used in Portugal for the manufacture of Sera da Estrêla, is used in the western parts of Spain for the manufacture of Serena, a hard cheese.

When the coagulum is sufficiently firm, it is cut into cubes of about 1 cm. A rennet-induced milk gel is quite stable if left undisturbed, but if cut or broken, the pieces of curd contract (synerese), expelling whey. By controlling the rate and extent of syneresis, the cheese-maker can control the composition of the cheese curd and hence the rate and direction of ripening and the quality and stability of the cheese. Syneresis is promoted by increasing the temperature, reducing the pH or agitating the curds/whey. In the case of Cheddar and related cheeses, the curds/whey mixture is cooked from 30 to 37–39 °C over 30 min and held at this temperature for about 1 h. At this stage, the pH should be ~ 6.1, and the whey is drained off; if the pH has not decreased sufficiently, removal of the whey may be delayed. The curds for Cheddar and related varieties are 'cheddared,' a process unique to, and characteristic of, these varieties. The traditional cheddaring process involves forming the drained curds into beds at both sides of the vat, separated by a trough for whey drainage. After about 15 min, the beds of curd are cut into blocks, which are inverted and piled at intervals. The cheddaring process allows time for acidity to develop in the curd (from *c.* pH 6.1 to 5.4) and subjects the curds to gentle pressure, which assists in whey drainage and causes the blocks of curd to flow and spread. During cheddaring, the curd granules fuse, and the texture becomes similar to that of cooked chicken-breast meat at the end of cheddaring. This textural change was considered to be the characteristic feature of Cheddar cheese manufacture, but the principal function of cheddaring is to promote curd syneresis and to allow development of sufficient acid as a result of which colloidal calcium phosphate dissolves, leaches out of the curd, and is lost in the whey. The calcium:-casein ratio has a major effect on the textural properties of cheese, including stretchability, pliability, and meltability; these features are particularly important in Cheddar and *pasta filata* cheeses.

When the pH reaches *c.* 5.4, the curd blocks are milled into chips and salted at a level of ~ 3%, to give ~ 2% salt in the finished cheese. The salted curds are 'mellowed,' during which the salt dissolves in moisture on the surface of the chips. Mellowing is critical for the proper control of the concentration and distribution of salt in the cheese. The curds are then molded, traditionally as 10–40 kg cylinders (typically, 20 kg), and pressed overnight at ~ 200 kN m^{-2}. Cheddar cheese curd is matured at 6–12 °C for a period ranging from 3 to 24, or more, months, depending on the maturity desired. Traditionally, the wheels of Cheddar were dried slowly to form a rind and then dipped in yellow or black wax.

Although the traditional manufacturing process described above, and summarized in **Figure 1**, is still practiced in small factories and on a farmhouse scale, most Cheddar cheese is now manufactured in large (20–50 000 tonnes per annum), highly automated factories (e.g., **Figure 2**). The principal features of automated Cheddar production include the use of large (30 000 l) enclosed vats in which cheese-making commences at 30 min intervals to provide a semi-continuous supply of curd. All operations in the vat (addition and mixing of starter and rennet, cutting of the gel, and cooking of the curds) are automated and computer-controlled. After cooking, the curds/whey mixture is pumped on to an inclined screen, on which the curds and whey are separated. The drained curds are moved pneumatically to a tower, *c.* 5 m high, or to a belt system on which restricted flow and slight pressing occurs. The pH of the curds should have decreased to ~ 5.4 as they exit the tower or belt. Since it is not possible in large automated factories to hold the curds until the pH decreases to 5.4, consistent production of acid is critical and is one of the principal advantages of using defined-strain highly selected starters.

Large blocks of curd are sliced off the body of curd as it exits the tower or belt and are milled and salted automatically on a belt system. The salted curds are conveyed pneumatically to the top of a 'block former,' a large tower in which the salted curds are compressed by their own weight and subjected to a slight vacuum. As the curds exit the block former, after ~ 30 min, 20-kg blocks are cut off by a guillotine, vacuum-packaged in plastic bags, placed in cardboard boxes, stacked on a pallet (usually 1 tonne per pallet), and transferred to ripening rooms. In many large factories, the boxed cheeses are cooled rapidly in a forced-air cooling tunnel before palleting; the objective is to retard the growth of nonstarter LAB, which may cause defects in flavor and texture.

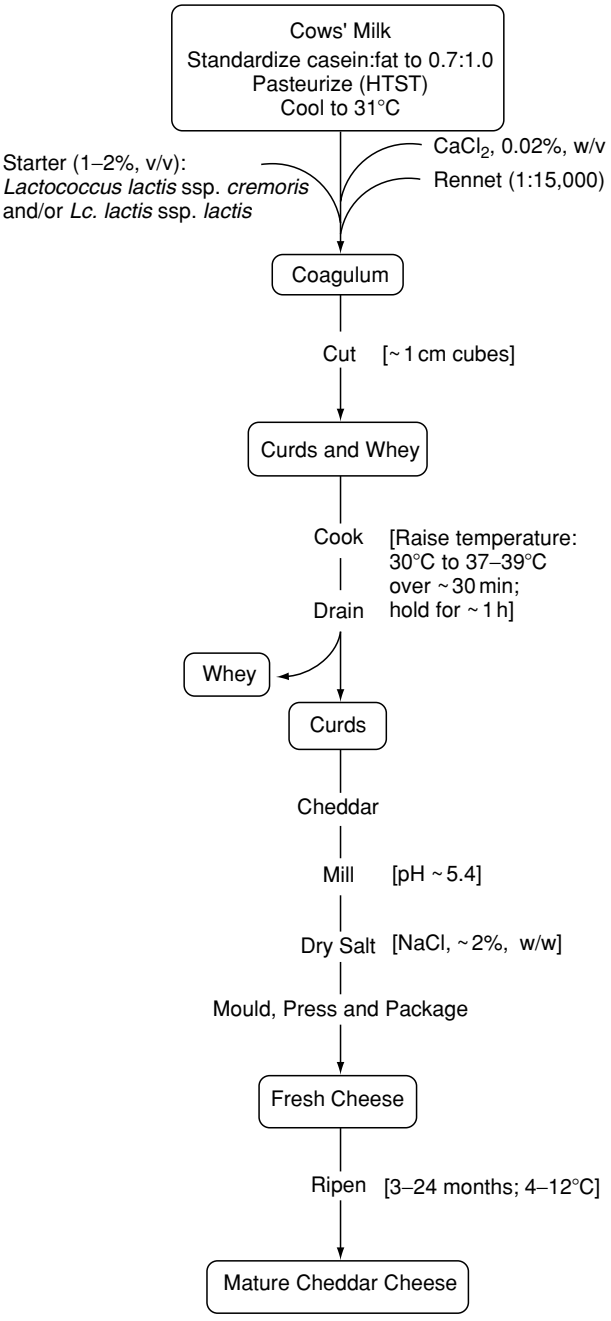

Figure 1 Protocol for the manufacture of Cheddar cheese.

The possibility of using ultrafiltration (UF) to concentrate milk to 'precheese' for Cheddar cheese has been investigated, but the texture and flavor of the product are unsatisfactory. However, UF retentate is used to standardize the fat and protein content of cheese-milk.

Other Hard Cheeses

British Territorial varieties are a group of cheeses which originated in various parts of Great Britain. The most important of these is Cheshire, which has a crumbly, hard texture and several mechanical openings. The milk is inoculated with ~4% of a mesophilic starter, and the curds are cooked at 32–35 °C, which results in a lower pH, a shorter manufacturing time, a higher moisture content, a lower calcium content (due to the lower pH at whey drainage), and a more crumbly texture than for Cheddar. The curds are held on the bottom of the vat after whey drainage, and the bed is broken occasionally to prevent the development of an extensive structure. Cheshire curds are dry-salted at ~3%, placed in molds, drained overnight, pressed, packaged, and matured at 6–8 °C.

Leicester is similar to Cheshire but is normally colored with annatto. The curds are cooked at ~37 °C and pressed after whey drainage; blocks of curd are placed on draining racks, turned, and cut to promote whey drainage. The cheeses are dry-salted and matured for 4–8 months at 10–15 °C. Derby is a little-known English variety with properties generally similar to those of Leicester; it contains 48% FDM and about 42% moisture.

Gloucester is manufactured by a process similar to that for Cheddar and is colored with annatto. The curds are cooked to 35–38 °C, textured, milled twice, dry-salted and pressed into cylinders about 40 cm in diameter and 6–8 cm high for 'Single' Gloucester and 15–20 cm high for 'Double' Gloucester. The cheeses are matured for 4–6 months at 10–13 °C.

Cantal, a hard cheese from the Auvergne region of France, is manufactured by a process somewhat similar to that used for British Territorial varieties. The milk is coagulated using calf rennet and acidified by a mesophilic lactic starter. The curds/whey mixture is not cooked, but the drained curds are cheddared and pressed to promote whey drainage. The blocks of curd are milled, dry salted, molded, pressed, and matured at 8–10 °C for 3–6 months.

Kefalotiri is a Greek cheese made from pasteurized sheep's or goats' milk standardized to *c*. 6.0% fat. The milk is inoculated with a thermophilic culture (usually *Sc. thermophilus* and *Lactobacillus delbrueckii* ssp. *bulgaricus*) and coagulated by calf rennet. The curds are cooked to 43–45 °C, transferred to molds lined with cheesecloth, and pressed at an increasing pressure. The pressed cheeses are brine-salted initially and then rubbed with dry salt for a few days to give a final salt content of *c*. 4%. The cheeses are washed occasionally with a brine-soaked cloth to control microbial growth on the surface and ripened for *c*. 3 months at ~15 °C. Kefalotiri has a hard texture and a strong, salty flavor.

Graviera is also produced in Greece, principally from ewes' milk, which is acidified by a mixed culture

of mesophilic (1%; *Lc. lactis* ssp. *lactis* or *Lc. lactis* ssp. *cremoris*) and thermophilic (0.1%; *Sc. thermophilus* and *Lb. helveticus*) organisms. The curds are cooked to ~ 50 °C and, after whey drainage, molded and pressed at an increasing pressure. The cheeses are salted by frequent application of dry salt to the surface for 2–3 weeks and ripened for 3–4 months.

Ras, the principal hard Egyptian cheese, is produced from cows' milk, standardized to 3% fat, by a process generally similar to that for Kefalotiri. The curds are cooked to 45 °C, salted at a level of 1% after whey drainage, molded and pressed as for Kefalotiri. The cheeses are brined for 24 h, rubbed with dry salt daily for several weeks, and washed with brine.

Manchego, a cheese with *appellation d'origine contrôlée* (AOC) status, is probably the most important Spanish variety. It is made from ewes' milk, although generally similar cheeses (but without AOC status) are manufactured from goats' or cows' or mixed milk. Manchego is produced on an artisanal scale from raw milk, without culture addition, or commercially from pasteurized milk, inoculated with a mesophilic starter. The milk is coagulated with standard calf rennet. The curds are cooked to ~ 38 °C, molded, pressed for 12–16 h, brine-salted and matured for at least 2, and up to 12, months, depending on the maturity required, at 10–15 °C and 85% equilibrium relative humidity (ERH).

Idiazábal, an AOC cheese, is produced in the Basque region of northern Spain from raw ewes' milk coagulated at 38 °C. The coagulum is allowed to cool to 25 °C, then broken and the curds ladled into molds. The cheeses are salted by brining or by the application of dry salt and matured in caves for 2 months at ~ 9 °C. The cheeses may be smoked in beechwood kilns and matured further for up to a year.

Roncal is another AOC cheese made in northern Spain from raw ewes' milk acidified by the adventitious microflora. The curds/whey mixture is cooked to ~ 37–40 °C and the curds then allowed to settle to the bottom of the vat. The whey is removed slowly and the curds pressed against the sides of the vat, molded, pressed, and dry-salted. Roncal is smoked and ripened at 6–8 °C and 100% ERH for 45–50 days.

La Serena is a hard cheese made in western Spain from ewes' milk. Traditionally, raw milk is used, but pasteurized milk is now used for large-scale production. The milk is coagulated at ~ 30 °C with rennet extracted from the thistle, *Cynara cardunculus*. The flat cylindrical cheeses are dry-salted for ~ 24 h and ripened for about 2 months at ambient temperature (10–18 °C).

São Jorge is an AOC cheese produced on a small scale from raw cows' milk on the island, São Jorge, in the Azores. The milk is coagulated using calf rennet, and acidification of the curd depends on the activity of the indigenous adventitious microflora. The pressed cheeses are ripened at 10–12 °C for up to 12 months and, being made from raw milk, develop a strong, piquant flavor. The cheese, which is considered to resemble Cheddar, has been the subject of very little study.

Leyden and Friesian are hard cheeses produced in The Netherlands. Leiden is made from partially skimmed milk, has a flat cylindrical shape, weighs 8–12 kg, and is matured for 6–12 months. Its texture is dry and hard (artisanal, ~ 30% FDM; commercial, 40% FDM), and it is flavored with cumin seeds. Traditional Friesian cheese is similar to Leiden and is made from partially skimmed raw milk. It has a very hard texture and ~ 20% FDM. It may be made without spices, with cumin, or with cumin and cloves. Today, most Friesian cheese is made from fresh, pasteurized, partly skimmed milk, acidified using a mesophilic culture.

Semihard Varieties

The 'semihard' group of cheeses is rather arbitary and heterogeneous, and the distinction between it and other groups, e.g., hard cheeses, smear-ripened varieties or *pasta filata* cheeses, is not clear-cut. Semihard cheeses include Colby and Monterey (stirred-curd Cheddar-type cheeses), some British Territorial varieties (Caerphilly, Lancashire, and Wensleydale), Bryndza (Slovakia), and Mahon and Majorero (Spain).

Caerphilly, which originated in Wales, is a crumbly, acidic cheese made from pasteurized cows' milk using calf rennet and a mesophilic starter. The curds are cooked to 32–34 °C and held at this temperature for about 1 h. The whey is drawn off and the curds held in the vat where rapid acidification occurs. Salt (1%) is added to the curds before molding and pressing overnight. The pressed curds are brine-salted for 24 h, packaged, and ripened at 10–13 °C for 10–14 days.

Lancashire is made from cows' milk using calf rennet and a mesophilic starter. The curds and whey are not cooked, but the drained curds are cheddared and held overnight for acidification. The next day, fresh curds are mixed with the acidified curds and the mixture milled to promote uniformity, dry-salted, molded, pressed, and ripened at 13–18 °C for 3–12 weeks.

Wensleydale cheese, which originated in Yorkshire, England, is made from cows' milk, inoculated with a mesophilic starter; the curds are cooked at 32–34 °C. The bed of drained curds is broken to assist whey drainage, dry-salted, molded, and pressed lightly. Wensleydale, which is matured for *c.* 1 month at ~ 12 °C, has mechanical openings and a mild, acidic taste. A blue variant is produced also.

Two stirred-curd variants of Cheddar cheese are recognized: Colby and Monterey. The manufacture of Colby, which originated in the USA, follows a protocol similar to Cheddar until after cooking, when some whey is removed and replaced by cold water, which reduces the lactose content and pH, and increases the moisture content of the cheese. The curds/whey mixture is stirred and most of the whey removed; the curds and remaining whey are stirred vigorously and the remaining whey drained off. The drained curds are stirred until the pH reaches ~ 5.4, when they are dry-salted, molded, pressed, and ripened for 2–3 months at 3–4 °C. Colby contains less than 40% moisture and $\geq$ 50% FDM.

Monterey (Monterey Jack) cheese was first made in California and is similar to Colby. The cheese, which contains < 44% moisture and $\geq$ 50% FDM, is allowed to form a rind before waxing or packaging in a plastic film. Monterey, which is ripened for 5–7 weeks at ~ 4 °C, has many mechanical openings.

Bryndza is made from sheep's milk coagulated with rennet (with significant lipase activity) and acidified by the adventitious microflora of the milk or by a mesophilic starter. The curds are allowed to settle to the bottom of the vat, most of the whey is removed, and the curds are consolidated manually into lumps, which are placed into cloth bags and stored until sufficient acidity develops (about 3 days). The fresh cheese is known as Hrudka and may be sold locally. However, most Hrudka is transferred to a central factory, where it is broken up, salted, passed between granite rollers to a smooth paste, packed in polythene-lined wooden tubs, and matured.

Mahon is produced in the Balearic Island of Minorca from raw cows' milk acidified by its adventitious microflora. Mahon is brine-salted and ripened at 18 °C for *c.* 2 months. Although the texture of Mahon is semihard, its moisture content is reported to be about 32%. Majorejo is made from goats' milk on the Canary Island, Fuerteventura. Milk is acidified by a mesophilic starter and coagulated using rennet extract, although artisanal cheesemakers rely on the indigenous microflora of the milk and use rennet paste as coagulant. The curds are molded in braided palm leaves (which give its surface a characteristic pattern), pressed lightly, and dry-salted. Majorejo develops a strong flavor during ripening.

Ripening

Although rennet-coagulated cheese curd may be consumed at the end of manufacture, it is usually ripened (cured, matured) for a period ranging from ~ 3 weeks to > 2 years; generally, the duration of ripening is inversely related to the moisture content of the cheese. Many varieties may be consumed at any of several stages of maturity, depending on the flavor preferences of consumers and economic factors.

The unique characteristics of the individual cheeses develop during ripening as a result of a complex set of biochemical reactions, which are largely predetermined by the manufacturing process, i.e., by composition, especially moisture, NaCl, pH, level of coagulant activity in the curd, type of starter, and an intentional or adventitious secondary microflora. The ripening agents in cheese are derived from one or more of the following:

- coagulant;
- indigenous milk enzymes, especially proteinase and lipase;
- starter bacteria and their enzymes;
- secondary microorganisms, both intentional and adventitious, and their enzymes.

The characteristics of many cheeses are dominated by the metabolic activity of the secondary microflora, but traditionally, Cheddar and the other varieties discussed here were not inoculated with a secondary culture, although an adventitious secondary microflora of nonstarter LAB (NSLAB), mainly mesophilic lactobacilli, grows to 10^7–10^8 CFU g^{-1}. The NSLAB are more heterogeneous in cheese made from raw milk than in that made from pasteurized milk, which probably explains the more intense, but more variable, flavor development in the former. The interior of Cheddar cheese is a rather selective environment: it has a low pH (~ 5) and a relatively high salt content, is anaerobic, lacks a fermentable carbohydrate, and may contain bacteriocins produced by the starter bacteria; hence, the rather limited diversity of NSLAB.

The primary biochemical changes in ripening cheese are the metabolism of residual lactose and the catabolism of lactate and citrate (often referred to collectively, but erroneously, as glycolysis), lipolysis and proteolysis, which are followed and overlapped by secondary catabolic changes to the products of these primary pathways, including deamination, decarboxylation, and desulfurylation of amino acids and β-oxidation of fatty acids. Considerable progress has been made on elucidating the primary reactions in Cheddar. Unfortunately, only limited information is currently available on the ripening of the other hard and semihard cheeses discussed here, but since the ripening agents and the composition of all these cheeses are generally similar, the overall features of ripening are probably similar. However, differences in flavor and texture between members of this group are readily apparent, due partially to the degree of maturity of the cheeses, but also reflect the effect of small differences in composition and manufacturing technology, which affects the microflora of the cheese.

Glycolysis and Related Events

Most ($\sim 98\%$) of the lactose in milk is removed in the whey as lactose or lactic acid but fresh curd for hard and semihard cheese contains 1–2% lactose. The catabolism of lactose and resulting lactic acid is understood at the molecular level. For most cheese varieties, the residual lactose is metabolized by the starter bacteria within about 12 h. However, owing to the low pH (~ 5.4) of curd for Cheddar and similar cheeses at molding and the practise of dry-salting the curd for these cheeses, which rapidly gives an inhibitory level of NaCl throughout the cheese, residual lactose is metabolized slowly, normally by residual starter activity to L(+)-lactic acid; young Cheddar cheese contains $\sim 1.5\%$ lactic acid. The curds for Colby and Monterey are washed to reduce the lactose content of the curd (and also to increase its moisture content).

In Cheddar and probably in related varieties, L(+)-lactate is racemized to DL-lactate. Racemization has no significant effect on cheese flavor, but if the concentration of D-lactate is too high, it may form undesirable crystals on the cheese surface. Oxidation of lactic acid to acetic acid occurs to an extent dependent on the concentration of O_2 in the curd, which is strongly affected by the gas permeability of the packaging material.

The pH of most cheeses increases during ripening, but the pH of Cheddar changes little. Cheese has a strong buffering peak at pH ~ 5.2, and if the pH of cheese falls below this value, as for Cheddar,

insufficient NH_3 and amines may be produced to cause an increase in pH. However, if the lactose content of Cheddar curd is reduced by washing or whey replacement, residual lactose in the cheese is metabolized rapidly, and the pH increases during ripening. Low-lactose cheese has a clean, mild flavor, whereas lactose-supplemented cheese develops a strong, harsh flavor, probably due to the low pH.

Cheddar-type cheese contains ~ 2 g of citrate per kilogram, which is fermented slowly by NSLAB, principally to formic acid and CO_2; the latter may cause an undesirable open texture.

Lipolysis

Lipolysis is quite limited in most cheese varieties, including Cheddar and related types. A low concentration of fatty acids is important, probably essential, for cheese flavor, but even slightly excessive lipolysis causes rancidity or unbalanced flavor in hard and semihard cheeses. Considerably more lipolysis occurs in raw milk than in pasteurized milk Cheddar, suggesting that the indigenous lipoprotein lipase in milk and/or NSLAB is significant. Although LAB are weakly lipolytic, they do possess esterases/lipases, which release a low level of fatty acids during a long ripening period. Fatty acids contribute directly to cheese flavor and also serve as substrates for several flavor-generating reactions (Figure 3). These secondary reactions are quite limited in hard and semihard, internal bacterially ripened cheese but probably do contribute to overall flavor intensity and balance, especially the lactones and thioesters. Esters, especially ethyl butyrate, ethyl hexanoate, and ethyl octanoate, are responsible for a fruity flavor, which is usually regarded as a defect in Cheddar-type cheese. The oxidation of fatty acids to alkan-2-ones (*n*-methyl ketones) is a key flavor-generating reaction in mold-ripened cheese, especially blue cheeses, but is very

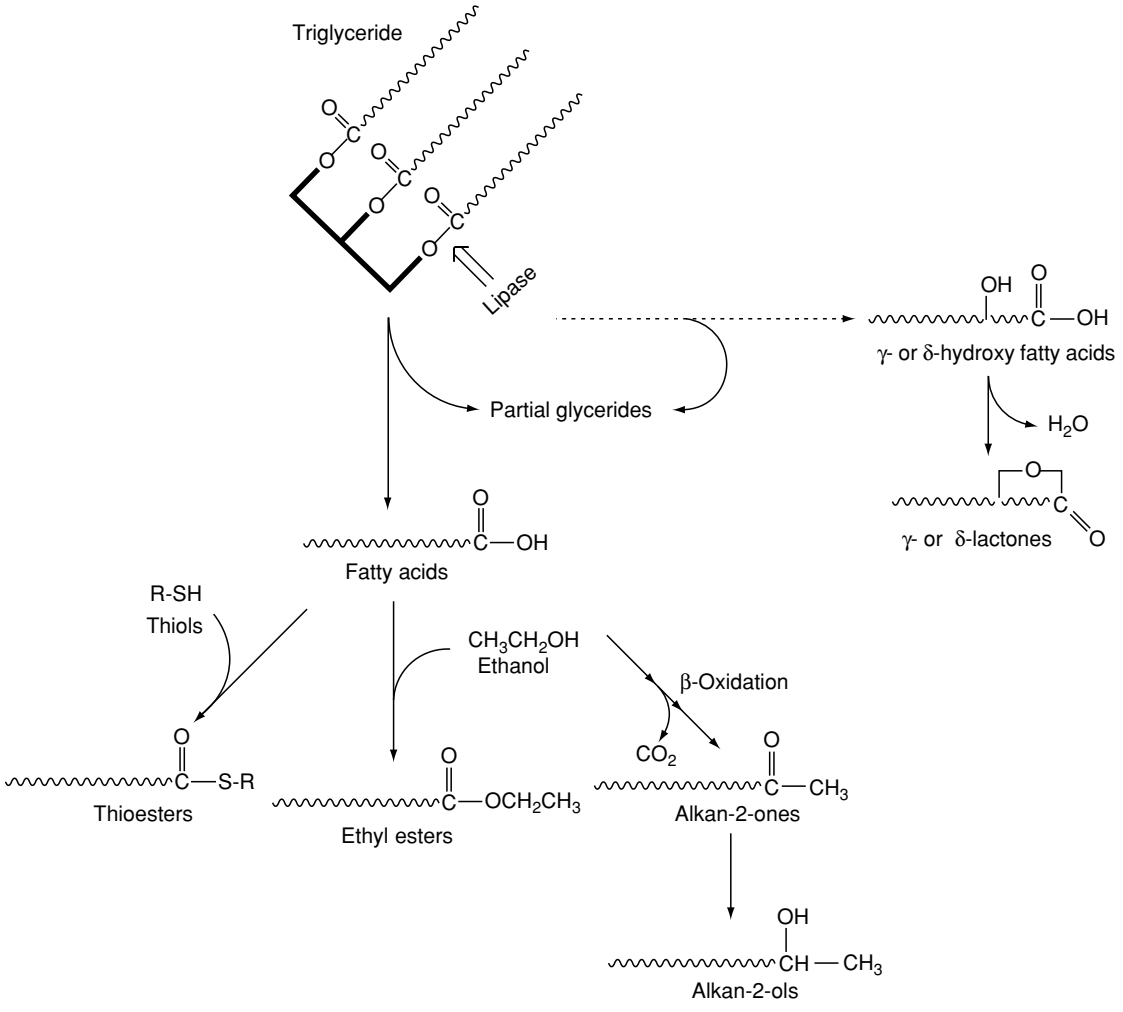

Figure 3 General pathway for the production and catabolism of fatty acids in cheese during ripening.

limited in hard and semihard bacterially ripened cheeses.

Proteolysis

Proteolysis is the most complex and perhaps the most important of the three primary ripening events, especially in internal bacterially ripened cheese. It is primarily responsible for changes in cheese texture and makes a significant contribution to flavor, especially background flavor *via* the formation of amino acids and small peptides. Catabolism of amino acids leads to many sapid and aromatic compounds, which are probably major contributors to cheese flavor and may be rate-limiting in flavor development in hard and semihard cheese. Owing to its perceived importance to the rate of ripening and to the quality of the mature cheese, proteolysis and related events have been the subject of intense research in recent years.

Cheddar-type cheese contains a broad range of proteinases and peptidases which originate from the coagulant, milk, starter, and NSLAB. The proteinases and peptidases from most of these sources have been isolated and characterized, and their contribution to cheese ripening established.

The sequence of proteolysis in Cheddar and similar varieties is summarized in Figure 4. Primary proteolysis is catalyzed mainly by the coagulant and is principally responsible for the hydrolysis of α_{s1}-casein which, in mature Cheddar cheese, is completely hydrolyzed at Phe_{23}–Phe_{24}, at least 50% at Leu_{101}–Lys_{102}, and, to a lesser extent, at other bonds. In cheese, β-casein is hydrolyzed only slightly by most coagulants, but about 50% is hydrolyzed by plasmin to γ-caseins and proteose peptones. Primary proteolysis contributes little or nothing to the flavor of cheese but is mainly responsible for the changes in cheese texture which occur during the early stages of ripening.

The large C-terminal peptides produced from α_{s1}- and β-caseins by the coagulant and plasmin, respectively, and *para*-κ-casein produced during milk coagulation, accumulate during ripening and are present even in extra-mature cheese. However, the complimentary N-terminal peptides from α_{s1}- and β-caseins are hydrolyzed by lactococcal proteinases and peptidases to smaller peptides and amino acids. The NSLAB contribute mainly at the level of amino acid production. About 200 peptides have been isolated from Cheddar cheese and characterized.

Small peptides and amino acids contribute to the background flavor of cheese, but an excessive concentration of small hydrophobic peptides may cause bitterness, which is probably the most common flavor defect in cheese. More importantly, amino acids can be converted to a range of flavor compounds, including amines, acids, carbonyls, NH_3, sulfur compounds, and hydrocarbons by enzymes derived from the starter or NSLAB or through chemical reactions. The enzymatic catabolism of amino acids is summarized in Figure 4 and elaborated in Figures 5–7. These reactions and the enzymes involved have attracted considerable attention during the past few years. The principal amino acid-derived flavor compounds in cheese are listed in Table 1.

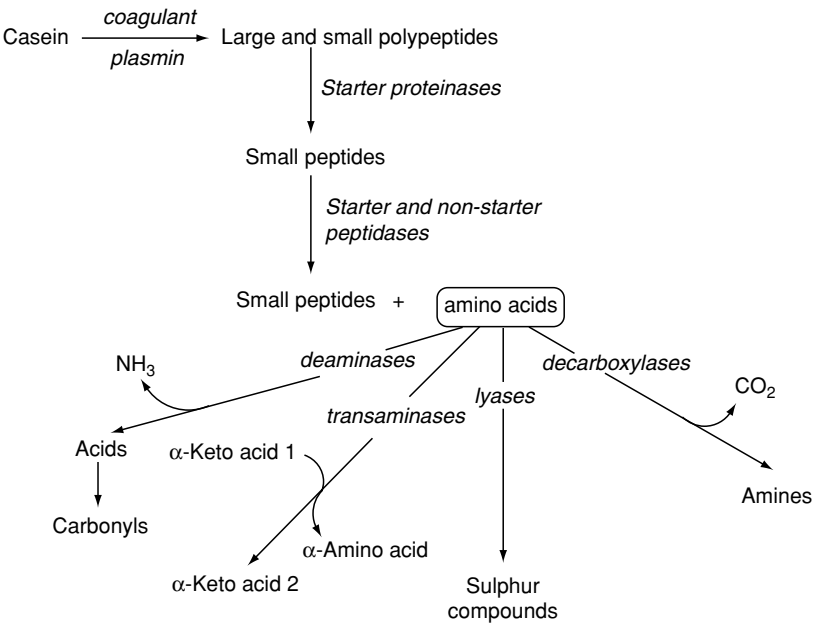

Figure 4 Summary of proteolysis and amino acid catabolism in cheese during ripening.

Table 1 Major aroma compounds derived from branched chain and aromatic amino acids and methionine in cheese during ripening

Amino acid	*Carboxylic acids*[a]	*Amines*	*Aldehydes*	*Alcohols*	*Thiols/others*
Valine	2-Methyl propionic acid	2-Methyl propylamine	2-Methyl propanal	2-Methyl propanol	
Leucine	3-Methylbutanoic acid	3-Methyl butylamine	3-Methyl butanal	3-Methyl butanol	
Isoleucine	2-Methylbutanoic acid	2-Methyl butylamine	2-Methyl butanal	3-Methyl butanol	
Phenylalanine	Phenylacetic acid	Phenylethyl amine	Phenylacetaldehyde, benzaldehyde	Phenylethanol	
Tyrosine	*p*-Hydroxyphenylacetic acid	*p*-Hydroxyphenylethyl amine (tyramine)	*p*-Hydroxyphenylacetaldehyde, *p*-hydroxybenzaldehyde	*p*-Hydroxyphenylethanol	*p*-Cresol, phenol
Tryptophan	Indole-3-acetic acid	Indole-3-ethyl amine (tryptamine)	Indole-3-acetaldehyde Indole-3-aldehyde	Indole-3-ethanol (tryptophol)	Skatole, indole
Methionine	3-Methylthiopropionic acid	3-Methylthiopropylamine	3-Methylthiopropanal (methional)	3-Methylthiopropanol	Methanethiol

[a]Further carboxylic acids can be produced from amino acids by deamination.

From Yvon M and Rijnen L (2001) Cheese flavour formation by amino acid catabolism. *International Dairy Journal* 11: 185–201.

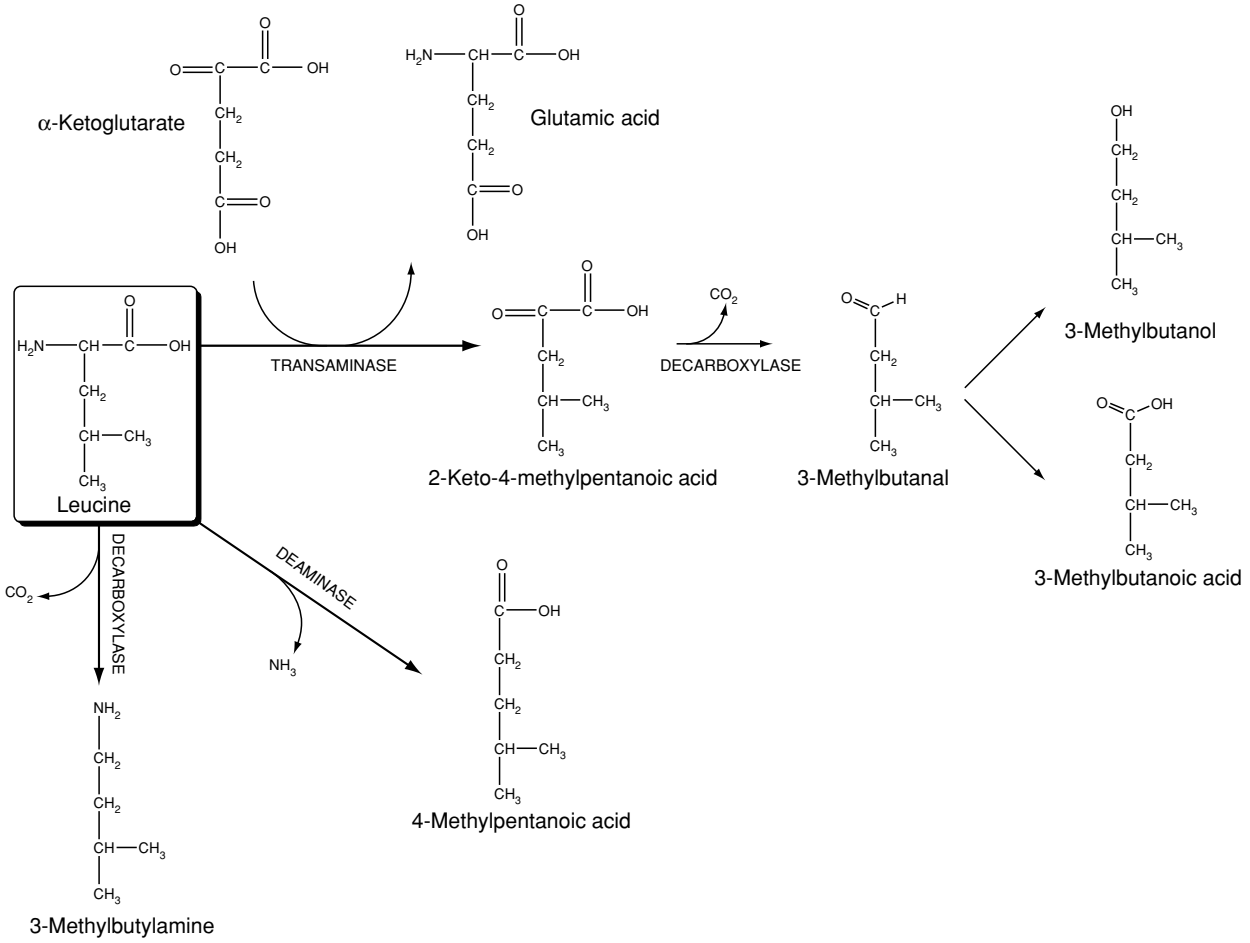

Figure 5 Catabolism of leucine. Similar pathways apply for the other branched-chain amino acids, isoleucine, and valine.

The Strecker reaction between an amino acid and a dicarbonyl (Figure 8) is an important chemical flavor-generating reaction involving amino acids in cheese, but the Maillard reaction between an amine (e.g., amino acid) and a monocarbonyl (e.g., a reducing sugar) may be significant to cheese flavor (and color) under certain circumstances, e.g., low-moisture grated cheese or cooked cheese.

Adjunct Cultures

The use of pasteurized milk for cheese-making dates from the beginning of the twentieth century but did not become widespread until about 1950. The principal objective of pasteurizing milk is to kill pathogenic bacteria, but most other microorganisms, including desirable NSLAB, are killed also, and many indigenous enzymes are inactivated. For public-health reasons and because the quality of cheese made from pasteurized milk is more consistent and uniform than that made from raw milk, it is very unlikely that raw milk will be used for the manufacture of Cheddar cheese in the very large, highly mechanized factories which are now common. However, there is a general perception that the flavor of modern Cheddar has become too mild, possibly owing to the use of very high microbiological quality cheese milk (pasteurization of which renders it essentially free of NSLAB), the use of highly active starters containing only a few strains of *Lactococcus*, and the manufacture of cheese in enclosed equipment which reduces contamination from the environment. While most consumers today prefer mild Cheddar, there are *niche* markets for more mature, intensely flavored cheese. Also, some retailers and cheese manufacturers wish to offer for sale cheese with a flavor identifiable with that company. The use of adjunct cultures (which are not required for acid production) is considered to be the most effective way of achieving this; essentially, these cultures diversify the microflora of the cheese and are an attempt to reproduce the microflora of raw milk cheese in a controlled way. Since the

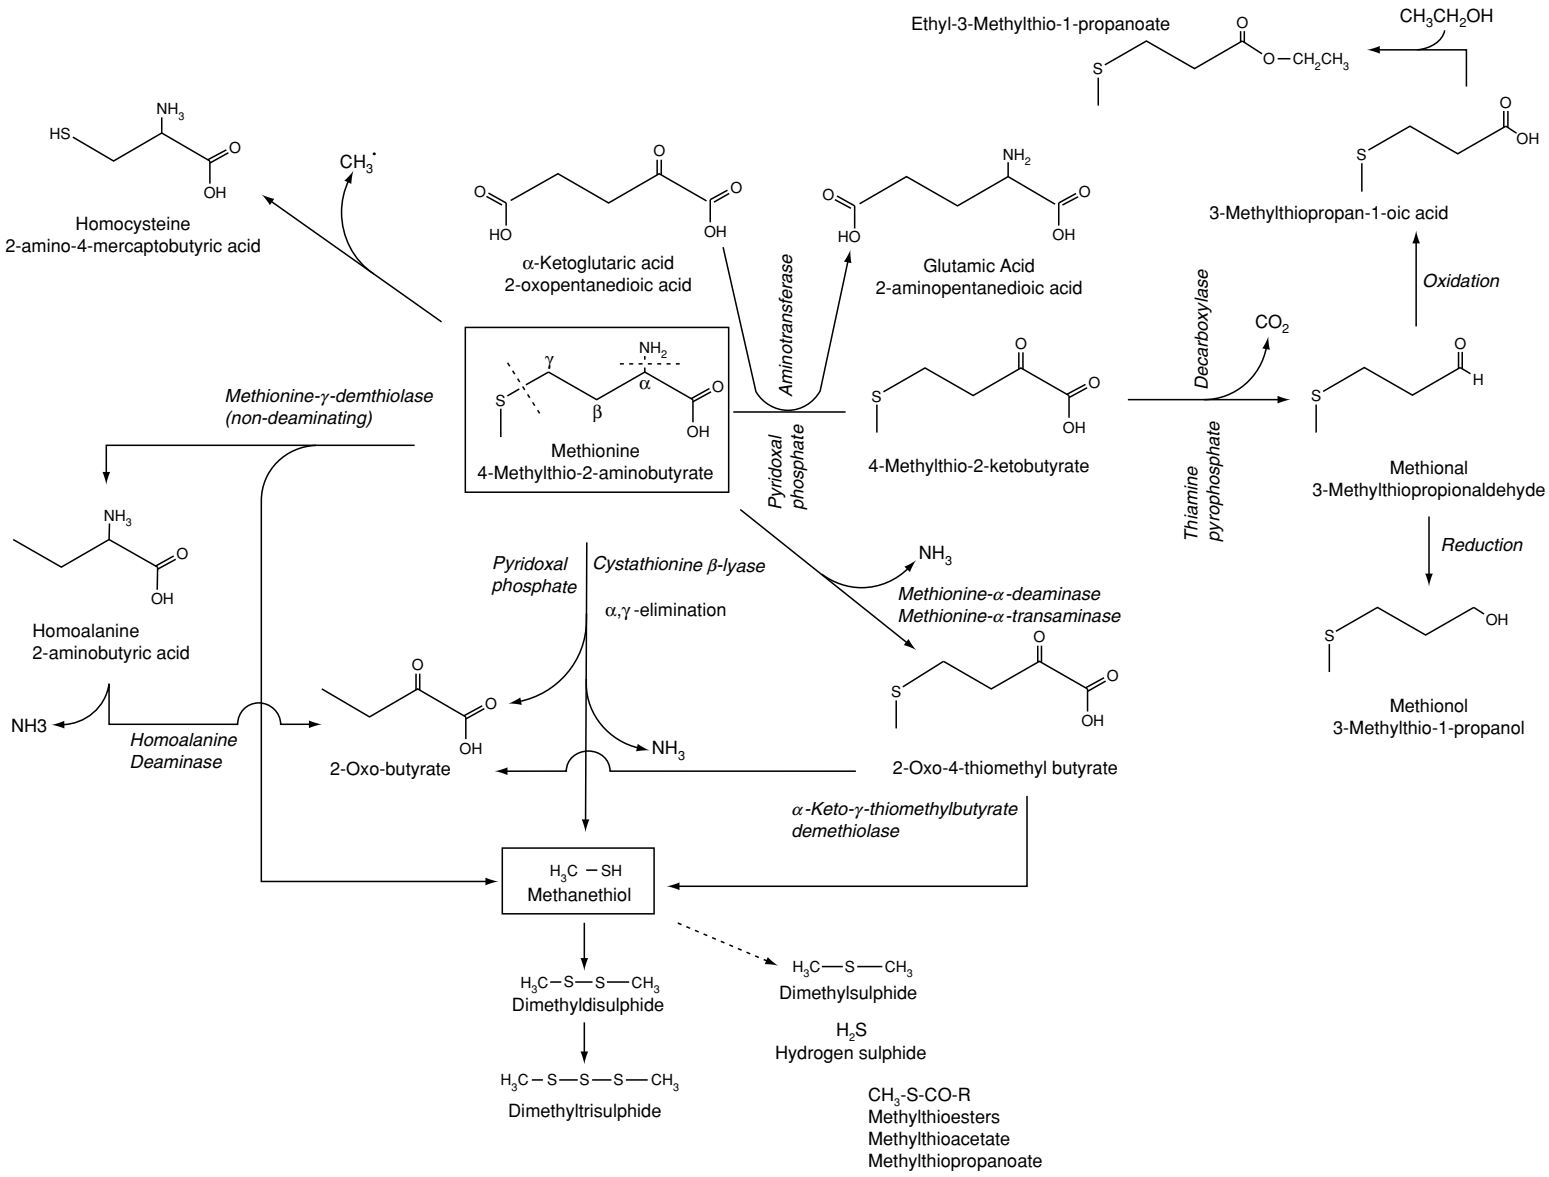

Figure 6 Suggested pathways for the catabolism of methionine in cheese during ripening.

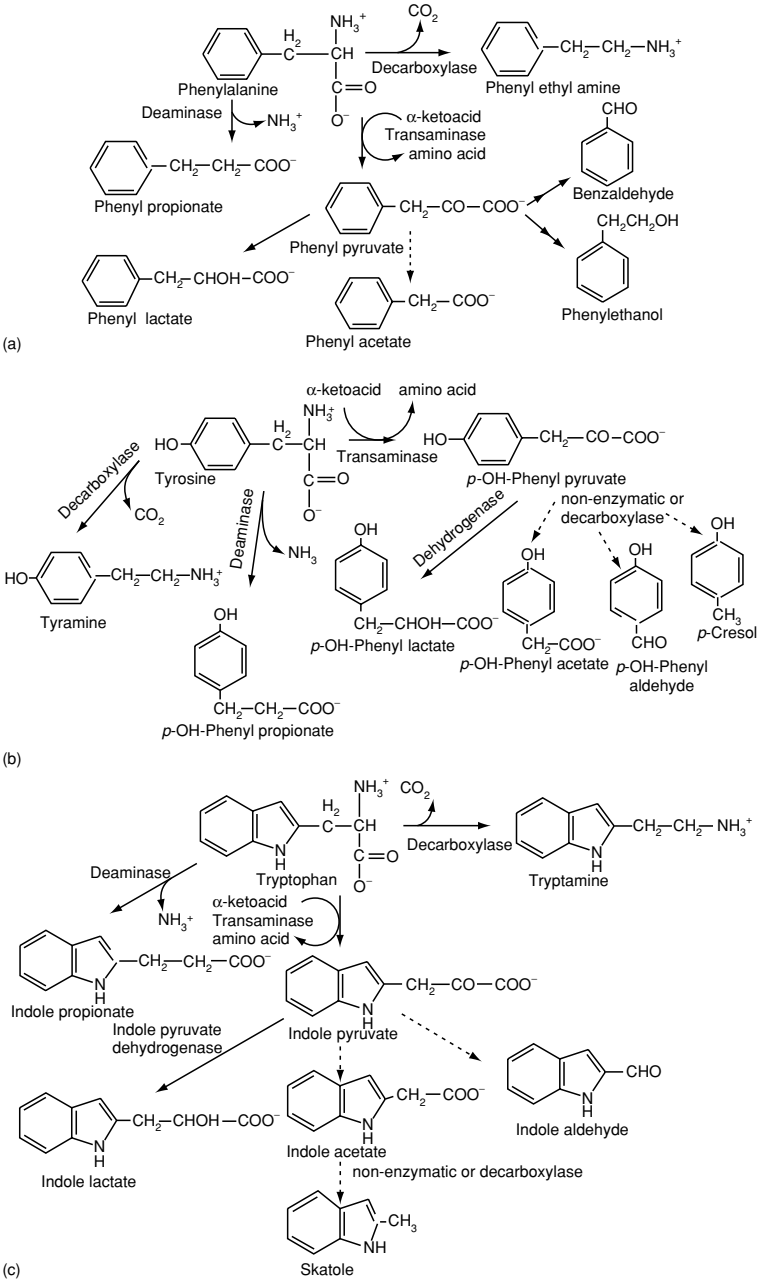

Figure 7 Suggested pathways for the catabolism of (a) phenylalanine, (b) tyrosine, and (c) tryptophan in cheese during ripening.

NSLAB in Cheddar cheese are mainly mesophilic lactobacilli, especially *Lb. casei* and *Lb. paracasei*, most studies on the use of adjunct cultures for Cheddar cheese have concentrated on mesophilic lactobacilli; most investigators report positive results. Thermophilic lactobacilli are more effective than mesophilic lactobacilli, possibly because the former die rapidly in cheese, releasing their intracellular enzymes, while the latter do not. However, the number of thermophilic lactobacilli added must be controlled carefully – if too numerous, a Swiss cheese-type flavor will develop.

Acceleration of Cheese Ripening

Some high-moisture cheeses develop an intense flavor through a very active secondary microflora, e.g., internal blue mold, external white mold, or a bacterial surface smear; these cheeses ripen rapidly. High-moisture internal bacterially ripened cheeses also mature rapidly but develop a low flavor intensity; if

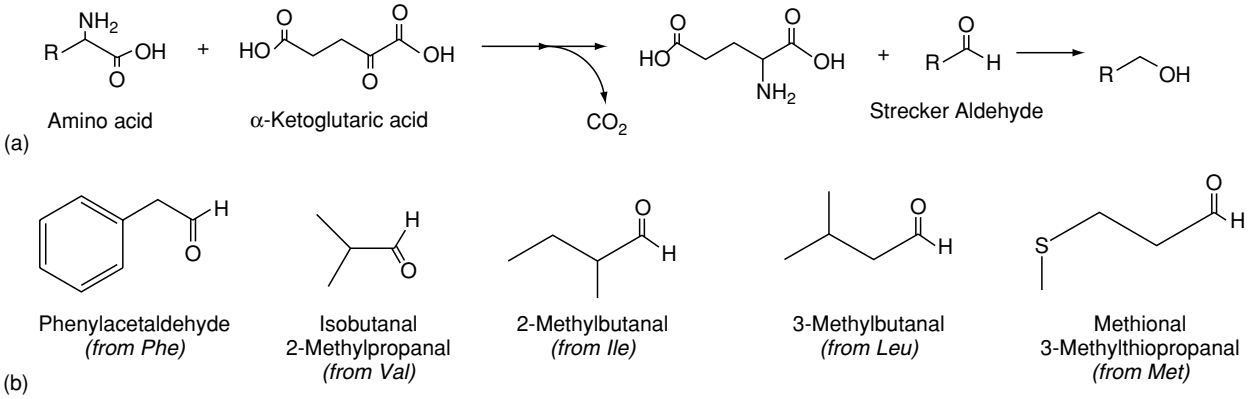

Figure 8 (a) Strecker reaction between an amino acid and an α-keto acid (e.g., α-keto glutaric acid) and (b) structures of some Strecker aldehydes found in cheese.

the ripening of such cheeses is extended, they will probably develop off-flavors. It is possible to develop an intense flavor in internal bacterially ripened cheeses, such as hard and semihard varieties, only if the moisture content is low and if they are ripened for a long period, e.g., 2–3 years. Owing to the high cost of ripening facilities and stocks, the ripening of extra-mature, low-moisture cheese is expensive, and there is commercial interest in accelerating the ripening process. Most of the work on accelerating cheese ripening has been on Cheddar.

Methods for accelerating cheese ripening fall into six categories:

- elevated ripening temperature;
- exogenous enzymes;
- chemically or physically modified cells;
- genetically modified starters;
- adjunct starters.

Ripening at an elevated temperature, e.g., up to 15 °C, is the simplest and cheapest method for accelerating the ripening of Cheddar cheese, but modified primary starters and adjunct cultures appear to be very promising. Techniques for accelerating ripening may also be applicable to low-fat cheeses, which tend to ripen slowly.

Cheeses with 'Eyes'

P L H McSweeney, University College, Cork, Ireland

Synopsis

Mechanical openings (resulting from the incomplete fusion of curd pieces) are common in many cheese varieties where they may be considered desirable (e.g., Monterey) or a defect (e.g., Cheddar). However, some internal bacterially ripened varieties are characterized by the development of 'eyes' caused by gas (CO_2), produced by bacterial metabolism, being trapped in the curd. The development of eyes in cheese is governed by the rate of gas production by bacteria and the ability of the curd to retain the gas. There are two main families of cheeses with eyes: Dutch types (Edam, Gouda, and related varieties), which have small eyes, and Swiss types, which are characterized by large eyes. In the case of Edam and Gouda cheeses, CO_2 is produced by the action of *Leuconostoc* spp. or citrate-utilizing (Cit^+) lactococci on citrate (*See* **Cheeses: Dutch-type Cheeses**), whereas in Swiss varieties, CO_2 is produced by *Propionibacterium freudenreichii* from lactate. These two families of cheeses are quite different in terms of their manufacturing protocol, ripening conditions, and flavor and appearance of the final product.

The most popular Swiss-type cheese is Emmental (Figure 1), which originated in the Emm river valley in Switzerland, but is now made world-wide. This article will concentrate on the manufacturing protocol for, and the ripening of, Emmental. A number of other related Swiss-type cheeses will be discussed briefly.

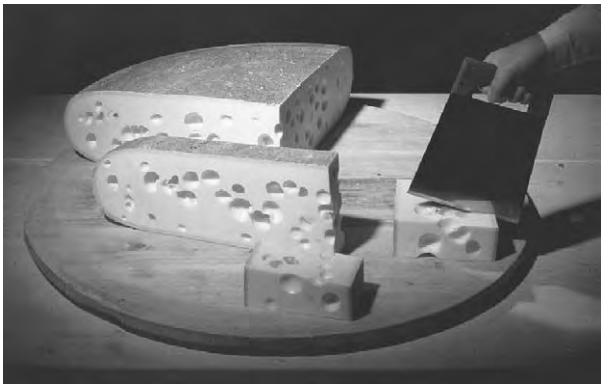

Figure 1 Emmental cheese. Reprinted with permission from Roginski H, Fuquay JW and Fox PF (eds) (1992) *Encyclopedia of Dairy Sciences*. Academic Press: London.

General Characteristics of Emmental Cheese

Typically, Emmental contains *c*. 30.5% fat, 35.5% moisture, 27.5% protein, 0.5–0.7% salt, and 3.5% ash, and has a pH of *c*. 5.6. It has a mild, sweet, and somewhat nutty flavor. Emmental cheese is characterized by large eyes that are caused by CO_2 produced by *P. freudenreichii*, which metabolizes lactate to propionate, acetate, and CO_2. Propionibacteria do not grow in the milk during cheesemaking but grow in the curd during the early stages of maturation when the cheeses are transferred to a 'hot room' ($\sim$20 °C) to promote their growth. The texture of Emmental is quite rubbery and entraps the CO_2 (which migrates through the curd until it reaches a fissure or weakness at which an eye develops). The texture of Emmental cheese results from a high cooking temperature ($\sim$55 °C), which inactivates much of the coagulant, and a high pH at draining, leading to a high Ca^{2+} content in the curd. Emmental cheese is brine-salted.

The manufacturing protocol for Emmental is shown Figure 2. Traditionally, Emmental is made from raw cows' milk, which is acidified through the action of a mixed thermophilic starter consisting of *Streptococcus thermophilus* and a *Lactobacillus* sp. *Lb. helveticus* was used traditionally, but *Lb. delbrueckii* sp. *bulgaricus* and *Lb. delbrueckii* sp. *lactis* are now common also. Propionibacteria are added to the milk (usually to *c*. 10^3–10^5 cfu ml^{-1}) or gain access to the milk from the environment (which is often the case in traditional manufacture). The milk, at 30 °C, is coagulated using calf rennet, and the coagulum is cut into small pieces and cooked to $\sim$55 °C until the curd pieces are of the desired firmness. The curds–whey mixture is transferred into molds where the whey is drawn off. The mold is sufficiently large to give a cheese wheel weighing up to *c*. 100 kg and with a diameter of up to 1 m. The size of the Emmental wheel is far from cosmetic. The large size of the wheel means that Emmental has a relatively low surface area-to-volume ratio. This is of significance, since it determines the rate of cooling of the curd (and thus the activity of the starter) and salt diffusion throughout the cheese mass, and helps to trap gas within the cheese and allows gas pressure to increase within the cheese until eye formation occurs. Over the next 1–2 days, the wheels are pressed and turned frequently. During this time, the curd cools, and acid production by the starter (which was dormant during the scalding step) recommences. Lactic acid fermentation in Emmental takes *c*. 12 h. After pressing, the cheese wheels are brine-salted. Swiss cheeses have the lowest NaCl content of all cheese varieties, permitting the growth of its

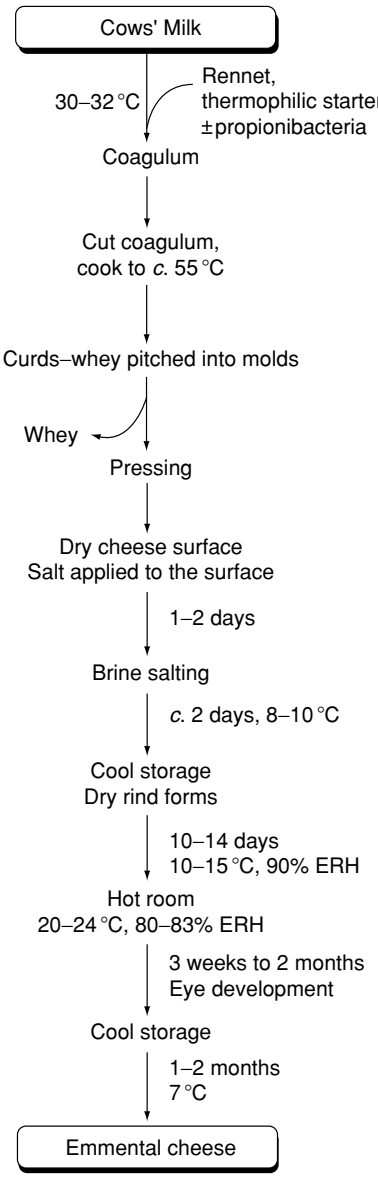

Figure 2 Traditional manufacturing protocol for Emmental cheese. Reprinted with permission from P.F. Fox, T.P. Guinee, T.M. Cogan and P.L.H. McSweeney. Fundamentals of Cheese Science, © 2000, Aspen Publishers, Gaithersburg, MD.

secondary flora during ripening (*P. freudenreichii*). *Propionibacterium freudenreichii* is very sensitive to NaCl and will not grow at a_w values below 0.96 (*c.* 1.2% NaCl).

Although Emmental is manufactured in industry by this traditional process, a rindless product is now produced in large factories and, in many countries with a developed dairy industry, is the major type of Emmental produced. Rindless, or 'block,' Emmental is manufactured by a process generally similar to that described for traditional Emmental, but this cheese is manufactured from milk with a lower fat content (*c.* 2.5%) and cooked to a lower temperature. The cheese is molded in the form of blocks that are wrapped in plastic film; thus, no rind develops during ripening.

Ripening of Swiss Cheese

In common with most, if not all, rennet-coagulated cheeses, immediately after manufacture, Swiss cheese has a bland flavor and a texture and appearance quite different from the mature cheese. The characteristic flavor, texture, and appearance of Swiss cheese develop during ripening. The ripening of Swiss cheese typically starts with storage in a cool room and 10–15 °C and 90% equilibrium relative humidity (ERH) for 10–14 days; in traditional practice, the cheeses are brushed, dry salt is rubbed on to the surface, and the cheeses are turned daily until a smooth rind develops. The cheeses are then transferred to a hot room (20–24 °C, 80–83% ERH) and held there for 3 weeks to 2 months. The cheeses are held in the hot room until adequate eye formation occurs (which is assessed traditionally by tapping the cheese and listening to the hollow sound produced); cheeses are then transferred to another ripening room at about 7 °C and matured for 1 or 2 months for further flavor development.

During the ripening of Swiss cheese, protein and, to a lesser extent, lipid in the cheese are degraded to flavor compounds, lactate is metabolized with important consequences for flavor and eye development, and changes occur to the microflora of the cheese. The ripening agents in Swiss cheese originate from the milk (particularly the principal indigenous proteinase in milk, plasmin), from the microflora of the cheese (starter, nonstarter bacteria, and propionic acid bacteria in addition to a minor contribution from the coagulant (usually chymosin). The ripening of Swiss cheese is summarized in Figure 3.

Starter bacteria reach maximum numbers in Swiss cheese soon after manufacture. Thereafter, their numbers decline rapidly as a result of the lack of a readily fermentable carbohydrate and low pH. Numbers of viable *Sc. thermophilus* decline at a slightly faster rate than those of the *Lactobacillus* sp. However, the importance of the starter to cheese ripening does not end with their death. After death, cells lyse at a strain-dependent rate, releasing their intracellular enzymes, which are of great importance in the ripening of Swiss cheese. Starter activity during acidification also has a major indirect effect on ripening since it is their action, together with the buffering capacity of the cheese, that controls pH and oxidation–reduction potential (E_h) which, in turn, have a very important effect on the rate of

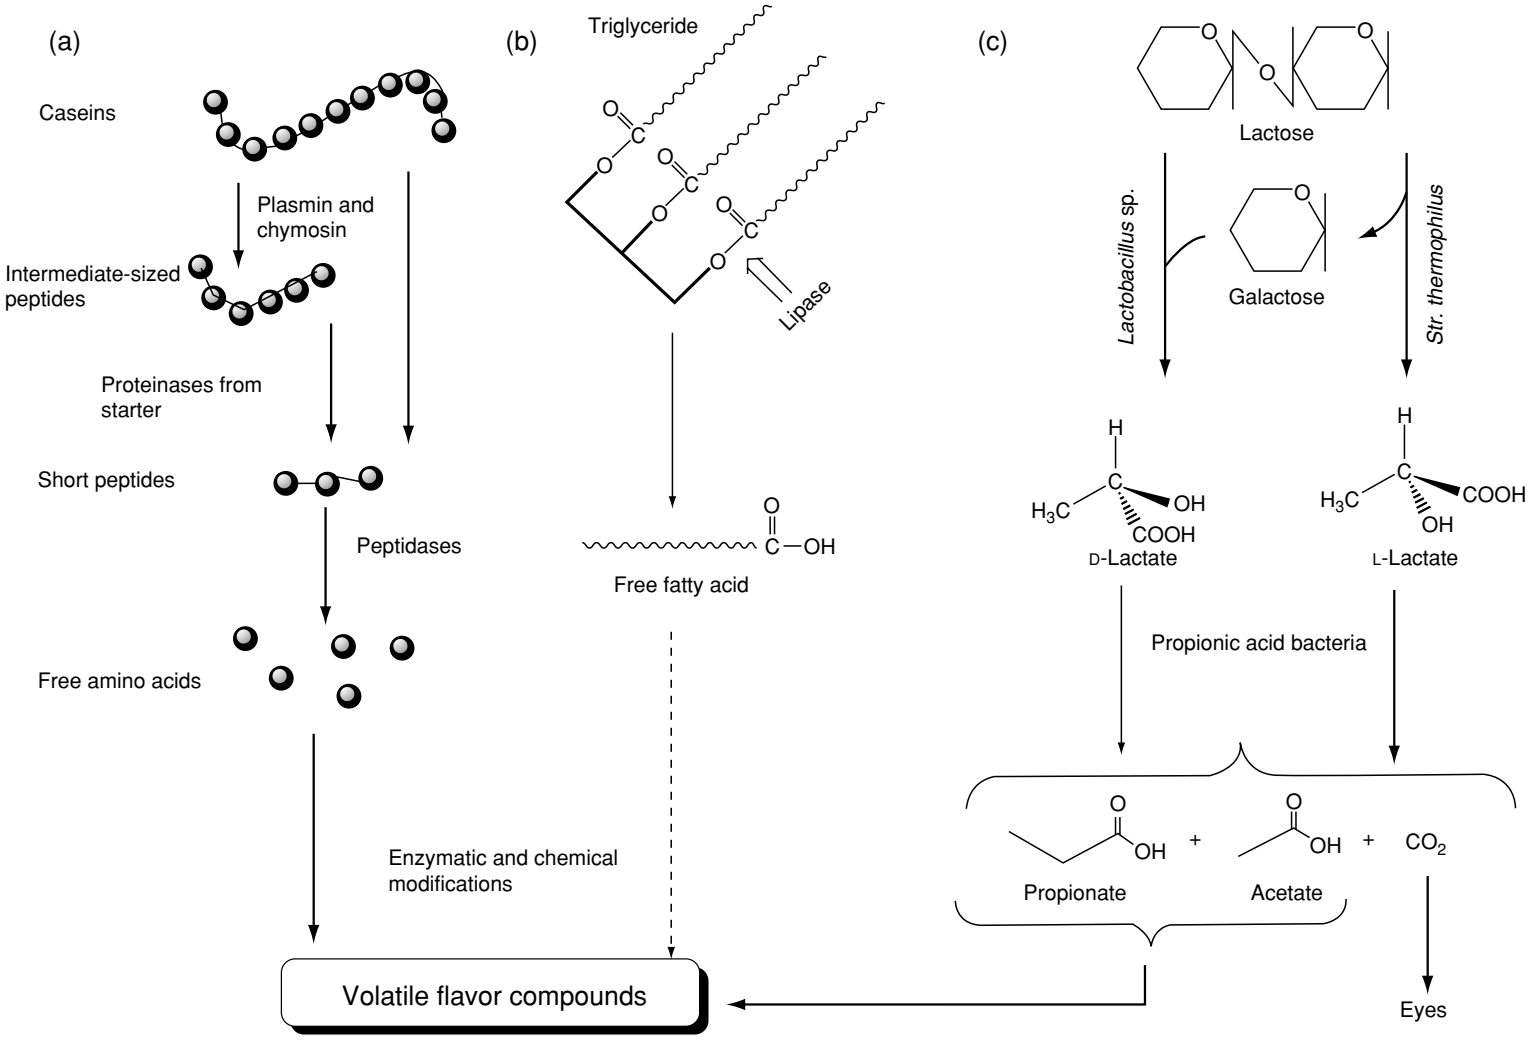

Figure 3 Schematic representation of the principal biochemical events occurring during the ripening of Swiss-type cheese. (a) Proteolysis and catabolism of amino acids, (b) lipolysis and (c) metabolism of lactose and lactate.

many ripening reactions. Most, if not all, ripened cheeses develop an adventitious secondary flora during ripening. These 'non-starter lactic acid bacteria' (NSLAB), typically mesophilic lactobacilli, are present in the raw milk or gain entry from the cheese-making environment; in the case of cheese made from pasteurized milk, they may survive pasteurization, perhaps in a heat-shocked state, or gain entry from the environment. NSLAB are quite different from the thermophilic lactobacilli used as starters in the manufacture of Swiss cheese, and include species of lactobacilli such as *Lb. casei* and *Lb. paracasei*. As with all other cheeses, the NSLAB flora of Swiss cheese is uncontrolled, but increases from very low numbers (particularly in the case of cheeses made from pasteurized milk) to *c.* 10^8 cfu g^{-1} cheese. Studies on the role of the NSLAB flora in Swiss cheese suggest that they contribute to the differences in flavor between raw and pasteurized milk cheeses and play a minor role in ripening.

The level of lactose in Swiss cheese decreases rapidly during the latter stages of manufacture and early in ripening, reaching very low levels after 24 h. Soon after manufacture, Emmental cheese typically contains ~1.7% lactose which is metabolized rapidly by *Sc. thermophilus* to L-lactate; after 24 h, the level of lactose in Swiss cheese is usually very low (Figure 4). However, *Sc. thermophilus* metabolizes only the glucose moiety of lactose and thus galactose levels in the curd increase initially, reaching a maximum *c.* 10 h after manufacture; galactose is then metabolized by the lactobacilli to D/L-lactate. It is important to use a Gal^+ *Lactobacillus* sp. in the starter mix or galactose will accumulate in the curd, the metabolism of which by NSLAB can lead to off-flavors. Metabolism of galactose is usually complete after 14 days. During the early stages of ripening, there is significantly more L-lactate than D-lactate in the curd.

Lactate metabolism is more important in Swiss cheese than in any other variety, with the exception of surface mold-ripened cheeses such as Camembert and Brie. *Pr. freudenreichii* added to, or contaminating, the milk for Swiss-type cheeses grow once the cheeses are transferred to the warm room after brining and metabolize L-lactate during ripening *via* a complex pathway to propionate, acetate, CO_2 and H_2O (Figure 5). The pathway for lactate metabolism by *Propionibacterium freudenreichii* (Figure 6) involves two separate cycles, one producing propionate and the other acetate. In general, propionic acid bacteria are able to metabolize both L- and D-lactate, but usually, they metabolize the former preferentially to CO_2, and so levels of L-lactate decrease with a concomitant increase in the levels of propionate and acetate (Figure 4). Later in ripening, the propionic acid bacteria utilize D-lactate, at which point, the concentration begins to decline. Carbon dioxide produced is essential for eye development, and the propionate and, to a lesser extent, acetate contribute to the flavor of these cheeses. Eyes are a characteristic sensory feature of Swiss-type cheeses and are a parameter used by the consumer to identify these cheeses.

An undesirable pathway for lactate metabolism in Swiss and many other cheeses is its anaerobic fermentation to butyrate and H_2 by *Clostridium* spp., resulting in a serious defect known as 'late gas blowing.' Spores of clostridia, which survive pasteurization of milk and cooking of Swiss cheese, may be removed from milk by bactofugation or microfiltration. Other approaches to avoid this problem include the use of lysozyme or NO_3^- (which degrade the cell

wall of Gram-positive bacteria and inhibit germination of spores, respectively) and good hygiene. In particular, feeding silage to cows, whose milk will be used in the manufacture of Swiss cheese, is forbidden in some regions.

Because of the absence of strongly lipolytic agents, lipolysis is quite limited in Swiss cheese. However, lipolysis does contribute to the flavor of Swiss cheese. Short-chain fatty acids contribute directly to cheese flavor, and low levels are desirable in Swiss cheese. However, high levels of free fatty acids give an undesirable, rancid off-flavor to Swiss cheese. Fatty acids also act as precursors for a range of further reactions (e.g., the formation of fatty acid lactones, hydroxyacids, esters, thioesters, and methyl ketones) that contribute to cheese flavor. Lipolysis in Swiss cheese is catalyzed by the indigenous milk lipoprotein lipase (LPL; particularly in the case of raw milk cheese, since this enzyme is extensively inactivated by pasteurization). The action of LPL is probably less important in raw milk Swiss cheese than in other raw milk varieties, since it is partially inactivated during the cooking step. Other sources of lipases and esterases in Swiss cheese are the starter and NSLAB; *Pr. freudenreichii* has also been shown to possess a lipase.

Proteolysis is a major series of events during the ripening of Swiss cheese. Proteolysis in Swiss cheese is catalyzed by enzymes indigenous to the milk and from the cheese microflora and, to a much lesser extent, from the coagulant. The principal indigenous proteinase in milk, plasmin, is particularly important for proteolysis in Swiss-type cheese. Plasmin (fibrinolysin, EC 3.4.21.7) is a serine proteinase with an alkaline pH optimum that is formed from an inactive precursor, plasminogen, by limited proteolysis. The activation of plasminogen and plasmin activity in milk are controlled by a system of plasminogen activators, plasmin inhibitors, and inhibitors of plasminogen activators. Plasmin is a particularly heat-stable proteinase, and hence its activity relative to other proteolytic enzymes (especially chymosin) is higher in Swiss cheese than in other varieties, since it survives the cooking step. Plasmin acts during ripening to degrade β-casein to γ-caseins; the latter accumulate to greater levels in Swiss cheese than in most other varieties. Chymosin, or other enzymes from the coagulant, are the most important enzymes for the initial degradation of the caseins during the ripening of most internal, bacterially ripened varieties. However, since chymosin is denatured extensively during the cooking step of Swiss cheese, its action is less important in this variety than in varieties such as Cheddar.

Intermediate-sized peptides produced by the action of plasmin or chymosin are hydrolyzed by proteinases and peptidases from the cheese microflora. Lactic acid bacteria are auxotrophic for a number of amino acids and therefore possess a range of proteolytic enzymes capable of liberating amino acids from the caseins. Although less well studied than the lactococci, thermophilic lactobacilli and streptococci used as starters in Swiss cheese possess generally similar proteinase and peptidase systems, including a cell envelope-associated proteinase that is responsible for degrading many of the intermediate-sized peptides produced by plasmin and chymosin to shorter peptides. Lactic acid bacteria, including those used as starters in Swiss cheese, possess a wide range of intracellular peptidases. These enzymes are released into the cheese matrix following cell lysis, which occurs during ripening, and are essential for the liberation of amino acids (AA). *Pr. freudenreichii* is weakly proteolytic, although it does possess intracellular peptidases that contribute to ripening.

Proteolysis results ultimately in the liberation of AA. AA contribute directly to the background flavor of cheese; some are sweet, some are sour, and many are bitter. However, the major role of AA in the development of cheese flavor is now thought to be as precursor molecules for a range of poorly understood catabolic reactions that lead to the formation of many volatile flavor compounds. Although amino acid catabolism has not been studied extensively in Swiss cheese, it is highly likely that it follows the same general pathways as in other internal, bacterially ripened varieties such as Cheddar and Gouda. Amino acid catabolic reactions include deamination (to yield NH_3 and α-keto acids), decarboxylation (to yield amines), formation of alkyl pyrazines, and catabolism of sulfur-containing and aromatic amino acids.

Other Swiss-type Cheeses

Although Emmental is the Swiss-type variety produced in the largest amount world-wide, there are several related Swiss cheese varieties. Gruyère is a popular Swiss-type cheese that differs from Emmental in being smaller, with a somewhat stronger flavor and fewer eyes, and is characterized by the development of a surface flora. This surface flora (similar to that which develops on smear-ripened varieties such as Tilsit and Limburger) is encouraged by ripening for 2–3 weeks at 10 °C and for 2–3 months at 15–20 °C and 90–95% ERH. During the hot-room stage, the cheeses are rubbed with a brine-soaked cloth. Further ripening at 12–15 °C is required before retail; the cheese is ripe in 8–12 months. Varieties similar to Gruyère include Raclette (which is manufactured from raw milk and is acidified by the natural flora of the milk) and Gruyère de Comté, which is produced in eastern France. Comté has smaller eyes than Emmental as a consequence of a low ripening temperature (*c.* 18 °C). The surface of this cheese is covered by an orange smear ('*morge*'); cell numbers at the surface are typically 10^{10} cfu cm^{-2}, and the microflora is very complex, consisting of coryneform bacteria, micrococci, and yeasts. Beaufort is a French variety that is similar to, but larger than (*c.* 45 kg), Gruyère and usually develops fewer eyes (as a result of the growth of mesophilic starter acting on citrate at a low ripening temperature) than Gruyère. Appenzeller, which originated in Switzerland, is a small cheese (*c.* 30 cm) with a soft texture and propionic acid fermentation that results in the development of a few eyes. The curds are cooked at 43–45 °C. Appenzeller is immersed in cider or spiced wine or coated with a mixture of salt and spices during ripening, which imparts a distinctive flavor to the cheese. Maasdammer, a variety developed recently in The Netherlands, is characterized by the use of a mesophilic starter and extensive propionic acid fermentation, which gives large eyes and a domed appearance to the cheese wheels. Jarlsberg is a Swiss-type cheese produced in Scandinavia, which is characterized by large eyes.

Soft and Special Varieties

R C Chandan, New Brighton, MN, USA

Introduction

This article contains terse description of cottage cheese, cream cheese, and cheese varieties commonly used in South Asia and Latin America. The typical composition of these products, compared with fresh Cheddar cheese, is shown in **Table 1**.

Table 1 Composition (%) of some soft cheeses

Cheese	*Moisture*	*Protein*	*Fat*	*Lactose*
Cottage cheese curd	79.8	17.3	0.4	1.9
Creamed cottage cheese	79.0	12.5	4.5	2.7
Neufchatel cheese	62.9	10.1	26.1	3.3
Cream cheese	53.8	7.6	34.9	2.7
Ricotta (whole milk)	71.7	11.3	12.9	3.1
Chhana – cow milk	53.4	17.4	24.8	2.6
Paneer – buffalo milk	51.3	17.3	27.0	2.6
Queso Blanco	55.0	23.0	15.0	2.7
Cheddar cheese curd	37.0	25.0	32.2	1.3

Cheddar is included for comparison.

Cottage Cheese

Cottage cheese belongs to the class of natural, unripened, soft cheeses. Since it has a significantly lower fat content than most cheeses and is a good source of protein, it is a popular part of low-calorie diets. This cheese is made from pasteurized skim milk, concentrated nonfat milk or reconstituted nonfat dry milk. Coagulation of skim milk is accomplished by fermentation with *Lactococcus lactis* ssp. *lactis* or *Lc. lactis* ssp. *cremoris*. Alternatively, food-grade acids may be used to set the milk, but the product must be labeled 'Direct Acid set.' It is marketed as a small-curd (< 4 cm diameter) or large-curd (> 8 cm diameter) product.

Cottage cheese is a major dairy product in North America. In 2000, total sales of cottage cheese in the US were 333.8 million kilograms, with average per caput sales of 1.18 kg. The market value exceeds one billion US dollars. The US Food and Drug Administration standards define cottage cheese as the product containing moisture not exceeding 80% and milk fat not less than 4%. Cottage cheese may be labeled as reduced fat if it contains at least 25% less fat than creamed cottage cheese. To qualify for a low-fat label, the product must contain not more than 3 g of fat per serving of 28.35 g. Fat-free or nonfat cheese must contain less than 0.5 g of fat perserving of 28.35 g. Certain preservatives, including sorbates, are allowed to extend the shelf-life of Cottage cheese. Cottage cheese may contain fruits, seafood, meats, or vegetables.

Cottage cheese is a major ingredient of salads and is used as a filling in the preparation of breakfast food, blintze. Good-quality cottage cheese should have a clean, creamy, cultured milk flavor, a natural, creamy color, and a meaty, soft texture. It should have a reasonably uniform curd size and should not be pasty or too firm. It should have a uniform cream layer around the curd particles with a little free cream.

Manufacturing Process

Depending on the plant schedule, a short-set, medium-set, or long-set method may be used. The long-set method involves using 1% starter, incubation at 22 °C for 12–16 h, whereas the short-set method uses 5–7% starter at 32 °C for 4–6 h.

The manufacturing operation may involve the use of simple cheese vat and equipment for whey removal, curd washing, draining, and creaming. The creamed curd is pumped to a filler for packaging. However, large-scale operations use automated systems to continuously carry out the various steps outlined below.

Setting Raw skim milk is pasteurized at 73 °C for 16.5 s. It is desirable to avoid previously heated milk because a minimal heat treatment is needed to avoid the formation of weak coagulum and subsequent shattering of the curd. The pasteurized milk is cooled to 32 °C and pumped into a cheese vat, where the jacket temperature is adjusted to maintain the milk temperature at 32 °C. Bulk culture is added at the level of 5–7% and mixed thoroughly. The titratable acidity is measured at this point. Stirring is continued at intervals of 30 min for 1.5 h. The increase in acidity at this point should be 0.05–0.07%. If not, 1% more culture is added for each 0.01% increment below 0.05%. Next, rennet, diluted 1 to 40 with water, is added at a level of 40 ml for a large curd and 12–20 ml for a small curd per 454 kg of skim milk. After mixing thoroughly, the vat is covered for about 2 h for fermentation, during which time the pH should drop to 4.6–4.7.

Cutting When the coagulum is ready, it is cut first along the length of the vat using appropriate horizontal knives to yield the desired small- or large-curd product. Wire knives with a 0.62-cm spacing are used for the small-curd product and with 1.86 cm spacing for the large-curd product. Next, the coagulum is cut lengthwise with the vertical knife and then crosswise with the vertical knife.

Cooking After cutting, the curd is allowed to heal for 10 min. The jacket water temperature is raised to 44–50 °C to initiate cooking of the curds. The temperature of curd is raised slowly to 54 °C over 1.5 h. The curd-whey is hand-stirred every 5–10 min, and a mechanical agitator is used after the temperature has reached 38–41 °C. The agitation speed is increased slowly to avoid matting of curd particles. Small curd particles cook faster than large particles. Agitation is continued until the curds become reasonably firm; the curd is adequately cooked when a handful of water-chilled curd springs apart when squeezed together with moderate pressure.

Washing After completion of cooking, the jacket water is drained off. Whey is removed until the curd begins to appear above the surface. Wash water, acidified with phosphoric acid to pH 4.6 and chlorinated to 10–20 mg kg^{-1} is then added to a volume equal to that of the whey removed. The temperature of curd should decrease to 27–30 °C. After agitation for 10 min, the water is drained off. Washing is repeated twice with chilled water to reduce the temperature of the curd to 13–16 °C and finally to 5 °C or lower. The curd is trenched and allowed to drain for 30–60 min before creaming.

Creaming The curd is blended with cream dressing in a blender or in the cheese vat. The dressing is formulated to contain 12.5% fat, 8.5% solids-not-fat (SNF), 2.7% salt, and 0.25% stabilizer. The stabilizer is especially designed for the dressing to achieve a high viscosity and to avoid wheying off. The dressing is pasteurized at 75–77 °C for 30 min and homogenized at 57 °C at a pressure of 13.8 MPa, single stage, followed by cooling to 4 °C or below. One part of the dressing is blended with two parts of curd to give at least 4% fat in creamed cottage cheese. The dressing can be treated further to enhance the shelf-life of cottage cheese to control the growth of spoilage psychrotrophic organisms. Cultures inhibitory to spoilage organisms may be added and the dressing itself may be fermented. Several bacteriocin-containing preservatives are commercially available to extend the shelf-life of cottage cheese. The typical shelf-life of cottage cheese packaged in moisture-barrier containers is 3–4 weeks at 4 °C.

The yield of cottage cheese curd is typically around 15.5% kg per 100 kg of skim milk of 9% SNF. A fortified skim milk containing 12% SNF should give 21.6 kg of curd per 100 kg of starting material.

Quarg, also called Quark, Kwarg, Koarg, Twarog, Tvorog, Taho, or Topfen, is a popular fresh cheese of central Europe. It has a slightly sour flavor owing to its low pH. It is generally made from skim milk. In some cases, some variations may be made from homogenized full-fat milk. Buttermilk is also used as a raw material. In a process similar to cottage cheese, the milk is cultured with selected strains of *Lactococcus* and *Leuconostoc* species. After fermentation, the curd is collected by centrifugation in a special separator. It may be also be produced by direct acidification with lactic acid, lemon juice, or vinegar. The curd is blended with cream to yield low-fat or full-fat Quarg.

Cream Cheese

Cream cheese contains at least 33% fat and not more than 55% moisture. It is a soft, unripened lactic acid-coagulated cheese, made by a process similar to that for cottage cheese. It has a mild, acid, and creamy flavor with a buttery aroma. The manufacturing procedures are similar for cream and Neufchatel cheese, but, compared with a fat content of 35% in cream cheese, Neufchatel cheese contains 23% fat.

Cream cheese is an important variety in North America. In 2000, cream and Neufchatel cheese production in the USA exceeded 331.8 million kilograms. Cream cheese is mostly used as a spread on bagels and toasted bread or as an ingredient of cheesecakes. At present, cream cheese is marketed in flavors like strawberry and other fruits. It is also flavored with vegetables, condiments, spices, and herbs. Low-fat versions are available.

Manufacturing Procedure

Several processes are used to produce cream cheese. Typically, the process involves standardizing cream to 11% fat, followed by pasteurization at time–temperature combinations (e.g., 68 °C/30 min) similar to normal pasteurization. Using a starter consisting of *Lactococcus lactis* ssp. *lactis/cremoris* and *Leuconostoc cremoris* at a level of 5–6%, the cream is cultured at 30–32 °C for 5 h. A long-set process uses 1% starter and incubation for 16 h at 22 °C. *Leuconostoc* sp. imparts a buttery aroma. In some plants, rennet is added at a low level. Fermentation is continued until a pH of 4.4–4.5 is attained.

In the traditional process, the cultured cream is drained in muslin bags by hanging overnight in a cold room. However, most modern plants are equipped with centrifuges to remove the whey. Cream cheese collects in the bowl. Membrane processes are also used for separation of whey. The cheese is subsequently packed by a cold-pack procedure without additives or heat. Cold-pack cream cheese has more aroma and flavor and lacks a pasty/sticky body than the hot-packed product. However, it lacks the long shelf-life obtained by the more commonly used hot-pack procedure. This procedure involves heat treatment of cream cheese in a kettle or scraped surface heat exchanger. Cream cheese is mixed mechanically with a stabilizer (0.35% locust bean gum) and 1% salt and brought to 70 °C. The hot mixture is homogenized at 13.8 MPa and transferred to the packaging machine for hot packaging. The hot process imparts a shelf-life of at least 2 months under refrigerated storage.

Cheeses Produced by Direct Addition of Acid and Heat

Worldwide, curd formation during cheese making is effected by the use of coagulating enzymes isolated from various sources in combination with or without a fermentation step. Alternatively, curd can be formed by direct acidification of hot milk with food-grade acids. Generally, the directly acidified cheeses are consumed in fresh, unripened form. The cheese varieties included in this category are quite diverse. From the standpoint of commercial importance, Ricotta, Chhana, Paneer, and Latin American cheeses will be discussed briefly.

Ricotta Cheese

Like cottage cheese, Ricotta cheese is high-moisture, unpressed cheese. Its composition varies, depending on whether it is made exclusively from whey or from a blend of whey and milk. Ricotta is also prepared from whole milk, with no addition of whey. When made from a blend of 95% sweet whey and 5% milk, Ricotta contains 68–73% moisture, 16% protein, 4–10% fat, and 4% lactose.

Ricotta has a bland to slightly cooked, but pleasing, flavor. Its texture is soft and creamy. It is consumed as such as a spread and may be used as a replacement for cream cheese or sour cream in dips. It is basically a nonmelting cheese. Its major use is in Italian cuisine, as in Lasagna and Ravioli, for example. (*See* **Whey and Whey Powders**: Production and Uses.)

Manufacturing Procedure Most Ricotta is produced by a batch process. Traditionally, open kettles are used. Heating may be direct, or steam jackets may provide heat transfer. Sweet whey from Italian cheese manufacture is suitable as long as its pH is 6.2 or higher. Ten to 25% milk is often blended to neutralize acid in the whey, enhance yield, and curd cohesiveness. The mixture is heated in a kettle to 82–93 °C, followed by the addition of sufficient food-grade acid, e.g., lactic, acetic, or citric, to reduce the pH of the mixture to 5.9–6.1. In some plants, cultured milk/whey may be used as a source of lactic acid. This pH range is crucial to maintain the sweet flavor of the cheese. As a result of heat and acidity, the proteins are denatured, and a foam-type curd ascends to the surface. The curd is then dipped with a perforated ladle and collected in muslin bags. The bags are allowed to drip and cool in a cold room. Alternatively, the curds are drained in perforated stainless hoops and allowed to dry. The curd is soft, fragile, and grainy, and may be pressed slightly to achieve cohesiveness. The yield of Ricotta is low, around 5–6% if no milk is mixed

with whey. Mechanized production for the continuous manufacture of Ricotta cheese involves adjustment of the pH of the whey–milk mixture to 6.9–7.1 with NaOH, heating the blend to 88–92 °C, and injecting in-line an appropriate quantity of salt and acid. Again, the target pH is 5.9–6.1. The hot acidified whey–milk blend is pumped into the bottom of a V-shaped vat, and the resulting curd is collected mechanically from the top of the vat into nylon mesh for the curd to drain. It is than transferred to perforated hoops, cooled, and packaged for sale.

Chhana

Chhana is a Ricotta-like cheese produced in India from hot milk by direct acidification. Although Chhana is an intermediate material for producing Paneer and various confectionery foods, the product standards for Chhana and Paneer are identical. According to Indian Pure Foods Act, Chhana (or Paneer) is defined as a product obtained from cow or buffalo milk or a combination thereof by precipitation with sour milk, lactic acid, or citric acid; it should contain not more than 70% moisture, and the milk fat content should not be less than 50% of the dry matter. Skim milk Chhana or skim milk Paneer is the product obtained from cow or buffalo skim milk by precipitation with sour milk, lactic acid, or citric acid; it should contain not more than 70% moisture, and the milk fat content of the product should not exceed 13.0% of the dry matter.

Manufacturing method The production of Chhana basically involves the precipitation of casein along with fat and entrapped water-soluble components of milk (lactose, whey proteins, minerals, vitamins) by the addition of an acidulant to milk at a near-boiling temperature, followed by removal of whey from the curd. Basically, Chhana is made by a batch process, but a continuous process may be adapted from the continuous process for Ricotta, as described above.

The texture of Chhana varies from smooth and pasty to crumbly. It is an intermediate starting material for the preparation of indigenous Indian dairy confectionery products. The preferred milk for Chhana is cows' milk. In Chhana production, pressing of the curd is restricted to pressing caused by gravity after draining of the whey in a cheesecloth/muslin bag. A longer draining time yields a hard product. Depending on its end use, Chhana may be soft or hard. For example, the confectionery product, Rasogolla, requires soft Chhana, whereas the confection, Sandesh, requires the hard variety. These two confections utilize the majority of Chhana production, and optimum functionality is required in each case.

Chhana is made in kettles. Cows' milk is brought to near boiling, and an appropriate acidulant is added quickly to the hot milk to bring the pH of the mixture to 5.4. The curd settles to the bottom, and whey is removed by filtration through a strainer lined with cheesecloth. The curd is then cooled in running tap water. Chhana can be used to make sweetmeats and other Indian confections. The coagulants used are lime or lemon juice, vinegar, citric acid, lactic acid, fermented milk, or whey. A solution of citric acid (0.5–1.5%) or lactic acid (1–2%) is appropriate to lower the pH of hot milk to 5.4. An interaction between the temperature of coagulation and final pH is observed in terms of obtaining the best yield and quality of Chhana. For cows' milk, a temperature of 80 °C at pH 5.4 is optimum, whereas for buffalo milk, 70 °C at pH 5.7 is desirable. A higher coagulation temperature imparts graininess and hardness to the texture, whereas lower temperatures result in a sticky Chhana, which drains too slowly. Chhana is an extremely perishable food product, and at ambient temperature, its quality deteriorates within a day or two and is used soon after production. Under refrigeration, the shelf-life is extended to 6 days.

Two important confections based on Chhana are Sandesh and Rassogolla.

Preparation of Sandesh Chhana is thoroughly kneaded to obtain a homogeneous mass. Ground sugar (30 parts) is added to Chhana (100 parts), and the mixture is cooked in a vessel until the confection stops sticking to the surface of a griddle. At this point, the hot mass is poured into molds or into a pan to cool and set. Cardamom and other flavors may be added prior to setting. Upon cooling, the surface of the confection may be sprinkled with cracked pistachio nuts and cut into the desired shapes and sizes. The typical composition of Sandesh is 24% moisture, 0.45% titratable acidity, 14.9% protein, 10.7% fat, and 47% sugar.

Preparation of Rasogolla Rasogolla, a widely popular sweetmeat in India, is the result of a puffing phenomenon in which milk protein, primarily the caseins, acquires a foam-type structure under special cooking conditions in sugar syrup. Accordingly, the product is a spongy, round ball, 2–4 cm in diameter, suspended in sugar syrup. Occasionally, the shape may be cylindrical. In this process, Rasogolla absorbs sugar syrup, providing a succulent, juicy texture. The ultrastructure of the product is stable for years, as evidenced in canned products, and the spongy texture may even be accentuated to give a variety called Sponge Rasogolla.

Most large manufacturers of Rasogolla in India prefer to use only Chhana to knead and prepare the dough. However, some sweetmakers knead together 100 g of Chhana, 0.7 g of cream of wheat, 5.2 g of white wheat flour, and 12 mg of baking soda. The dough is portioned and rolled into balls (10–20 g each) and cooked in a medium consisting of 50% sugar, 17% whey, and 33% water. The pH of the cooking solution is adjusted to 6.8 with $Ca(OH)_2$. Cooking is completed in 25 min. The cooked balls are conditioned in water at 30–35 °C for 10 min, immersed initially in 59–60 ° Brix syrup and finally in 50 ° Brix syrup, and then refrigerated. They may be canned to enhance their shelf-life and to extend marketing range. Rasogolla contains 38–55% moisture, 37–48% sugar, 5.3–5.7% fat, and 5.0–5.5% protein.

Paneer

It is estimated that about 4–5% of the total milk produced in India is converted into Paneer. The distinctive texture of Paneer is obtained by the application of low pressure to the cheese in hoops, followed by immersion of the blocks in chilled water. The cooling step results in reabsorption of some water, which imparts a characteristic springy and rubbery body to Paneer blocks. Paneer offers outstanding nonmelt functionality. Its ability to withstand frying temperatures makes it suitable for use in Indian cuisine. Paneer is suitable for the preparation of fried cheese snacks. It may be included as an entrée item in a meal, with or without a suitable batter and breadcrumbs. Such items resemble fish sticks, chicken nuggets, or tofu chunks.

Manufacturing Method Buffalo milk containing 6% fat and 9.5% SNF is preferred for Paneer production. The milk is heated in a plate heat exchanger to 85–90 °C and pumped into a water/steam jacketed cheese vat. By circulating cold water in the jacket, milk is cooled to 70–75 °C in about 10 min prior to acid blending. Sufficient citric acid (1% solution), warmed to 70 °C, is gently but quickly blended with the milk (within 1 min) to reduce the pH to 5.3–5.4. Normally, it requires about 1.8–2.0 g of citric acid to coagulate 1 kg of milk. At this point, clear greenish yellow whey separates, and the curd sinks to the bottom. The coagulation temperature influences the moisture content of Paneer; a temperature of 70 °C gives the best organoleptic quality as well as the most desirable frying quality in terms of shape retention, softness, and integrity maintenance. The coagulated milk is allowed to separate into curd and clear whey. After 10 min, the curd chunks sink to the bottom. At this point, a strainer is fitted into the outlet of the vat. The whey drainage valve is then opened, and the whey flows into a surge tank partitioned by a strainer to retain any curd fines that escape from the vat. Hot whey accumulates in the second section of the surge tank from which it is pumped out, cooled to 4 °C, and stored in a whey tank for further processing. The curd is transferred to molds/hoops lined with cheesecloth. For culinary purposes, unflavored and unsalted Paneer is traditionally used. The paneer hoops are pressed with a hydraulic press to exert a low pressure (10 kPa) on the curd. The pressing time is generally 10–15 min, after which time, the wrapped block of paneer is ejected from the hoop for quick cooling by immersion for 1–2 h in cold water (4 °C) containing 3–5 mg per kilogram of chlorine. Cooled blocks are then mechanically cut into convenient retail size and packaged. A yield of 18–20 kg of Paneer per 100 kg of standardized milk is expected. (*See* **Buffalo**: Milk.)

Latin American Cheeses

Latin American White (LAW) cheeses, known by various names, are produced throughout Mexico, Central and South America, and the Caribbean Islands. These cheeses are made from whole milk, skim milk, cream, or a mixture. Queso blanco and Queso del pais are the only varieties produced by direct acidification of hot milk with vinegar or fruit juice. Rennet is used for the coagulation in Queso de prensas in El Salvador, Mexico, and Venezuela, Queso estera in Colombia, and queijo Minas in Brazil. Starter cultures are also used and allowed to generate a high acidity. LAW cheeses are white, creamy, highly salted, and acidic in flavor. They have a body and texture similar to young high-moisture Cheddar, and can be sliced for sandwich use. The fresh or dry 'Criollo' product is grated or macerated to accompany beans, rice, or tortilla (flat corn bread). These cheeses can be used as a snack, in salads and as a cooking cheese in casserole dishes, grated for use in pizza and other foods, or included as an ingredient in the manufacture of processed cheese. Like paneer, LAW cheese can be made to be resistant to melting at frying temperatures. However, these are highly salted products, unlike paneer.

Manufacturing method Directly acidified Queso blanco is produced from whole/part skim milk by heating to 80–88 °C, holding for 15 min, followed by quick addition of diluted vinegar/citric acid solution to bring the pH to 5.3–5.7. The acidified milk is stirred gently for 2–3 min, and the curd is allowed to settle to the bottom of the vat. As for paneer, both casein and heat-denatured whey proteins are retained in the curd. After 15 min, the settled curd is recovered

by whey drainage, and up to 5% salt is mixed in. The salted curd is soft and dry, and forms large chunks; it is pressed overnight in molds to yield a more cohesive product. The blocks are refrigerated and packaged.

The yield of Queso blanco varies from 11 to 14.6%, depending on the moisture content. It typically contains 51–57% moisture, 18–22% protein, 15–17% fat, and 3.5–4.5% salt. A drier variety suitable for maturation may have 35–39% moisture, and a hard variety may have an even lower moisture (27–32%).

White Brined Varieties

M H Abd El-Salam, National Research Centre, Dokki, Cairo, Egypt

Introduction

It is evident from ancient literature (Homer, 1184 BC) and archeological findings (tomb Hor Aha, Saqqara, Egypt) that this group of cheeses is probably the origin of various types of cheeses known now.

The production of brined (pickled) cheeses has long been limited to the Mediterranean and southeast European Countries. Nowadays, the international recognition of brined cheeses and the dynamic growth in their demand have extended their production to other countries, including Denmark, Ireland, the UK, the USA, New Zealand, and Australia. Feta cheese is the most significant type of brined cheese marketed in the world. The consumption of brined cheese varies between countries, but the highest per- capita consumption of Feta cheese is recorded in Greece (12 kg).

Characteristic Properties

Preservation in brine (pickle) is the main characteristic of this group of cheeses. The brine serves to preserve the cheese and prevent it drying out. Consequently, the composition and properties of these cheeses and those of the brine are interrelated.

Brined cheeses are generally rindless and are produced in the form of blocks of various shapes and sizes (cubes, bricks, or segments) covered in salt brine or whey.

Brined cheeses are either ripened in wooden barrels and then marketed in tins or packed and ripened directly in retail packages. They are marketed fresh or after storage of up to one year.

Their clean, acidic and salty taste, and sharp flavor characterize brined cheeses. The high salt content of the cheese and brine allows for a good keeping quality in hot climates without the need for cold storage.

The color of brined cheeses is pure white, as they are traditionally made from ewes', goats' or buffaloes' milk, which are known for their whitish color.

Although all brined cheeses are subjected to the same practice of storage in pickle for extended periods, they differ significantly in their manufacturing technologies, composition, and properties.

Classification

As shown in **Table 1**, brined cheeses include soft and semihard varieties, and nearly all of them are made by rennet coagulation. In general, brined cheeses can be made from different kinds of milk, but sheeps' milk is preferred for most of these varieties. (*See* **Buffalo**: Milk; **Goat**: Milk; **Milk**: Liquid Milk for the Consumer; **Sheep**: Milk.)

Methods of Manufacture

Traditional Methods

Feta cheese Normally, ewes' milk is used, but a mixture with goats' milk (up to 30% goats' milk in

mixture) can be used. The milk is heated to 65 °C for 30 min (optional) and then cooled to 32–33 °C; 1–3% starter (*Lactococcus lactis* plus *Lactococcus lactis* subsp. *cremoris*) is then added (optional); 20–30 ml of rennet (preferably lamb or kid rennet) per 100 l are used to coagulate the milk in 50–150 min; the curd is then cut into 2–3-cm cubes and left in the whey for 10–15 min, after which it is scooped into metal hoops, 20 cm deep, and left for 1 h; the hoops are transferred to a room (16–18 °C), and the surface of the curd is lightly salted; the cheese is turned upside down and left for 20 h; the curd is then cut into pieces (different sizes), placed in wooden barrels in layers, and dry salted with 3% coarse salt over a period of 3 days; and the barrels are topped up with 5% brine and left for 15 days, prior to being transferred to cold storage (4 °C) until marketed. (*See* **Lactic Acid Bacteria**; **Starter Cultures**.)

Telemea cheese Whole milk (usually cows' milk) is heated to 60–68 °C for 20–30 min, 0.5% starter (mesophilic bacteria plus *Lactobacillus casei*) is added at 28–31 °C, followed by 25–30 ml of rennet per 100 l of milk, and held at 30–34 °C for 60 min, and the curd is transferred into cheesecloth in layers. The resultant curd is cut crossways with a long knife and pressed for 2 h. The cheese is cut into blocks and immersed in a salt bath (18–22% NaCl) at 15–16 °C overnight, and layered in tins, which are then completed (filled) with acid (1.3–2% lactic acid), salted (4–5% NaCl) whey for 1 month, then stored at 5–10 °C. (*See* **Whey and Whey Powders**: Production and Uses.)

White pickled cheese Whole milk is flash-heated to 70 °C or 68 °C for 10 min (optional), and a starter (sour milk or mesophilic bacteria 0.5–1.0%) is added followed by rennet (25–30 ml per 100 l of milk at 30–31 °C) to complete coagulation in 60–70 min; the curd is ladled into a cheesecloth, which is laid over a wooden frame, placed over a drainage table; the cheese is pressed by tightening the cloth and by the use of weights; the curd is cut into cubes (10 cm^3) and immersed in saturated brine overnight; and the cheese is packed into barrels or tins filled with salted whey (8–12% NaCl).

Brinza Milk is coagulated by rennet at 25–32 °C for 40–90 min, after which the curd is transferred to the drainage table for cutting, tuning, and pressing (whey is removed in 2 h), cut into rectangular blocks (1 kg) and salted in brine at low temperature (10–12 °C). The cheese is then packed into wooden barrels or lacquered tins filled with brine or salted whey and stored at 4 °C or 12–20 °C.

Bli-Sir-O-Kriskana Starter (0.1% *Lactococcus lactis* plus *Lactobacillus casei*) is added to the milk, followed by rennet (20–30 ml per 100 l at 30–32 °C) in order to achieve coagulation in 70–90 min. The

curd is cut horizontally and vertically, and left for 15–20 min, recut into smaller cubes and ladled into a cheesecloth, pressed for 1–4 h, then cut into cubes (10 cm^3) for dry salting or immersion in brine (20–25% NaCl) for 10–20 h at 12–15 °C. The cheese is packed in parchment-lined casks or tins completed with brine (10–12% NaCl) and held at 12–15 °C to ripen in one month and then stored at 10 °C.

Bjalo (Belo Salamureno Sirene) Milk is heated at 68 °C for 10 min, then cooled at 31 °C; 0.1–0.3% starter (*Lactococcus lactis* plus *Lactobacillus casei*) is added followed by 20 ml of rennet per 100 l (coagulation time: 60–90 min). The curd is cut into cubes (2–3 cm^3), which are ladled into a cheesecloth, then cut into strips, and the cloth tied over the curd. It is then left to drain, pressed for 4–5 h at 14–16 °C, cut into pieces (12 × 12 cm), immersed in saturated brine or dry-salted for 24 h, and packed into metal or plastic drums filled with brine (10–12% NaCl). The cheese is ripened for 2–4 weeks and stored at 4–8 °C.

Domiati Dry salt (5–15%) is added to the milk and stirred until dissolved. The salted milk is then strained through cheesecloth, heated to 37–42 °C, and rennet (30–40 ml per 100 l) added to achieve coagulation in 2–3 h. The curd is scooped into wooden frames lined with cheesecloth, placed over a wooden board on a draining table and allowed to drain for 3–4 h. The curd is then broken and pressed to achieve complete drainage in 16–24 h. The cheese is cut into blocks, wrapped in cheesepaper, and packed into 2–20-l tins filled with salted whey (from the same cheese) and stored at room temperature.

Halloumi A sufficient quantity of rennet is added to sheep's milk to coagulate the milk at 34 °C within 7–8 min. The curd is cut after 30 min into grains (1 cm^3) and left for 10 min, stirred gently for 10 min, scalded at 60 °C for 15 min, transferred to hoops, then pressed with weights (3 kg per kilogram of cheese) for 35 min. The pressed curd is cut into small blocks (10 × 10 × 3 cm), transferred to deproteinized whey, then heated to 90–92 °C for 30 min. The cheese is then drained and sprinkled with dry salt and dried *Mentha viridis* before conservation in brine.

Medaffara Rennet is added to raw milk at 32–37 °C for 40–60 min and left to ripen (30–60 min). After the curd cutting and partial removal of the whey, the cubes are left to ripen in the whey until they form a slim block about 2 m long. The ripened curd is then kneaded in hot water at 80 °C for 10 min, after which black cumin spice (*Nigella sativa*) is added; the curd is then shaped, while hot, to form a cord that is braided and then brined.

Industrial Scale Methods

Equipment and process development Rapid developments in the technology of brined cheeses have been achieved during the last two decades; the application of ultrafiltration (UF) in the manufacture of feta cheese is one of the most outstanding developments. Industrial-scale production of brined cheeses is based on modifications of traditional methods. The main differences between the traditional and industrial scale methods are:

- Type of milk: Cows' milk is usually used on an industrial scale. This requires the treatment of milk fat in order to retain the white color of brined cheeses. Blue–green dye (e.g., chlorophyl) is added mainly for this purpose. Decolorization of pure milk fat by heat treatment/use of oxidants is practiced to produce a special milk fat for recombined brined cheeses.
- Heat treatment: Milk is normally pasteurized before cheese making to ensure public safety, to minimize quality defects, and to allow the cheese to retain more moisture.
- Homogenization: This step is essential for the manufacture of brined cheeses from recombined milk. It also improves the fat retention and smoothness of cheese from fresh milk. Cheese from homogenized milk appears whiter in color.
- Additives: Mesophilic and thermophilic lactic starters, or a combination of these, are used. Also, lipases, acidulants (glucono-δ-lactone), and calcium chloride are frequently used.
- Ultrafiltration: Most of the progress in brined cheeses has been achieved through the use of ultrafiltration techniques. Such techniques result in a substantial increase (20–30%) in cheese yield, saving manpower, additives, and energy consumption. Also, the compositional quality of the product can be easily controlled.
- Packaging: New packaging materials and equipments are used. In addition to tins, laminated paper cartons (tetrabricks), special polymeric films, and rigid plastic containers are now being used in retail packaging.

Several systems have been developed for the continuous manufacture of brined cheeses from milk or partially ultrafiltered milk using all or part of the following processes and mechanized equipment.

- Dosing equipment. For continuous blending of milk/UF retentate with various additives, i.e., a starter culture, coagulant, or decolorizing agent.

Such equipment consists of metering devices and in-line static mixers.
- Coagulator/cutting devices.
- Molding and dewheying.
- Bulk packaging, salting, and brining.

UF-cast feta cheese Two systems are in use for the production of UF-cast feta cheese:

1. Standardized pasteurized milk (12.5% total solids (TS), 3.5% fat) is ultrafiltered to give a retentate of 37–38% TS. The retentate is then pasteurized, homogenized, and pumped from a balance tank by means of a finely controlled, positive pump to the filling, mixing, and dosing aggregate. At the same time, precise amounts of rennet, lipase, NaCl, and acidulant (glucono-δ-lactone and blue phosphoric acid) are dosed into the concentrate before it reaches the filling head. The concentrate is filled into laminated 'tetra bricks' (250–500 g), or it can be packed into a special polymeric film and encased in a rectangular carton.
2. The UF-milk retentate (37–38% TS) is pasteurized, homogenized, and directed into an intermediate tank. After cooling to 30 °C, 3% mesophilic starter and lipase (4–8 g of pregastric lipase powder/100 kg) are added. No time is allowed for acid development to take place. Rennet is dosed in-line into the retentate before casting in tins (10/20 l). Filling takes place in three stages as each layer is coagulated separately. The tins are then taken to the portioning section, where the cheese is cut by a cutting machine equipped with vertical knives. The cheese is salted with 4–5% NaCl, which is dosed and spread automatically on the top of the cheese; the tins are then closed and stored in a cold room until marketed.

UF-structure feta Continuous coagulation of retentate with 26% TS takes place in a coagulator, followed by continuous cutting of the coagulum. The cheese grains are treated in the permeate (from the UF process), in which syneresis takes place. The cheese grains are filled into molds, whey is drained off, and the finished cheese is cut into blocks, filled into tins, and salted with dry salt, as described for cast feta.

UF-Domiati Standardized pasteurized milk (12.5% TS, 3.5% fat) is concentrated by UF to 35% TS. The retentate is homogenized, heated to 75 °C for 1 min, and cooled to 34 °C; 1% mesophilic starter, rennet (3 g of rennet powder/100 kg), and 3–4% NaCl are added and treated as follows:

- The retentate is poured into stainless steel trays (50 × 50 × 10 cm) and left to coagulate. The cheese is then cut manually into cubes (0.5 kg), wrapped in polyethylene sheet and packed into a 1-kg rigid plastic container (consumer package) or in 10/20-1 tins; the containers or tins are filled with 5% salted permeate and then closed.
- The retentate is cast in plastic containers (750 g) placed in a moving conveyer in a constant temperature tunnel (40 °C), in which there is complete coagulation before the package leaves the tunnel. Salted brine (5% NaCl) is dosed, and packages are sealed with aluminum foil and covered with a plastic lid.

Recombined feta/Domiati cheeses Recombined feta/Domiati cheeses are made from recombined milk using either low-heat skim milk powder or skim milk powder retentate and anhydrous milk fat. Recombination is carried out in batches or continuously depending on the scale of production. Immediately after mixing, the recombined milk is homogenized, heated, cooled, and made into cheese as for fresh milk. Commercial pregastric lipase is added to improve the acceptability of the product.

Changes in the Composition of Brined Cheeses During Storage

Table 2 shows the average composition of several brined cheeses. General factors affecting the composition of other cheese varieties apply also to brined cheeses. These include the type of milk, heat treatment received, and conditions and duration of storage. In addition, storage in brine plays a special and important role in determining the changes in composition of brined cheeses. This can be understood from the following:

- brine provides a very high water activity for stored cheeses;
- there is a continuous equilibrium in the distribution of soluble constituents between cheese and brine;
- there are ion-exchange equilibria between Na^+Cl^- in the brine and the ions in the cheese;
- brine partially solubilizes the protein matrix of cheese;
- brine controls the cheese microflora; the surface microflora are of limited significance.

In general, the changes occurring in brined cheeses can be described as follows.

Table 2 Average composition of some brined cheeses

Cheese	*Moisture (%)*	*Fat/dry matter (%)*	*Total protein (%)*	*NaCl (%)*	*pH*
Feta	48–54	48–52		4–5	4.3–4.6
Telemea	55	48–51		3–5	4.4–4.7
Bjalo	58–60	27–31	10–12	3–4	
Brinza	58	45–50		4–10	
Domiati (fresh)	60	40		8–10	6.6
Domiati (3 months)	54	45–50		6–8	3.7–4.2
Halloumi	35–48	38–50	24–30	2–5	5.3–6.1
Medaffara	53–54	17–22	21–24		5.1

Moisture Content

Depending on the initial moisture content, pH, and concentration of brine, the moisture content of brined cheeses decreases on storage. This is obvious in Domiati cheese, where a 5–10% decrease in cheese moisture is normally observed during storage.

Nitrogenous Constituents

The different cheese proteins are subject to variable proteolysis: α_S-casein is extensively hydrolyzed, while β- and *p*-χ-casein are less affected. An increase in the soluble nitrogenous constituents is normally observed during storage of brined cheeses. These compounds include peptides, amino acids, and ammonia, but the formation of biogenic amines is very limited.

Milk Fat

The rennet used in brined cheeses traditionally contained pregastric lipases, and in developed technologies, lipase is added. Lipolysis is therefore one of the characteristics of brined cheeses. The mono- and diglyceride content of the cheese increases on storage with the formation of variable free fatty acids. However, the volatile fatty acids of brined cheeses contain a high percentage of acetic acid, originating from microbial fermentations. (*See* **Fatty Acids**: Properties.)

Lactose

Fresh brined cheeses retain variable quantities of lactose, and those stored in salted whey have access to a continuous supply of lactose during storage. It is not surprising, therefore, to find measurable quantities of lactose in brined cheeses throughout the storage period. The presence of galactose in stored Domiati cheese has been reported.

Mineral Constituents

The calcium content of brined cheeses decreases as a result of acid development and ion exchange with NaCl in the brine; the phosphate content of cheese also decreases during storage. Changes in Na^+ and Cl^- contents of cheese are dependent on: (1) the concentration of the brine, (2) the initial NaCl content of cheese, and (3) any decrease in cheese moisture during storage.

Vitamins

Vitamin A is stable, but thiamin, riboflavin, and nicotinic acid show a variable decrease in cheese stored in tins. (*See* **Niacin**: Properties and Determination; **Retinol**: Properties and Determination; **Riboflavin**: Properties and Determination; **Thiamin**: Properties and Determination.)

Volatile Flavor Compounds

Brined cheeses develop a mixture of short-chain fatty acids. Acetic acid is the major volatile fatty acid in Domiati cheese, whereas in feta cheese, butyric acid is present in significant quantities, particularly in traditional feta. In feta cheese, several alcohols and carbonyl compounds increase in concentration on prolonged storage.

Texture and Structure

The textures of cast UF and traditional brined cheeses are significantly different. However, the texture of both is affected by several factors including homogenization, amount of rennet used, pH, NaCl content, and storage period/conditions. Generally, brined cheeses retain a softer texture during ripening that is related mainly to proteolysis and the level of whey proteins in cheese.

Electron microscopic examination of feta and Domiati cheeses indicates that the internal structure of fresh cheese is composed of a framework of spherical casein aggregates, held together by bridges and enclosing fat. During storage in brine, the casein aggregates in Domiati cheese disintegrate into smaller spherical particles, forming a loose structure. The casein particles in Feta cheese coalesce as particles cling to one another, forming larger clumps than in Domiati cheese. The changes in the protein matrix

during storage are generally responsible for the smooth body of ripened brined cheeses. These changes are likely to arise from (1) the partial loss of calcium from the cheese matrix into the brine and (2) continuous proteolysis of α_s-casein, known for its important role in linking the cheese protein network.

Microbiology

Microorganisms Present

Lactic acid bacteria are dominant in Domiati cheese, Streptococci during the early stage of pickling, and later Lactobacilli. *Streptococcus faecalis*, *Lactococcus lactis*, *Lactobacillus casei*, *Lactobacillus plantarum*, *Lactobacillus brevis*, and *Lactobacillus fermeti* are the most common Streptococci and Lactobacilli present in Domiati cheese. Several nonlactic bacteria and yeasts are also found.

The predominant lactic acid bacteria in other white brined cheese are Streptococci (*S. faecalis*, *S. faecium*, *S. durans*), Leuconostoc (*L. dextrerincum*) and Lactobacilli (*Lb. plantarum*, *Lb. casei*, *Lb. brevis*). The principal psychrotrophs found are from the genera *Pseudomonus*, *Aeromonas* and *Rhodotorula*. Salt-resistant yeasts growing on the surface of feta cheese during ripening may contribute to ripening.

Effect of Manufacturing and Storage Conditions

Raw-milk cheese generally has higher bacterial counts than the pasteurized-milk cheese during early stages of ripening, but both cheeses have similar counts thereafter. The total bacterial count of Domiati cheese increases rapidly, reaching a maximum after a week of manufacture, and then declines. Streptococci are dominant in the early stages of pickling and then replaced with Lactobacilli, or Lactobacilli and Micrococci, in the later stages of ripening, depending on the level of NaCl in cheese. Micrococci and Lactobacilli dominate in Domiati cheese with a high salt content.

The number of aerobic, lactic, and proteolytic bacterial counts of feta cheese reaches a maximum after 5, 20, and 45 days, respectively, and then decreases markedly at 3–4 months of storage. The lipolytic count shows a slight increase during ripening and storage.

The fresh Hallomi cheese has very limited bacterial counts, but these increase significantly during storage. Spore formers contribute to this flora.

Survival of Harmful Organisms

Coliform bacteria are frequently found in white brined cheeses in large numbers mainly due to the use of raw milk and poor sanitary conditions during small-scale cheese making. No less than 9.5% NaCl should be added to the milk to suppress the growth of coliforms in Domiati cheese from raw milk. The presence of coliforms is responsible for the blowing defect in white brined cheeses.

Staphylococcus aureus can tolerate 2.5–15% NaCl in Domiati cheese. Also, *Salmonella typhi* can survive for up to 16 days in Domiati cheese from milk containing 10% NaCl. Brined cheeses are also good media for the survival of *Listeria monocytogenes* and *Yersinia enterocolitica*. *Nocardia*-like organisms dominate the microflora of the surface slime defect observed in Domiati cheese from raw milk. Introduction

Acid fresh, unripened cheeses are produced throughout the world, but consumption is extremely variable, even within individual countries. Besides Israel (*c.* 11 kg per head per annum), high consumption is observed in central Europe (Poland, 10 kg; Germany, 9 kg), Iceland (7 kg), former Czech Republic and France (5 kg), and Hungary and Austria (4 kg) (for comparison: UK, 0.1 kg). About 30–40 different types of unripened cheeses are mainly made from cows' milk, but also from ewes' milk and especially from goats' milk, these latter products being rather popular in the Mediterranean countries. A common criterion for all cheeses of this class is the low pH value and a calcium content of 0.6–0.9% in the dry matter.

Historically, the lactic curd cheeses are mainly byproducts of butter manufacture, i.e., they are produced from partly skimmed milk. Before 1888, the separation of cream occurred by gravitation. The milk was set at rest in a cool place in shallow pans, during which the cream and the skimmed milk became acid. After skimmed milk had clotted, the coagulum was scrambled and drained of whey, either in cloths or in bags. Sometimes the curd was pressed or even washed to remove most of the whey. Handling of the lactic curd (quarg) was different in individual countries. In central Europe, for example, small cheeses were sometimes prepared from salted quarg, either mold-ripened (Korbkäse, Graukäse, Schabziger, etc.) or smear-ripened with yellow-reddish smear-forming, wild-type coryneformes (Harzer Käse, Mainzer Käse, Olmützer Quargel, etc.), or heated with a mild base (e.g., sodium hydrogen carbonate) and spiced to form cooked cheese. Originally, all these types of cheese had a variable content of fat, owing to the fact that creaming was more or less incomplete before the acid coagulation of the milk took place in the vats.

After introduction of the milk centrifuge (separator) in 1888, sweet skimmed milk became available, which could be used for the production of lactic as well as rennet-coagulated cheeses. However, in most countries, the consumption of lactic curd cheeses decreased constantly because of their very limited shelf-life (less than 2 days), their often unclean flavor, bitterness due to proteolytic activity, and short consistency. In addition, the rather high fat content of the traditional products had made them much more tasty than the new products made from pure acid casein. Even in central Europe, where quark had a long tradition, the product remained a homemade one.

About the time of World War I, the taste of quarg was improved by adding about 2% buttermilk (which contains homofermentative lactic starters, and heterofermentative, aroma-producing lactic acid bacteria) as fermentation culture, e.g., starter to skimmed milk, and by combining the acid-induced formation of the curd with coagulation by renneting. This not only caused a change in the consistency (acid casein gels are hydrophilic, rennet-induced gels are hydrophobic with a tendency to syneresis, especially when heated (maximum 65 °C)) but also permitted a certain heat treatment of the curds which led to products with shelf-lives of up to a week (Dauerquark) at temperatures below 15 °C. This development enabled the production and distribution of quarg outside the home. At the same time, emigrants from Europe introduced into the north-west of the USA a variant of drained quark, namely cottage cheese, which became very popular, at least in North America.

Up to that time, fresh cheeses were prepared from unheated milk to avoid the precipitation of denaturated whey proteins on to the casein, a change which induces a higher water-binding capacity in the protein, and gives a very soft, smooth consistency to the product. In former Federal Republic of Germany in 1951 it was required by law that milk used for unripened cheeses must be pasteurized (72–74 °C for 20 s) in order to avoid health risks. This led to a further reduction in the level of dry matter in quarg, and the new product, Speisequark, became very popular, particularly when enriched with cream. Up to that time, quarg had been mainly used for cooking and baking, but it then lost its cheese image and became a lactic acid dairy product for direct consumption, either sweet with fruit, or salty with herbs and spices.

The problem of limited shelf-life was overcome by the development of special separators (up to 10 000 l h^{-1}) for quarg in the 1950s. It became possible to produce Speisequark on a large scale in enclosed sanitary production lines, avoiding recontamination during packaging. The shelf-life of this product was extended to 22 days (12 °C), even without adding preservatives. (In some countries, preservatives such as sorbic acid and hydrocolloids are used to prolong the shelf-life of fresh cheeses.) Within a 10–15-year period, consumption of the new type of quarg increased in Germany about 10-fold, and production lines handling 200 000 kg of milk per day made the product a rather low-priced one.

Consequently, new developments were necessary to overcome the resulting low profits of the dairies.

In the middle of the 1970s, a product (Thermoquark) was developed which contained, besides the caseins, all of the whey proteins of milk. They were denatured by high-temperature heat treatment (82–92 °C for 5–6 min) of the milk prior to fermentation, and special centrifuges were developed for the Thermoquark. Some manufacturers also started to add denaturated whey protein concentrates – separated from heated whey either by the 'centriwhey' process or by ultrafiltration – to quarg. Since some dairies added up to 30% whey proteins to fresh cheeses, the International Dairy Federation and the German government limited the use of whey in fresh cheeses 'up to the natural whey protein content of the milk', i.e., 16–18% of the total milk protein. (*See* **Casein and Caseinates**: Uses in the Food Industry; **Membrane Techniques**: Principles of Ultrafiltration; **Whey and Whey Powders**: Protein Concentrates and Fractions.)

Direct concentration of sweet milk up to 18% dry matter by ultrafiltration, fermentation, and curd formation without whey drainage was studied extensively for the production of quarg, but without success, since calcium ions (Ca^{2+}), which are not removed from sweet milk by ultrafiltration (UF), lead to the development of a bitter flavor in the product during storage. For this reason UF-Quark is now produced by a method similar to Thermoquarg, mainly from high-temperature-treated milk and not from a milk concentrate, but the separation of the curd from the whey is achieved mechanically by concentrating the fermented milk by UF with stable membranes instead of a special separator. The benefit for the producer is that the dry matter of UF-quarg contains more lactose and ash in the dry matter compared to Thermoquarg, and thus there is a saving in expensive protein. As a result of this development, the law in Germany was revised, and Speisequark must now contain at least 12% total protein; otherwise, the product must be named 'fresh cheese.'

Industrially produced fresh cheeses containing high amounts of whey proteins are heat-treated at about 60 °C before separating the whey by centrifugation or ultrafiltration, otherwise it is impossible to obtain a dry-matter content of 18% and more. Lactic acid bacteria and their enzymes are inactivated at this temperature, as are the enzymes produced by psychrotrophs. The shelf-life of unripened cheeses is nowadays not limited by bacterial contamination, but rather by a decline in sensory properties, e.g., from light-induced off-flavors. (*See* **Lactic Acid Bacteria**; **Pasteurization**: Principles.)

A special group of products, e.g., double cream cheeses, is made from quarg containing high levels of cream. Sometimes, they are stabilized with hydrocolloids (not allowed in Germany) and pasteurized by heating to 60–80 °C for 2–5 min. Hot packaging guarantees a shelf-life of at least 12 weeks. During the last few years, some rather unique products of this type, containing herbs and spices, have been produced by techniques and equipment used for the manufacture of processed cheese. Products with a very high fat content are made by adding emulsifiers (e.g., phosphates and citrates). Italy seems to be the leading country in the development of this type of product. (*See* **Emulsifiers**: Phosphates as Meat Emulsion Stabilizers.)

Within the last 100 years, the character and composition of fresh cheeses have changed completely, at least where the quarg-type products are concerned. However, besides the newly developed varieties of product, the traditional products are still available, e.g., in shops for alternative food or in Italian specialty shops, so that the range of fresh cheeses available to modern-day consumers has expanded greatly during recent decades. Table 1 shows changes in the composition of quarg within the last century.

Production

Milk

The raw material for most fresh cheeses is (partly) skimmed milk, but some types are produced from (homogenized) full-fat milk or even from fat-enriched

Table 1 Mean composition of quarg from skimmed milk in former Federal Republic of Germany within the last century

Product	*Year*	*Dry matter (%)*	*Lactose (%)*	*Lactic acid (%)*	*Salts (%)*	*Protein (%)*	*Ratio of whey protein to casein*	*Milk content (kg) per kg of quarg*
Traditional quarg	1871	32–35	2	1.5	1	27	0.02:1	10
Dauerquark	1910	23.3	3.5	0.9	0.9	18	0.04:1	6.7
Quark	1947	21	3.0	1.0	0.7	16.0	0.07:1	5.8
Speisequark	1951	17	3.0	0.8	0.7	12.5	0.04:1	4.8
Thermoquark	1977	17	3.2	1.0	0.8	12.0	0.19:1	3.9
UF-Quark	1985	17	3.7	1.3	1.3	10.7	0.20:1	3.4

Mean values from different sources.

milk (up to 12% fat). In the case of Speisequark, it is usual to add the desired amount of cream to the low-fat curd after separation of the whey. This is impossible in the case of highly structured products such as full-fat cottage cheese. Besides milk, considerable amounts of buttermilk are used nowadays to produce fresh cheeses. Owing to the fact that most fresh cheeses have a soft consistency, reconstituted milk from low-heat powder is also a rather good raw material; however, some $CaCl_2$ should be added. Some varieties of lactic cheese are prepared from milk–whey mixtures.

As already mentioned, heat treatment of the milk varies between zero and high heating, according to the individual products and the technology in use. However, it should be remembered that fresh cheeses do contain a low amount of their own flavor compounds and they are very sensitive to off-flavors from the milk used. Only raw milk of the best quality yields fresh cheeses with the typical and delicate flavor.

Acidification

Some (Mediterranean) fresh cheeses are prepared by direct acidification with lemon juice or vinegar, but nowadays commerically available lactic acid may be used, and even phosphoric acid has been mentioned as an acidulant. However, most fresh cheeses are produced by acidification of the milk with lactic acid bacteria, i.e., by fermentation. In the northern countries, mesophilic starters are used and in oriental areas with warm climates, thermophilic microorganisms, or even pure yogurt cultures, are used.

Industrial production of fresh cheeses involves the use of selected strains of *Lactococcus lactis*, and *L. lactis* subsp. *cremoris* to develop lactic acid, and sometimes *Lc. lactis* spp. *lactis* (*L. lactis* biovar. *diacetylactis*) or *Leuconostoc mesenteroides* subsp. *cremoris* to form flavor compounds. To avoid proteolysis, which causes loss in yield and initiates off-flavors, *Lc. lactis* spp. *lactis* may be removed from some selected starters.

With thermophilic starters (optimum 43 °C) it is easier to limit acidification; *Lactobacillus acidophilus* is a typical species in use. For example, cultures with limited acidification not lower than pH 4.8–5.0 are produced by Biogarde® containing *Streptococcus thermophilus, Lactococcus lactis*, *Lc. lactis* biovar. *diacetylactis, Leuconostoc mesenteroides* subsp. *cremoris, Lactobacillus acidophilus* and even *Bifidobacterium bifidum*. Labaneh and labneh, which are very popular in the Middle East, are acidified with thermophilic yogurt starters. Industrially used starters should not produce gas (CO_2); this avoids problems in the production line, especially in the separators. (*See* **Starter Cultures**.)

Normally, 0.5–1% starter is added to the milk at about 30 °C. When pH 6.3 is reached (after about 1.5 h), rennet may be added (in this case, the milk is stirred well to distribute the enzyme), and in about 16 h the desired acidity of pH 4.5–4.55 is reached. During acid development, the milk should not be stirred. Clearly, acid development is strongly dependent on some important factors, which are part of the typical and individual technology for the different unripened cheeses.

Curd Formation and Treatment

Rennet, if any, is used in small amounts, e.g., 0.5–1.0 ml (1:10 000) per 100 l of milk for quarg.

Pure acid casein curds are rather sensitive to heat, a temperature around 43 °C and a pH of 4.3 seem to be optimal for whey drainage. If the temperature is only a few degrees higher, the curd changes from dry to smeary. After cutting, traditionally prepared lactic curds are therefore normally filled into cheesecloths and drained at room temperature, and afterwards at a low temperature (4–5 °C) for many hours.

In the case of renneted acid curds, heating to 50–55 °C for 1.5 h (cottage cheese) or even 60–64 °C for 4–5 min (quarg) improves syneresis of the coagulum. Owing to these effects, cottage cheese is prepared in a granular form; the curd is washed three times with water at decreasing temperature (30 °C, 16 °C, 4 °C) to remove lactose and to stabilize the pH and shelf-life.

Centrifugation of quarg curds is performed at about 40–44 °C; ultrafiltration is performed over the same range of temperatures or even higher. Cooling of quarg takes place in special tubular coolers, and the product is transported through the line by positive pumps. At the end of the line, a quarg mixer may be installed to enrich the product with cream, salt, fruits, stabilizers, etc. Fresh cheeses are normally packaged in plastic containers, glass jars, etc., preferably under aseptic conditions. Some types of fresh cheese with a high content of dry matter are sold as small, round, or wedge-shaped bodies packaged in foil.

This is certainly true for the high-fat cream cheeses. They are produced from homogenized milk containing 10% or more fat (with 9% fat, the curd has the same specific weight as whey, so that centrifugal separation is impossible!). The acidified milk is heated to 80 °C before separation. The total solids content of the hot drained curd is 44%, and after salting and cooling, it becomes a viscous mass due to crystallization of fat.

Miscellaneous Products

Cottage cheese represents the most structured type of lactic cheese. 'Dry curd' quality (< 0.5% fat) is produced from skimmed milk; cottage cheese (low-fat) contains 0.5–2% fat, and cottage cheese itself usually contains > 4% fat. It is normally produced by treating the grains with a cream dressing. According to the size of the grains, it is distinguished as Californian-style, popcorn-style, and country-style, as well as large- and small-curd style. Block-pressed cottage cheese is called farmer's cheese.

Although cottage cheese is slightly salted (1% NaCl), the shelf-life is often below 2 weeks, owing to the rather high pH value and sometimes poor bacteriological quality of the wash water. In Germany, products with a fat in dry matter up to 20% are made, and manufacturing technologies involving ultrafiltration of the milk are also applied.

Quarg (Quark, Topfen, Koarg, Kwarg, Twarog, Tvorog, Taho, lactic cheese, fromage frais, etc.) is available with different levels of fat, up to 45% in the dry matter. With increasing fat content, the consistency changes from crumbly-dry to smooth, but this texture can be influenced by technology (e.g., dry-matter, casein, and whey protein content). A foamed quarg is named Bresso. Whipped quarg with not more than 15% dry matter is fromage frais battu maigre. Baker's cheese is characterized by a high dry-matter content (22–26%). Schichtkäse, like Cambridge and York, is prepared from layers of low-fat and high-fat lactic curd. Danish smoked quarg is named Rygeost.

Typical lactic curd, fresh cheeses with a high fat in dry-matter content are cream cheese (70% fat in dry matter), Petit-Suisse (> 70% fat in dry matter) and Demisee (40% fat in dry matter), Neufchâtel (55% fat in dry matter), Doppelrahmfrischkäse (< 85% fat in dry matter) and double cream cheese (> 65% fat in dry matter). Some of these products are stabilized with hydrocolloids, and the milk is homogenized. Products such as Philadelphia, Gervais, Boursin, and Le Tartar (with herbs and spices) are internationally distributed.

A very-high-fat Italian fresh cheese is mascarpone (Mascherpone). It is produced from full-fat cream, heated to 90 °C, and acidified with citric acid. Whey drainage is performed at 8–10 °C for 12–18 h. In the new Sordi process, cream (40–60% fat) is pasteurized, mixed with milk concentrate from ultrafiltration, and acidified with citric acid in heated vats. After careful stirring, the product is packaged and stored for about 12 h in the cold to crystallize the fat. Mascarpone is very popular for sweet desserts.

Ricotta was prepared originally by the direct acidification of heated cheese whey from ewes' milk (ricotta di pecora). Many varieties of ricotta are now available, mainly from cows' milk (ricotta di vacca). The consistency varies between soft and dry (ricotta secca). Salted varieties (ricotta salata), as well as the smoked cheeses, are used in the kitchen, whereas the unsalted product (ricotta tipo dolce), like the baked ricotta (ricotta salata al forno), are consumed directly as appetizers or desserts. Ricotta is named requesón in Spain and requeijao in Portugal.

Queso blanco (queso del país, queso fresco) is also available in many varieties in Spanish-speaking countries, but is now also manufactured in the USA. It is produced by a combined heat-acid process (82 °C and pH 4.6–4.7). Citric acid is said to give the best results, but acetic acid is the most popular acidulant. This cheese can be fried without melting, and is used in the preparation of snack foods; with spices and tomato sauce or chilli sauce, it is consumed fresh. The organoleptic qualities can be improved using yogurt starters instead of mesophilic starters. The moisture content is about 50–54%. (*See* **Acids**: Natural Acids and Acidulants.)

Yogurt starters are used exclusively in the production of labaneh and labneh. Labaneh is the pure acid curd from skimmed milk, and it can be stored for a long time in olive oil. Labneh is prepared from full-cream milk by acidification and by rennet coagulation. The dry-matter content is approximately 40%. These products are the Middle East equivalents of quarg.

Last, but not least, the Swiss Zieger (named Seirass in Piemont, Cérat in Savoy) should be mentioned. Originally prepared by heating acidified whey, they are now also produced from mixtures of milk and whey, or even from skimmed milk. The cheese is white or somewhat yellow, spreadable, and crumbly-soft.

Processed Cheese

A Gouda and A Abou El-Nour, Suez Canal University, Ismailia, Egypt

Introduction

Cheese in general, including processed cheese, is rich in different nutrients such as proteins, fats, minerals, and vitamins. It is reported that utilization of proteins of processed cheese is better than proteins of natural cheese.

Processed cheese, compared to natural cheese, is a new product which originated at the beginning of the twentieth century. Spoilage of cheese exported to distant places was the motive behind the trials to improve the shelf-life of cheese. Some of these trials succeeded in prolonging the keeping quality of soft or even semihard cheese by applying heat treatment, but the situation was not the same for hard cheese, due to shrinkage of the cheese protein by heat and separation of the water and fat phases. In 1912–13, the Swiss workers, Walter Gerber and Fritz Settler, solved these problems by heating hard cheese to which sodium citrate was added. This treatment was the real invention of processed cheese. Later, phosphate salts were introduced as emulsifying salts, and the development of the processed cheese industry continued and different patents were granted. In 1916 Kraft established the first commercial factory for processed cheese in the USA. Production and consumption of processed cheese increased steadily and, today, large tonnages of natural cheeses are converted to processed cheese. The production and consumption of processed cheese products showed a constant increase during the period from 1990 to 1994 (**Table 1**), notably in the European Union, the USA, and Japan. Production of processed cheese affects – directly or indirectly – dairy production in general in the following ways:

1. It encourages cheese production as a base for the manufacture of processed cheese.
2. It makes it possible to use second-grade cheese or cheese with mechanical or surface defects.
3. At peak times of cheese production, young cheese could be precooked and stored until it is used for processed cheese. In this way it is possible to control ripening and save the cost of storing fresh cheese for long periods in expensive stores.

Processed cheese products have many advantages over natural cheese:

1. In most cases, processed cheese can be stored without refrigeration.
2. Processed cheese can be produced in different shapes, flavors, and physical properties, e.g., soft, firm, spreadable, in variable and attractive packages, and it has a relatively long shelf-life.
3. It is free from pathogenic microorganisms.

Principles of Processed Cheese-Making

Processed cheese is made by heating natural cheese of different types, age, and maturity in the presence of suitable emulsifying salts and with the help of mechanical agitation. In making processed cheese, the insoluble calcium *para*-casein gel of the natural cheese, under the influences of heating and the action of emulsifiers and agitation, is changed to a *para*-casein sol – a homogeneous, flowing mass. This sol is changed again to a gel by the influences of cooling and polymerization forces resulting in processed cheese. By understanding the role of different factors related to processed cheese manufacture, it is possible to control and select the characteristics of the end product – soft, firm, sliceable, spreadable, etc.

Types of Processed Cheese

Processed cheese can be grouped into three main types.

Pasteurized Processed Cheese

Pasteurized processed cheese is made from one or more lots of cheese of the same or different varieties. Water, NaCl, coloring, and flavoring materials may be added. The moisture content of the processed cheese may exceed by not more than 1% the maximum permitted in the natural cheese from which it is made, while the fat content may not be less than that of the natural cheese. Processed cheese bears the name of the natural cheese from which it is made. The processing temperature varies from 80 to 85 °C and the pH of the end product ranges from 5.4 to 5.6. Good processed cheese has a smooth, compact, firm body, and can be cut into slices.

Pasteurized Processed Cheese Foods

Processed cheese food resembles the above processed cheese but contains more moisture and less fat. Optional ingredients may be added, including dried whey, dried skim milk, lactose, and organic acids. The moisture content should not exceed 44% and the fat content should be not less than 23%. The processing temperature is normally 85–90 °C and the pH of the processed product is 5.6–5.8. Processed cheese food has a softer body and milder flavor than processed cheese. (*See* **Lactose**; **Whey and Whey Powders**: Production and Uses.)

Pasteurized Processed Cheese Spread

The constituents of pasteurized processed cheese spread are similar to those used for making processed cheese food, but it contains more moisture in order to achieve a soft body and spreading properties. In many standards, the moisture content should not exceed 60% and the fat should be not less than 20%. This cheese is normally processed at a high temperature (85–95 °C) in traditional cookers, and has a pH between 5.7 and 5.9. Binding agents may be added in amounts not exceeding 0.8% of the finished product to improve water retention. Processed cheese spreads are characterized by a mild flavor, and a smooth, soft body that is easy to spread at room temperature.

Processed Cheese Analog

Recently, a new version of processed cheese has been introduced under the name of imitation or analog processed cheese: the natural cheese and fat are replaced by caseinates, vegetable proteins such as soya bean protein, and a suitable vegetable oil. The processing conditions, i.e., emulsifiers, heating temperature, and pH, are quite similar to that reported for processed cheese spread. (*See* **Casein and Caseinates**: Uses in the Food Industry; **Soy (Soya) Beans**: Processing for the Food Industry; **Vegetable Oils**: Types and Properties.)

Processed cheese analog may be produced either as block or spread and should have good melting properties and good shredding or slicing behavior. A small amount of free oil may be acceptable, particularly for use in pizza making. Rennet casein is commonly used in making processed cheese analog as it gives ideal properties to the cheese, especially casein, which contains 0.1–0.3% lactose and has a particle size of about 30 mesh.

Analog processed cheeses have some advantages compared to processed natural cheese:

- Cheaper ingredients may be used.
- A wide range of suitable proteins is available.
- Ingredients can be stored for a long time without spoilage.
- The properties of the final product can be controlled.
- It is more stable and has greater flavor.

The limits for moisture and fat in processed cheese are quite flexible and may vary from country to country according to specific standards implemented in each country.

Raw Materials for Processing

The main materials used for the manufacture of processed cheese include natural cheese, emulsifiers, water, and other additives.

Cheese

Two main factors should be considered in selecting the cheese for processing – type and degree of maturity.

Type of cheese In general, all rennet-curd cheeses, i.e., soft, semihard and hard cheese, can be used for making processed cheese, but it is common practice to use only hard and semihard cheeses; soft cheeses are only used for flavoring. The selected cheese should be checked for dry matter, fat, pH, protein content, age, and degree of maturity. In many countries, Cheddar cheese is preferred as a main base for processed cheese. A single type of natural cheese can be used but it is more common to use more than one variety of cheese with the aim of giving the desired body, texture, and flavor to the final product. It is worth mentioning that good-quality natural cheese is essential for producing high-quality processed cheese. Second-grade cheese or cheese with mechanical defects can be used, but cheese with a putrid or rancid flavor must not be used, even in small quantities, as the fault will appear in the processed cheese.

Degree of maturity In general, hard cheeses may be grouped according to the degree of maturity:

- Fresh, green or young cheese – 1–2 weeks old.
- Medium ripened cheese – 2–4 months old.
- Ripened cheese – over 4 months old.

Natural cheeses of different degrees of maturity are selected for processing to obtain the required composition, physical properties and flavor in the processed cheese. Young cheese has a high level of intact casein as most of the protein has not been hydrolyzed to soluble components; the ratio between insoluble casein nitrogen and the total nitrogen is called relative casein. The higher the relative casein (90–95% in young cheese), the more stable the resultant processed cheese will be. Processing young cheese results in processed cheese with a long structure, and the body tends to be smooth or firm depending on the moisture content. It is difficult to use only young cheese in processing, as it will result in a processed cheese of 'flat' flavor.

However, the long structure of young cheese can be altered by the action of various factors during processing. These factors are mainly related to the use of suitable emulsifying salts together with prolonged agitation during the thermal process. Changing the long structure of young cheese to a short one with good spreadability is known as creaming. During the creaming process, the large casein particles, with a low level of hydration in young cheese, are split into small casein particles with increased surface area, hydration, and good spreadability. However, excessive hydrolysis of cheese casein when making processed cheese will lead to an overcreaming defect in the cheese texture. Thus, young cheese, with proper processing, is convenient as the main base for making processed cheese spreads containing a high level of fat-in-dry-matter (60–70%); young cheese also contains a high level of intact casein necessary for stability. It is reported that stable processed cheese should contain not less than 12% intact casein. In a recent study in the authors' laboratory processed cheese spreads containing 60–65% fat in dry matter, 60% moistures and pH 5.85 were made from cheese blends containing 9.8–10.2 of intact casein. The resulting spreads had a good body and texture and could be packed in triangular portions without sticking in the foil. The spread was stable (without fat or water separation) through the storage period. As the ripening cheese progresses, its relative casein content decreases as a result of proteolysis; hence, fully ripened cheese is normally added to the processed cheese blend at a level of 10–20%, mainly to give the desired flavor. It is too difficult to use fully ripened cheese as the main base for processing, as its intact casein is already degraded and is not able to form a stable emulsion.

Also, use of too much of a very mature cheese, which contains considerable amounts of low-solubility amino acids as tyrosine, results in precipitation of these free amino acids as white crystals within the processed cheese structure.

Normally medium-ripened cheeses are blended with young cheese in different ratios to make processed cheese spread. If a high percentage of medium-ripe cheese is used in a processed cheese spread blend, there is no need for extensive processing to achieve the necessary creaming properties as the intact casein is, to some extent, already hydrolyzed. Different ratios of young medium, and fully ripened cheese have been reported for the manufacture of processed cheese products. These ratios are not fixed figures, and may vary according to the type, characteristics, and composition of the natural cheese; they may also vary if other dairy products, such as milk or whey powder, are used in the blend. Some typical blends are presented in Table 2.

The storage of cheese for ripening is rather expensive; hence, many attempts have been made to render young cheese, or even rennet curd, suitable for processing a few days or weeks after manufacture. The addition of lipolytic and/or proteolytic enzymes has been investigated, cooking the curd in a lactic acid solution. There has been success in using a hard cheese with a low pH (4.8–5.0) a few days after

Table 2 Suggested blends of natural cheeses for producing processed cheeses

Processed cheese types	*Natural cheese (%)*		
	Young	*Medium-ripened*	*Fully ripened*
Block	50–60	20–30	10–20
Processed cheese foods	30–40	50–60	10
Spread	50–60	30–40	10

manufacture as the main base for a good processed cheese spread, aiming at the release of calcium from the curd. This process has been employed on a commercial scale. (*See* **Enzymes**: Uses in Food Processing.)

Also, ultrafiltered retentates have been used as a part of the blend for processed cheese. Many studies reported that 60–80% of processed cheese blends could be replaced by ultrafiltered retentate.

Emulsifying Salts

Natural cheese is basically an oil-in-water emulsion, stabilized by cheese protein. Heating and agitation, or changing the pH, will affect the protein which may lose all or part of its ability to effect stabilization; defective texture, water and fat separation will occur. In the presence of emulsifying salts, the separated water and fat are reincorporated into the cheese mass, resulting in a homogeneous mixture. As the emulsifiers (melting salts) work mainly on the cheese protein (casein) they have a direct effect on the physical properties of processed cheese. The action of emulsifiers is through the displacement of the calcium of the insoluble *para*-caseinate by sodium ions, resulting in a more soluble casein. The role of emulsifying salts in processed cheese manufacture can be summarized as follows:

1. Removal of calcium from the protein system
2. Dispersion of the protein
3. Hydration and swelling of the protein
4. Control and stabilization of the emulsion system and the pH of the cheese
5. Control of spoilage of the cheese

(*See* **Emulsifiers**: Phosphates as Meat Emulsion Stabilizers; Uses in Processed Foods.)

The major emulsifying salts which are used on a large scale are the sodium salts of citrates, monophosphates, diphosphates, and polyphosphates. Sodium aluminum phosphate is also used. Some emulsifying salts are listed in Table 3.

It is common practice to use a mixture of emulsifying salts rather than one salt to obtain the general desired characteristics. The amount of emulsifiers used in processed cheese is normally 2–3%, depending on type, maturity, and amount of natural cheese in the blend. It has been reported that some emulsifying salts, especially phosphate, have a bacteriostatic effect on some microorganisms and accordingly improve the shelf-life of the processed cheese.

Table 3 Some emulsifying salts used in processed cheese

Type	*pH (1% solution)*
Monosodium citrate	3.75
Trisodium citrate	8.55
Monosodium phosphate	4.5
Disodium phosphate	8.9–9.1
Trisodium phosphate	11.9
Disodium pyrophosphate	4–4.5
Trisodium pyrophosphate	6.7–7.5
Tetrasodium polyphosphate	10.2–10.4
Tetrasodium polyphosphate	9.0–9.5
Sodium hexametaphosphate	6.0–7.5

Water

Water is very important for producing a stable emulsion. Emulsifying salts need water to dissolve and act properly on the casein. Water is added to the blend to give the required water content in the processed cheese. In calculating the amount of water, it should be borne in mind that heating by direct steam injection will add some condensed water to the blend. Water may be added at the start of processing, as in the case of block-processed cheese, or in portions, as for processed cheese spread. The addition of only part of the water at the start of processing increases the concentration and action of the emulsifiers on the casein.

Additives

Optional ingredients may be added to the processed cheese blend for economic reasons, or to improve the shelf-life and quality of processed cheese.

Dried skim milk and dried whey Dried skim milk or whey can be used to replace part of the cheese solids in the blend for processed cheese food or spread. Skim-milk powder and whey powder promote the creaming process and improve spreadability, but the amount must not exceed 10% of the blend in order to avoid a sweet-salty taste, especially when young cheese is used and to prevent browning and crystallization owing to excess lactose in the processed cheese.

Fats Different fats may be added to the blend to increase the fat-in-dry-matter content of the processed cheese. High-fat cream, butter or butter oil may be used as a source of fat. For processed cheese

spread of defined total solids, increasing the fat content causes a decrease in the solids-nonfat (SNF) in the blend; hence, young cheese with a high intact casein should be used as the main base to give a stable emulsion; caseinates may also be used. The emulsifying salts used in processed cheese have no direct effect on the fat. (*See* **Fats**: Uses in the Food Industry.)

Precooked cheese Precooked cheese may be used to improve the stability of processed cheese. It is normally produced at peak times of cheese production when the volume of cheese exceeds the capacity of the ripening rooms, or when the cheese is not fit for maturation. Precooked cheese made from young cheese has a long structure and can be added to a processed cheese blend containing overripened cheese to improve its stability. Precooked cheese made from mature cheese has a short structure and can be used to promote the creaming property of a processed cheese spread. The amount of precooked cheese added to a blend varies according to the degree of maturity of the cheese in the blend and the type of processed cheese to be manufactured.

Flavoring materials Flavoring materials may be added to give a particular flavor to the processed cheese, or to improve the flavor, especially when young cheese is used. Among these materials, meat, ham, wine, fruit, spices, and essences are commonly used in processed cheese. Flavoring materials should be of good microbiological quality, and this can be attained by thermal treatment before addition to the blend. The physical properties of the processed cheese are not affected by the use of such additives. (*See* **Flavor (Flavour) Compounds**: Structures and Characteristics.)

Binding agents Binding agents or stabilizers are sometimes added to processed cheese spread to absorb some of the water and improve the stability of the cheese. The amount of stabilizers, if permitted, should not exceed 0.8% of the processed cheese. Gum arabic, locust bean gum, gelatin, pectin, carboxymethyl cellulose, and agar are examples of such materials. (*See* **Stabilizers**: Types and Function; Applications.)

Preservatives The addition of preservatives to processed cheese is prohibited in many countries. However, preservatives such as benzoic and sorbic acids are used to overcome the blowing of processed cheese. In addition, biological substances, such as nisin, are used as inhibitory agents to prevent the growth of anaerobic spore-formers (*Clostridium*), the main cause of blowing in processed cheese. Nisin is a polypeptide produced by cultures of some strains of *Lactococcus lactis*, and is produced commercially in powder form. Although nisin is used successfully in many processed-cheese factories, there is some doubt concerning its efficiency against some strains of *Clostridium*. (*See* **Preservation of Food**.)

Manufacture of Processed Cheese

The steps involved in the manufacture of processed cheese can be summarized as follows.

Selection and Calculation of the Raw Materials

Two important factors must be considered in selecting the cheese for the blend: (1) the characteristics of the natural cheese, i.e., type, age, maturity, pH, fat, total solids, and the physical properties; (2) the desired properties for the processed cheese, i.e., firmness and spreadability.

The amount of cheese and other ingredients in the blend are calculated according to their fat and dry-matter contents, so that the product conforms to the legal standards of the specific type of processed cheese.

Cleaning

Hard and semihard cheeses selected for processing are subject to cleaning before use. Very hard rind, waxes, or wrapping materials used to cover rindless cheeses and surface defects must be removed manually or mechanically before processing.

Cutting, Mincing, and Milling

The selected blocks of cheese are cut manually, or mechanically with special knives, into small slices suitable for the mincing machines. The slices are then minced or shredded through special mincing machines into fine granules, which are ground through roller mills to make them soft, smooth, and free from small, hard particles. Mincing and milling of the cheese enable the emulsifying salts to be in contact with the cheese, and facilitate the absorption of water and dispersion of the cheese protein.

Processing

Milled cheese and other ingredients of the blend are placed in the processing kettle. Heating may be carried out directly by steam injection, indirectly, or by both methods to a temperature normally not less than 75 °C to insure complete pasteurization of the processed cheese. Agitation during processing is important for the complete emulsification of the cheese blend. Processing kettles are operated either batchwise or continuously. They are available in various

shapes and capacities. A normal kettle consists of two pans equipped with one movable cover which bears an agitator, steam injection nozzles, vacuum tubes, and gages for temperature and pressure. While processing is carried out in one of the pans, the other one is loaded with raw materials ready for processing.

The temperature and duration of processing are determined by the type of processed cheese and by the condition of natural cheese in the blend. In general, a period of 2–4 min is required to reach the processing temperature, and the temperature is kept constant for a further 5–10 min. Processed cheese spread is processed at 80–85 °C for 8–10 min while block-processed cheese is processed at 85–95 °C for 8–15 min in a traditional kettle. The duration of processing is related to the speed of agitation. Stephan kettles are equipped with very fast agitators, so that a period of 4–5 min is sufficient for processed cheese spread. In modern continuous processed cheese-making, the processing is carried out in horizontal or vertical tubes in which the blend is heated by direct steam to 135–145 °C for a few seconds.

Homogenization

Homogenization is an optional operation used for processed cheese spreads, especially those with a high fat content, and is conducted directly after processing. It improves the consistency, stability, and appearance of the processed cheese. Contamination during homogenization should be avoided.

Packaging

The hot, flowing mass of processed cheese is transported manually in stainless-steel buckets or by special pumps to the filling machines. Keeping the processed cheese quite hot in the filling machines eases the sealing of the packaging materials. Processed cheese is packed in thin aluminum foil coated with a special lacquer, in plastic membranes, or in tins; it is packed in different shapes in amounts varying from 13 g to 3 kg.

Storage

Directly after packing, the processed cheese is still quite warm (40–60 °C), but it should be cooled to room temperature in a time that varies according to the type of processed cheese. As a rule, processed cheese spread should be cooled quickly (30–60 min) to prevent the creaming phenomenon; otherwise, overcreaming will cause fat and water separation and a defective texture. In cooling processed cheese spread, a space should be left between the boxes to facilitate the movement of cool air. For block-processed cheese, a long time (10–15 h) is needed to cool it down, but the slow cooling, especially in the presence of lactose, may result in browning or firming-up of the cheese, and may allow the growth of spore-forming microorganisms. After the cheese has been cooled, it should be kept in a cold store (5–10 °C). It is advisable to keep processed cheese above 0 °C – to prevent the freezing of the product – and below 20 °C; otherwise, surviving microorganisms, especially *Clostridium*, may grow and cause defects. (*See* **Spoilage**: Molds in Spoilage.)

Defects in Processed Cheese

The two main defects in processed cheese are microbiological defects and those of physicochemical origin.

Microbiological Defects

Microbiological defects are mainly related to the blowing of the processed cheese as a result of gas formation by anaerobic spore-formers (*Clostridium*). Spongy texture and bad odor are indicators of a heavy contamination with *Clostridium*.

In addition, molds may grow on the surface of poorly sealed packs of processed cheese. However, proper processing and the addition of permitted antimicrobial materials should minimize or eliminate these defects.

Defects of Physicochemical Origin

Too firm a block results from one or more of the following:

- low moisture content
- high casein content
- use of the wrong emulsifiers
- strong overcreaming
- low pH

Too soft a block may occur as a result of:

- high moisture content
- unsuitable or insufficient emulsifiers
- too high pH
- excessive processing
- addition of milk or whey powder
- use of too much mature cheese

Inhomogeneous cheese could be the result of:

- insufficient milling, especially of cheese with a hard rind
- improper processing time, temperature, or agitation
- unsuitable or insufficient emulsifiers
- use of raw materials of too low pH, particularly an acid-precipitated cheese or curd

Gum-like spread could be caused by:

- use of too much young cheese
- insufficient processing to achieve proper creaming
- absence of creamed, precooked cheese
- addition of all the water at one time

'Sticky spread' is the term used when the processed cheese adheres to the aluminum foil. This defect may be attributable to:

- excess water content or all the water added at once
- the blend contains too much young cheese
- proper creaming is not achieved
- no well-creamed, precooked cheese has been added
- the level of intact casein in the blend is insufficient

Reasons for brittle spread are:

- overcreaming during processing
- addition of too much overcreamed, precooked cheese
- decrease of pH after processing or during storage

Gas formation As result of a chemical reaction between the aluminum foil and the cheese, the resultant hydrogen can cause gas 'holes' on the cheese surface without odor formation. This defect can be attributed to the absence of, or use of poor-quality, lacquering materials or to the use of an emulsifying salt which is too acidic or too alkaline.

Browning (Maillard reaction) The normal color of processed cheese is between white and pale yellow. Browning may occur directly after processing, or during storage as a result of a reaction between amino compounds and reducing sugars. This defect may be caused by:

- Use of too high a processing temperature for a long time, especially in the presence of lactose.
- Storage of the processed cheese at a high temperature, particularly when the pH is high.

This defect is more common in processed cheese spread than in block-type cheese. (*See* **Browning**: Nonenzymatic.)

Crystallization Crystallization is a defect which can be seen inside or on the surface of the cheese; a 'sandy' texture may result. The reasons for this defect may be:

- precipitation of calcium monophosphate, diphosphate, polyphosphate or citrate, particularly when excess emulsifier has been used
- undissolved particles of emulsifier, owing to poor storage of the emulsifier or improper processing
- use of precooked cheese with a sandy texture
- precipitation of lactose crystals as a result of too much dried milk or whey in the blend
- use of very mature cheese may result in white precipitates of some amino acids, such as tyrosine

Water separation Water separation can take the form of small droplets inside the cheese, or wetting of the cheese surface. It is caused by the following factors:

- too low pH of the processed cheese
- changes in the cheese structure (overcreaming)
- unsuitable storage conditions, e.g., the cheese is subjected to mechanical pressure

Fat separation Fat separation could be the result of the following:

- use of too much mature cheese
- insufficient or excess emulsifiers
- too low a pH of the processed cheese
- storage of the cheese for a long time at a high temperature

Flavor Defects

Examples of the more common flavor defects are:

- sharp flavors, owing to use of too much mature cheese
- flat flavor, owing to use of too much young cheese
- salty taste, owing to use of salty cheese or excess emulsifiers
- putrid taste, owing to use of putrid cheese or the growth of *Clostridium*
- rancid taste, owing to use of rancid cheese and/or butter, or cheese ripened by molds
- chemical taste, owing to use of impure emulsifiers, addition of certain preservatives or stabilizers, or use of too salty cheese

Dietary Importance

J Buttriss, British Nutrition Foundation, London, UK

Introduction

Cheese is the oldest way of preserving the nutrients in milk and is essentially a concentrated form of milk. Most cheese is made from cows' milk, but other milks including sheep's, goats', and buffalos' can be used also. The process used to make the cheese tends to determine the nutritional value. This article will review the nutritional value of different types of cheese, its role in the diet for different groups of the population, and trends in cheese consumption around the world.

Hard Cheeses

Hard cheeses such as Cheddar and Cheshire retain most of the protein, fat, calcium, and some other minerals, and vitamins such as vitamin A, riboflavin (vitamin B_2), and vitamin B_{12}. **Table 1** shows the nutrient composition of some hard cheeses. Refer to individual nutrients.

Hard cheese contains very little lactose as most is either lost with the whey during the cheesemaking process or converted to lactic acid. The major protein in cheese is casein, which is a high-quality protein containing all the essential amino acids in roughly the proportions required by the body for health. Minerals in cheese, such as calcium and zinc, are particularly well absorbed and utilized (high bioavailability).

Low-fat hard cheeses are available in the UK. They typically contain about half the quantity of fat found in the traditional cheese and remain a valuable source of essential nutrients.

Soft Cheeses

Soft cheeses vary widely in nutritional composition, depending on whether they belong to the ripened or unripened varieties. Fresh, unripened cheeses, such as cottage cheese, are low in fat, relatively low in calcium, high in moisture and contain unfermented lactose. Very-low-fat versions are also available. However, a surface-mold-ripened cheese, such as Brie or Camembert, contains a high proportion of fat and protein and less water (**Table 2**). Mold-ripened soft cheeses have a slightly lower fat content than traditional hard cheeses. The addition of salt is an essential part of the cheese-making process. The salt is added to help preserve the cheese and to bring out the flavor.

Cheese from Unpasteurized Milk

Most of the cheese produced in the UK is made from pasteurized milk. However, there is a demand for cheese made from unpasteurized milk, as it is believed by some to have a superior flavor. Provided that the milk used has come from farms operating to the highest standards, so that the milk is free of pathogens, and that the creamery operates to the same high standards, the resulting cheese will not pose a health hazard.

Tyramine in Cheese

In common with foods such as red wine, hung game, soused herrings, and yeast extracts, certain cheeses (e.g., mature Cheddar, Roquefort, and Gruyère) contain an amino acid derivative known as tyramine.

In sensitive individuals, tyramine can provoke migraine and skin rashes. This may occur, for example, in those taking drugs that block the enzyme monoamine oxidase, which metabolizes tyramine. (*See* **Migraine and Diet.**)

Trends in Cheese Consumption

Table 3 shows the consumption of cheese in different countries. Compared with most European countries, cheese consumption in the UK is low. Consumption is particularly high in France and The Netherlands.

In the UK, cheese consumption has risen from 4.7 kg per person per year in 1966 to 9.8 kg per person per year in 1998, according to National Dairy Council estimates (Figure 1). Data from the National Food Survey, conducted by the UK Ministry of Agriculture, Fisheries and Food, indicate that cheese consumption is greater in higher income groups and smaller households. There are no strong regional differences.

Importance of Cheese for Different Groups

As a product of milk, cheese confers similar nutritional benefits. In particular, it is a rich source of protein, calcium and vitamins A, B_2 (riboflavin), and B_{12}. It is also a useful source of highly bioavailable

zinc. In addition, cheese is a very versatile food that can be incorporated into many different dishes. It keeps well if properly stored in the refrigerator, wrapped in greaseproof paper or foil. Hard cheeses such as Cheddar freeze well and can be kept for up to 3 months. On thawing, best results are achieved if the cheese is allowed to defrost gradually, preferably in the refrigerator.

Mild hard cheeses and fresh soft cheeses such as cottage cheese can be introduced into a child's diet from the age of 6 months. Cheese can be a useful snack food for children. It is one of the few foods that do not contribute to dental caries, and it may even have a protective effect against dental decay, perhaps by controlling the pH at the surface of the tooth. Some dentists recommend a small piece of cheese at the end of a meal for this reason. (*See* **Dental Disease:** Role of Diet.)

Calcium requirements are particularly high during pregnancy, and cheese, an excellent source of calcium, is therefore a valuable food for pregnant women. However, as a precaution, pregnant women are advised to avoid mold-ripened soft cheese such as Brie and Camembert because of the increased chance of their containing *Listeria monocytogenes*, the bacterium that causes listeriosis. Most healthy people are unaffected by listeriosis, but pregnant women are at a greater risk. Fresh soft cheeses, e.g., cottage cheese,

and hard cheeses such as Cheddar, are considered safe in this respect. The pH of Cheddar and other such cheeses limits the growth of this bacterium, which prefers more alkaline conditions. *See* ***Listeria***: Listeriosis.

For vegetarians who include dairy products in their diet, cheese can be an important source of protein, vitamin B_{12} and minerals. Vegans, who exclude all foods of animal origin, will require vitamin-B_{12}-fortified foods or supplements, since the vitamin is found only in dairy foods and other foods of animal origin, such as meat. (*See* **Vegetarian Diets**.)

Hard cheeses, such as Cheddar, have a very low lactose content and can be a useful source of calcium and other essential nutrients for those people who are lactose-intolerant. (*See* **Food Intolerance**: Lactose Intolerances.)

Mold-ripened Cheeses: Stilton and Related Varieties

P A Atkinson, Formerly of Long Clauson Dairy Ltd, Melton Mowbray, UK

Stilton and Related Varieties

Varieties of internally mold-ripened, hard-pressed cheeses include Stilton, Blue Shropshire, Blue Cheshire, Blue Wensleydale, Buxton Blue, Blue Vinney, Danish Blue, Roquefort, and Gorgonzola. All these varieties of blue cheese are considered to be hard cheeses, although only the Blue Cheshire and Blue Wensleydale are actually pressed during manufacture. The other varieties are turned regularly during manufacture, the only pressure being the weight of the curd.

Specifications and Standards

The 1970 Cheese Regulations in the UK require that all full-fat hard cheese shall contain not less than 48% milk fat in dry matter, and not more than 48% moisture. In addition, the standards for Stilton are stated in Schedule 2 of these regulations as follows:

	Fat in dry matter	Moisture
Blue Stilton	48%	42%
White Stilton	48%	46%

The Stilton Cheese Makers Association (SCMA) has registered the name of Stilton and defined Blue Stilton as follows:

> A fully matured, blue-veined Blue Stilton Cheese is an English made cheese produced within the Counties of Leicestershire, Derbyshire and Nottinghamshire with no applied pressure, forming its own crust or coat and made in cylindrical form from full cream milk produced in English and Welsh Dairyherds.

The SCMA also describes flavor, internal and external body, and shape. These will be discussed in more detail below when grading is described.

Method of Manufacture – Stilton Cheese

Stilton cheese is made at nine factories within the three counties stipulated in the SCMA schedule, and the overall process is shown in Table 1.

It is made from cows' milk produced locally, except in times of peak production when cows' milk may be used from anywhere within England and Wales. The milk is collected in bulk and it is now all pasteurized (71.6 °C/15 s); the last factory stopped using raw milk in 1989. After pasteurization the milk is cooled to between 26 and 32 °C according to season and individual factory variations, and put into cheese vats. (*See* **Milk**: Processing of Liquid Milk.)

Table 1 Flowchart of the manufacture of Stilton

	Time/age	*Temperature*
Milk pasteurization	0	
Starter addition	0	26–32 °C
Rennet addition	1–2 h	26–32 °C
Cutting	1–2 h	26–32 °C
Whey separation	1–2 h	26–32 °C
Milling and salting	24 h	26–32 °C
Mold filling and turning		
Maturation	5–7 days	26–30 °C
Coating		26–30 °C
Maturation: white store	5–10 days	13–15 °C
Maturation: blue store	6–12 weeks	13–16 °C
Piercing	6–7 weeks	13–16 °C
Grading	9–10 weeks	
Extended maturation	As directed by flavor	5 °C
Packing and distribution		8 °C

The temperature of milk in the vat at this stage has a very strong influence on the texture of the curd formed and, as a result, will have a marked effect on the openness of the curd when the cheese is made. Seasonal and geographical variations in milk composition require variations in the cheese-making technique to give consistent cheese quality; one of these is variation in milk temperature.

Starter cultures are added to the milk in the vats at varying rates from 50 ml to 2 l per 4500 l (1000 gallons), or as recommended by the supplier if concentrated (direct vat inoculation, DVI) cultures are used. Considerable variations in starter culture are used by the different manufacturers of Stilton, but one consistent factor is slow, but persistent, acid development throughout the early stages of the cheese-making process. The presence of *Lactococcus lactis* biovar. *diacetylactis* and *Leuconostoc* spp. in low numbers in the culture can help to achieve this. (*See* **Cheeses**: Starter Cultures Employed in Cheese-making.)

Spore suspensions of *Penicillium roqueforti* are added to the vat at the same time as the starter culture. The strains used vary with different manufacturers and can have an effect on the final flavor of the mature cheese. The cheese-makers' judgment in the selection of mold strains is very important in ensuring consistent product quality and market acceptance.

Rennet is added to the milk after a period of ripening, usually of 1–2 h. As the starter addition rate is very low, there is a negligible rise in acidity. This necessitates an increase in the quantity of rennet

used to give a satisfactory coagulation. The rate of rennet addition is between 1.18 and 1.48 l per 4500 l of milk (0.025–0.03%). This compares with 0.88–1.03 l per 4500 l for normal cheddar cheese manufacture, where a very much higher starter inoculation is used, and higher acidities are achieved. Animal rennet is generally used, although a 'vegetarian Stilton' is now being produced in which microbial rennet is used. Some manufacturers have suggested that cheese of satisfactory quality can be made with microbially derived coagulants, but that the texture of the cheese is not the same as that made from calf rennet. (*See* **Cheeses**: Chemistry of Gel Formation.)

The curd is cut using American knives or nylon grids which give cubes with 1.25 cm sides. The cutting time is determined by the experience and skill of the cheese-maker and is influenced by the firmness of the curd. After cutting, the curds and whey separate and the curd sinks to the bottom of the vat. Over a further period of usually 1–2 h, syneresis continues and, when the curd occupies about half the volume of the original milk, the curd may be stirred to aid subsequent whey drainage. A further period is then allowed for whey separation. At this stage the whey is removed progressively, taking 12–18 h before the last of the whey is drained away. As the whey is drained, the curd is cut into blocks to aid drainage. At the end of the draining period the titratable acidity will have risen to between 1.1 and 1.3% lactic acid, and the curd texture should be firm but crumbly (easily broken).

The curd is then passed through a peg mill which breaks it into pieces 1.25–2.5 cm in diameter. Salt is added to the curd and mixed evenly at the rate of 2½% w/w. After salting, the curd is put into cylindrical, open-ended molds (22.8–25 cm diameter), with 9–11 kg of curd per mold, depending on the final weight of each cheese. At this stage the curd is put into the molds with no pressure. The presence of the salt increases syneresis and curd drainage. (*See* **Cheeses**: Chemistry and Microbiology of Maturation.)

After 1–2 h drainage the molds are turned over. This first turn is quite critical and failure to turn at this stage can result in uneven drainage of the cheese at later stages in the maturing process. The cheeses are then turned daily for a further 5–7 days, allowing migration of the salt through the curd and further whey drainage. During this period the curd becomes much firmer and, at the end of this period, the cheese will slide easily within the mold when it is turned.

The mold is then removed and the cheeses are rubbed with the flat side of a knife to give a smooth coat over the whole surface. This is thought to prevent ingress of oxygen at too early a stage in the ripening process.

The temperature and humidity from filling the vat with milk until the cheeses have been rubbed or coated are maintained at 26–30 °C and 90% relative humidity (RH). This insures that the curd does not get cold and does not dry out and become discolored. It also influences the microflora of the finished cheese by encouraging the growth of starter organisms, particularly the slower-growing *Lactococcus lactis* biovar. *diacetylactis*.

After coating, the cheeses are transferred to the first maturing room or 'white room', so called because the cheeses remain in this room for 5–10 days, and at the end of this time those produced for White Stilton (without the blue mold being added) may be sold. Cheeses are turned daily at this stage.

The humidity in the white room is maintained at 85–90% RH, but the temperature is reduced to 13–15 °C. This allows the cheese to cool and the coat to dry. Humidity control at this stage is important as too low an RH would cause excessive drying and the coats would crack. Too high an RH would result in wet coats which would encourage the wrong microflora and could result in off-flavors developing; for example, *Brevibacterium linens* frequently occurs on wet-coated cheese and can cause very uncharacteristic flavors to develop. Also, as the natural coat flora begins to develop and get thicker, a condition known as 'slip coat' can occur. In this case, proteolysis occurs just beneath the coat and causes the whole coat to slip down the cheese and fall off, so making the cheese unsaleable.

After 5–10 days in the white room, the cheeses are transferred to a blue maturing room where turning continues daily, but may become less frequent as the coat develops and the cheeses start to dry out. The temperature and humidity levels are controlled at 13–16 °C and 90% RH in these stores.

At approximately 6–7 weeks after production (from the day of rennetting), the cheeses are pricked, spiked, or skewered. This operation involves piercing the cheese with stainless-steel needles to allow air into the cheese, thus encouraging growth of the *Penicillium* spores put into the milk.

Up to this stage the pH within the cheese has initially dropped to 4.8–5.0, but, as the mold grows, the pH rises. In addition, the temperature rises as a result of the metabolic activity within the cheese. Lipolysis and proteolysis occur, releasing carbon dioxide and ammonia. The ammonia can frequently be detected in the atmosphere in the maturing rooms at levels up to 30–40 p.p.m. When this occurs it is necessary to increase the ventilation in order to reduce it to an acceptable level.

As the maturing process continues, the piercing is usually carried out twice more with between 100 and

300 needle insertions at each skewering. In order to insure a good blue mold development, it is essential to have created an open-textured curd which will allow easy penetration of the mold hyphae between the curd particles. This will give the characteristic blue veining effect which radiates out from the center of the cheese where the spike holes are most dense.

After a period of 2–3 weeks from the onset of mold growth, the blue veining should have radiated out to the edge of the cheese. At this stage the cheeses are transferred to a cool store at 2–5 °C where mold growth will be somewhat retarded. Flavor and texture continue to develop and the byproducts of fat and protein degradation accumulate in the cheese.

With the advent of the Food Hygiene Amendment Regulations (1989) and the need to store mold-ripened cheese at temperatures below 8 °C (5 °C from 1993), the flavor development in cold storage is slowed down, but still continues and can give a strong mature flavor (and texture) after a further 2–6 weeks of storage.

Grading

Grading usually takes place at 8–9 weeks and involves examination of every cheese for the following characteristics.

External

- Shape – should be regular and uniform.
- Coat – should be dry, firm, slightly wrinkled, intact, drab in color, and free from surface mold blemishes.

Internal

- Flavor should be clean and mild.
- Body should be uniform creamy white except for blue-green mold radiating from the center.
- Texture should be velvety or flaky and open with an absence of discoloration, gas holes, or chalkiness.

The variability within Stilton makes it necessary to examine each cheese individually. It is not possible to take a random sample out of a larger batch, as is normally done with the other UK hard cheeses.

Modern Approaches to Manufacture

The current trend in the marketplace is towards a more mature-flavored Stilton, which has been described as 'vintage' or 'extra mature.' This is Stilton which has been allowed to develop a stronger flavor either in the maturing stores or in cold stores.

In recent years, some manufacturers have moved away from the manual handling of the curd at the stage where it is being made in the vat. Fully enclosed vats have been used which allow mechanical cutting of the curd followed by very gentle transfer of the curds and whey into drainers where the curd is separated. Another alternative involves vats that open completely at one end, allowing the curd to move on to draining tables. However, the most successful innovation in this area has been the transfer of curds and whey from vats to drainers through pipes.

Mold-turning systems have been tried in various forms ranging from very sophisticated pallet-handling systems to more simple pallet inverters. They all work on the principle that it is quicker and cheaper to turn pallets containing 64 cheeses than to turn each individual cheese by hand.

Packing

Traditionally, Stilton was always sold as a whole cheese wrapped in vegetable parchment. However, in recent years, the proportion of prepacked cheese for supermarket sales has increased to the point at which prepacked Stilton accounts for more than 50% of sales.

After cutting into triangular portions from the round cheese, prepacked Stilton is almost always wrapped in polyvinylidene chloride (PVDC) film; it is always sold with the crust on. In recent years, there has been some interest shown in alternative packing, and modified-atmosphere packing (MAP) has been tried. Alternative films with greater oxygen permeability have also been tried. (*See* **Chill Foods**: Effect of Modified-atmosphere Packaging on Food Quality; **Chilled Storage**: Use of Modified-atmosphere Packaging.)

The problem with Stilton cheese is that the absence of oxygen eventually causes the loss of the blue color, which progressively changes through green to yellow and then disappears. This means that vacuum packing in barrier bags has a very limited application. The other alternative is an oxygen-permeable barrier or a loose wrap which allows oxygen in and thus maintains the blue mold. This will also support the growth of any other aerobic organisms which may be present; this includes *Penicillium roqueforti*, which is quite acceptable as blue veining but is unacceptable as adventitious growth on the cut surface of the cheese. This latter growth is usually seen after 4–5 weeks under refrigeration.

The reduction in product temperature during storage has had the effect of extending the shelf-life slightly, but it only slows the adventitious growth of the mold, it does not stop it.

Another method of packing Stilton that has gained considerably in popularity in recent years is putting it into ceramic jars with a wax or plastic seal. This involves breaking the cheese into small pieces and pushing them into the jars. Alternatively, some companies are using an extrusion technique to fill the jars. It has always been found necessary to put a note on the pot/jar advising the customer that the blue veining will have disappeared in storage, and that removal of the wax seal will result in it returning after about 1 h.

Hygiene

Increased awareness of the need for high standards of hygiene in food production and distribution has resulted in a great deal of legislation being introduced. The food industry has also introduced a number of Codes of Practice to guide manufacturers through the pitfalls of *Listeria* and *Salmonella*. (*See* ***Listeria***: Properties and Occurrence.)

Stilton cheese is covered by the Code of Practice for the Production of Soft and Mould-Ripened Cheese which has been produced by the UK Dairy Trade Federation.

The result of manufacturers' increasing awareness of the problems of bacterial contamination has had the effect of making dramatic changes in the construction of buildings and the training and control of staff. Some aspects of the manufacturing procedures have come under very close scrutiny; for example, the last factory producing cheese from raw milk has now decided to pasteurize its milk. It is argued that, in some cases, higher hygiene standards are being achieved at the expense of a loss of 'character' and 'individuality' in some of the speciality cheeses, such as Stilton.

Related Varieties

Although a number of other internally mold-ripened cheeses can be found worldwide, the most famous are Roquefort and Gorgonzola. The origins of Roquefort can be traced back with some degree of certainty to the fifteenth century, and the name is now internationally recognized for a cheese made from sheeps' milk and matured in huge limestone caves in the region of Aveyron, France. The method of manufacture is broadly similar to that of Stilton, except that the milk is not pasteurized. The strain of *P. roqueforti* may also be unique to the region, but the differences in flavor between Roquefort and Stilton arise mainly from the higher content of short-chain fatty acids associated with sheeps' milk. (*See* **Sheep**: Milk.)

Gorgonzola derives its name from a village in Italy where it is supposed to have originated around 1000 years ago. It is made from cows' milk, and again derives its veining from a strain of *Penicillium*.

More recent in origin is Danublu or Danish Blue cheese, which is extensively manufactured in Denmark, North America, and Australia. The process is, in essence, a more industrial version of Stilton manufacture, in that mechanization is heavily involved, and a more limited ripening period insures a rapid throughput of the product; as a result, connoisseurs claim that it lacks the unique character of the more traditional blue cheeses. (*See* **Cheeses**: Dietary Importance.)

Surface Mold-ripened Cheese Varieties

M J Sousa, University College, Cork, Ireland

Surface Mold-ripened Varieties

Surface mold-ripened cheeses represent a relatively small proportion of world cheese production, but they are becoming increasingly popular with consumers. In surface mold-ripened cheese varieties (e.g., Brie and Camembert), mold grows as a mat on the surface, whereas blue-veined varieties (*See* **Cheeses**: Mold-Ripened Cheeses: Stilton and Related Varieties) are characterized by the growth of *Penicillium roqueforti* in fissures throughout the cheese. Hybrid

mold-ripened cheeses are also produced (e.g., Cambazola); these have a growth of white mold on the surface and blue mold in the interior.

Surface mold-ripened cheeses are soft varieties characterized by the growth of white mould (*Penicillium camemberti*) on the surface of the cheese (Figure 1). The first microorganisms that become established on the surface are yeasts, including *Debaromyces* spp., and *Kluyveromyces* spp. *Geotrichum candidum* also becomes established at this time, although its growth may be limited if the level of salt is high. Growth of *P. camemberti* is observed after 6–7 days of ripening, and this mold forms the characteristic mat on the surface of the cheese. After the surface of the cheese has been neutralized by yeast and moulds (~15–20 days), aerobic bacteria (particularly micrococci and coryneforms), which are inhibited by the low initial pH, begin to grow.

Surface mold-ripened varieties originated in France a few hundred years ago; Camembert and Brie, which originated in the eighteenth century, are prime examples of this type of cheese. Camembert is a small flat cylindrical (~10 cm diameter, 5 cm thick and ~250 g) surface mold-ripened cheese that originated in Normandy, France; it has a moisture content of 46–47% and fat-in-dry-matter (FDM) of at least 40%. Traditionally, Camembert has been manufactured from raw milk (e.g., Camembert de Normandie), but nowadays, industrial Camembert is manufactured from pasteurized cows' milk in large, automated factories. Camembert has a close, smooth texture that usually becomes soft and spreadable, depending on the degree of maturation. Young Camembert has a mild, slightly aromatic taste, but as ripening progresses, it develops a distinctive, piquant flavor. Brie is a flat cylindrical surface mold-ripened cheese with a larger diameter than Camembert, which it resembles closely in flavor, texture and manufacturing protocol. Carré de l'Est is a square (10 cm side and 2.5 cm thick) surface mold-ripened cheese that originated in eastern France; it has a moisture content of 50–53% and an FDM of 45–50%. It resembles Camembert and Brie, although its flavor is normally milder. Neufchâtel cheese is manufactured near Rouen, France, at the farm level, in a wide variety of shapes and dimensions; the ripened cheese has a moisture content of 51–53% and an FDM of 45–51%. Tomme de St. Marcellin is a flat, cylindrical (8–10 cm diameter and 2–3 cm thick) cheese that was manufactured traditionally from goats' milk but is now made from cows' or sheep's milk or a mixture of these milks. There are many minor goats' milk cheese varieties that develop a surface mold growth during ripening, but the microflora of these minor varieties is often uncontrolled. The flavor of such cheeses is usually strong (mainly due to the presence of short-chain fatty acids), giving the products a characteristic flavor, and their rinds are often colored as a result of the growth of bacteria.

Figure 1 Examples of surface mold-ripened cheeses (Maison du Lait, Les patés molles à croute fleurie, Centre Interprofissional de Documentation et d'Information Laitiéres, www.cidil.fr).

Production of Surface-mold Cheeses

There are several basic steps in the manufacture of cheese. *See* **Cheeses: Chemistry and Microbiology of Maturation**. Acidification, dehydration, shaping, and salting, in the usual order of occurrence, are common to most varieties; the reason for the individuality of each variety is due mainly to differences in detail (Figure 2).

These five operations, along with the chemical composition of the milk, determine the degree of dehydration. The flavor, aroma, and texture of the finished product are determined by the moisture content, salt level, pH, and microflora, and by regulating and controlling the biochemical changes that occur during the ripening process.

The manufacture of surface-mold cheese begins by selecting milk of high quality, both chemically and microbiologically. Raw milk is still sometimes used for both commercial and farmhouse cheesemaking; however, cheese milk is now usually pasteurized or heat-treated immediately before use. In addition to killing pathogens, pasteurization eliminates certain other indigenous microorganisms, and hence cheese of a more uniform quality can be produced. The surface microflora is often more complex than that of the core, particularly in cheeses made from raw milk by traditional technology.

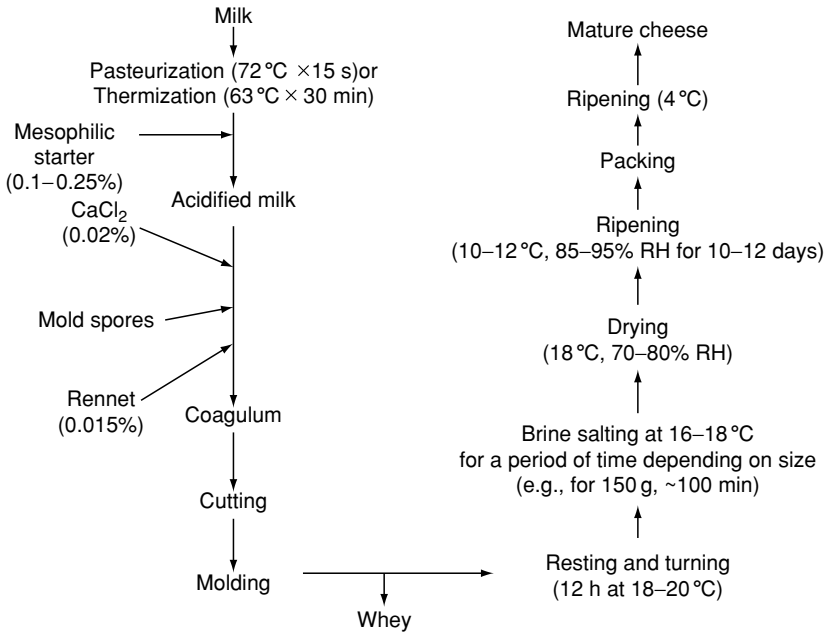

Figure 2 Manufacturing protocol for Camembert or Brie cheese.

Once the milk has been selected and pretreated (if desired), the acidification process is started and continues for up to 24 h. It is now almost universal practice to use a starter culture of known lactic acid-producing bacteria, the predominant function of which is to produce acid at the appropriate rate during cheesemaking. The lactic starters used for Camembert and other surface-ripened cheeses are generally homofermentative mesophiles (e.g., *Lactococcus lactis* ssp. *lactis* and *Lc. lactis* ssp. *cremoris*) that produce lactic acid by the hexose diphosphate pathway. The rate of acidification for Camembert cheese is slower than for hard varieties (e.g., Cheddar; *See* **Cheeses**: Manufacture of Hard and Semi Hard varieties of Cheese) owing to the quantity of starter added to cheese milk, usually ~0.1% and 1–2% starter for Camembert and Cheddar, respectively.

At the same time, the milk can be inoculated with microorganisms that will later make up the surface flora (i.e., a suspension of spores of *P. camemberti*). Usually, $CaCl_2$ (0.02%) is added to the milk to promote coagulation.

Coagulation of the casein component of the milk protein system involves forming a gel, which entraps the fat, water, salts, and lactose. Chymosin is the principal proteinase in traditional rennet used for cheesemaking, and its main role is to specifically hydrolyze the Phe_{105}–Met_{106} bond of the micelle-stabilizing protein, κ-casein, leading to coagulation in the presence of Ca^{2+} at a temperature > 20 °C.

A rennet-induced gel or coagulum is quite stable until it is cut or broken, which causes syneresis. Brie and Camembert are high-moisture cheeses (45–55% moisture), and to prevent excessive syneresis, the coagulum is cut or broken into very large pieces, and the curds are not cooked and only very slightly stirred in the whey, thus discouraging dehydration. Traditionally, an alternative means of whey and curd separation, called 'dipping,' is practiced, in which the uncut coagulum is scooped from the vat into perforated molds, where drainage occurs. To facilitate industrial-scale manufacture, the coagulum for Brie or Camembert is first cut into large cubes and then transferred to molds without cooking.

After molding, the body of curds in the molds is turned at intervals over a period of 3 h and allowed to cool overnight; Brie and Camembert are pressed under their own weight only. Shortly after manufacture, the pH of the cheese is low (4.6–4.9).

Surface mold-ripened cheeses are generally salted by immersion in brine for long enough to give an overall salt content of 1.5–2.5%. Generally, salting stops the production of acid in the curd, preventing a further decrease in pH. Along with having a direct effect on cheese flavor, the salt encourages curd syneresis and therefore has an effect on the moisture content; it reduces the water activity in the curd and influences the activity of rennet, indigenous milk enzymes, and other enzymes. The Na^+ of the salt exchanges with the calcium in the curd matrix, causing dissociation of proteins, and thus enhances the emulsification of fat by the protein matrix.

In surface mold-ripened varieties, mold spores are introduced as a secondary starter during the

cheesemaking process. Generally, *P. camemberti* spores are sprayed on to the surface of each newly shaped cheese, although it is now industrial practice to inoculate the cheese milk with spores before coagulation. Under suitable conditions [10–12 °C and 85–95% relative humidity (RH) for 10–12 days], these spores result in a white mold developing on the outside of each cheese. This mold gives the cheese its characteristic appearance and produces enzymes that play a major role in the hydrolysis of the lipids and proteins during ripening. After mold development, cheeses are packaged in waxed paper and placed in wooden or cardboard boxes prior to final ripening at 4 °C for a further 7–10 days. In traditional Camembert, in which ripening continues for up to 12 weeks, the mold is subsequently overgrown by *Brevibacterium linens* and other coryneform bacteria to form the yellow crust, a distinct sulfur flavor, and the very soft texture of extra-mature Camembert.

Biochemical Pathways during Ripening

Three main biochemical events occur during cheese ripening: metabolism of lactose and lactic acid (generally called glycolysis), lipolysis, and proteolysis (Figure 3). (*See* **Cheeses:** Chemistry and Microbiology of Maturation.)

Cheese ripening can be a relatively slow process, but in the case of Camembert and other soft cheeses, ripening occurs very rapidly, owing to their moisture content and the rapid growth of surface mold.

Metabolism of Lactose and Lactate

During the manufacture of cheese curd, the lactose in the milk is converted mainly to L-lactate by starter bacteria. In surface mold-ripened cheeses, the lactic acid produced by the starter culture is utilized by the secondary microflora, first by *G. candidum* and yeast, principally *D. hansenii*, followed by *P. camemberti*, all of which catabolize lactate to CO_2 and H_2O and hence have a major role in the deacidification of the cheese. There is clear evidence of this event in the dramatic increase of the surface pH during the sixth and seventh days, as the mold grows. Deacidification occurs initially at the surface, resulting in a pH gradient from the surface to the core, which causes lactate to diffuse outwards. Neutralization of the surface causes precipitation of Ca^{2+} at the surface as $Ca_3(PO_4)_2$, causing minerals in the cheese curd to migrate to the surface, developing a gradient within the cheese, which has a major effect on cheese texture. This loss of calcium, as a consequence of neutralization, leads to considerable softening of the body of Camembert, as calcium is necessary for the integrity

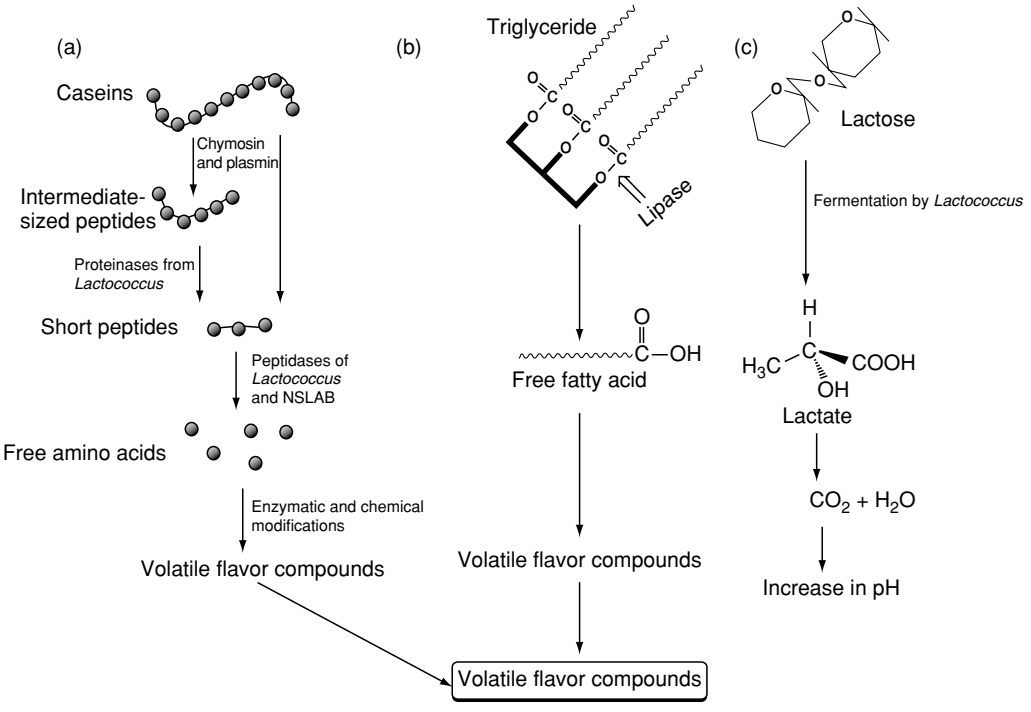

Figure 3 Summary of the biochemical pathways involved in the ripening of surface mold cheeses; (a) proteolysis, (b) lipolysis and (c) glycolysis and their role in flavor biogenesis. Adapted from McSweeney PLH and Sousa MJ (2000) Biochemical pathways for the production of flavour compounds in cheeses during ripening. A review. *Lait* 80: 293–324.

of the protein network. When the lactic acid has been exhausted, *P. camemberti* catabolizes amino acids released from the caseins with the production of NH_3, which diffuses inward, further increasing the pH. Deacidification of the cheese surface has a major impact on the growth of coryneform bacteria (*Br. linens* does not grow below pH 5.8), plasmin activity (which is optimally active at alkaline pH), and coagulant activity (the activity of which decreases with increasing pH).

Lipolysis and Catabolism of Fatty Acids

In most cheese varieties, relatively little lipolysis occurs during ripening. Lipases and esterases in cheese can originate from milk, rennet preparation, starter bacteria, secondary nonstarter bacteria and secondary cultures (e.g. *P. camemberti*). The limited lipolysis is a consequence of the fact that there is normally no significant exogenous or endogenous lipases in pasteurized cheese milk, and the starters used are only weakly lipolytic. The extent of lipolysis in surface mold ripened cheeses (e.g., Brie and Camembert) is generally between 6 and 10% of the total fatty acids. However, significantly lower levels of free fatty acids are present in surface-mold cheeses than in blue-veined cheeses, in which lipases have more contact with fat because of the development of molds in the interior of the cheese and their longer ripening time. Lipolysis tends to be highest towards the surface, suggesting that *Penicillium* is the principal lipolytic agent in Camembert. *P. camemberti* produces a high level of extracellular lipase, which is optimally active at about pH 9.0 and 35 °C, resulting in an increase in lipase activity as the mold develops during ripening. Most free fatty acids between C_4 and C_{20} are produced via lipolysis of triglycerides by fungal lipases, but a smaller proportion of acids between C_2 and C_6 originate from the degradation of lactose and amino acids.

In addition to their direct impact on cheese flavor, free fatty acids act as precursors for series of catabolic reactions, which lead to the production of other flavour compounds (Figure 4). Molds play an important role in the degradation of fatty acids to methyl ketones and their reduction products (secondary alcohols) by a pathway related to β-oxidation. *P. camemberti* and *G. candidum* possess an enzymatic system that oxidizes free fatty acids to β-ketoacyl-coenzyme A, and the action of a thiolase yields a β-ketoacid that is rapidly decarboxylated by a β-keto-acyl-decarboxylase to give a methyl ketone with one less carbon than the initial fatty acid.

A complex array of compounds are produced as a result of lipolytic activity, which contributes to flavor. However, lipolysis is not accompanied by a rancid taste, probably because the fatty acids are neutralized on elevation of the pH.

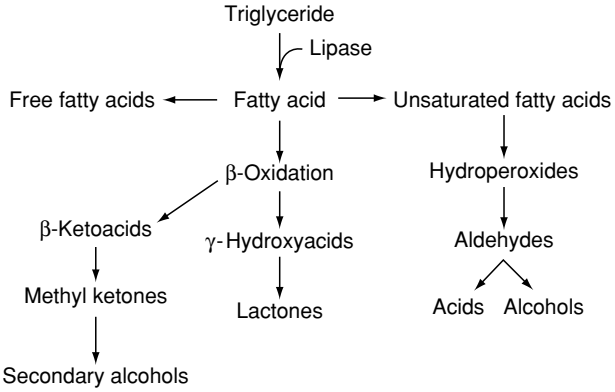

Figure 4 Lipolysis and catabolism of fatty acids during ripening of surface mold-ripened cheeses.

Proteolysis

Proteolysis makes a direct contribution to the flavor, and perhaps to off-flavor (e.g., bitterness), of cheese through the formation of peptides and amino acids, liberation of substrates (amino acids) for catabolic changes (e.g., deamination, decarboxylation, transamination, desulfuration, catabolism of aromatic compounds such as phenylalanine, tyrosine, and tryptophan, and reactions of amino acids with other compounds), and textural changes in the cheese curd, owing to breakdown of the protein network, a decrease in a_w through water binding by formed carboxyl and amino groups and an increase in pH.

Surface mold-ripened cheeses undergo considerable proteolysis during ripening due to the activity of proteinases from starter microorganisms, rennet, milk and, especially, the proteinases and exo- and endopeptidases secreted by the *Penicillium* species. The progression of proteolysis can be summarized as follows: initial breakdown of caseins, which is catalyzed mainly by the residual coagulant, plasmin, and perhaps cathepsin D and other somatic cell proteinases, followed by the production of large water-insoluble polypeptides and intermediate-sized water-soluble peptides, which are degraded by proteinases and peptidases and peptidases from the starter, nonstarter bacteria, and secondary microflora (*P. camemberti*) of the cheese to small water-soluble peptides and amino acids.

As in other cheeses, coagulant is considered to be essential for the development of the correct texture in surface mold-ripened cheeses. Since plasmin is not inactivated by pasteurization, proteolytic activity owing to plasmin is high in the surface of these cheeses owing to their high pH (~7) and higher

than in cheese varieties without molds. the increase in pH may also increase the proteolytic activity of secondary microorganisms.

While rennet, plasmin, enzymes from starter or nonstarter microflora have an effect on proteolysis, enzymes of *Penicillium* spp. are the principal proteolytic agents in surface mold-ripened cheeses. These molds have very potent proteolytic systems, which include an aspartyl proteinase, a metalloproteinase, an acid carboxypeptidase, and an alkaline aminopeptidase. The aspartyl proteinase is the principal enzyme produced by cultures at grown pH 4.0; its optimum pH is ~5.0 on casein as substrate. It is generally stable between pH 3.5 and 5.5. It is active on α_{s1}-, β- and κ-caseins with different pH optima, but it tends to be most active on α_{s1}-casein. It releases a number of short peptides (soluble in 12% trichloroacetic acid, TCA) from α_{s1}-casein, whereas it releases predominantly 12% TCA-insoluble peptides from β-casein. The metalloproteinase has a pH optimum of 5.5–6.0 and is stable over the range pH 4.5–8.5, which suits the conditions in Camembert and other surface mold-ripened cheeses. The metalloproteinase hydrolyses α_{s1}-casein better than β- or κ-casein. Quantitative studies show that the aspartyl proteinase is more active than the metalloproteinase during ripening. *Penicillium* spp. also have carboxy- and aminopeptidase activities. There are two carboxypeptidases, one with an acid and the other with an alkaline pH optimum. The carboxypeptidase activity shows differences in behavior, depending on whether its origin is intra- or extracellular; the extracellular carboxypeptidase is a serine enzyme optimally active on X–Glu–Tyr substrate at pH 3.5, whereas the intracellular carboxypeptidase is optimally active on X–Gly–Val at pH 6. Owing to their broad specificity, the acid carboxypeptidases of *Penicillium* spp. may contribute to the breakdown of bitter peptides in surface mold-ripened cheese. The aminopeptidase has an optimum pH around 8.0–8.5; it is a metalloenzyme with the ability to release apolar amino acids, but peptides with glycine in the penultimate position or N-terminal are hydrolyzed slowly.

Proteolytic activity at the center of Camembert and other surface-ripened cheeses is low, but it is high at the surface, indicating that the migration of *Penicillium* proteinases in the curd is limited. However, peptides produced by the aspartyl proteinase have been detected inside the cheese at a depth greater than 7 mm at the end of ripening. This is probably due to the migration of peptides produced by the aspartyl proteinase, rather than of the enzyme.

The final products of proteolysis are free amino acids, and their concentration at any stage of cheese ripening is the net result of the liberation of amino acids from casein and their catabolism to a number of compounds, including ammonia, amines, aldehydes, phenols, indole, and alcohols (Figure 5), all of which contribute to the flavor of all cheese varieties, especially surface mold-ripened cheeses.

Flavor of Surface Mold-Ripened Cheeses

Numerous compounds contribute to the flavor of surface mold-ripened cheeses including fatty acids, methyl ketones, ketones, alcohols, sulfur compounds, amines, lactones, esters, aldehydes and pyrazines, derived mainly from the three metabolic pathways described above.

Fatty acids are important to the aroma of surface mold-ripened cheeses, not only directly, but also as precursors of methyl ketones, alcohols, lactones, and esters. Short- and medium-chain, even-numbered fatty acids (C_4 to C_{12}) have low perception thresholds, and each has a characteristic flavor. Acetic acid has a typical vinegar odor, butyric has a rancid, cheesy aroma, isobutyric and isovaleric acids have a mild aroma, suggestive of sweet or rotten fruit, and

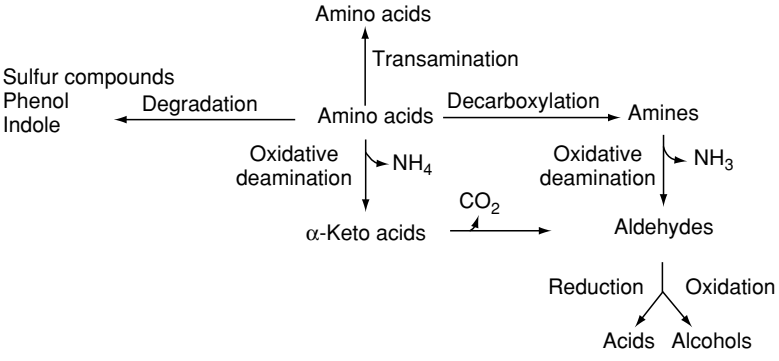

Figure 5 Pathways for the catabolism of free amino acids in surface mold-ripened cheeses.

octanoic, 4-methyloctanoic and 4-ethyloctanoic acids have a goaty aroma. Long-chain free fatty acids ($> C_{12}$) play a minor direct role in cheese flavor because of their high perception thresholds.

Ketones have different perception thresholds and different odor characteristics. The most important ketone in Camembert cheese is octan-1-en-3-one, which has mushroom note; octan-2-one, nona-2-one, and decan-2-one are described as having a musty note, and diacetyl and acetoin are well known for their buttery aromas.

Methyl ketones (C_3 to C_{15}, odd chain) are the most abundant aromatic compounds in surface mold-ripened cheeses and are present in Camembert and Brie cheeses from the eighth day of ripening. Several methyl ketones (e.g., 3-methylpentan-2-one, 4-methylpentan-2-one, non-1-en-2-one, and undec-1-en-2-one) have been identified in Camembert, but the two major methyl ketones are nonan-2-one and heptan-2-one, produced by *P. camemberti* from long-chain fatty acids by β-oxidation, and their concentrations increase during ripening *G. candidum* produces methyl ketones, such as pentan-2-one, hepta-2-one, nonan-2-one, undeca-2-one, and pentan-3-one. Octan-2-one, nonan-2-one, decan-2-one, undecan-2-one, and tridecan-2-one are described as having fruity, floral, and musty notes, whereas heptan-2-one has a blue cheese note. Methyl ketones with even-numbered carbon chains (except butan-2-one) appear later during ripening and are never present in large amounts, except in extra-ripe cheese.

Primary and secondary alcohols, along with ketones, are considered to be the most important compounds in the aroma of surface mold-ripened cheeses. 3-Methylbutan-1-ol is present at a relatively high concentration in Camembert cheese and gives it an alcoholic floral aroma. The principal secondary alcohols present are heptan-2-ol and nonan-2-ol, which are derived from their respective methyl ketones. Oct-1-en-3-ol, which is well known for its raw mushroom aroma, is produced by *P. camemberti* during ripening and represents 5–10% of the aroma compounds in ripened Camembert. This alcohol has a low perception threshold and is one of the key compounds in the aroma of Camembert. Phenyl-2-ethanol is one of the major compounds in Camembert after 7 days of ripening; it exhibits a characteristic rose floral note, and its ester, phenylethylacetate, plays an important role in the flavor of raw milk Camembert.

Sulfur compounds (2,4-dithiopentane, diethyldisulfide, 2,4,5-trithiohexane and 3-methylthio-2,4-dithiapentane) also play important roles in the flavor of surface mold-ripened cheeses; they cause the strong garlic notes characteristic of the mature cheese. Coryneform bacteria are thought to be the key contributors to the formation of sulfur compounds in surface-mold-ripened cheeses. *Br. linens* can produce methanethiol, because these bacteria have a methionine-γ-lyase, which produces methanethiol from methionine, although methanethiol can also be produced from methionine by cystathionine-β-lyase, methionine-α-deaminase or methionine-α-transaminase. *P. camemberti* and *G. candidum* produce methanethiol and other sulfur compounds.

Numerous volatile amines have been identified in Camembert cheese (e.g., methylamine, ethylamine, dimethylamine, isopropylamine, or *n*-butylamine). Ammonia is also an important contributor to the aroma of surface mold-ripened cheese, and *P. camemberti, G. candidum*, and *Br. linens* play major roles in its production. Nonvolatile amines (i.e., tyramine, histamine, tryptamine, and putrescine) have also been identified in this cheese type.

The lactones, γ-decalactone, δ-decalactone, γ-dodecalactone and δ-dodecalactone, are present in Camembert cheese; they are characterized by very pronounced fruity notes (peach, apricot, and coconut).

Many esters are present in surface mold-ripened cheeses; they are characterized by fruity, floral notes (e.g., pineapple, banana, apricot, pear, floral rose, honey, and wine). 2-Phenylethyl acetate and 2-phenylethyl propanoate are quantitatively important in Camembert.

The main aldehydes in Brie and Camembert cheeses are hexanal, heptanal, nonanal, 2-methylbutanal, 3-methylbutanal, and benzaldehyde, and they appear in trace amounts as early as the first week of ripening. Hexanal gives the green note of immature fruit, nonanal is described as having an aromatic note resembling orange, while benzaldehyde is described as having an aromatic note of bitter almond.

Compounds like styrene, which have a very strong plastic odor, have been found in trace amounts in Camembert, when the degradation of linoleic and linolenic acids by *P. camemberti* is higher than usual. Pyrazines (e.g., 2,5-dimethylpyrazine and 2-methoxy-3-isopropylpyrazine) are also present in Camembert. The former imparts a toasted hazelnut note, whereas the latter is responsible for the rotten soil, raw potato aroma note, which is regarded as a defect.

Bitterness in surface mold-ripened cheese has been correlated with the concentration of pH 4.6-soluble nitrogen and thus with the formation of peptides. Bitterness could be eliminated by ripening cheese in an atmosphere containing NH_3, which results in slower growth of *P. camemberti* on the cheese surface

and therefore less proteolysis and a lower level of bitter peptides, or by inoculating with secondary microorganisms (*P. camemberti, G. candidum*, and *Br. linens*) with a higher aminopeptidase activity.

The characteristic appearance of surface mold-ripened cheese is due to the presence of mold (e.g., *P. camemberti*), which produces enzymes with high lipolytic and proteolytic activities, which play a major role during ripening. These molds also lead to more complex ripening patterns than in other varieties of cheese with simpler flora. Much progress has been made during the last 15 years in elucidating the mechanisms of ripening in surface mold-ripened cheeses. However, further work is required to understand the enzyme systems and the mechanisms involved in the conversion of the primary products to volatile flavor compounds.

Dutch-type Cheeses

G van den Berg, NIZO Food Research, Ede, The Netherlands

Introduction

Dutch-type cheeses represent the most important kinds of semihard cheese. They are manufactured from bovine milk, although small amounts of similar cheeses are made from ovine or caprine milk. Other semihard cheese types are also manufactured according to a largely similar technology but their characteristics are different. For this reason, Jarlsberg or Maasdam and Tilsiter or Havarti cheese will not be treated here.

Gouda and Edam cheese are the primary Dutch-type cheese varieties and they are made all over the world. However, in many countries a similar technology is used for related cheese types manufactured under various names. The majority of all these cheese varieties contain 40–52% fat in dry matter, and the water content in the (unripened) fat-free cheese ranges from 55 to 63%. They are made in sizes between 0.2 and 20 kg. Their shape can be a flat cylinder, often with somewhat bulging sides, a sphere, a rectangular block, or a loaf. The latter are often used for foil ripening (rindless cheese). The standard cheeses are naturally ripened under drying conditions.

Dutch-type cheeses are ripened for some weeks or longer, sometimes for more than a year, and are often covered with a plastic coating. The consistency varies from rather firm and smooth to semisoft and changes during natural ripening to a firmer and more brittle structure. The flavor also changes from mild to strong during such long ripening times. The interior of the main cheese types shows some round eyes about the size of a pea. Substances like cumin seeds or other spices may be added. There is essentially no surface flora.

Production Statistics

The worldwide production volume of Dutch-type cheeses can only be estimated because from many countries there are no official figures for individual cheese types. Moreover, all related cheese types are not always well described in different countries. So a worldwide picture can only be estimated.

World cheese production in 1998, excluding processed cheese but including fresh cheese and quark, is estimated as $12\,800 \times 10^3$ t. The share of the Dutch-type varieties is estimated to be approximately 15%

of this volume, which is based on a mix of real figures for various European countries and estimates for others. The production of these cheese types in The Netherlands in 1999 was 535×10^3 t and in Germany 415×10^3 t as the two countries with the highest production, while the whole European Union produced approximately 1300×10^3 t. Dutch-type cheese is usually made from pasteurized milk; only 10×10^3 t, mainly Gouda cheese, is farm-made from raw milk in the Netherlands and will not be considered further.

Technology

A typical manufacturing scheme for Gouda cheese is given in Figure 1.

The milk is thermized and standardized for its fat : protein ratio in order to control the fat content in the dry matter of the cheese. It is cold-stored until cheese-making can take place. Then, the milk is pasteurized and pumped into the cheese vat. During one of these heat treatments, the milk is often bactofugated to reduce the number of spores of butyric acid bacteria. The total heat load must be sufficient to inhibit pathogenic microorganisms and some spoilage organisms but not xanthine oxidase (EC no. 1.2.3.2). The denaturation of whey proteins should be limited.

For the manufacture of Dutch-type cheeses, the milk is coagulated at approximately 30 °C by the action of renneting enzymes, usually a chymosin (EC 3.4.23.4) preparation (calf rennet). This is added together with the mesophilic starter and calcium chloride to control the renneting process. Other additives, such as nitrate and coloring agents, like anatto (E160b) or carotene (EE160a), are often used. The resulting coagulum consists of a continuous network of strands of (*para*)casein micelles that extends throughout the milk volume. (*See* **Cheeses: Starter Cultures Employed in Cheese-making.**) In general, this gel is not as firm when cut as is the case for soft cheese-making. It is divided into fairly small particles but not so fine as is the case for hard cooked cheese.

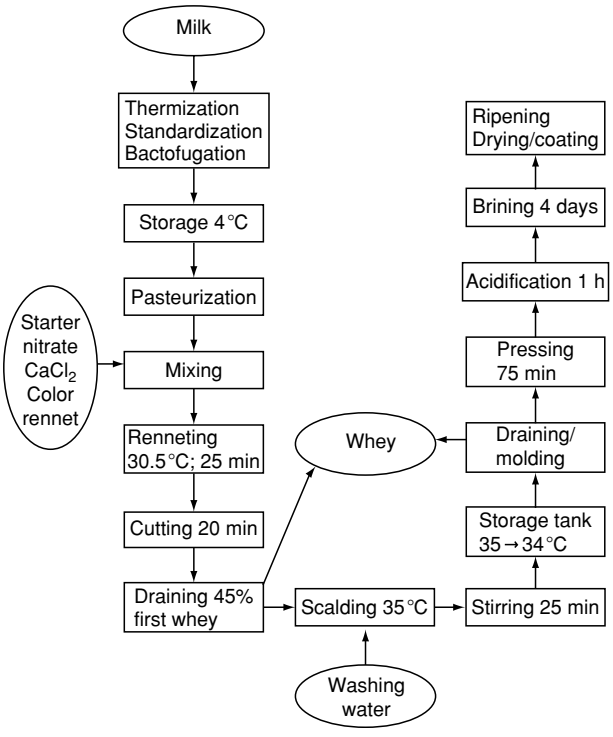

Figure 1 Main process steps of a modern manufacturing scheme for 12-kg Gouda cheese.

After cutting, a part of the (first) whey already liberated from the curd particles by syneresis (shrinkage and expulsion of whey) is removed and warm water is added. This scalding of the curd serves to reduce the lactose content and to enhance syneresis of the curd during further stirring. The amount of this curd wash water is related to the desired pH of the final cheese. This parameter is a result of the ratio between the amount of lactose that is fermented to lactic acid and the amount of the (*para*)caseinate–phosphate complex (the acid buffering substance). So in this respect, the lactose content of the milk and the water content of the nonfat matter after pressing/before brining are important. This water content is important because it is equal to that of the center of the cheese when all lactose has been fermented. The higher these parameters, the more lactose remains in the curd and the more water that has to be added to maintain a constant pH.

The scalding temperature is primarily used to influence the dry-matter content of the cheese because it affects syneresis. This is an intrinsic property of the (*para*)casein gel that leads to the protein strands, breaking whereupon new bonds will be easily formed because the whole surface of the casein micelle can be considered as reactive. The network is rearranged when the moisture with dissolved components (whey) is expelled. Increasing the surface of the coagulum (cutting), acidification, temperature increase, and stress (by stirring the curd or, during a successive stage, by taking the curd out of the whey) all enhance syneresis. The increase of the scalding temperature is limited because of the use of a mesophilic starter.

After making curd, the curd particles are collected under the whey to exclude air. Subsequently, the free whey between the curd particles must be expelled by drainage in order to obtain a closed texture in the final cheese. However, even after pressing, some whey still remains in the small interstices between the curd particles, but during later stages, the temperature drops and this whey is readsorbed by the curd so

that fusion can be completed. In fact, a section of the cheese will show a closed texture only after some days.

The blocks of curd are pressed in perforated molds covered with a lid, allowing whey drainage. A rind of a few millimeters thick is created by deformation of the curd around threads of the liner or edges of perforations in the mold. This rind formation is due to strong local syneresis and further fusion of the curd particles, and more bonds between the casein strands are created than elsewhere in the cheese. In essence, syneresis, fusion, and rind formation are similar processes.

A closed rind is necessary, for the natural ripening cheese in particular, to withstand the tension caused by brining and to protect the cheese from penetration of undesired microorganisms during brining and from molds during ripening. (*See* **Cheeses**: White Brined Varieties.)

During curing the integrity of the rind has to be maintained. Coating the cheese makes it much easier to maintain the rind and gives a smooth and glossy appearance when the optimal climatic conditions, air flow, and cheese treatment scheme in the ripening room are applied. The polyvinylacetate-based coating layer reduces water evaporation from the cheese surface to some extent. However, too strong drying will make this hydrophilic coating layer too brittle and mold will penetrate into cracks. On the other hand, too little drying will easily allow undesired development of bacteria that make the surface sticky, and the presence of natamycin will not be sufficient to prevent the growth of yeasts and molds. The normal ripening temperature is rather moderate, approximately 13 °C. In the case of ripening in foil, or in wax, this temperature is normally lower and the moisture content is often somewhat lower to keep the cheese in better shape and to prevent it from being too soft after curing.

It is obvious that cheese composition has to be controlled carefully. During the manufacture of Gouda cheese, the casein is concentrated at the end of curd preparation by a factor of approximately 4.5 and in the final cheese by approximately 10. In parallel with this, the dry-matter content of the curd mass increases to approximately 32% at the end of curd preparation, to 42% after drainage, to 53% after pressing, and to 57% after brining. The composition of the cheese directly influences the product yield. However, milk composition is the primary factor to reckon with. Of the components to be concentrated, casein is the most expensive one. The fat in the whey can be recovered in the cheese by adding the whey cream to the cheese milk whereas the casein (curd fines) cannot when making quality products. So it is good to express yield as kg per kg casein of the milk. However, in a quantitative sense, water is the most important cheese component but cheese quality demands optimal water content, before brining in particular, which depends on the cheese type involved. This is important for the desired consistency of the young cheese and for the conditioning of the ripening processes.

Nowadays, the cheese-making process is carried out in factories manufacturing 3–5 tonnes of cheese per hour, and mechanization and automation based on a good understanding of the technology are well developed.

Starters and Lactose Fermentation

The role of starter bacteria is discussed elsewhere (*See* **Starter Cultures**). The starters for Dutch-type cheese have always been mesophilic lactic acid bacteria (LAB). The commonly used starters consist of combinations of acid-producing *Lactococcus lactis* subsp. *lactis* and *cremoris* strains and citrate-fermenting (and carbon dioxide-producing) *Leuconostoc lactis* and/or *L. mesenteroides* subsp. *cremoris* (L-starters) or *Lactococcus lactis* var. *lactis* biovar *diacetylactis* and *Leuconostoc* strains (DL-starters). DL-starters are normally used when stronger eye formation is desired because they ferment citrate faster and to a greater extent than do L-starters. When in particular cases no eye formation must occur, then a starter without citrate-fermenting bacteria is often used (O-starter). Mixed-strain starters are mainly used in Europe for Dutch-type cheese. This is also true in the case of an O-starter. Manufacturers, especially the bigger factories, prefer to use their own bulk starter, to realize lower starter costs and a better yield in comparison with the use of a DVS (direct to the vat) system. Such a bulk starter system is provided with the means to avoid bacteriophage contamination, such as a bacteriophage-free mother starter concentrate and a starter propagation tank with an overpressure of bacteriophage-free air. Such starters have to be well selected because of their major influence on cheese quality.

The amount of bulk starter of normal activity used to inoculate cheese milk is 0.5–1.0%. During cheesemaking, starter LAB grow until a level of 10^9 colony-forming units (cfu) g^{-1} has been reached. In Gouda and Edam cheese, the pH at that time is approximately 5.7 and the cheese has already been pressed. A picture of the usual pH course during cheesemaking is given in Figure 2.

During curd preparation, the pH remains rather high until most of the whey is separated by drainage in order to obtain the desired cheese consistency and

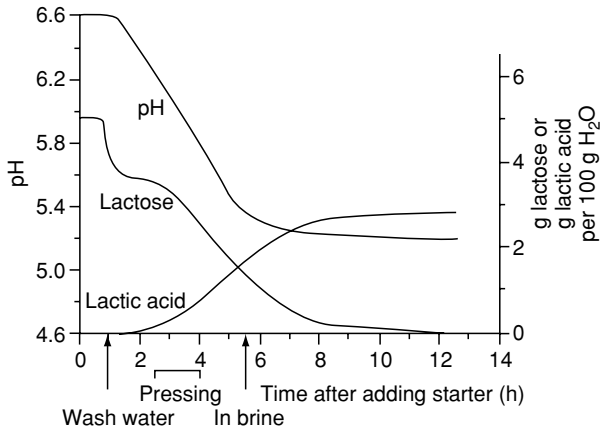

Figure 2 Lactose fermentation, acid production, and the pH of curd and cheese during the manufacture of Gouda cheese after starter addition.

yield. Moreover, less chymosin is bound to the casein and the danger of bitterness after ripening is diminished. Before lactose fermentation has finished, the cheese has already been put into the brine. The moisture diffusing out of the cheese still contains lactose and so does the brine, which is used for a long time. As a result, after brining, the rind of the cheese still contains some lactose, which disappears within the first few weeks of ripening. For foil-ripened block cheese, in particular, the time between pressing and brining is often still shorter after pressing and these effects are stronger.

There is a strong interest in acceleration of ripening and product differentiation, not only from differences in packaging and shape, but also in flavor. To this end, attenuated LAB starters are introduced as an extra means of enhancing flavor development. They are often thermophilic and propagated or treated in such a way that they practically do not grow or contribute to acidification, so that normal manufacturing procedures can be maintained. In the case of low-fat cheese, the ability to enhance protein degradation is of special interest in order to achieve a more acceptable consistency and a stronger flavor of the final product.

Ripening Patterns

After fermentation of lactose and citric acid, proteolysis is the main phenomenon in the manufacture of Dutch-type cheese, followed by amino acid degradation. Within 24 h the pH of the cheese is 5.1–5.2, increasing during the first 2 weeks by approximately 0.15, and thereafter only slightly during maturation. The redox potential in the cheese has been reduced by the lactic acid fermentation to approximately −140 mV. In the center of Gouda cheese the original water content in the fat-free cheese is approximately 65%, but this decreases gradually by salt diffusion and water evaporation. Under these conditions, casein is degraded by chymosin (not inactivated by high scalding temperatures), and to a lesser extent by plasmin, into larger peptides. These are further degraded, finally into amino acids, by peptidases of the starter LAB that also provide amino acid-converting enzymes (AACEs) for the production of various volatile (flavor) components.

Under the gradually changing conditions in normal Gouda cheese, only a very global quantitative picture can be given of how degradation of the (total) casein proceeds during ripening. To this end, the nitrogen-containing fraction of the cheese is separated into a fraction which is soluble under cheese conditions (SN) and a fraction which is still soluble in 12% trichloroacetic acid (AN). The latter fraction of < 1400 molecular weight contains only very small peptides, amino acids, and further converted components.

Figure 3 gives the average increase of these fractions (expressed as a percentage of total nitrogen) in normal Gouda cheese during ripening at 13 °C. Generally, the SN fraction is mainly dependent on chymosin activity and the AN fraction on activities of enzymes associated with the starter bacteria. However, the production of peptides by the former stimulates activity by the latter.

The use of attenuated thermophilic starters in addition to the normal culture causes a greater increase of the AN fraction while hardly affecting the SN fraction. In fact, the peptidase and AACE activity is primarily increased.

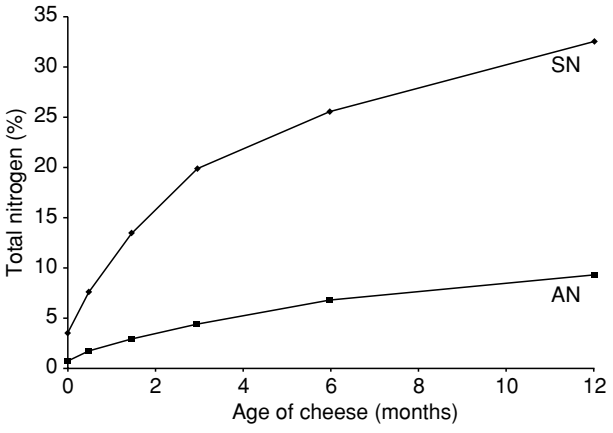

Figure 3 Increase of the soluble nitrogen-containing fraction (SN) and the amino acid-containing fraction (AN) during ripening of normal Gouda cheese as a percentage of total nitrogen fraction in the cheese.

As noted, Figure 3 gives an overall picture of the cheese. The center shows a greater degradation because of the higher moisture content and the (initially) lower salt content. In the rind, proteolysis stops within 3 months because of the low water content. It will be obvious that when water evaporation is prevented by packaging in foil or wax one may speak of rindless cheese, because then the internal ripening processes also continue in the rind zone. However, such cheese is usually ripened at a low temperature.

Lipolysis is very limited in Dutch-type cheese.

Textural Characteristics

Figure 4 gives an impression of the desired eye formation in normal Gouda cheese.

For eye formation, a certain gas pressure in the very young cheese is necessary when the consistency of the cheese is still very elastic. To this end, saturation of the milk with air, in particular with nitrogen – because oxygen disappears due to the activity of the starter bacteria – and citrate fermentation by the starter bacteria during the first weeks after manufacture are crucial. The partial pressure of nitrogen in the young cheese is approximately 0.9 bar and that of carbon dioxide 0.4 bar, which together are sufficient for eye development in Gouda cheese. Without the nitrogen, the cheese would be 'blind.' However, without 'nuclei,' eye formation does not take place either, because then the pressure necessary to start the development of an eye can never be reached. Various deviations in the structure of a curd block may serve as such 'nuclei,' like tiny air bubbles or remaining whey pockets, but also foreign particles with certain apolar surface properties. Faster citrate fermentation by DL-starters can give more or bigger eyes, dependent on the 'nuclei' available, because of the increased gas pressure before the carbon dioxide can diffuse through the rind. A sufficiently elastic texture is necessary because too low a fracture stress will result in cracks instead of eyes.

Such a short consistency is to be expected at low pH. However, the desired consistency also depends on the correct moisture and fat content and the presence of sufficient calcium phosphate. Therefore the pH before pressing must be high. Proteolysis turns the consistency during ripening from rather elastic to smooth within 1–2 months and later to short. In the meantime, the water content has considerably decreased and the consistency will also be rather hard after a year. The rind zone increases in thickness during ripening; it is tougher and harder than the interior and becomes somewhat translucent. The increase in 'shortness' of Gouda cheese during ripening is illustrated in Figure 5 by the shift in the stress–strain curves.

In Gouda cheeses ripened for more than 1 year, tyrosine crystals are often visible as a result of the progress of proteolysis. If attenuated thermophilic starters are added, these crystals will be present after a shorter period.

Flavor Characteristics

Primary products produced during cheese-making, like lactic acid, diacetyl, and carbon dioxide and related fermentation products, are essential for the basic flavor of the young cheese. The same holds for the very small amount of free fatty acids but the desired flavor is based on the right balance of all components. However, ripening starts immediately after manufacture and causes development of a strong flavor in the matured cheese. In this process, all components are probably involved in numerous conversions. So it is understandable that the flavor of the young cheese depends more directly on the type of

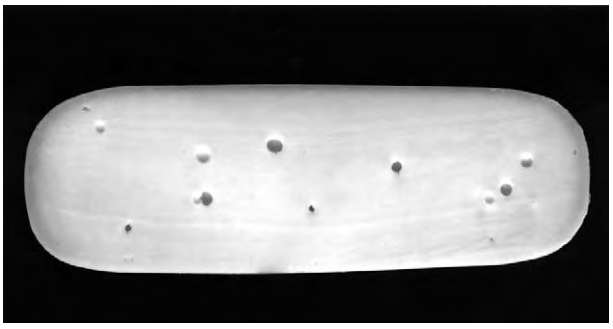

Figure 4 Section through a normal Gouda cheese.

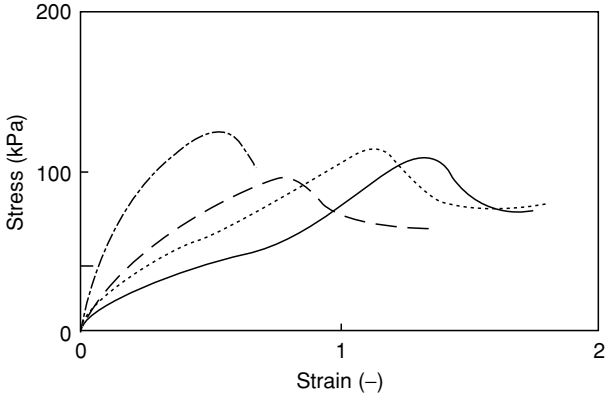

Figure 5 Stress–strain curves obtained for Gouda cheese in a compression test at 2 (———), 6 (·····), 13 (— —), and 26 (—·—·-) weeks. From Zoon P, NIZO Food Research.

starter. Cheeses made using an O-starter have a less creamy flavor than do those with an L-starter and certainly those with a DL-starter. For the more mature cheese, these differences disappear but other starter-related differences are then observed, such as more or less sweetness or fruitiness.

During ripening, the effect of proteolysis becomes more dominant, including amino acid conversion into a great number of volatile flavor compounds. Pathways from protein to these compounds are becoming better known. In good cheese, made with a mixed-strain starter, they are quantitatively well balanced. Some are more characteristic for a particular cheese type than others. This is illustrated in Figure 6, which shows the gas chromatogram area with the most important differences between a Gouda cheese and a similar cheese with an extra attenuated thermophilic starter APS (Proosdij cheese).

All volatile flavor components are already present in small amounts in a 6-week-old cheese but the different flavor is due to the difference in concentration of the key components. Proosdij cheese has larger amounts of peak 8 (butanone), 12 (3-methylbutanal), 14 (2-pentanone), and 22 (2-heptanone), while Gouda cheese shows more of peak 7 (diacetyl), 11 (2-methylpropanol), 13 (1-butanol), 16 (3-methylbutanol), and 21 (ethyl butyrate). The taste of Proosdij cheese has more sweet, caramel, bouillon, and fruity notes than the taste of Gouda cheese.

Defects

Process control is necessary to avoid a number of defects in the cheese. The most important ones are listed, with the main measures required to avoid them.

Butyric Acid Fermentation

This 'late blowing' (large eyes and/or cracks with a sweet and butyric off-flavor) is caused by the growth of the anaerobic bacterium, *Clostridium tyrobutyricum*, originating from spores in the milk, in the 1–5-month-old cheese. The use of nitrate and bactofugation of the milk mainly prevent it.

Mesophilic Lactobacilli

Various strains of *Lactobacillis plantarum, L. casei*, or *L. brevis* are able to grow in cheese and to produce various off-flavors (gassy, putrid, fruity, etc.) and/or carbon dioxide, causing cracks in the mature cheese. Contamination and growth during cheese-making must be avoided as much as possible. Some of these bacteria are salt-tolerant and may contaminate the cheese during brining. So the rind has to be closed during pressing and the bacterial counts of the brine must be controlled.

Thermoresistant Streptococci

In particular, strains of *Streptococcus salivarius* subsp. *thermophilus* may be responsible for excessive carbon dioxide production and some sweet off-flavor in 1–2-month-old cheese. Counts of this organism in the cheese milk have to be controlled, especially by regularly cleaning the plate heat exchangers, because the streptococci grow on the surface of the plates in the regenerator section.

Slimy Rind

Growth of coryneform bacteria on the surface of the cheese should be avoided by good acidification during cheese-making and good curing conditions. Otherwise they may cause gas production under the wax layer which is applied before selling the cheese. A slimy rind without bacterial growth is possible when the calcium content of the brine is too low.

Mold Growth

Mold growth on the surface of the cheese must be avoided by the right curing conditions and turning and coating program. Under normal conditions, the use of natamycin in the coating inhibits mold growth.

Bitterness

This is a ripening defect that can be caused by using too much rennet or a low pH before pressing so that more rennet is entrapped in the cheese, but mainly by using the wrong starter with insufficient peptidase activity to break down bitter peptides.

Texture Defects

Besides the formation of cracks or over-large holes, it is also possible to have too many small eyes or even pinholes. The renneting milk should not contain many very fine air bubbles and air inclusion during drainage of the curd must be avoided. Curd lumps that do not lose their whey properly during drainage mainly cause nesty holes.

CHERRIES

W Loescher, Michigan State University, East Lansing, MI, USA

Background

In some temperate regions of the world, i.e., Eastern Europe, Western Asia, and parts of North America, sweet and sour cherries are second only to apples in their economic importance as tree fruits. Sweet cherries are primarily grown for fresh consumption, but sour cherries are almost entirely processed, i.e., dried, canned, or frozen. These differences profoundly affect production, harvest, handling, shipping, and marketing. Although cultivated since ancient times, both sweet and sour cherries have undergone relatively little advanced breeding. Improvement has primarily been through selection, but there is the potential to deal with cultural, pest, disease, and quality problems that now limit production and economics of both types. There are significant

opportunities to expand markets for fresh sweet cherries and for some sour cherry products.

Cherry Taxonomy and Types

Commercially, the two most important cherry species are: sweet cherry, *Prunus avium*, L. and sour cherry, *Prunus cerasus* L., both tree fruits native to southeastern Europe and western Asia. They are closely related, graft-compatible, and hybridize to form interspecific (Duke) cultivars. Sweet cherry (diploid, with a base chromosome number of 8, and a somatic number of 16) probably originated somewhere between the Black Sea and the Caspian Sea, but it spread into Europe in ancient times. Sour cherry (tetraploid, with a base chromosome number of 16, somatic chromosome number of 32) is native to the same areas as sweet cherry, and there is good evidence that crosses between *Prunus avium* and the ground cherry, *P. fruticosa* Pall, gave rise to sour cherry. There are several other cherry species, but most, e.g., Nanking cherry (*Prunus tomentosa*), have limited commercial value as fruits.

Sweet cherries can be divided into two major types based on fruit characteristics. Heart-type cherries are ovoid or heart-shaped with a relatively soft flesh, often ripening early. Most of the commercially important cultivars, however, are of the Bigarreau type with firmer, crisp-fleshed fruit, ripening mid to late season. Fruit flesh may be red or yellow, and the skin may be dark (red to nearly black) or light (yellow–red to yellow–white).

Many sweet cherry cultivars grown throughout the world originated in Europe, but a number of important cultivars were selected or bred in local cherry districts. European cultivars grown in the USA are Napoleon (Royal Ann), Black Tartarian, Eagle, Early Purple, Early Rivers, Elkhorn, Hedelfingen, Knight's Early Black, Lyon, and Schmidt. The cultivars Windsor, Van, Sam, Vista, Victor, Sue, Vega, Summit, and Stella were developed in Canada. Chinook and Rainier were developed in Washington. Bing, Lambert, Black Republican, Corum, and Hoskins were selected and developed in Oregon. Chapman, Burbank, Bush Tartarian, and the new cultivars Mona, Larian, Jubilee, Berryessa, and Bada originated in California. Recent introductions include Ulster and Hudson from New York, and Angela from Utah.

The most important sweet cherry cultivars in the western USA, where about 80% of the US crop is produced, have been dark-fruited, crisp-fleshed cultivars: Bing (the leading cultivar in North America), Van, and Lambert. But others may be available because of their use as pollinators or as the result of recent fresh market demand for large, light-colored, and crisp fleshed fruits from cultivars like Rainier. Firmness, size, color, and soluble solids are all important market considerations, and growers in regions where summer rains are prevalent, e.g., the eastern USA and eastern Europe, are at a disadvantage because the main cultivars are often the softer fleshed, rain-cracking resistant types, e.g., Emperor Francis, Hedelfingen, and Schmidt. In these regions, light-fleshed cultivars, Rainier, Napoleon (Royal Ann), Corum, and Emperor Francis, are best for making into maraschino cherries (because the pigment is undesirable), but a few are nevertheless grown for the fresh market. Napoleon is also used for canning. Bing is mainly a fresh-market cultivar, and Lambert is used both for canning and fresh market. Black Republican and other very firm, dark cherries are good for freezing.

Sour cherry fruit are generally soft, juicy, and depressed-globose in shape, but colors may range from the Morello types, with red to dark red flesh and juice, to the Amarelle types with an almost colorless juice and flesh.

Although new cultivars are being tested, there are only a few sour cherry cultivars commonly grown in North America, ranging from the light red Early Richmond, the medium red-skinned Montmorency, to the late dark red English Morello, but Montmorency is still the standard. In western Europe, Schattenmorelle and Sternsbaer are common, but many others are grown in Russia, the former Yugoslavia, Romania, and Hungary. Most, unlike sweet cherry, are more or less self fertile and generally do not require pollinators. Almost all of those grown in the USA and western Europe are harvested mechanically and sold for processing, primarily as a frozen or canned ingredient for use in manufactured food products such as pies but more recently as a dried fruit product, and in Europe and other areas, several other uses have been developing for juice, liqueur, and marmalade production, and combinations with yogurt.

Production Areas

The USA, Russia, and Germany are large producers of both sweet and sour cherry (Table 1). In some areas of northern Europe, sour cherries are, after apples, the second most important fruit grown. Otherwise, within Europe and western Asia, sour cherry production is concentrated in the Ukraine, Russia, Poland, Turkey, and Germany, whereas sweet cherry production is concentrated in Iran, Turkey, Italy, and Germany. Sweet cherry production is increasing in the Southern Hemisphere, in New

Zealand, Australia, and Chile, for shipment to northern markets in their winter season. In the USA, sweet cherry production is mostly in the west, primarily in Washington, but also in Oregon and California. Most USA sour cherry production occurs near the Great Lakes, primarily in Michigan with 70–75% of the US crop, which, with New York, Wisconsin, and Pennsylvania totals 90–95% of the US crop.

Maximum world production values for sweet and sour cherry are approximately 1 450 000 and 1 600 000 tonnes, respectively. Wide annual supply fluctuations, especially regionally, in both sweet and sour cherries characterize production and create high risks in product availability and price change for producers, processors, and marketers. The annual US sour cherry production has ranged, for example, from 63 600 to 141 000 tonnes, but there has been a gradual downward trend in average production since the mid-1960s to about 125 000 tonnes during recent years, with a farm value of about $50 million, but the processed value is at least three times that. Sweet cherry production, however, is increasing, especially as markets develop in Japan and the Far East of the Pacific Rim for fresh cherries grown in the western USA and elsewhere.

Growth and Management

Flowering and Fruit Set

Sweet cherry flowers are in clusters of two to four, usually borne laterally on short spurs on 2-year-old twigs or near the base of longer 1-year-old shoots. Floral initiation takes place in July, after the crop is harvested, and only on buds where the subtending leaves opened relatively early in summer. Flower buds are of the unmixed type and do not give rise to a lateral or bourse shoot. As a result, flowering spurs, unlike those on apples and pears, do not remain productive. Flowers generally have a single pistil but, in very hot summers, may form two pistils that result in undesirable double fruits. With few exceptions, e.g., 'Stella' (and its progeny), and the new 'Lapins' and 'Sweetheart' cultivars, commercial sweet cherries are self-sterile (self-incompatible), and therefore require another cultivar for pollination. There are, however, intrasterile groups, where none of the group will cross-pollinate any other member of the group. Bing, Lambert, and Napoleon are one such group.

Sour cherry flowers develop much like sweet cherry, with buds of two to four flowers on either spurs or lateral buds. Sour cherry cultivars range from compatible to self-incompatible. Montmorency, for example, is only partially compatible, but is always grown without a pollinator. Fruit set, however, clearly limits yield or the fully incompatible cultivars, but overcropping may occur in other cultivars with excessive flowering or fruit set resulting in too few leaves or leaf buds to develop fruit of an adequate size and quality.

In both sweet and sour cherry, flower development and fruit set may frequently be harmed by late frosts,

although sour cherry is hardier and generally blooms later than sweet cherry. Wide annual supply fluctuations are consequently common in major growing areas for both species owing to spring frosts or to low midwinter temperatures where a lack of wood hardiness is a contributing factor. Sweet cherries are less hardy than apples, but some sour cherry cultivars may be as hardy as the apple cultivars McIntosh or Northern Spy. In addition, the best-quality sweet cherry cultivars tend to be more susceptible to rain cracking, and do best in regions with dry summer growing conditions. Fruit also develop a good quality in regions often too cool for peaches or apricots. The climate also dictates that cherries be grown where winter chilling temperatures (about 1000 h for most sweet cherries, longer for sour cherry) are adequate to break rest, and so cherry culture is generally limited to cooler temperate regions.

Tree Size and Rootstocks

Tree size plays a central role in production of quality fruit. Dwarf trees have many advantages: light penetrates better, favoring photosynthesis, and the tree produces more and better fruit; spraying can be done more efficiently, usually with a reduced use of chemicals; and dwarf trees are easier to harvest. Cherries are no exception, but dwarfing rootstocks have not been available for either sweet or sour cherry. The common rootstocks, 'Mazzard' and 'Mahaleb,' only slightly affect tree size, if at all. 'Colt' is similar, and may be somewhat drought- and cold-susceptible. Recently, however, dwarfing rootstocks have been developed in several breeding programs, and these are being tested. For example, of 17 cherry rootstocks developed in Giessen, Germany, most produce relatively large trees, but two of these rootstocks give trees about 25% of the standard, and several rootstocks developed in Belgium may also be promising.

Harvesting and Handling

Sweet cherries are almost all hand-harvested, particularly those intended for the fresh market. Avoiding pitting and bruising throughout harvest, sorting, and packing is a major problem in delivering high-quality fruit to the fresh market. The susceptibility of some white- or yellow-fleshed cultivars to bruising may even require field packing to minimize loss. Mechanical harvesting of sour cherries for processing, however, has been a major technological development that substantially reduces grower costs. A grower and their family plus a group of six to eight high-school students can harvest mechanically as much as 200–300 hand pickers formerly did. The results include huge savings in direct labor costs, large reductions in housing costs, plus substantial savings in direct labor fringe costs. The US sour cherry industry became essentially completely mechanically harvested during the 1970s, although there have since been additional improvements in equipment and techniques.

Some aspects of cherry processing have also changed substantially, which has led to greater efficiencies and product quality in the cherry industry. Almost all sour cherry processors have adopted electric-eye sorting equipment that substantially reduces in-plant sorting labor, and destemming equipment efficiently removes the stems from mechanically harvested cherries. Although picking of sweet cherries for the fresh market is still by hand, subsequent handling has been improved dramatically very recently with the substitution of hydraulic flumes for conveyor belts to reduce bruising and pitting throughout sorting and packing.

Quality Factors

Soluble solids (primarily hexose sugars and sorbitol) and fruit color (depending on the type) are the best indicators of quality for both sweet and sour cherry, although the fruit acid level may be important in sour cherry. Except for soluble carbohydrates, vitamins A and C, and certain flavonoids that may be important as antioxidants in some cultivars, cherries are relatively low in nutrients, but calcium, iron, magnesium, phosphorus, and copper contents are high compared with apple, peach, grape, and strawberry. High-quality sour cherry fruit typically have at least 15% soluble solids, whereas sweet cherries should be nearer 20% (or higher). Standards for harvest and marketing may, however, often be lower. Optimum conditions also often vary with use. To facilitate brining (bleaching in sulfur dioxide solutions for maraschino cherries), fruit may be picked prematurely before color and soluble solids are adequate for the fresh market. Stem-fruit removal force is carefully monitored for sour cherries that will be mechanically harvested, and abscission can be brought on by treatment with ethephon, which releases ethylene, expediting abscission and fruit drop in response to mechanical shaking.

Disorders, Diseases, and Pests

Disorders

In processing brined sweet and sour cherries, the solution pocket problem involves subepidermal splits in the flesh that fill with brine solution and ruptured

cell contents. The time of harvest, degree of turgidity at brining, temperature, or any procedures that reduce either the sugar or water content of the fruit will tend to reduce the problem.

Rain cracking (swelling followed by rupture of the epidermis) of sweet cherries occurs mostly during the harvest period when the fruit is mature or almost mature and has been wet with rain for some time. The primary cause is absorption of water directly through the skin of the fruit, and not through the root system. Cultivar-cracking susceptibility has been tested extensively. In testing, Bing, one of the best quality cultivars, was worst, followed by Napoleon, Lambert, Emperor Francis, Giant, Schmidt, Yellow Spanish, and Montmorency, which did not crack. In another ranking, Bing invariably cracked very badly, and was followed by Lambert, Giant, Gil Peck, and Hedelfingen. In yet another test, Van, Merton Glory, Vega, and Vista were very susceptible, whereas Emperor Francis, Schmidt, and Sam were less susceptible, and Sue, Kristin, Ulster, and Early Rivers were least susceptible. From the long-range viewpoint, breeding programs under way ultimately may produce desirable crack-resistant cherries. Cracking may be reduced by some chemical treatments, e.g., rain activated calcium sprayers, but results with hormones, auxin (NAA, naphthalene acetic acid) and gibberellin (GA_3) applications are equivocal. In some parts of the world, e.g., Norway, covering trees with plastic film has been widely used to avoid cracking, and the method is being tested elsewhere despite the high costs.

Pitting of sweet cherry is a condition in which areas near the surface of the fruit become sunken, forming dimples or pits, and may occur before or after harvest, and there are at least three different sources: usually from bruising during handling, but also from feeding by sucking insects such as the soldier bug, and perhaps from physiologic injuries, e.g., adverse low-temperature stress during postharvest cooling or growing conditions.

Diseases

Bacterial canker, one of the most important sweet and sour cherry pathogens, is caused by two different pathogens, *Pseudomonas syringae* and *P. morsprunorum*, and is characterized by oozing of gum (gummosis) at infection sites. Disease development is most prevalent during the cool, wet periods of early spring. Crown gall, caused by *Agrobacterium tumefaciens*, can affect sweet and sour cherry rootstocks and is characterized by galls forming usually near infection sites caused by wounds, sometimes man-made, e.g., cultivation injuries, or resulting from damage from subterranean chewing insects or rodents. Some rootstocks, however, are only moderately susceptible, and some hybrids may be tolerant. Brown rot, caused by the fungi *Monilinia fructicola* or *M. laxa*, affects both sweet and sour cherries and reduces yield in infecting and decaying blossoms, twigs, and fruit. Fruit decay after harvest is also a problem. The fungi persist in mummified fruit on the tree and the ground, and infection continues from these inocula the following spring. Growing regions with cooler and drier summers provide some relief. Cherry leaf spot, *Blumeriella jaapii* (*Coccomyces hiemalis*), is the most serious disease affecting sour cherry and most ground cherries. Infection occurs in the spring on expanding leaves and continues throughout the season under favorable conditions, e.g., high humidity. Severely infected leaves become chlorotic and abscise, and if defoliation is severe, fruit may not ripen properly, and tree vigor and hardiness are reduced. Powdery mildew (*Podosphaera ocyacanthae*) is similar. Other fungal pathogens may sometimes be important, causing blights, crown or root rots, and replant (orchard reestablishment) problems. Cherry dieback is thought to be a complex of several disorders, one of which may be mycoplasma. X-disease, leafhopper-transmitted and often devastating, is also due to mycoplasma.

Several viruses cause poor vegetative growth, reduce yields, and may even result in tree death, but others are symptomless. Among the most severe is Prunus Necrotic Ringspot Virus, which is pollen transmitted and present in all cherry growing areas of the world. Little Cherry (Prune Dwarf) disease is another pollen-transmitted virus and very destructive. *Prunus* stem pitting disease is caused by the tomato ringspot virus and is spread by nematodes.

Pests

Bird damage can be very serious, and some areas may require protective netting to reduce predation. The major insect pest, the cherry fruit fly passes the winter in the soil as a pupa, adult flies emerge in late spring, and females feed on the surfaces of leaves and fruit and lay eggs in the nearly ripe fruit. On hatching, the larvae (maggots) feed on the fruit flesh. The larvae are easily killed by holding fruit near 0 °C, but fumigation, until recently carried out most often with methyl bromide, may be required to meet quarantine restrictions for shipping overseas. Other pests include black cherry aphid, plum curculio, European red mite, peach tree borer, and two-spotted mite.

Economic Problems and Future Developments

Although the sour cherry industry is facing a serious problem of excessive productive capacity in some years and persistent oversupplies, this industry has adopted new technologies and practices in the last 10 years that substantially improve its cost efficiency and productivity. Much of the newly planted acreage uses efficient trickle irrigation and closely planted orchard systems that also involve hedging techniques. These recent new techniques, especially in combination, provide large increases in yields per hectare and hence substantial reductions in costs.

Considerable genetic diversity still exists in Eastern Europe and Russia, the center of origin for both sour and sweet cherries. Although breeding programs have been limited, exploiting that diversity should do much to overcome the growing, handling, and processing problems that face growers using the industry standards, the sweet 'Bing' and the sour 'Montmorency' in the USA. Sweet cherry growers especially need dwarfing rootstocks and spur types for growth control, and all growers need disease and pest resistance, less self-sterility, and cultivars with a range of maturities so that there are longer seasons for fresh markets. Sweet cherry growers also need raincracking resistance and, for postharvest fresh-market quality, resistance to bruising. Sour cherry growers need new cultivars for diversifying and strengthening marketing options, e.g., fresh and frozen juice products, dyes for cosmetics and the food processing industry, and dry stem scars and small freestone pits to facilitate handling and processing. A combination of new marketing strategies and products for sour cherries and advances in breeding of both sweet and sour cherries would clearly benefit the economic potential of the entire cherry industry.

CHESTNUTS

N A M Saleh, National Research Centre, Cairo, Egypt

Global Distribution

Castanea is a genus of about 12 species native to the north temperature regions, belonging to the family Fagaceae with close botanical relationship to birch. The sweet chestnut (*Castanea sativa* Mill. synonyms: *C. vulgaris* Lam., *C. vesca* Gaertn., and *C. castanea* Karst.) is native from southern Europe, north Africa, and Asia Minor to China. The main center of origin of chestnut is thought to be located in the Ponto-Caucasian region. It is cultivated in many parts of the Himalayas, especially in Punjab and the Khasia Hills. Naturalized in central, western, and northern Europe, and introduced on the Pacific Coast of the USA, Australia, and New Zealand, it is commonly known as European, Spanish, Italian, Eurasian, or sweet chestnut.

Description

Chestnut is a deciduous tree, which reaches heights of up to 30 m. The shiny leaves, of about 20 cm in length, are the most characteristic part of the tree. They are lanceolate, with serrated margins, and have 15–20 pairs of straight, parallel veins. The female flowers are green and rounded, growing at the base of male catkins or in separate round catkins. The male flowers are long, slender, creamy-white and grow upright in catkins. The flowers appear in June to early July. Fruits are in groups of one to three single-seeded nuts, often 2–3.5 cm in diameter. Shiny brown, with paler bases, they are thickly pubescent at the tip, bearing a short-stalked perigynium with its

persistent styles. The seed has a large embryo but no endosperm. Nuts of the European chestnut are generally dark brown in color and often lightly striped. The nuts contain an edible kernel, enclosed in a thin, tough, and astringent skin (pellicle) and surrounded by a spinous, cup-like organ termed a cupule. The latter is a unique feature of the family. The kernel of European chestnut is often deeply grooved, with the fibrous pellicle folded into the grooves, making it difficult to separate this bitter covering from the kernel. There are several cultivars of chestnut, differing in the quality of kernels; the forms grown in India, for example, are inferior to those cultivated in Europe.

Cultivars

In the past, only two cultivars were known: Asplenii-folia with narrow leaves, often linear and irregularly lobed, and Macrocarpa with large fruit. Later, the following examples were cultivated: Marron Combale, Marron Noursillard and Marron Quercy, which originated in France. All have very large, light- to dark-brown nuts and are very productive. Numbo and Paragon are the most frequently grown cultivars in the USA: they have medium-large, roundish nuts of fair quality, and bear regularly. Ridgely, which originated in Dover, Delaware, has fair-sized nuts, of very good quality and flavor, with two to three nuts per bur; it is vigorous and productive. Rochester and Comfort are grown to a limited extent. A number of factors are involved in choosing a given cultivar: (1) resistance to chestnut blight (caused by *Cryphonectria parasitica* Murr.); (2) size of fruit, as large-sized nuts are more profitable to sell; and (3) the ease with which the 'skin' or pellicle can be removed from the kernel.

Commercial and Industrial Importance

Uses

Chestnuts are grown as ornamentals and for the edible nuts. Trees often bear nuts 2 or 3 years after plantation. Propagation is by budding or grafting on chestnut stocks. They are naturally tolerant of acid soils and present no special cultural difficulties on well-drained land. The chestnut blight may be injurious or fatal to susceptible species, and weevils may be troublesome.

The Fagaceae family is the source of some of the most important hardwood timbers of the world, the most notable being oak, beech, and chestnut. The timber of the sweet chestnut is almost equal to oak in strength and durability, and the one is often substituted for the other. Coppiced chestnut is in great demand for fencing, which lasts for very many years, even when not treated with creosote. The relatively hard, durable, fine-grained wood is easy to split but not easy to bend (density, 593–865 $kg\,m^{-3}$). It is used for general carpentry, railway ties, and the manufacture of cellulose. The bark and wood are used for tanning. Wood and burs may be used for firewood or for the production of charcoal.

European chestnuts are grown for the kernels of the nuts, and are extensively eaten by humans and animals. The nuts are used as a vegetable, boiled, roasted, steamed, puréed, or in a dressing (stuffing) for poultry and meats. In some European mountainous regions, chestnuts replace wheat and potatoes in the form of chestnut flour bread, and mashed chestnuts. Flour made of ground chestnuts is said to have provided a staple ration for the Roman legions. In Italy, chestnuts are prepared like a stew with gravy. Dried nuts are used for cooking purposes in the same way as the fresh nuts, or eaten like peanuts. They are also used in brandy, in confectionery, in desserts, as a coffee substitute, for thickening soups, and as a source of oil. The largest nuts, called marron, command the highest price and are used to make the famous French delicacy, *marrons glacés*. Culled chestnuts are safely used for fattening poultry and hogs, as well as for feeding cattle.

Yields

Chestnut trees begin to produce at an early age, and can produce two tons or more of fresh nuts per hectare. Yields average from 45 to 136 kg of nuts per tree. In 60–80-year-old stands in Russia, yields average 770 $kg\,ha^{-1}$ and up to 1230 $kg\,ha^{-1}$ in better stands. Italy reports *c.* 1100 $kg\,ha^{-1}$, France *c.* 1500–2200 $kg\,ha^{-1}$, and Spain *c.* 2800 $kg\,ha^{-1}$. In the best years, 5000 $kg\,ha^{-1}$ are reported. Nuts are marketed to a limited degree, but are mostly locally cultivated and used.

Biological Properties

The Greek physician Dioscorides noted the *Castanea sativa* as a tree was a fruitful source of medicinal remedies. The leaves, twigs, bark, flowering catkins, and spiny cases of the nuts are good astringents, which cause mucous membranes and skin to contract. They were therefore used to control bleeding, aid in healing wounds, and against diarrhea. The leaves, which contain demulcents, were used in teas to soothe irritated throats and in relieving symptoms of coughs and colds. The nuts are also reported in folk remedies for the treatment of fever, hematochezia, infections, sores, inflammation, wounds, sclerosis, kidney ailments, myalgia, nausea, and stomach ailments.

Sweet chestnut (*C. sativa*) is related to the beech family (Fagales) with close botanical relationship to birch, which is known as a major pollen allergen in Europe. It is not surprising that *Castanea* pollen can cause allergies – particularly in areas where *Castanea* trees are frequently found. Southern Switzerland (Lugano) is reported to experience the highest *Castanea* pollen loads and hence high *Castanea* allergy rates. It is reported that patients allergic to pollen are affected by oral allergy syndrome (allergy to food resulting from contact between food and the oral mucosa). A reported case of oral allergy syndrome to chestnut appears to be a manifestation of immediate immunoglobulin E-dependent hypersensitivity. It was also reported in a second study that a patient with latex allergy has a high risk of contact urticaria or even anaphylaxis to the related fruits such as chestnut. Class I chitinases are relevant allergens of avocado and chestnut, and could be the panallergens responsible for the latex-fruit syndrome.

Chemistry

General

C. sativa leaves proved to contain two flavonoid aglycones (quercetin and myricetin) along with their glycoides. A study of *Castanea* species indicated that catechol tannins were more abundant in buds at the tip and base, while bud scales contained about 80% of the tannis of the whole bud. The leaves, bark, and wood also contain tannins. High concentrations of ellagic acid were found to be present in the hardwood of European chestnut (89 mg g^{-1} wood) as compared to those of a number of red and white oaks (19–63 mg g^{-1} wood). After mimosa and quebracho extracts, chestnut extract is the third most important vegetable tannin used for leather production. It is only the wood (8–13% tannins), however, that is used in the tanning industry and for commercial preparation of the chestnut extract. The chestnut bark contains a number of polyphenols based on ellagitannins, galloylesters, phenolic glycosides, and hamamelitannins. Countries manufacturing the extract are France, Italy, and the USA. Commercial liquid extracts contain 29–49% tannin, while solid extracts contain 56–76% tannin.

Chestnut seeds are desiccation-sensitive and have high moisture contents in the mature stage. For this reason, they are possibly better targets for pathogenic fungi than nonrecalcitrant seeds, which might explain in turn why chitinases are abundant and stable proteins in chestnut cotyledons. A study of class Ib endochitinase from *C. sativa* cotyledons showed *in vitro* antifungal properties when assayed against *Trichoderma viride*. (*See* **Tannins and Polyphenols**.)

Nutritional Composition

Recent reports of the US Department of Agriculture for nutritional composition of unpeeled and roasted chestnut seeds are outlined in Table 1. The chemical composition is similar to that of wheat, and the starch is easily digested after cooking. Spanish chestnuts are reported to contain 2.87–3.03% ash, 9.61–10.96% total protein, 2.55–2.84% fiber, 73.75–77.70% total nitrogen free extract, and 7.11–9.58% fat. Chestnuts from 19 natural stands in southern Yugoslavia showed a total fat content of 4–5%; oleic and linoleic acids predominated, followed by palmitic acid. (*See* **Wheat**.)

Handling and Storage

Harvesting

The nuts fall to the ground within about a week after they have become ripe in the hulls. Once fallen, they are subject to depredation by birds, squirrels, and mold. Traditionally, mature chestnuts have been gathered from the ground after they fall. Some cultivars stick, and shaking or jarring the limbs is useful. In other cultivars, burs open, and nuts fall to the ground. Burs that fall and do not open can be made to shed their nuts by pressure of the feet, or by striking with a small wooden mallet. Some harvesters use heavy leather gloves and twist nuts out of burs by hand.

Unopened burs stored in a humid, cool 12–18 °C location will continue to mature and open in a week. In gathering nuts, the collector usually has two pails or containers, one for first-grade, perfect nuts, the other for culls. Some sort of harvest mechanization is essential for the development of a chestnut orchard industry.

Storing

Fresh chestnuts contain 40–50% carbohydrate, mostly in the form of starch, about 5% oil, 5% protein, and 40% moisture. They are highly perishable because they lose water rapidly at normal room temperature and humidity, causing the kernel to become hard and incapable of germinating. Numerous fungi and bacteria attack the nuts, causing decay and spoilage. High temperatures, as a result of remaining in the sun, cause rapid kernel deterioration. The nuts should be stored at 0–4 °C under conditions of high humidity but no free moisture. (*See* **Storage Stability: Mechanisms of Degradation**.)

Table 1 Nutrients of unpeeled and roasted chestnuts

Nutrient	*Units*	*Value per 100 g of edible portion (unpeeled)*	*Value per 100 g of edible portion (roasted)*

Nuts should be picked up every morning and stored in sacks, if they are to be shipped at once. If they are to be kept for a while, they should be piled on the floor to sweat. The pile should be stirred twice a day for 2 days; then the nuts should be sacked. Nuts should always be stored in a manner so that air can circulate freely. A practical method for storing small quantities of nuts is to mix the freshly harvested nuts with dry peat moss in plastic bags, close the bags, and refrigerate. Properly stored, they will keep satisfactorily for 6 months and have been kept for as long as 3 years.

Nuts to be eaten raw should be 'cured' for several days by allowing the kernel to dry to a spongy texture. The amount of free sugar and sweetness is maximized in this way.

Seed Propagation

Chestnut seeds require a moist cold treatment of at least 1–2 months at 0–4 °C to insure good and uniform germination. Stored nuts should not be subjected to temperatures much below freezing (irreversible damage begins to occur around − 4 °C) or above 7 °C.

CHICORY BEVERAGES

K Löhmar and V Theurillat, Nestlé Product Technology Centre Orbe, Orbe, Switzerland

Introduction

Chichorium intybus L., the wild chicory, has been adapted to a 2-year vegetation cycle. The cultivation of chicory started in several European countries at the end of the eighteenth century and spread from there to other countries, e.g., the USA, India, and South Africa. Only the root of the chicory plant is used for making various beverages; the plant is shown in **Figure 1**. This article describes the cultivation of chicory, the processing of the roots to roast and ground blends and to soluble beverage powders in which chicory is an ingredient. Furthermore, the composition of chicory and changes taking place during processing are discussed.

Figure 1 Photograph of a harvested chicory plant. Reproduced from Chicory Beverages, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Cultivation, Drying, and Roasting

In central Europe, sowing is at the end of April or at the beginning of May. Three types of seed are

employed: ordinary naked seed, seed coated with dyes and fungicides, and seed pelleted with nutrients, fungicides, and insecticides. Coated and pelleted seeds facilitate the control of the right sowing depth. Protection and the conditions for germination of the seed embryo are optimal in pelleted seed.

In order to produce chicory roots of a suitable size for industrial processing, a space of about 600 cm^2 per plant is recommended. The distance between the seed rows is usually 45 cm; pelleted seeds are drilled within the row at a distance of 6 cm. After emergence and when the plants have reached the three- or four-leaf stage, they are thinned out to distances of about 14 cm in the row. The plant density should not exceed 160 000 plants per hectare in order to attain the right root size and a good field yield.

Chicory requires a vegetation period of about 160 days. In Europe, the chicory harvest is from the end of September to the middle of November. Machines are used which carry out the entire harvesting operation: cutting of leaves, lifting of the roots, their collection in containers, and transfer to trailers. The yield of chicory roots varies from 30 to 45 t ha^{-1}, depending on the climate, weather, and soil conditions. The harvested chicory roots are delivered to the drying plant, where the quantity of roots is determined by weighing the trailer loaded and unloaded. The farmers are paid for the root weight reduced by the amount of soil present. The chicory roots are stored until processing in long, extended heaps with heights of up to 3 m.

Figure 2 illustrates the processing of the fresh chicory roots to soluble powder. The drying of chicory is a seasonal operation which starts in central Europe at the beginning of October. The installation for washing the roots comprises several compartments; it operates on the counterflow principle and rinses the roots with clean water during discharge. The roots are cut into slices (6×22 mm cross-section and of varying length) and cubes (lengths of sides between 12 and 16 mm). Chunks are also produced, having a thickness of more than 16 mm.

Drying of chicory reduces the water content from about 75 to 12%. Dried chicory with a water content of less than 12% is considered to be stable and can be kept in storage for several years. A rotary drum drier is the most frequently used equipment for drying. It is equipped with baffles inside and works continuously. Only those driers furnished with gas firing allow direct contact of the combustion gases with the cut material. The chicory moves in the slowly rotating drum in the same direction as the hot air is drawn through. The temperature of the hot air at the inlet reaches 400–500 °C; at the outlet it is about 120 °C. The dried chicory leaves the drum at a temperature of about 80 °C. The necessary cooling and the final drying are accomplished on well-ventilated conveyor belts. The chicory fragments produced through breakage and abrasion are sifted off.

Chicory is roasted in batches using drum roasters and long cycle times. Since smaller chicory pieces are roasted faster than larger ones, a narrow size distribution of the dried chicory should be used to obtain a homogeneous roast. The rotating drum is heated by a gas burner and charged with chicory.

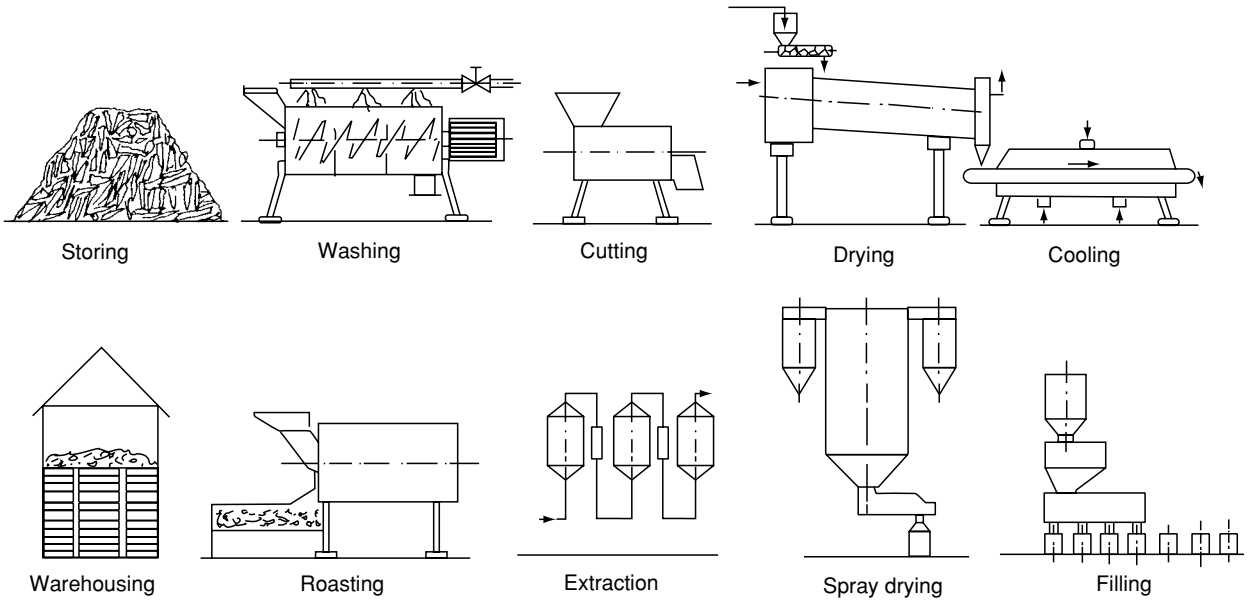

Figure 2 Processing of fresh roots to soluble powder. Reproduced from Chicory Beverages, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Vegetable oil in a quantity of about 1% of the chicory load is added to bind the dust and to prevent sticking of chicory to the roaster wall and baffles. The combustion gases are first directed around the drum and are then drawn through the drum. The moisture in the chicory is driven off and is removed by the combustion gases. In the later stages of roasting, the heat supply is reduced by steps and the heating gases are only drawn outside around the drum. The actual roasting takes place at temperatures of 170–180 °C. After a roasting time of 60–80 min the chicory reaches the required color and is discharged into the cooling screen. The total roast loss is in the range of 15–25%.

Roast and ground chicory is usually blended with coffee or cereals and marketed as coffee mixture or coffee substitute. (*See* **Coffee**: Roast and Ground.) Otherwise, it may be extracted and dried.

Extraction and Spray Drying

Roasted chicory is more frequently extracted in blends with roasted coffee or roasted cereals than alone by itself. This extraction with coffee or cereals is done in percolation batteries which consist of about six columns connected in series. Hot water is pumped into the column which contains the most spent roasted material, flows in a counterclockwise fashion through the plant and finally enters the column with fresh roasted material. The concentration of the draw-off extract varies from 15 to 30% and depends on, among other factors, the composition of the roast blend. Each column with an exhausted blend is replaced by one with a new roast blend. The feed water temperatures may be up to 180 °C with blends of coffee and chicory, or up to 140 °C with blends of cereals and chicory. Heat exchangers placed between the columns lower the extract temperature in stages down to 90 °C in the column with the fresh roast blend. The extraction yield and the draw-off concentration increase with higher temperature profiles. Since chicory contains a high proportion of soluble carbohydrate, it can be extracted efficiently at temperatures below 100 °C.

The extraction of roasted chicory by itself is performed in twin-screw conveyors or hydraulic piston presses. Pure chicory extracts are, for the most part, subsequently mixed with coffee or cereal extracts. The liquid extracts are sometimes concentrated before spray drying or mixed with glucose syrup in order to improve the drying properties of the extract. (*See* **Coffee**: Instant.)

The spray drying of the liquid extracts with soluble solid contents of 30–45% is conducted in tall towers in which the extract is pumped under high pressure through nozzles and is dispersed into small droplets. In the upper part of the tower the water in the droplets evaporates in a flow of hot air; in the lower part the exhaust air is drawn off and the separated powder is collected in bins. The instant powders, which have a moisture content of about 3%, are filled into water vapor-tight containers such as jars with sealable lids.

Composition and Varieties

The composition of two chicory varieties based on dry matter is given in Table 1. The water content of fresh chicory roots is in the range 70–80% and is influenced by the variety, the soil, and weather conditions. The solid matter of finely ground chicory roots is extractable in boiling water to an extent of 80%. Chicory is characteristic in that the main constituent of the roots is the polysaccharide inulin. This reserve carbohydrate with a molecular weight of approximately 6000 comprises up to 65% of the dry matter of the root. About 35 fructose molecules are linearly linked together with one glucose molecule at the end. The polymer chain of inulin is completed by a sucrose molecule and, therefore, it has no reducing power. In addition, chicory roots contain further carbohydrates, including usually contents of about 5% sucrose and about 15% fiber substance. During extraction, the fiber remains insoluble in the residue. Nitrogenous compounds amount to about 6% and comprise protein and free amino acids. The content of organic acids is about 3%, of which malic acid and citric acid are about 30% each. Mineral substances are present at about 5% in the root, the most important components being potassium, calcium, phosphate, and sulfate. Furthermore, the roots contain lactucin and lactucopicrin in a total amount of about 0.4%. These sesquiterpene lactones are

Table 1 Composition (grams per 100 g) of chicory varieties

	Variety superior in

responsible for the bitter taste of fresh and dried chicory. Both lactones are completely decomposed during roasting. (*See* **Acids**: Natural Acids and Acidulants; **Amino Acids**: Properties and Occurrence; **Carbohydrates**: Classification and Properties; **Minerals – Dietary Importance**; **Protein**: Chemistry.)

It is known from screening tests of chicory varieties that a negative correlation exists between the root quality and the field yield. Breeding of chicory aims at combining both attributes. A variety with a superior root quality has a higher content of inulin, and dry and soluble matter, and, conversely, a variety with a superior field yield has a high root weight, and a high content of protein and minerals. For these two opposing chicory varieties, yields of fresh roots and calculated yields of dry matter and soluble solids are given in Table 2.

Changes in Composition During Processing

Higher temperatures in the root heaps during longer storage periods induce the start of hydrolysis of the polysaccharide by the enzyme inulinase present in the roots. The generated sugars favor loss of material as a result of respiration of the roots and also by decay through microbial activity. Fresh roots should, therefore, not be stored for long periods at high temperatures in order to minimize inulin hydrolysis and other causes of losses. The ideal storage conditions would be temperatures of about 5 °C and air humidities of about 95%, which normally cannot be achieved in practice.

Very high temperature profiles during drying cause puffing of the wet chicory pieces. Hollow spaces remain inside after drying which reduce the firmness of the cubes or slices and increase the tendency to break more easily during transport. Chicory pieces with larger dimensions usually leave the drum drier still with moist centers. During storage, enzymatic hydrolysis of the inulin proceeds at a rate dependent on the moisture content, and the sugar content increases. Dried chicory should normally show a bright color, a low content of reducing sugar, and a high content of extractable solids and inulin. Darker outer colors and burnt edges of dried chicory enhance water uptake during storage and make it more difficult to obtain a homogeneous roast. Higher sugar contents of dried chicory are sometimes accepted in view of the taste of the product, but they impair further processing due to the higher hygroscopicity.

Roasting of chicory results in the formation of specific color, flavor, and aroma compounds which are characteristic of the product. The constituents of chicory, such as inulin, sucrose, protein and free amino acids, partially or totally undergo various changes. Most alterations in the chemical composition are connected with two browning reactions – the Maillard reaction and the pyrolysis of the inulin. The Maillard reaction takes place between the reducing sugars and the amino groups of free amino acids and proteins, giving the melanoidins (brown polymeric materials) and volatile aldehydes. These give chicory its typical flavor. The pyrolytic degradation of inulin yields high-molecular-weight caramel compounds and low-molecular-weight carbonyl compounds, such as aldehydes, ketones, and organic acids. These compounds likewise contribute to the color and the taste of roasted chicory. (*See* **Browning**: Nonenzymatic.)

The analytical values in Table 3 illustrate the changes in the carbohydrate composition and the free acidity during chicory roasting. The decomposition of inulin and the formation of free acids steadily proceed with increasingly darker roasting. The contents of reducing sugars, of fructose, and of glucose first increase during roasting, reach a maximum, and decrease again. The content of reducing sugars in, for example, cubes or slices reaches a maximum value of 15%. Insoluble matter is formed by the strongly exothermic pyrolysis of inulin and lowers the amount of extractable material, especially of dark roasted chicory. Light and medium roasted chicory are

Table 3 Characteristic values (grams per 100 g of dried matter) of dried and roasted chicory

		Roasted		
	Dried	*Light*	*Medium*	*Dark*

[a]Defined as millimoles of sodium hydroxide per 100 g of soluble solids.
[b]Grams per 100 g of dry matter.

extractable in boiling water to about 80%, whereas the extractable content of dark roasted chicory is lower. In addition, the heat generated inside the chicory pieces by the pyrolytic reaction accelerates the roasting and leads to charring of the cores.

During extraction, free acids already present in roasted chicory hydrolyze inulin to monosaccharides. Fructose, itself thermally unstable, is subjected to further decomposition, the extent of which depends strongly on the extraction conditions. Shorter extraction times and lower water temperatures are considered favorable to minimize the amount of free fructose and free acids in the chicory extracts.

The analytical values stated in Table 4 show that temperatures below 100 °C should be applied for the extraction of chicory.

Fructose has a steeper sorption isotherm than inulin and is very hygroscopic. As a result, light roasted chicory with more inulin and less fructose is preferably used for the production of instant powders. Chicory extracts have a higher hygroscopicity and an increased stickiness, in contrast to coffee or cereal extracts. This means that, compared to pure coffee, the output capacity of the spray drier is reduced by extracts produced from roasted coffee–chicory or cereal–chicory blends and, in particular, by pure chicory extracts. (*See* **Fructose**.) In addition, spray drying of extracts containing chicory-soluble solids is more difficult and requires certain precautions.

Taste and Physiological Effects

Infusions of light roasted chicory have a sweetish and mild flavor. In combination with coffee or cereals, the chicory imparts to the beverage a smooth and round taste. With darker roasting of the chicory, the sweet taste diminishes and the strength, astringency, acidity, and bitterness of the brew increase.

Information concerning the physiological effects of roasted chicory is exceedingly scarce. A lot of practical advice compiled over the years, concerning natural medicine, is found in old literature. According to this knowledge, infusions of roasted chicory are beneficial and contribute to the well-being of the body. Chicory brews are supposed to be mild diuretics and are said to have sedative effects. It has been known for a long time that chicory promotes digestion by stimulating the secretion of the gastrointestinal glands and especially by increasing bile production. Some investigators claim that the digestion of milk is facilitated by the addition of chicory because the finer milk particles formed in the stomach are more easily digested. Modern scientific studies confirm these conclusions. Tests performed on animals and humans substantiate the fact that chicory is perfectly safe and has no adverse effects. Some physiological effects were thought to be related to the sesquiterpene lactones contained in fresh or dried chicory. These lactones are decomposed during roasting and therefore are absent from roasted chicory.

Soluble chicory powders can contain up to 60% inulin or oligomer compounds derived from it. Inulin and fructose oligomers are soluble dietary fibers. This means that they are not hydrolyzed in the small intestine. In the intestine, however, they are fermented by the microflora, so a considerable amount of bacterial mass is produced and bifidobacteria development is promoted. These fibers are well tolerated. As inulin is not hydrolyzed in the stomach and the small intestine, it has no influence on the blood glucose and can be used in diabetic diets. (*See* **Coffee**: Physiological Effects.)

Use as an Adulterant and Analysis

Roast and ground coffees or instant coffee powders may be adulterated by mixing chicory with coffee after roasting, before extraction or even after drying. Microscopic, physical, and chemical methods are applied to detect and to analyze the adulteration of roasted or soluble coffee with chicory. Cell structures from chicory can be identified by the examination of suspicious samples of roasted coffee under the microscope. The extractability of roasted coffee and roasted chicory differ enormously: finely ground coffee is extractable in boiling water to about 30%, chicory to about 80%. From the increase in coffee extractability, the portion of chicory in roast and ground coffee can be estimated. Several methods depend on the analysis of specific constituents present in either coffee or chicory, but not both. The determination of the content of total fructose appears most suitable, since the content of fructose in chicory is relatively high compared to the content of caffeine and chlorogenic acids in coffee. Although all these methods detect the adulteration of coffee, it is

difficult to specify the blend quantitatively. (*See* **Adulteration of Foods:** History and Occurrence.)

Nutritional Requirements

B Caballero, Johns Hopkins University, Baltimore, MD, USA

Nutritional Requirements

Assessment of Nutritional Status

Normal growth is one of the most important indicators of nutritional status. Monitoring of weight and height (or recumbent length when appropriate) should be performed at regular intervals, with frequency depending on the age of the child. Infants are usually measured monthly during the first 6 months of life, and at bimonthly intervals during the remainder of the first year.

However, it is difficult to determine the adequacy of children's diet only by physical examination. Many clinical signs of nutrient deficiencies only appear in the advanced stages. Thus, interrogation on food habits and intake, and even use of dietary records may be necessary when the possibility of inadequate intake is considered.

Nutrition from 1 to 5 Years of Age

The first 5 years of life are among the periods of more rapid growth. Major changes also occur in the relative size of the body regions and in the proportions of water, fat, and lean mass tissues. Over these years, nutrition must accommodate a changing pattern of energy, protein, and micronutrient needs. (*See* **Infant Foods:** Weaning Foods; **Infants:** Weaning.)

The growth pattern after the first year of life shows periods of both rapid and slow gain in stature and weight. Children tend to grow 12 cm during the second year, 9 cm in the third, and 7 cm or less thereafter. (*See* **Growth and Development.**)

After the first year, healthy children should be able to eat virtually the same as adult members of the family. Indeed, it is at this stage that family dietary practices have the most significant impact on the child's preferences and food intake patterns. It is thus important for parents to be aware of their role in educating and forging sound dietary habits in their children.

The feeding behavior of children at this age is much more variable than previously. Children have a much wider repertoire of eating behaviors, and should be allowed, within reason, to practice them. As a rule, a healthy child should be allowed to eat as much or as little as he or she wishes. Forced feeding or threats around food do not lead to good nutrition, but rather to sometimes long-term confrontation, to the detriment of actual food intake. Furthermore, there is evidence that healthy children have a quite accurate mechanism of maintaining energy balance by compensating for deficient or excessive food intake over periods of days or even weeks. (*See* **Infants:** Feeding Problems.)

Nutrition over 5 Years of Age

The growth pattern between 5 and 10 years of age is usually more stable than during earlier years,

averaging about 5 cm per year. Weight gain is around 2 kg per year at 5–6 years of age, and increases rapidly as puberty approaches, reaching as much as 4 kg per year by age 10. Physical activity also increases markedly during school years, as children become more involved in sports and outdoor activities in general.

Recommended Nutrient Intake

Gender differences in nutrient requirements are usually not substantial until preadolescence and menarche. At that time, genders begin to diverge in terms of body fat and skeletal muscle accumulation, which are to be reflected in nutrient requirements.

Protein and Energy Requirements

Dietary energy needs of infants are usually estimated from the *ad libitum* energy intake of healthy children growing at a normal rate. In older children estimates can be derived, as for adults, from equations based on resting energy expenditure and body size. Since recommended energy intakes should match energy expenditure (with normal growth and adequate physical activity), the best approach to estimate energy needs would be from measurements of daily energy expenditure. Until recently, the number of studies measuring daily energy expenditure in free-living individuals has been small, due mainly to the cost and complexity of the doubly labeled water technique. But the increasing number of studies with that technique is now approaching a critical number that will allow ongoing revisions of recommended energy intakes to be based on direct energy expenditure measurements. Until these revisions (by the US Institute of Medicine, the World Health Organization, and others) are released, existing recommendations are presented in Table 1.

For protein, estimates of requirements continue to be based primarily on patterns of dietary protein intakes of normal infants and children, with the consideration of nitrogen balance data when available. Requirements for indispensable amino acids have also considered the information obtained by stable isotope tracer studies (Table 2). (*See* **Protein**: Requirements.)

Vitamins and Minerals

Recommendations for most vitamins and minerals were recently revised by the US Food and Nutrition Board (*See* **Dietary Reference Values**), and are presented in Table 3. For nutrients and age groups for which there are no sufficient data to determine the traditional recommended dietary allowance (RDA), the committee introduced the adequate intake (AI). This variable indicates observed intakes in healthy groups, and thus is assumed to be adequate. It can be used as an RDA, but it is obviously less accurate.

Food Additives

Over the years, several investigators have proposed that certain food additives could have a major behavioral impact on young children. But in spite of many years of research and controversy, there is no compelling evidence supporting those claims. Nevertheless, there are documented intolerances to some additives such as sodium glutamate and sulfites in adults, which can also occur in children.

Dental Development

Dental development is another important milestone during school age. Dental caries can appear early, and some surveys found that over 50% of children aged 3–4 years of age had dental caries. Major nutrients

Table 1 Recommended energy and protein intake in children aged 1–10 years

Selenium (μg day^{-1})	**20**	**30**

This table presents recommended dietary allowances (RDAs) in **bold** type and adequate intakes (AIs) in ordinary type followed by an asterisk (*). RDAs and AIs may both be used as goals for individual intake. RDAs are set to meet the needs of almost all (97–98%) individuals in a group.
[a]As cholecalciferol. 1 μg cholecalciferol = 40 IU vitamin D.
[b]In the absence of adequate exposure to sunlight.
[c]As niacin equivalents (NE). 1 mg of niacin = 60 mg of tryptophan; 0–6 months.
[d]As dietary folate equivalents (DFE). 1 DFE = 1 μg food folate = 0.6 μg of folic acid from fortified food or as a supplement consumed with food = 0.5 μg of a supplement taken on an empty stomach.
[e]As α-tocopherol. α-Tocopherol includes RRR-α-tocopherol, the only form of α-tocopherol that occurs naturally in foods, and the 2R-stereoisomeric forms of α-tocopherol (RRR-, RSR-, RRS-, and RSS-α-tocopherol) that occur in fortified foods and supplements. It does not include 2S-stereoisomeric forms of α-tocopherol (SRR-, SSR-, SRS-, and SSS-α-tocopherol), also found in fortified foods and supplements.

related to dental development are fluoride, and vitamin D, calcium and phosphorus (enamel formation), vitamin A and C, zinc, and folate (gum integrity). Adequate intake of these nutrients is usually not a problem in developed societies. Of more practical importance are, perhaps, a number of dietary habits which may favor dental caries: excessive use of sugar and other fermentable carbohydrates, the nursing bottle syndrome (the baby is allowed to fall asleep while sucking a sweetened beverage, or even human milk), and poor dental hygiene. (*See* **Dental Disease:** Etiology of Dental Caries.)

A Prudent Diet for Children

There is growing awareness of the importance of diet in the development of chronic diseases, e.g., obesity and coronary heart disease. A number of changes in the current dietary practices of developed societies have been proposed, although the long-term impact of these changes is still unclear. There is also the question of how early in life a 'prudent' diet should be adopted. Special issues of nutrition in childhood, such as nutrient density, protein digestibility, and micronutrient requirements, need to be recognized. For example, there must be awareness of the potential negative impact that high-fiber or all-vegetable diets may have on protein digestibility, mineral bioavailability, and energy density. (*See* **Dietary Fiber:** Effects of Fiber on Absorption.)

Nutritional Problems

D Bentley, Imperial College of Science Technology and Medicine, London, UK

Rickets

Deficiency of vitamin D in the growing child leads to rickets (**Figure 1**), a metabolic disorder common in English and American polluted cities during the Industrial Revolution. The term indicates a failure in mineralization of growing bone or osteoid tissue. The typical clinical picture was well described in the seventeenth century and the cause was secondary to poor nutrition, arising from both financial and educational poverty as well as the result of a hazy, smoggy atmosphere with little exposure to sunshine or ultraviolet (UV) radiation. Adequate sunshine

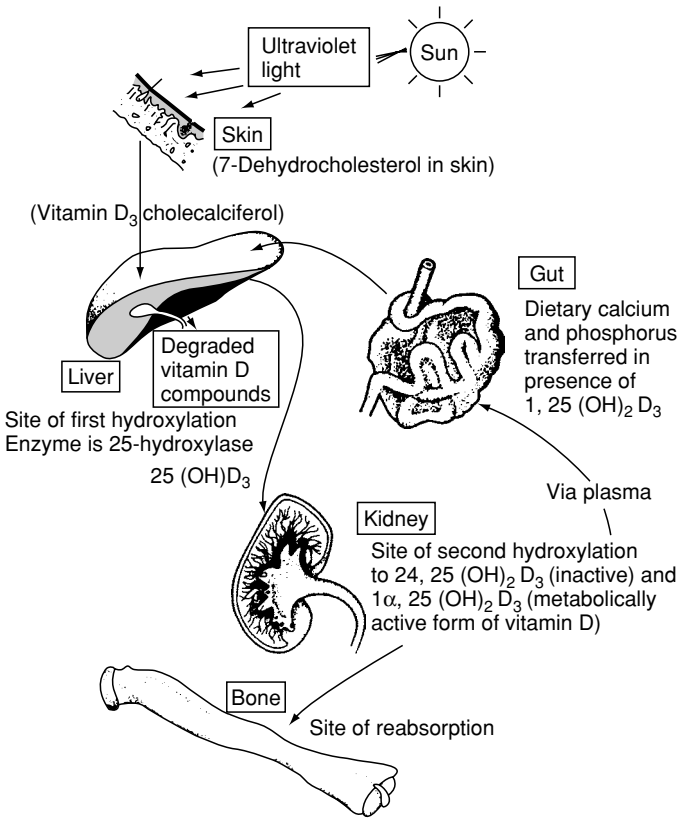

Figure 1 Vitamin D is derived from the diet and from the effect of ultraviolet light on the skin. It is hydroxylated in the liver ($25(OH)D_3$) and undergoes a second hydroxylation in the kidney to the biologically active form, 1,25-dihydroxycholecalciferol ($1\alpha 25(OH)_2D_3$), which acts on the gut and bone to increase gut absorption. $24,25(OH)_2D_3$ is 24,25-dihydroxycholecalciferol. Courtesy of Professor P. Byrne.

is not the entire explanation because rickets was common in the 1940s in southern California as it is today in India. Furthermore, from October to March no UV light reaches the earth's surface in the UK and consequently vitamin D is not formed in the skin during that period. The incidence of rickets declined after the 1927 discovery that UV irradiation of ergosterol, a vitamin D plant derivative, increased its antirachitic effect.

Skin photochemical synthesis is the major source of vitamin D, and tanning prevents further formation. Black infants have lower circulating vitamin D levels than white children. This is because white skin allows vitamin D-inducing wavelengths to pass through but black skin filters UV radiation under wavelengths of 436 nm. With the development of vitamin D-fortified milks and milk products, rickets has decreased in incidence. However, in some countries, cows' milk is not routinely fortified. Human milk contains almost 20 times more of this vitamin than unmodified whole cows' milk, yet in the USA a revival in breast-feeding has been linked to an increase in cases of nutritional rickets.

Rickets was described in Asian immigrants in Glasgow, Scotland in 1956. An estimate of the 1977 incidence of clinical overt rickets among UK Asians aged 0–16 years was 4 cases per 1000 in London and 10 per 1000 in the Midlands and the north of England. Rickets seemed to increase in the UK from 1960 to 1973, then decreased but has returned to the West Midlands in the UK (2002). Pregnant Asian women with osteomalacia risk having infants with neonatal convulsions as a result of hypocalcemia. Typically rickets is seen in breast-fed premature and growth-retarded infants and is especially prevalent in those born to Asian mothers in the UK. Phytic acid is a modifier of calcium absorption and one source is unrefined cereals such as chapattis (unleavened breads). This has been implicated in the causation of Asian rickets. High-phytate diets will increase vitamin D requirements. Infants on macrobiotic diets (e.g., unpolished rice, pulses – rich in fiber) and who do not receive vitamin D supplements are at risk. Rickets has also been described in the fetus. Adolescent Asian rickets, characteristically in children 8–14 years old, may present with gross genu valgum

(knock knee) and aching joints. Other clinical features include leg bowing, poor linear growth, delayed dental eruption, and impaired closure of the skull's fontanelle. Other skeletal deformities may develop.

Causes

The causes of rickets in children are as follows:

1. Inadequate exposure to sunlight
2. Inadequate vitamin D intake
3. Malabsorption of vitamin D, e.g., celiac disease, short-bowel syndrome, bacterial overgrowth in the bowel, deficiency of bile salts, cystic fibrosis
4. Increased enzyme activity; anticonvulsants (phenobarbital and/or phenytoin) will increase metabolic degradation of $25(OH)D_3$ by stimulating hepatic microsomal enzymes
5. Decreased enzyme activity: vitamin D-dependent rickets (pseudovitamin D deficiency; deficiency of the renal enzyme, 25-hydroxyvitamin D_1 α-hydroxylase)
6. Acquired deficiency of 1α-hydroxylase, e.g., chronic renal failure
7. Failure of 25-hydroxylation, e.g., chronic liver failure
8. Fanconi's syndrome – phosphaturia: the principal component of the disorder results in hypophosphatemic rickets

Diagnosis

Early manifestation of rickets includes:

1. Craniotabes (skull feels like a ping pong ball)
2. Frontal bossing and thickening of the skull (hot cross bun appearance)
3. Rachitic rosary (enlarged costochondral junctions of the ribs)
4. Widening of the epiphyses at the wrists

In active rickets, there is cupping and fraying of the distal ends of the forearm and parts of the skull are demineralized. There is an increased distance between distal ends of the forearm bones and the metacarpals.

Biochemical Findings

The following biochemical findings are characteristic of rickets:

1. Increased plasma alkaline phosphatase (isoenzyme originating in bone)
2. Phosphate reduced or normal
3. Calcium reduced or normal
4. Serum parathyroid hormone normal or increased

Treatment

Adequate amounts of dietary calcium and phosphate should be insured with vitamin D therapy.

Obesity

It is somewhat ironic that the commonest nutritional problem in affluent countries is obesity, in sharp contrast to the undernutrition in less privileged societies. Overweight and obesity are important public health problems and are increasing at an alarming rate. Obesity is the presence of excessive body fat and the visual identification of severe obesity is readily made. Weight in itself is an unsatisfactory way to assess fatness and particularly so in younger children where there is a poor relationship between weight and fat. (*See* **Obesity**: Etiology and Diagnosis.)

In adults one indicator of obesity is Quetelet's index (QI), which determines the body mass, or $(\text{weight})/(\text{height})^2$, but in children it is less useful because of a variation with age. The weakness of the QI is that it fails to take account of the distribution of body fat which influences health risks. However, this parameter can be related to a theoretical child with height and weight upon the 50th centile, and the measure then gives a percentage value; 90% indicates underweight, 90–110% normal weight, 110–120% overweight, and > 120% obese.

Clinical examination needs to include an assessment of pubertal development and anthropometry, which must be carefully evaluated. In addition, the observer ought to be aware of particular disorders associated with obesity, e.g., Down's syndrome, Prader–Willi syndrome, Klinefelter's syndrome and the Laurence–Moon–Biedl syndrome, as well as some endocrine diseases (hypothyroidism, Cushing's syndrome).

Body fatness can be assessed with a skinfold calliper at a number of sites, a tape measure, a stadiometer, and weighing apparatus. Bioelectrical impedance (BIA) and dual X-ray absorptiometry (DEXA) are the most widely used of the more elaborate options. Other techniques include underwater weighing and densitometry, near-infrared spectroscopy (NIR), and measurement of naturally occurring isotopes. Centile charts for triceps skinfold thickness, in boys and girls, are available. Values exceeding the 97th centile are indicative of obesity. (*See* **Obesity**: Fat Distribution.)

Prevalence

As many as one-third of the population of some industrialized nations are obese; in North America obesity affects 25% of children and adults, yet in

other communities, such as Finland, it is seen in only 3%.

Etiology

It is uncommon for a child to be obese because of an underlying pathological condition (e.g., Prader–Willi syndrome or the Laurence–Moon–Biedl syndrome). Obesity develops only if there is a positive energy balance; this is contrary to some views – there are opinions which imply that not all obese children eat excessively. Overweight children are less active than their leaner counterparts and this pattern of reduced physical activity is of importance.

Many factors are involved in the etiology of fatness, including behavioral problems, feeding patterns within the family, nature of newborn feeding, attitude of parents and siblings to obesity, and physical activity. Fetal and neonatal growth factors are also associated with the pathogenesis of obesity.

Recent discoveries regarding obesity are related to the hormone leptin and the identification of certain genes in animal models. Leptin precursors and the hormone itself are produced by placenta, fetal tissues, gastric mucosa, and hepatic stellate cells, which can participate in many physiological functions.

Management

Specialized obesity clinics have many advantages, particularly if located at school. Serial measures of height, weight, and skinfold thickness need to be recorded. Whatever the cause of obesity, management must include a reduction in intake of energy. Regular exercise also aids weight loss. Behavioral therapy has been shown to have a role. Anorectic drugs are only a transient aid because the original obesity will reappear after a time. (*See* **Obesity**: Treatment.)

A multidisciplinary support group made up of parents, peers, nutritionist, pediatrician, and a therapist or clinical psychologist has much to offer. Food fads or crash diets are potentially dangerous and must be avoided in childhood, if not in adulthood too. The aim of treatment is to correct faulty eating habits and not to induce ketosis.

Parents of children under 5 need advice to avoid offering a high intake of fat and sugar. Incidences of moderate obesity can be managed by allowing the children to grow into their present weight.

As 450 g of excess body weight represents 14.7 MJ, a daily reduction of 2 MJ is needed to lose 450 g of weight a week. Dietary restriction is not recommended for infants under 18 months of age. Greater affluence will inevitably mean than an ever-increasing number of youths will be obese, with all the associated phenomena. Determined educational and nutritional efforts must be adopted to avoid this scourge of life in privileged communities.

Protein–Energy Malnutrition (PEM)

Formerly known as protein–calorie malnutrition, PEM is a major global problem and one which arouses much controversy even in terms of its classification. Although PEM is rare in adults, it is responsible for a high mortality and indeed morbidity amongst children in developing countries. At one end of the spectrum PEM includes marasmus, and at the other the distinct syndrome of kwashiorkor, with intermediate deficiencies between both polarities. (*See* **Protein**: Deficiency.)

Within this band there are deficiencies of specific dietary constituents, particularly folate and vitamin A. Many children with severe PEM have infestations due to *Giardia lamblia, Strongyloides stercoralis*, or *Ascaris lumbricoides*. Tuberculosis, bronchopneumonia, and measles are significant secondary complications.

Anorexia plays a dominant role in PEM, as does the presence of small-bowel mucosal atrophy. These phenomena may be accompanied by the presence of both a protein-losing enteropathy and iron deficiency. (*See* **Anorexia Nervosa**.)

These disorders can be grouped together. Some workers regard marasmus as a successful adaptation to nutritional stress, and kwashiorkor as the failure of such an attempt. A comparison of kwashiorkor and marasmus is given in Table 1. (*See* **Kwashiorkor**; **Marasmus**.)

Malnutrition and its associated infections cause the death of many millions (Figure 2).

PEM is not limited to nonindustrialized countries. Fad and strict vegetarian diets as well as medically unsupervised elimination regimes all have the potential for causing PEM. (*See* **Vegetarian Diets**.)

Table 1 Comparison of marasmus and kwashiorkor

	Marasmus	*Kwashiorkor*
Weight	↓↓↓	↓↓

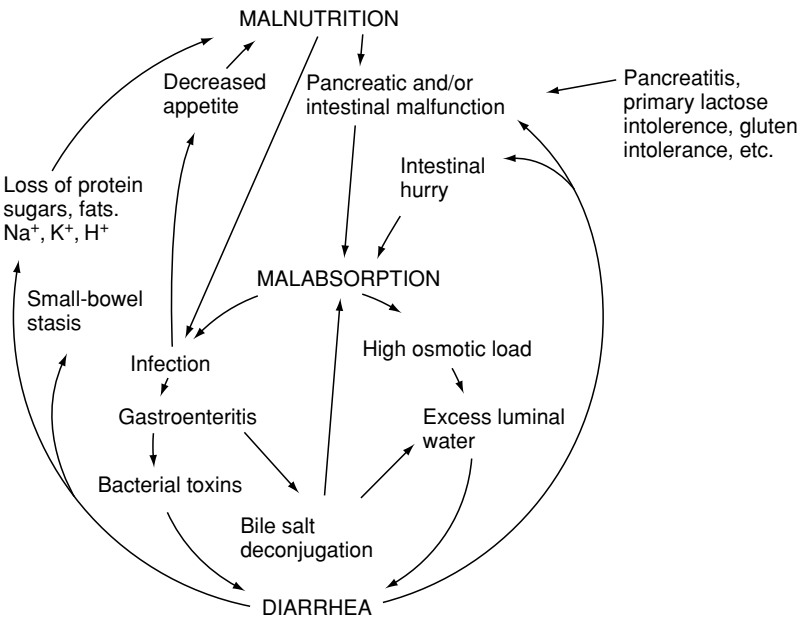

Figure 2 The vicious cycle of diarrhea and malnutrition. Courtesy of WF Balistreri.

Lack of nutritional knowledge and financial resources within a household, the community or society at large is responsible for the appalling childhood mortality and morbidity seen in PEM. Malnutrition ought to be regarded as the consequence of adverse social and economic conditions rather than a primary medical problem. Simple measures, such as the encouragement of breast-feeding, personal hygiene, improved sanitation, and the establishment of adequate and safe drinking water, would do much to prevent the many potentially hazardous enteric infections seen in malnourished infants and children.

Food Fads

Food fads are not only potentially dangerous for adults but also particularly hazardous in childhood. Apart from human milk for babies and young infants, there is no other single food which supplies all nutritional needs, yet food faddism seems increasingly attractive to many seeking 'healthy foods' and a diet free of all alleged contaminants.

As food technology and supermarket retailing become more sophisticated and food processing is seen as an adulteration of our food, some will seek alternatives via the use of 'natural, organic, and health foods' – all loose terms. There is an organic food myth and we do not even have an acceptable definition of 'organic foods' – a term introduced by the late JI Rodale. Consumers presume such food is grown in soil free of artificial fertilizer, is pesticide-free, and does not contain additives, preservatives, hormones, or antibiotics. In northern Europe, 70% or more of all foods now consumed is processed, preserved, and/or packaged. There is no evidence to support the contention that 'organic foods' are healthier for the consumer.

Synthetic vitamins are as effective as natural vitamins. Food grown in rich soil is not nutritionally dissimilar to that found in poor soil. Unfortunately, disinformation by the healthy-food movement has facilitated the public acceptance of food mythology as a reality. Nutrition is a subject that is ill understood. (*See* **Organically Farmed Food**.)

Tragically, children have died from malnutrition when fed weird and unconventional diets. Growth failure and anemia were found in a small group of infants fed a formula of barley water, corn syrup, and whole milk.

Faddism can result in many diverse and potentially dangerous outcomes. There are those who expect their children to survive solely on fruit (fruitarians); others are committed to a diet of raw foods. The discovery of fire 40 000 years ago by primitive humans via our ancestors brought an end to reliance on diets comprised solely of raw food. Some uncooked foods are toxic and unsafe, e.g., meat might become contaminated by bacteria, and raw foods may contain substances that interfere with vitamin B_1 (antihistaminases). Raw red kidney beans possess natural toxins (hemagglutinins). The Zen-macrobiotic diet has been associated with deaths. The ever-increasing restrictive nature of this diet is such that

ultimately only cereals are used, with disastrous consequences. (*See* **Macrobiotic Diets**.)

Embroiled in this widening saga of unconventional diets is the use of vitamin supplements in megadoses. It is now increasingly evident that such therapy is metabolically hazardous, particularly for children.

Food Intolerance and Aversion

There are few subjects that are so enigmatic, confusing, and clouded with anecdotal clutter as that of food adversion (intolerance) and aversion (psychological intolerance or avoidance). It has been suggested that the term 'allergy' which implies an unpleasant and immediate response should be applied only to those with immediate allergic reactions to food and with the presence of specific immunoglobulin E (IgE) antibodies. Mast cells, basophils, eosinophils, macrophages, and platelets can all be activated by IgE antibodies, causing the release of preformed or instant mediators. (*See* **Food Intolerance**, Types; Food Allergies; Lactose Intolerance.)

Food Intolerance

Clinical manifestations of food intolerance can be diverse and may include diarrhea, abdominal pain, failure to thrive, urticaria, eczema, migraine, behavioral disturbance, and food-sensitive colitis. Food intolerance occurs in approximately 5% of the pediatric population and can be caused by the following:

1. Allergic reaction(s). This mechanism is mediated via IgE antibody, a T-cell-mediated reaction, or the systemic formation of antigen–antibody complexes.
2. Pharmacological factors, e.g., tyramine. There is a high concentration of tyramine in fermented cheese and this can elevate the blood pressure and produce symptoms. Caffeine in coffee and tea, in the hypersensitive, can cause symptoms such as anxiety and tachycardia.
3. Enzyme deficiency, e.g., lactose intolerance caused by hypolactasia. It has been suggested that a deficiency of the enzyme phenolsulfotransferase may have a role in food-induced migraine.
4. Toxic effect. In many foods there are naturally occurring toxins, e.g., mycotoxins from storage of foods contaminated with molds.
5. Food fermentation. Bacteria in the colon, particularly *Proteus morganii*, can produce decarboxylase, an enzyme that will convert dietary histidine to histamine. However, as histamine does not cause an immunological reaction, its effect is pseudoallergic.
6. Other intolerances: tartrazine, an azodye, is a common coloring substance contained in many foods, soft drinks, and pharmaceutical products; benzoates or sulfur dioxide preservatives and butylated hydroxyanisole or butylated hydroxytoluene antioxidants may cause urticaria and asthma.

Acetylsalicylic acid (ASA), present in some vegetables and a variety of fruits, can cause a range of symptoms in sensitive patients, including asthma, urticaria, and rhinitis; synthetic salicylates are found as flavoring products.

Food Aversion

Food aversion is the result of either psychological intolerance or food avoidance.

Pathogenesis

The permeability of the gastrointestinal tract mucosa to food allergens is believed to be a major factor in the pathogenesis of antigenic food reactions. It is known that intestinal permeability is increased following an acute gastroenteritis. Temporary changes in the gut have been demonstrated after rotavirus enteritis by studying the differential permeation of the sugars, lactose, lactulose, and rhamnose. Studies using the inert probe, polyethylene glycol, have shown increased intestinal permeability in allergic children. Moreover, using a radioimmunological method for measuring serum concentration of human α-lactalbumin, preterm infants have an increased absorption of macromolecules compared with that seen at term.

The integrity of the bowel mucosa is maintained in part by secretory IgA and the glycocalyx (a glycoprotein coating the bowel enterocytes) as well as the mucosa-associated lymph tissues (MALTs). It has been suggested that following food challenge there is the deposition of immune complexes in different target organs and sites which can result in migraine, arthalgia, or eczema.

Treatment

Treatment is often unsatisfactory because of difficulties in identifying and then removing the offending allergen(s).

Food Additives, Salicylates, and Hyperactivity

Pediatricians and nutritionists seem to polarize themselves into either protagonists or vehement opponents of this theory which postulates that hyperkinesis can

be managed in 30–50% of children by eliminating artificial food-coloring matter, preservatives, and other additives from the diet, and by eliminating fruits and vegetables containing natural salicylates. The major symptoms of this psychological disorder are overactivity, distractibility, restlessness, impulsive behavior, and a short attention span, identifying this syndrome in part as a conduct disorder. It is probably not a single entity and the etiology is multifactorial. Unfortunately, it is now accepted that as many as 50% of all children with this disorder show some of its features in adulthood.

CHILL FOODS

Effect of Modified-atmosphere Packaging on Food Quality

A G Smith, The University of Huddersfield, Huddersfield, UK
B P F Day, Campden & Chorleywood Food Research Association, Gloucestershire, UK

Introduction

One form of food preservation technology that has grown in importance in recent years, often in combination with chilled foods, is modified-atmosphere packaging (MAP). The market for products using MAP has grown rapidly because of the benefits that this technique offers, particularly in respect to maintaining the quality of food throughout the extended shelf-life that the application of the method achieves. Estimates of sales indicate that around 1.6 billion modified-atmosphere (MA) packs of food were sold in 1990; this had risen to 2.6 billion by 1997 and is expected to exceed 3.3 billion in 2002.

MAP can be described as a food preservation technique in which the composition of the atmosphere surrounding the food, inside its hermetically sealed packaging, is different from the normal composition of air. Within the food packages air is replaced by a blanket of gas, a mixture of gases, or even no gas at all in the case of vacuum-packing, which is a form of MAP. Under MAP the growth of bacteria, molds, and yeasts that cause food to deteriorate is inhibited and other forms of physiological decay are slowed down. When applied effectively, MAP extends the shelf-life of food – the period of time for which it might be considered to be of saleable quality.

Consumers increasingly demand the natural qualities of fresh foods in raw, part-prepared, and even ready-to-eat products, whilst also preferring them to be free from additives. Retailers wish to provide the widest possible range of products for the consumer to choose from but need to be assured that items will have a long enough life on the display shelf to make them viable to stock. MAP contributes towards the fulfillment of these diverse demands by extending the shelf-life of food items whilst maintaining the product's original quality.

Unlike controlled-atmosphere bulk storage, where precise control of the gaseous components in a food warehouse atmosphere is possible, in MAP there is no way of varying the concentration of these components once the packaging has been sealed. Highly perishable foods will only achieve their full potential in terms of extended life when packed in MA if they are handled hygienically throughout any processing and, in most cases, also held chilled.

Chilled products already sold in MAP include cheeses, cooked and cured meats, cooked and dressed vegetable products, crustaceans, dairy and bakery goods, fish, kebabs, pasta, pizza, red (uncooked) meats, ready meals, whole and prepared fresh fruit and vegetables (Figure 1), and this range continues to expand rapidly.

MAP cannot in itself enhance the quality of food, be it raw or prepared in some way. The technology can only be used to extend the reasonable life of a food product because it can preserve food at or very near to its original quality due to its ability to inhibit the various forms of deterioration that naturally occur when products are stored in air. Any positive impact that MAP has on maintaining food quality will be limited by the need for foods:

1. to be of prime quality in all respects in the first instance
2. to be handled in an appropriate manner that minimizes risk from any form of contamination or deterioration prior to and throughout the packing process
3. to be held at appropriate temperatures after packing and prior to sale (ideally between 0 and 3 °C for chilled foods).

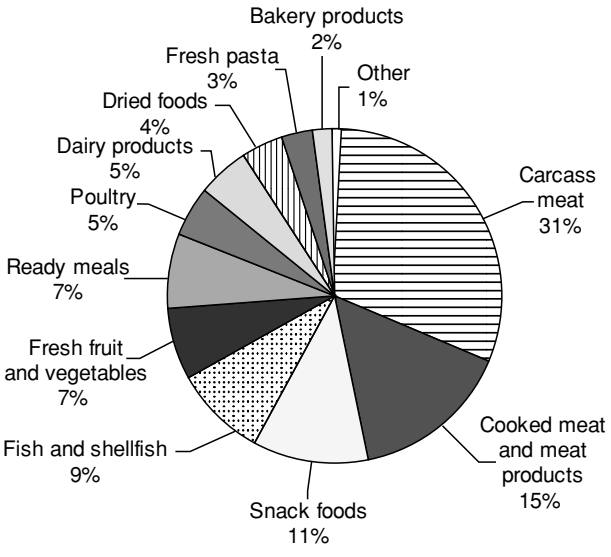

Figure 1 Relative importance of major food sectors to the modified-atmosphere packaging retail market (UK) 1997. Data from MSI Data Report (1998).

With these issues in mind, this chapter aims to outline the effects of MAP on the quality of food purveyed to consumers. The typical gases used in MAP and their applications are briefly considered and the impact of this technique on the quality of the major categories of chilled foods is discussed.

The Gases Used in MAP

It is necessary for manufacturers to utilize food-grade gases for the safe and hygienic MAP of food products. These high-purity gases are produced in hygienic conditions applicable to food production systems and are stored in dedicated containers made and maintained to the standards required in any food-handling environment.

The gases most commonly used for food MAP are those found naturally in air: carbon dioxide (CO_2), nitrogen (N_2), and oxygen (O_2). The effectiveness and safety of other gases that might be used for MAP are being examined and gases such as argon, helium, nitrous oxide, and sulfur dioxide are already permitted for food use in the European Union (EU). Other gases, such as carbon monoxide, hydrogen, and chlorine, are also being investigated, although their commercial application may be limited due to negative effects on food quality and regulations relating to use.

Air consists of N_2 (78.09%), O_2 (20.95%), argon (0.93%), and CO_2 (0.03%), and in the majority of MAP applications, N_2, O_2, and CO_2 are currently the only gases used. The ratio of each gas employed in MAP mixtures varies significantly from air according to the food commodity being packed. It is the careful maintenance and monitoring of the proportions of each gas and the utilization of correct mixtures of gases for specific products that are important to insure that the benefits of MAP are fully exploited.

Carbon Dioxide

Whilst CO_2 provides particular benefits in concentrations that can enable the shelf-life of food to be extended considerably, it can also have some disadvantageous effects on food quality. CO_2 effectively inhibits most bacteria (aerobic strains) and molds that need O_2 to survive. Generally, the greater the concentration of CO_2 around packaged foods, the longer its shelf-life can be extended.

CO_2 is easily absorbed into fats or water which are key constituents of many perishable foods. The mild carbonic acid that forms from the absorption of CO_2

into the food's natural moisture has further preservative effects. However, this factor can lead to 'pack collapse,' as the package's gas volume reduces due to such CO_2 absorption, and, although foods might still be edible, it can also result in other undesirable changes in the sensory properties of some foods.

The determination of the proportion of CO_2 used in MAP gas mixes will relate to achieving an acceptable balance between extending shelf-life and avoiding the potentially undesirable effects. However, the concentration of CO_2 should not normally be below 20% if it is required to inhibit mold growth effectively (Table 1).

Nitrogen

This inert gas is useful for excluding or reducing the relative proportion of O_2 in the atmosphere around food. It is also used to counter the effects of pack collapse caused by the absorption of CO_2 by fatty or moist food items, which is particularly likely to occur under chilled storage.

Whilst N_2 does not support the growth of aerobic microorganisms, it is neither absorbed by foods nor does it have the mildly acidifying effect of CO_2. This means that on its own it is not as effective as CO_2 for inhibiting microorganisms. However, N_2 has little impact on the sensory qualities of food which makes it particularly useful for gas-packing foods that might be adversely affected in this way by CO_2, such as creams and other dairy products (Table 1). N_2 is also used in the head space of beverage containers, to flush out O_2, and in packaging dry food which does not require the bacteria and mold-inhibiting properties of CO_2 yet needs to be protected from oxidative deterioration.

Oxygen

It is the O_2 in the air that causes most of the spoilage problems that MAP seeks to reduce. Not only is oxygen needed for survival by many microorganisms, it can also cause oxidative deterioration in foods. Hence, MAP largely originated from the objective of excluding O_2 from around foods to obviate potential quality problems. However, there are applications when a controlled amount of oxygen in MA gas mixes is necessary when packing certain food commodities.

For example, O_2 can maintain acceptable color quality in raw meats and is needed to avoid anaerobic respiration in fruits and vegetables. O_2 is also used in packing white fish and seafood products because it inhibits *Clostridium botulinum*, a highly toxic anaerobic pathogen. These benefits mean that carefully

Table 1 Recommended gas mixtures for retail modified-atmosphere packaging of a selection of food commodities

Food item	*CO_2 (%)*[a]	*O_2 (%)*[a]	*N_2 (%)*[a]
Most raw red meats (beef, lamb, pork)	30	70	
Venison/wild boar	20	80	
Raw offal	20	80	
Raw poultry/game[b]	30		70
Raw fish and seafood crustaceans/molluscs	40	30	30
Raw oily fish	40		60
Cooked, cured, and processed meats	30		70
Cooked, cured, and processed fish/seafood	30		70
Cooked, cured, and processed poultry and game products	30		70
Ready meals and cook-chill products	30		70
Fresh pasta products	50		50
Bakery products	50		50
Dairy products – hard cheeses (not mold-ripened varieties)[c]	100		
Dairy products – grated and soft cheeses (not mold-ripened varieties)[c]	30		70
Dairy products – other products, including butter, cream, custard, margarine, yogurts[d]			100
Dried foods			100
Combination products (pies, pastries, pizzas, battered products)	30		70
Cooked/sauced/stuffed vegetable products	30		70
Most liquid food and beverages (beers, cider, cordials, yogurt drinks, oils, wines)			100
Carbonated drinks	100		
Fresh whole and prepared fruit and vegetables	5	5	90

[a]Gas mixtures relate to retail packaging only. Bulk and primal storage require different optimum gas mixes.
[b]Dark poultry meat such as skinned and diced turkey leg meat requires a gas mixture similar to red meats to retain acceptable color quality.
[c]CO_2 and N_2 inhibit mold growth, therefore mold-ripened cheeses are not normally modified-atmosphere packaged.
[d]Aerosol creams excepted, which are packaged under nitrous oxide (N_2O).
Adapted from Air Products (1995) *The Freshline Guide to Modified Atmosphere Packaging (MAP)*. Basingstoke, Hants: Air Products, with permission.

monitored amounts of O_2 may be used in MAP for certain major food commodities.

Recent research has indicated that a novel form of MAP utilizing high levels of O_2 (over 70%) has the potential to maintain both quality and food safety, particularly for respiring fruit and vegetable items and where products involve a combination of respiring and nonrespiring chilled foods, such as sandwiches, pizzas, and ready meals.

Recommended gas mixtures to be used for maximizing shelf-life whilst maintaining sensory quality of a range of major food commodities being packed for retail sale are summarized in Table 1.

Other Gases

As noted, numerous other gases are being examined for use in MAP. Some are already permitted for specified food use in the EU such as argon (E938), helium (E939), nitrous oxide (E942), and sulfur dioxide (E220). Of these, argon (Ar) appears to inhibit enzyme activity and tissue fermentation more effectively than N_2. Ar may also be better at displacing O_2 from the cells of food than N_2, so might further reduce the occurrence of oxidative deterioration. Nitrous oxide (N_2O) and Ar are also claimed to enhance the effect of antimicrobial agents used in food products. Research is continuing into the development of novel forms of MAP using such alternative gases.

Major Chilled Food Categories and the Effect of MAP

Red Meat

Today's consumers demand bright red meat. A generation or more ago, butchers' meat was expected to have 'hung' well, and, if anything, exhibit a deep red color, which was seen as an indicator of tenderness and flavor, but most meat purchasers today would probably infer that such meat was 'past its best.' Retailers are largely responsible for promoting and displaying meat of a fresh red hue and this is now perceived as a key quality indicator. MAP has a major contribution to make in respect to extending the life of meat in a desired red color. This is because gas mixtures containing high levels of O_2 react with the natural postmortem blood chemistry to maintain a 'consumer-attractive' appearance for longer. Typically, raw meat will have a shelf-life of up to 4 days, but packaged in a modified gas mix, this can be doubled.

MAP producers acknowledge that gas mixes that are high in O_2 contribute to the maintenance of color quality preferred by today's consumers. In fact, if meat is packed in a CO_2-rich atmosphere, excluding O_2 which many microorganisms need to thrive, shelf-life could be extended for considerably longer. However, the consequent innocuous darkening of the meat color that would occur in the presence of CO_2 is regarded as an undesirable quality characteristic and hence this is not done.

Raw meats require cooking before they are edible. If the cooking process is undertaken effectively, there should be minimal risk of food poisoning. It is therefore considered that, whilst O_2-rich atmospheres might support aerobic microflora, the risks are acceptably small if meat is hygienically handled prior to packing and held chilled prior to sale. Thus, MAP protects the meat from contamination and enables the maintenance of visually appealing fresh color during the period of extended shelf-life, a quality characteristic which is highly valued by both the retailer and the consumer.

Cooked and Cured Meats

Cooked meats are considered a 'high-risk' food since they do not undergo further processing prior to consumption. It is therefore imperative that producers of such products employ hazard minimization techniques during handling, preparation, cooking, and packaging of such foods. If this is done then MAP has an important role to play in the safe extension of product shelf-life whilst simultaneously insuring that the product exhibits all the expected qualities of a freshly cooked item.

As can be seen in Table 1, the gas mixture advised for MAP of cooked meats and poultry excludes O_2. The cooking process will kill any vegetative pathogens and also fix color, unlike raw meat. Without the need for O_2 for the maintenance of visual quality, a mixture of N_2 and CO_2 is used for MAP, affording the advantage of increased inhibition of microbial deterioration. The maximal extension of shelf-life is dependent on appropriate chilled storage, ideally between 0 and 3 °C.

Some lightly cured meats, such as bacon, may require cooking before consumption but because they are usually treated with salts such as nitrites, their pink coloring is assured, hence the same CO_2/N_2 gas mixture as for cooked meats is recommended. Keeping quality of these products may be adversely affected if lower salt formulations are developed however. It is also imperative that appropriate storage temperatures are rigorously maintained below 8 °C and preferably between 0 and 3 °C.

Other cured products, such as salami, do not need further cooking and the curing process is a traditional preserving method that may even be effective enough

to insure considerable shelf-life, even if stored in ambient conditions. However, fattier meat products may be subject to oxidative rancidity, so packing in an MA without O_2 can be useful to inhibit this process.

Although vacuum-packing has been successfully employed in the production of retail cooked and cured meat products with enhanced shelf-life, gas-filled MAP provides a better-looking product that is easier to handle after removal of the packaging. However, vacuum skin packaging (VSP), where a lightly applied, highly ductile plastic barrier laminate forms itself around the food during the vacuum process, without squashing it, has been seen to be a particularly useful innovation by retailers for some sliced cooked meat products. VSP not only achieves the benefit of easy separation of meat slices but also enables packs to be stacked vertically for more attractive and efficient merchandising.

Fish

MAP is particularly useful for extending the shelf-life of raw fish which normally deteriorates rapidly after exposure to air. The controlled proportions of gases used in MAP can contribute towards reducing the formation of peroxides and other chemicals, which create characteristic off-odors and taints in fish.

Fish are particularly susceptible to oxidative rancidity; however, MAP gas mixtures cannot contain too high a concentration of CO_2 alone as absorption into the moist tissues will cause packs to collapse. CO_2 absorption also exacerbates drip and affects color and flavor adversely, especially in seafood. O_2 must also be incorporated into the gas mixture used in MAP of white fish, shellfish, and crustaceans to insure sensory quality and also to inhibit the growth of toxin-forming anaerobes, such as *Clostridium botulinum*. Oily fish, however, such as mackerel, herring, tuna, and salmon, need an MAP gas mixture consisting of CO_2 (40%) and N_2 (60%) alone. This is because oxidative deterioration is considered the major potential quality problem.

From catch through to MAP, fish must be handled hygienically and rigorously stored in temperature-controlled conditions. The fish species and season, affecting such factors as fat content, will also influence the keeping quality of the product. The extension of shelf-life and the maintenance of acceptable food quality using MAP can only be fully exploited if the product being packaged is initially of prime quality and has been handled appropriately at all times prior to packaging. Overall shelf-life and acceptable quality can be prolonged by MAP for up to 6 days – around twice as long as fish would keep held chilled in air.

Fruit and Vegetables

Fresh fruit and vegetables continue to respire and ripen after harvesting. MAP has an important role in extending the life of these commodities in that it can be used to reduce the rate of respiration and delay ripening. By slowing textural softening, chlorophyl degradation, and other ripening processes and by reducing the impact of chilling injury and other physiological problems, product quality can be maintained for up to five times longer than if stored in air. This means that shelf-life can be increased from 2 to 5 days for highly perishable items, and increased from up to 7 to around 35 days for hardier fruit and vegetables. The potential increase in shelf-life that can be attained through the use of MAP is inversely proportional to the rate of respiration naturally occurring.

There are certain technical issues that must be considered when packaging fruit and vegetables in MAs. The natural respiration process tends to deplete O_2 and cause CO_2 levels to increase. A minimum level of O_2 is required in the gas mixture to avoid anaerobic respiration occurring, as this would result in the development of undesirable sensory qualities in the food. Without any O_2 present there would also be an increased risk of food poisoning by pathogenic anaerobes such as *Clostridium* species, the hardy spores of which, should they be present in any soil remnants, might germinate if storage temperatures are not well controlled at any time.

The packaging itself must be carefully selected to insure that the correct level of gas permeability can occur. In order to achieve optimal conditions, the MA within the packaging must be maintained such that the gas mix contains between 2 and 10% of both O_2 and CO_2. With commodities such as beansprouts, broccoli, leeks, mushrooms, and peas, which exhibit a high rate of respiration, traditional MAP films are not permeable enough to maintain the gas mixture. With these foodstuffs, a microperforated film is more appropriate for their level of respiration, but has the consequent disadvantage of potentially allowing ingress of microorganisms and other forms of organoleptic deterioration to occur.

Recent research has shown that freshly prepared vegetables packed in high O_2 atmospheres (> 70%) may offer a solution to the disadvantages of gas mixtures currently in use. High O_2 MAP has been shown to prevent the formation of anaerobic fermentation byproducts and inhibit both enzymic deterioration and the growth of microorganisms. Research is currently continuing in this area.

Dairy Products

Ideal gas mixtures for the range of dairy products vary according to the likely types of deterioration to which specific items are most susceptible (Table 1).

As hard-cheese quality is most likely to be affected by mold growth, an atmosphere consisting solely of CO_2 is most appropriate for MAP. Acceptable eating quality can be maintained and shelf-life trebled from around 4 weeks to up to 3 months by using MAP.

Softer cheeses are more likely to deteriorate by separation and can be affected by yeasts, bacteria, and oxidative rancidity. A mixture of CO_2 and N_2 is recommended to counteract the likely pack-deforming absorption of CO_2 by these moister products. For the most perishable products, MAP can help to maintain quality whilst doubling normal shelf-life to around 2 weeks and for many items this could be considerably longer.

It is because of the mold-inhibiting properties of CO_2 and N_2 that cheeses that incorporate natural molds are not normally packed using MA technology.

Creams and similar dairy products are packed solely in N_2 because flavor quality would be adversely affected by CO_2 absorption. N_2 would also be recommended for packaging butter and yogurts should MAP be applied to such products.

Ready Meals

The range of chilled products available from the major retailers has increased greatly in recent years. Major retailers have developed their own brands, often in collaboration with large manufacturers who have the technical capability to produce cook-chill products safely and hygienically.

Within the UK, current regulations stipulate that the maximum shelf-life for cook-chill products utilized in commercial operations is limited to a maximum of 5 days. This does not apply to retail foods for the domestic market, which means that, by using MAP, or by cooking under vacuum, as in the sous-vide process, shelf-lives of ready meals and the like can be safely extended considerably further.

Whilst proper storage is essential, ideally below 3 °C, food safety and eating quality can be maintained for up to 10 days without any appreciable risk when using MAP technology or sous-vide methods to produce such foods.

Temperature control is imperative throughout the production process, be it to insure proper cooking, or to insure the minimization of risk from bacterial growth after chilling. This is particularly important for preventing the germination of hardy spores of

Table 2 Examples of active packaging systems and their applications

Active packaging system	*Active element*	*Actual/potential food applications*
O_2 scavengers	1. Iron-based 2. Metal/acid 3. Metal catalyst (e.g., platinum) 4. Ascorbate/metallic salts 5. Enzyme-based	Bread, cakes, cooked rice, biscuits, pizza, pasta, cheese, cured meats and fish, coffee, snack foods, dried foods and beverages
CO_2 scavengers/emitters	1. Iron oxide/calcium hydroxide 2. Ferrous carbonate/metal halide 3. Calcium oxide/activated charcoal 4. Ascorbate/sodium bicarbonate	Coffee, fresh meats, and fish, nuts and other snack foods products and sponge cakes
Ethylene scavengers	1. Potassium permanganate 2. Activated carbon 3. Activated clays/zeolites	Fruit, vegetables and other horticultural products
Preservative releasers	1. Organic salts 2. Silver zeolite 3. Spice and herb extracts 4. BHA/BHT antioxidants 5. Vitamin E antioxidants	Cereal, meats, fish, bread, cheese, snack foods, fruit and vegetables
Ethanol emitters	1. Encapsulated ethanol	Pizza crusts, cakes, bread, biscuits, fish and bakery products
Moisture absorbers	1. PVA blanket 2. Activated clays and minerals 3. Silica gel	Fish, meats, poultry, snack foods, cereals, dried foods, sandwiches, fruit and vegetables
Flavour/odor absorbers	1. Cellulose triacetate 2. Acetylated paper 3. Citric acid 4. Ferrous salt/ascorbate 5. Activated carbon/clays/zeolites	Fruit juices, fried snack foods, fish, cereals, poultry, dairy products and fruit

BHA, butylated hydroxyanisole; BHT, butylated hydroxytoluene.

Bacillus or *Clostridium* species which might remain after cooking.

The quality of cook-chill meals has improved dramatically in recent years, but MAP can only maintain the quality of the product as originally produced. This means that retailers must insure that product formulation incorporates efficient organoleptic assessments as well as risk control methods such as Hazard Analysis Critical Control Points (HACCP) if they wish to guarantee that consumers receive products of acceptable quality in all respects.

Conclusion – The Future of MAP

Innovations in MAP and related packaging technologies are continuously being made. In recent years these innovations have improved the utility and function of such packaging. This has resulted in MAP providing additional benefits that have a positive impact on the quality of food as it reaches the end consumer, particularly through retailers.

Innovations in film materials have allowed the development of vacuum MAP methods such that VSP (vacuum skin packaging) can be formed around food without squashing it, unlike earlier vacuum pack technology.

Active packaging refers to systems and devices which incorporate certain additives, such as oxygen scavengers, carbon dioxide emitters, ethylene scavengers, moisture absorbers, and other 'active' elements (Table 2).

The overall aim of these developments is to act as 'freshness enhancers' and hence to achieve even longer extensions in the shelf-life of foods, whilst maintaining sensory and nutritional quality and microbial safety. Advances in biotechnology, the science of materials and packaging methods are continuously being made and hence will influence the future development of MAP.

Future innovations in packaging in general may be driven by environmental concerns such as the implications arising from the increasing problem of disposing of packaging waste. Consumers' desire for easier-to-use packs, along with other added-value features, may also influence future developments in food packaging. However, the potential to prolong the shelf-life of food whilst retaining desirable fresh qualities is likely to remain the key benefit and purpose of employing MAP.

CHILLED STORAGE

Contents

Principles

S James, University of Bristol, Langford, North Somerset, UK

Basic Theory

The complete chill chain for a food will contain many of the following unit operations: prechilling preparation, primary or secondary chilling, storage, transportation, and display. Storage, transport, and display are temperature maintenance operations. Chilling results in a substantial decrease in the mean temperature of the product, whereas during the preparatory treatment, there can be a range of temperature responses from a large gain to a small decrease in the temperature of the foodstuff.

The initial and final temperatures, and the maximum and minimum desirable rates of temperature reduction during chilling, depend on the food being processed. In all cases, the final product temperature must be above the initial freezing point of the food, but in a number of products, biological factors dictate higher storage temperatures.

The principle factors that control the rate of heat and mass transfer during cooling are independent of the foodstuff. Heat can be lost from the surface of a body by four basic mechanisms: radiation, conduction, convection or evaporative cooling. (*See* **Heat Transfer Methods**.)

To determine the rate of heat transfer (Q_r) by radiation from food, the following approximation may be applied:

$$Q_r = \varepsilon A \sigma (T_s^4 - T_e^4), \qquad (1)$$

where ε is the emissivity, A is the surface area of the food, σ the Stefan–Boltzman constant, and T_s and T_e the temperature of the surface and the enclosure, respectively. To achieve substantial rates of heat loss by radiation, large temperature differences between the product and the enclosure are required. Such differences are not normally present during food cooling operations, except in the initial chilling of bakery products. However, researchers in Russia have used banks of refrigerated plates to enhance radiant heat transfer during the chilling of beef carcasses.

The rate of one-dimensional heat transfer (Q_{cd}) by conduction is given by:

$$Q_{cd} = k A \frac{\partial T}{\partial x}, \qquad (2)$$

where k is the thermal conductivity of the medium through which the heat is passing, and $\partial T/\partial x$ is the temperature gradient.

Physical contact between the product and a cooler surface is required to extract heat by conduction. The irregular shape of most foodstuffs precludes this mechanism in many applications. Plate coolers are routinely used to freeze fish and offal, which have soft pliable surfaces. Belt freezers are used for steaks, fish fillets, and other thin products. However, the rate at which heat can be conducted away from the surface is not the sole criterion that governs the time taken to cool a product. Heat must also be conducted from within the product to its surface before it can be removed. Most foodstuffs are poor conductors of heat, and this imposes a severe limitation on attainable chilling times for either large individual items or small items cooled in bulk.

The rate of mass transfer (M) from the surface of an unwrapped food is described by the equation::

$$M = mA(P_s a_w - P_m), \qquad (3)$$

where m is the mass transfer coefficient, A the area, P_s the saturated vapor pressure at the surface, a_w the water activity, and P_m the vapor pressure above the food surface. Q_e, the heat loss due to evaporation, can be obtained by multiplying M by the appropriate latent heat. The heat lost in the evaporation of water from the surface of the product is a minor component of the total heat loss for most foodstuffs. In

spray-cooling systems, the rate of heat removal is enhanced by evaporation from the surface. However, the main advantage of spray cooling is a reduction in weight loss. In a number of specific cases, i.e., vacuum cooling, evaporation is the primary cooling agent.

Most food-chilling systems rely on convection as the principal means of heat removal. The rate of one-dimensional heat transfer (Q_c) by convection is given by::

$$Q_c = h_c A(T_s - T_a), \quad (4)$$

where h_c is the convection or film heat transfer coefficient, and T_a is the temperature of the cooling medium. The most common media are air or water, although sugar solutions, salt brines, and other refrigerants have been used. Each combination of product and cooling system can be characterized by a specific surface heat-transfer coefficient. The value of the coefficient depends on the shape and surface roughness of the foodstuff and, to a much greater degree, on the thermophysical properties and velocity of the medium. Values range from $5\,W\,m^{-2}\,K^{-1}$ for still air to over $500\,W\,m^{-2}\,K^{-1}$ for agitated water.

Chilling Methods for Solid Foodstuffs

Moving Air

This is the most widely used method as it is economical, hygienic, and relatively noncorrosive to equipment. Systems range from the most basic, in which a fan blows the cooled air around an insulated room, to products on conveyors passing through blast chilling tunnels or spirals. Low rates of heat transfer are attained in air-cooling systems, but this is not important if conduction within the product is the rate-controlling factor. A major disadvantage is excessive dehydration from the surface of any unwrapped product, whilst the need to avoid surface freezing limits the lowest air temperature that can be used. In practice, air distribution is a major, often overlooked, problem.

A batch system where warm food is placed in refrigerated rooms is the most common method of chilling. Individual items such as carcasses, tuna, or bunches of bananas are hung from rails, smaller products are placed on racks or pallets, and bulk fruits and vegetables are placed in large bins.

Conveying products overcomes problems of uneven air distribution since each item is subjected to the same velocity/time profile. In the simplest continuous systems, the food is suspended from an overhead conveyer and moved through a refrigerated room. This process is often used in air chilling of poultry or in prechilling of pork carcasses. Some small cooked products are continuously chilled on racks of trays, which are pulled or pushed through a chilling tunnel using a simple mechanical system. In more sophisticated plants, the racks are conveyed through a chilling tunnel in which the refrigeration capacity and air conditions can be varied throughout the length of the tunnel.

In larger operations, it is more satisfactory to convey the cooked products through a linear tunnel or spiral chiller. Linear tunnels are far simpler constructions than spirals but require more space.

Hydrocooling/Immersion Cooling

Hydrocooling is probably the least expensive method of achieving rapid cooling in small products. The product is immersed in, or sprayed with, cool water, either at ambient or near 0 °C. Practical systems vary from simple unstirred tanks to plants where the product is conveyed through agitated tanks or under banks of sprays. Such systems are typically used for celery, asparagus, peas, sweet corn, carrots, peaches, etc.

Immersion chilling also has application with larger products. Most poultry to be frozen is initially cooled by immersion in chilled water or an ice/water mixture. The procedure is very fast, and the birds gain weight during the process. The maximum weight gain is controlled by legislation.

An alternative system to air or immersion is spray chilling. Practical spray-chilling systems use a combination of air and sprays for the initial part of the chilling period and then air only for the rest of the chilling cycle. The sprays of cold water at 2–3 °C are applied not continuously but in short bursts. The main advantage claimed for these systems is reduced weight loss.

Plate Cooling

With thinner materials, a plate-cooling system has the potential to halve the cooling time required in an air-blast system. Continuous horizontal and rotary plate freezing systems have been produced commercially and could be modified to operate at higher temperatures. They tend to be expensive, especially if automatic loading and unloading are required, but have low running costs. Designs have been produced for continuous belt coolers similar to those used for belt freezing.

Ice or Ice/Water Chilling

Chilling with crushed ice or an ice/water mixture is simple, effective, and commonly used for fish cooling. The individual fish are packed in boxes between layers of crushed ice, which extract heat from the fish and consequently melt. The temperature of the

'coolant' remains at a constant 0 °C until all the ice has turned into water. The process is labor-intensive, although automatic filling systems have been developed. Cabbage and root crops are also cooled with crushed ice.

Vacuum Cooling

Solid products with a large surface area-to-volume ratio and an ability to release internal water are amenable to vacuum cooling. The products are placed in a vacuum chamber, and the resultant evaporative cooling removes heat from the food. In general terms, a 5 °C reduction in product temperature is achieved for every 1% of water that is evaporated. Prewetting is commonly applied to facilitate cooling without any loss of weight.

Vacuum cooling is rapid and economical to operate because of low labor costs, but the capital cost of the large vacuum vessels is high. Large amounts of lettuce, celery, cauliflower, green peas, and sweetcorn are vacuum-cooled.

Cryogenic Cooling

Avoiding surface freezing of the product is the main problem in using liquid nitrogen or solid carbon dioxide for chilling. Continuous chilling systems using liquid nitrogen either immerse the product in the liquid, spray the nitrogen on to the surface, or vaporize the nitrogen in a forced draught and pass it over the surface of the foodstuff.

Direct spraying of liquid nitrogen on to a food product, whilst it is conveyed through an insulated tunnel, is the most common method. Surface freezing is still a problem, but an extra refrigeration effect is obtained by precooling the food with the cold gas produced by the vaporization.

Chilling Methods for Liquid Foodstuffs

The majority of liquid foodstuffs require cooling after a heat-processing operation such as cooking, pasteurization, or sterilization. Milk is cooled at the point of collection to maintain its quality, unpasteurized fruit juices are cooled immediately after production, whilst fermented beverages are often cooled during primary and secondary fermentation, and before storage. (*See* **Fermented Milks**: Products from Northern Europe; **Milk**: Processing of Liquid Milk; **Pasteurization**: Principles.)

In simple or small-scale processes, containers of hot liquids are allowed to cool in ambient air or placed inside chill rooms. Other cooling systems for liquid foods rely on direct expansion refrigeration, the use of a secondary refrigerant that is passed through or around the foodstuff, vacuum cooling, or a combination of liquid and vacuum.

Batch coolers for liquid foods range in capacity from 100 to 10 000 l with the foodstuff contained in a stainless steel vessel. The cooling medium may circulate through the jacket of the vessel, through a coil immersed in the liquid, or both. Most vessels are provided with agitators to improve convective heat transfer and stop temperature stratification. One common method used to decrease cooling times in a closed vessel is to apply a vacuum to produce evaporative cooling.

Continuous cooling used to be achieved in falling film or surface coolers in which the hot liquid was pumped over the top of a horizontal bank of refrigerated coils and flowed down over the cooled surfaces. These systems have now been replaced by totally enclosed coolers. Double-pipe coolers have also been employed in specialized applications but have a limited heat-transfer surface. Multiplate coolers are extensively used for liquid foods. They have the highest available heat-transfer surface, lowest material requirements, and maximum efficiency, and are very flexible in operation and easy to clean. In certain applications, such as beer and wine cooling, multitube coolers that have a much higher resistance to pressure and can use primary refrigerants have advantages over multiplate coolers.

Scraped surface heat exchangers can have advantages in the cooling of very viscous liquid foods and where surface fouling is a potential problem. Currently, there is interest in the use of pumpable ice in the form of an ice 'pig' to clean heat exchangers and pipeline systems for liquid foods.

Chilled Storage

Theoretically, there are clear differences between the environmental conditions required for chilling, which is a heat removal/temperature reduction process, and storage where the aim is to maintain temperature. However, in many air-based systems, chilling and storage take place in the same chamber, and even where two separate facilities are used, in many cases, not all the required heat is removed in the chilling phase. With some fruits and vegetables, the rate of respiration during storage is sufficient to require heat removal if product quality is to be maintained. (*See* **Storage Stability**: Mechanisms of Degradation; Parameters Affecting Storage Stability.)

Bulk Storage Rooms

Most unwrapped meat and poultry and all types of wrapped foods are stored in large air-circulated

rooms. To minimize weight loss, air movement around the unwrapped product should be the minimum required to maintain a constant temperature. With wrapped products, low air velocities are also desirable to minimize energy consumption. However, many storage rooms are designed and constructed with little regard to air distribution and the maintenance of low localized velocities over products. Horizontal throw refrigeration coils are often mounted in the free space above the racks or rails of product, and no attempt is made to distribute the air around the products. Using air socks, it is claimed that an even air distribution can be maintained with localized velocities not exceeding $0.2\,m\,s^{-1}$.

Controlled-atmosphere Storage Rooms

Controlled-atmosphere storage rooms were developed for specialized fruit stores, especially those for apples. Interest is growing in the application of this technique to other commodities including meat and fish. In addition to the normal temperature control plant, these stores also include special gas-tight seals to maintain an atmosphere, which is normally lower in oxygen and higher in nitrogen and carbon dioxide than air. An additional plant is required to control the CO_2 concentration, generate nitrogen and consume oxygen. (*See* **Controlled-atmosphere Storage**: Applications for Bulk Storage of Foodstuffs.)

There is growing interest in the use of controlled atmosphere retail packs to extend the chilled storage and display life of meat and meat products. Since the packs insulate the products, efficient precooling before packaging is important.

Transportation

Developments in temperature-controlled transportation systems for products have been one of the main factors leading to the rapid expansion of the chilled food market. The sea transportation of chilled meat from Australasia to European and other distant markets, and road transportation of chilled products throughout Europe and the Middle East, are now common practice. Air freighting was initially used for high-value perishable products such as strawberries, asparagus, and live lobsters. It is now increasingly used to provide consumers with a year-round supply of locally out-of-season products such as green beans, mangetout, and green on carrots.

Overland Transport

Overland transportation systems range from 12-m refrigerated containers for long-distance road or rail movement of bulk chilled products to small uninsulated vans supplying food to local retail outlets. The majority of current road transport vehicles for chilled foods are refrigerated using either mechanical, eutectic plates or liquid nitrogen cooling systems.

Many types of independent engine and/or electric motor-driven mechanical refrigeration units are available for lorries or trailers. One of the most common is a self-contained 'plug' unit mounted in an opening provided in the front wall of the vehicle. The condensing section is on the outside and the evaporator on the inside of the unit, separated by an insulated section, which fits into the gap in the wall. Units have one or two compressors, depending upon their capacity, which can be belt-driven from the vehicle but are usually driven direct from an auxiliary engine. This engine may use petrol from the vehicle's supply or an independent tank, or liquid petroleum gas. Many are equipped with an additional electric motor for standby use or for quiet running, e.g., when parked or on a ferry. Irrespective of the type of refrigeration equipment used, the product will not be maintained at its desired temperature during transportation unless it is surrounded by air or surfaces at or below that temperature. This is usually achieved by a system that circulates moving air, either forced or by gravity, around the load. Inadequate air distribution is probably the principal cause of product deterioration and loss of shelf-life during transport. Conventional forced air units usually discharge air over the stacked or suspended products either directly from the evaporator or through ducts towards the rear cargo doors. Because air takes the path of least resistance, it circulates through the channels, which have the largest cross-sectional area. These tend to be around, rather than through, the product. If products have been cooled to the correct temperature before loading and do not generate heat, they only have to be isolated from external heat ingress. Many trucks are now being constructed with an inner skin that forms a return air duct along the side walls and floor, with the refrigerated air being supplied via a ceiling duct.

Sea Transport

Recent developments in temperature control, packaging, and controlled atmospheres have increased substantially the range of foods that can be transported around the world in a chilled condition. Control of the oxygen and carbon dioxide levels in shipboard containers has allowed fruits and vegetables such as apples, pears, avocado pears, melons, mangoes, nectarines, blueberries, and asparagus to be shipped from Australia and New Zealand to markets in the USA, Europe, Middle East, and Japan. With conventional vacuum packing, it is difficult to achieve a shelf-life in excess of 12 weeks with beef and 8

weeks for lamb. However, a study has found that a shelf-life of up to 23 weeks at −2 °C can be achieved in cuts of lamb that are individually packed in evacuated bags of linear polyethylene, and then placed in a foil laminate bag that is gas-flushed and filled with a volume of CO_2 approximately equal to that of the meat. Similar storage lives are currently being achieved with beef primals transported from Australia and South Africa to the EU. Assuming good standards of preparation and prompt cooling, the times given in Table 1 could be used as approximate guidelines for long-distance meat shipment.

These times rely on the meat being at or below the storage temperature before loading. The 2–4-week advantage of transporting meat at −1.5 °C rather than 0 °C will be lost if the meat is loaded at a temperature above 0 °C. Cooling in the center of a load of meat is very slow, and the meat will be well into its journey before the desired temperature is achieved.

International Standard Organization (ISO) containers for food transport are 6 or 12 m long, hold up to 26 tonnes of product and can be 'insulated' or 'refrigerated.' The refrigerated containers incorporate insulation and have refrigeration units built into their structure. Insulated containers either utilize plug-type refrigeration units or may be connected directly to an air-handling system in a ship's hold or at the docks. Refrigerated containers are easier to transport over land than the insulated types, but have to be carried on deck when shipped because of problems in operating the refrigeration units within closed holds. On board ship, they are therefore subjected to much higher ambient temperatures and consequently larger heat gains, which make it far more difficult to control product temperatures. Close temperature control is most easily achieved in containers that are placed in insulated holds and connected to the ship's refrigeration system.

Air Transport

Although air freighting of foods offers a rapid method of serving distant markets, there are many problems because the product is unprotected by refrigeration for much of its journey. Up to 80% of the total journey time is spent on the tarmac or transport to and from the airport. Perishable cargo is usually carried in standard containers, sometimes with an insulating lining and/or dry ice, but is often unprotected on aircraft pallets.

Studies in Australia have led to the following recommendations for air transport of chilled foods:

1. Insulated containers should always be used to reduce heat gain.
2. Product should always be precooled and held at the required temperature until loading.
3. With products that deteriorate after any surface freezing, dry ice should not be used.
4. Containers should be filled to capacity.
5. A thermograph should accompany each consignment.

Table 1 Recommended transportation life of meat

	Vacuum pack 0 °C	*Vacuum pack −1.5 °C*	*CO_2 −1.5 °C*
Pork	6 weeks	8 weeks	
Lamb	7 weeks	10 weeks	> 12 weeks
Beef	10 weeks	14 weeks	

Retail Display

The retail display of chilled food is probably still the weakest link in the cold chain. In the UK, the Food Hygiene (Amendment) Regulations 1990 required food retailers to maintain the temperature of certain chilled foods below 5 °C and others 8 °C during storage, transport, and display. This legislation, which contained severe financial penalties for temperature infringements, produced a marked improvement in the design, construction, and operation of retail display cabinets. However, the legislation has since been relaxed, and there is currently less emphasis on the maintenance of food temperatures.

The required retail display life and consequent environmental conditions for wrapped chilled products differ from those for unwrapped products. The desired display life for wrapped meat, fish, vegetables, and processed foods ranges from a few days to many weeks and is primarily limited by microbiological considerations. Retailers of unwrapped fish, meat, and delicatessen products normally require a display life of one working day.

Display cabinets for delicatessen products are available with gravity or forced convection coils, and the glass fronts may be nearly vertical or angled up to 20 °. In the gravity cabinet, cooled air from the raised rear-mounted evaporator coil descends into the display well by natural convection, and the warm air rises back to the evaporator. In the forced-circulation cabinets, air is drawn through an evaporator coil by a fan and then ducted into the rear of the display. It then returns to the coil after passing directly over the products, or forming an air curtain, via a slot in the front of the cabinet and a duct under the display shelf.

Although the same cabinets can be used for wrapped foods, most are sold from multideck cabinets with single or twin air curtain systems. It is important that the front edges of the cabinet shelves do not project through the air curtain since the

refrigerated air will then be diverted out of the cabinet. However, if narrow shelves are used, the curtain may collapse, and ambient air can be drawn into the display well. External factors such as the store ambient temperature, the siting of the cabinet, and poor pretreatment and placement of products substantially affect cabinet performance. Computational fluid dynamics is increasingly being used as a valuable modeling tool to improve air distribution and temperature control in retail display cabinets and retail stores themselves.

Attainment of Chilled Conditions

S James, University of Bristol, Langford, North Somerset, UK

Background

The purpose of the chill chain is first to reduce the temperature of a food to below a set temperature and henceforth maintain it at or below that temperature. Since the growth of both pathogenic and food spoilage organisms is very temperature-dependent, the rapid attainment and maintenance of low temperatures are important to food safety and shelf-life. In this article, the cooling rates and temperatures that can be attained and maintained are discussed together with the limiting physical factors.

The speed at which a food can be cooled can be limited by either the rate of heat removal from its surface or internal conduction. Heat removal from the surface is a direct function of the surface heat transfer coefficient (h). Typical values of h range from $5\,W\,m^{-2}\,°C^{-1}$ for slow-moving air to $500\,W$ $W\,m^{-2}\,°C^{-1}$ for agitated water. **Table 1** shows that, at low values of h, a 10-fold increase, 5 to $50\,W\,m^{-2}\,°C^{-1}$, makes a substantial, 3.2- to 4.2-fold reduction in cooling time. A further 10-fold increase from 50 to $500\,W\,m^{-2}\,°C^{-1}$ decreases the cooling time threefold for a 2-cm-thick slab but only results in a 60% reduction at a thickness of 8 cm. This indicates that in the thicker material internal heat conduction is becoming rate-controlling.

Primary Chilling

Primary chilling after harvest or slaughter is usually applied to large individual items or small items cooled in bulk. Air cooling is often used in primary chilling because internal conduction controls the rate the products can be cooled. Data from the cooling of beef sides (**Figure 1**) illustrate the relative influence of air temperature and air velocity. The data have been presented as a plot of the logarithm of temperature against time and, provided air temperatures are chosen to avoid substantial surface freezing, it is quite feasible to determine the cooling time for any other air temperature. The fractional unaccomplished temperature on the y-axis can be replaced by the meat temperature calculated from $y = (t-t_f)/(t_i-t_f)$, where t is the meat temperature, t_i the initial meat temperature, and t_f the air temperature.

Cooling in air at a constant 4 °C, compared with 0 °C, at $3\,m\,s^{-1}$ will increase the time to reach 7 °C in

Table 1 Predicted cooling time (h) from 40 °C to 2 °C at the center

Cooling method	h *($W\,m^{-2}\,°C^{-1}$)*	*Meat thickness (cm)*		
		2.0	*4.0*	*8.0*
Air (still)	5	5.0	11.0	24.0
Air ($5\,m\,s^{-1}$)	50	1.2	2.8	7.4
Plate	360	0.7	1.8	5.5
Immersion	500	0.4	1.2	4.4

the deep leg of a 100-kg side from 20.3 to 27.7 h (36% increase). At 0.5 m s^{-1} the same rise in air temperature for a 220-kg side will increase the chilling time from 45.9 to 68.3 h (49% increase).

The shelf-life of vegetables is largely governed by the amount of water that is lost from the vegetables. Leafy vegetables have a relatively short shelf-life because of the potential for high weight of evaporation. Their shelf-life can be greatly improved if the field heat is removed immediately after harvesting and the temperature of vegetables subsequently maintained at their optimum. For most winter vegetables, which have their origins in temperate climates, this temperature is close to 0 °C. Some tropical fruits and vegetables are damaged if the temperature is reduced too low and they should, therefore, be chilled and maintained at warmer temperatures.

Vegetables are cooled in many ways. One convenient bulk system is to pack the vegetables into large crates which are then stacked in front of a chiller and air is forced to flow through the crates back to the chiller in order to effect a fast rate of cooling. Weight loss will be rapid during the first parts of the process but when the temperature of the surface of the vegetables approaches that of the air then the relative humidity of the air will become important. Artificial ways of increasing the humidity of the air are common for vegetable cooling. The most normal system utilizes an ice bank from which chilled water at 0 °C is drawn. This is passed over packing to extend the surface area of water through which air from the chill room is drawn. The resulting air is at very high humidity and with a temperature of close to 0 °C. By controlling the temperature of the water and bypassing the air, the bulk humidity and temperature of the air can be controlled to lower relative humidities and warmer temperatures than these.

Vegetables can be readily cooled with running water. This reduces the evaporation of water to zero and even small weight gains can be achieved. The water can also be used to wash the vegetables. Subsequent storage should be in very high humidities to prevent further deterioration.

Leafy vegetables can be cooled in a vacuum cooling process. In this process, the vegetables are placed in a vacuum chamber and a vacuum is drawn. The

evaporation of water from the plant is used to promote rapid cooling. The small loss, 2% in the case of lettuces, is considered acceptable, given that the subsequently chilled lettuces have a longer shelf-life than those chilled by conventional means.

Secondary Chilling

Cooking rarely eliminates all food-poisoning organisms and a number survive as spores which will germinate and grow if cooling rates are slow. Rapid reduction in surface temperature retards microbial growth and consequently extends shelf-life. This is especially important when chilling cooked products that will eventually be consumed cold or in a warm reheated state. Rapid rates of cooling are required without surface freezing. The problem is complicated in two-compartment ready-meal consumer packs. These typically contain rice or pasta in one compartment, and a meat- or fish-based product in the second. The thermal properties of the two items are often very different and they may be filled to different depths. Air at $-10\,^{\circ}C$ and $5\,m\,s^{-1}$ produces a cooling time of 34 min, but substantial quantities of the product are frozen. At an air velocity of $0.5\,m\,s^{-1}$ the cooling time is doubled but only a small area of the rice is frozen. With higher air temperatures, the extent of freezing is reduced. A cooling time of approximately 0.75 h is achieved at $-5\,^{\circ}C$, $5\,m\,s^{-1}$ with acceptable freezing.

The importance of achieving a minimum required air velocity around small products is clearly demonstrated by data obtained from cooling pork pies (Figure 2). To guarantee that all the crust remained above $-2\,^{\circ}C$ on the unwrapped 400-g (70-mm high, 95-mm diameter) pies, an air temperature of $-1.5 \pm 0.5\,^{\circ}C$ was used. At this temperature, a small increase in air velocity from 0.5 to $1.0\,m\,s^{-1}$ reduced the cooling time by 85 min (almost 30%). Even at very high velocities ($> 6.0\,m\,s^{-1}$) appreciable reductions in cooling time were still being achieved.

Rapid rates of temperature reduction can be achieved in trays of cooked product such as mince, baby foods, and poultry portions when cooled under vacuum.

Slow cooling of large hams and cooked meat has been implicated in a number of food-poisoning outbreaks. It is now recommended that large uncured joints are cooled in < 8 h and cured joints in < 10 h. In laboratory studies three different cooling methods – forced air at $0\,^{\circ}C$, $1.2\,m\,s^{-1}$, immersion in water at $0\,^{\circ}C$, and cooling under vacuum – for large (6.8–7.3 kg) hams, and other meats were compared (Table 2). Although cooling times are much faster under vacuum, weight losses (typically 7.5–9.5%) are much higher than those in air (typically 2–3%).

Storage, Transport, and Display

In general, after initial chilling, as a chilled product moves along the chill chain it becomes harder to control and maintain its temperature. Temperatures of bulk packs of chilled product in large storerooms are far less sensitive to small heat inputs than single consumer packs in transport or open display cases. If primary and secondary cooling operations are

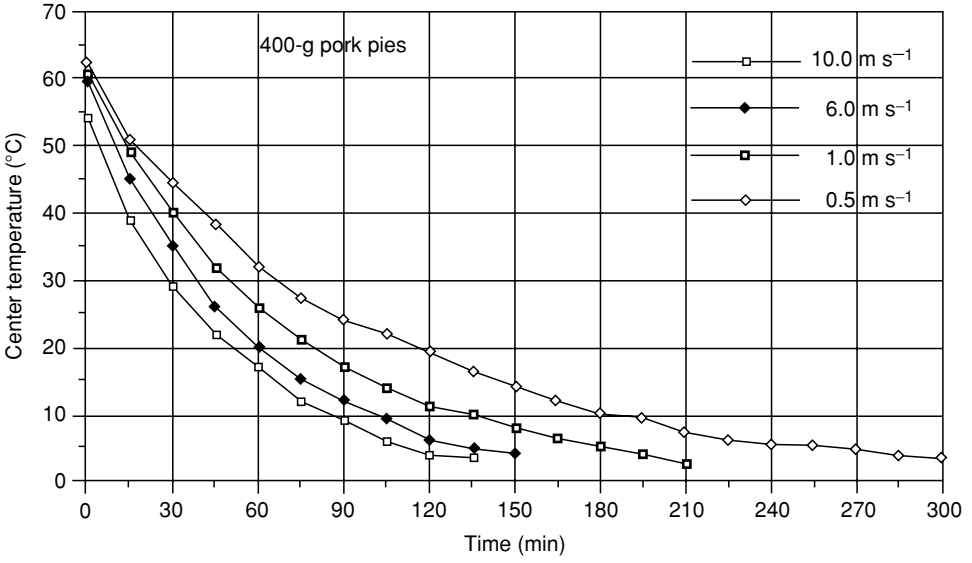

Figure 2 Temperature at slowest cooling point in 400-g pork pies at $-1.5\,^{\circ}C$ air temperature and velocities of 10, 6, 1, and $0.5\,m\,s^{-1}$.

efficiently carried out, then the food will be reduced below its required temperature before it is placed in store. In this situation the store's refrigeration system is only required to extract extraneous heat that enters through the walls, door openings, etc.

Efficient cooling is also important before transportation. A study of different transportation methods found that the deep temperature in beef sides and quarters at the time of their loading into transport vehicles in three USA plants ranged from 6 to 18 °C (Figure 3). In rail wagons the surface temperature declined during the first 24 h and was subsequently maintained at a temperature of 0 ± 1 °C. In the road vehicles the surface temperature fell slowly during the whole journey and had not attained a steady minimum value when unloaded. On average the deep temperature of sides in rail wagons reached 1 °C after 72 h. Temperatures in quarters in road vehicles were still above 2 °C after 120 h.

Even when temperature-controlled dispatch bays are used, there is a slight heat pick-up during loading. In bulk transportation, the resulting temperature rise is small and the refrigeration system of the vehicle rapidly returns the product to the required temperature. Larger problems exist in local multidrop distribution to individual stores. There are substantial difficulties in maintaining the temperature of chilled foods transported in small refrigerated vehicles that conduct multidrop deliveries to retail stores and caterers. The vehicles have to carry a wide range of products and operate under diverse ambient conditions. During any one delivery run, the chilled product can be subjected to as many as 50 door openings, where there is heat ingress directly from outside and from personnel entering to select and remove product. The design of the refrigeration system has to allow for extensive differences in load distribution, dependent on different delivery rounds, days of the week, and the removal of product during a delivery run. A refrigeration system's ability to respond to sudden demands for increased refrigeration is often restricted by the power available from the vehicle. All these problems combine to produce a complex interactive system. Computer programs such as CoolVan are now available to aid the design and operation of local delivery systems.

Surveys carried out in the UK, Denmark, and Sweden (Figure 4) have revealed a very wide range

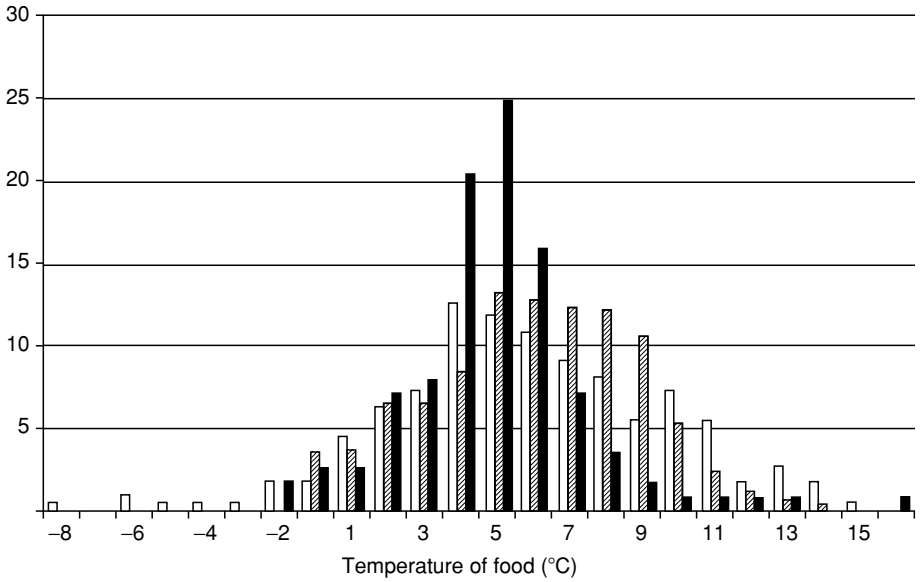

Figure 4 Temperature of chilled foods in retail display cabinets in the UK (open columns), Denmark (cross-hatched columns), and Sweden (filled columns). 	Cool box in car	12	0	< 0.1

of temperatures within foods on retail display. Legislation on maximum temperatures for the display of chilled foods is in place in many European countries.

Domestic

Although legislation such as that introduced in the UK should insure that food producers and retailers maintain acceptable product temperatures during the distribution chain, they lose control when the product leaves the retail store. After a chilled product is removed from a display cabinet it spends a period outside a refrigerated environment whilst it is carried around the store and then transported home.

Investigations have compared unprotected transportation in a car boot with that in an insulated box. Initial product temperatures measured when the food reached the car ranged from 4 to over 20 °C. Some product temperatures on samples placed in the boot rose to approaching 40 °C (Table 3) during the 1-h car journey whilst most of the samples placed in the insulated box cooled during the car journey, except for a few at the top of the box which remained at their initial temperature. Small products, i.e., prawns, showed the highest temperature changes during transport. Thicker products like cooked chicken were less influenced. After being placed in the domestic refrigerator it required approximately 5 h before the temperature was reduced below 7 °C.

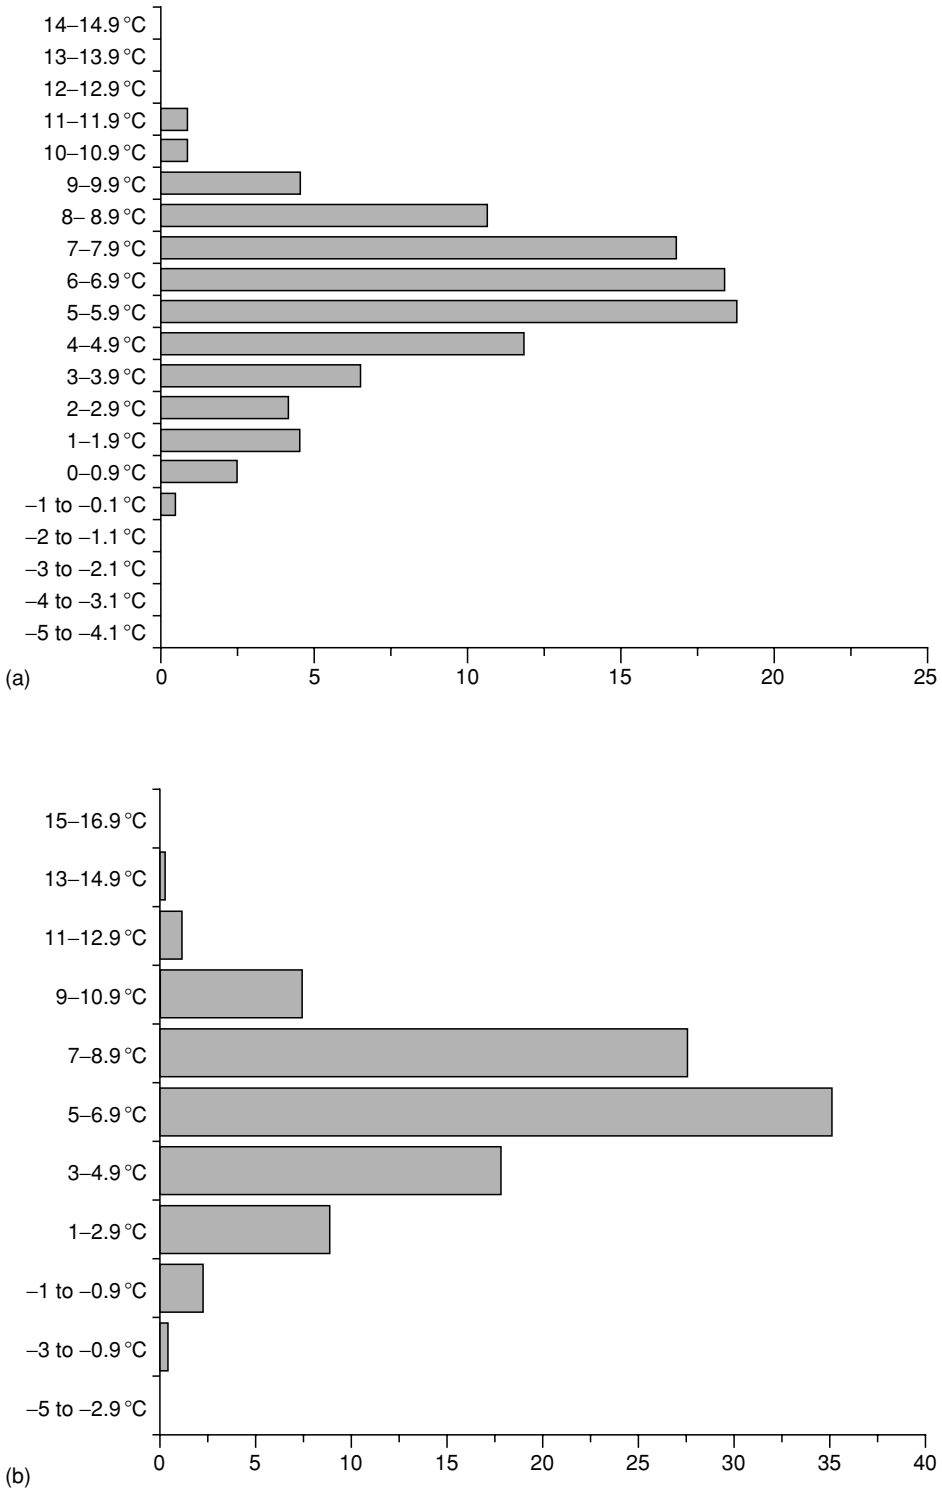

Figure 5 (a) Food temperatures and (b) air temperatures measured in domestic refrigerators in 252 households in the UK. (a) percentage of food with temperature in stated range; (b) percentage of refrigerators with overall average temperatures within stated range.

Predictions made using a mathematical model that calculated bacterial growth from temperature/time relationships indicated that increases of up to 1.8 generations in bacterial numbers (Table 3) can occur during this transport and domestic cooling phase. The model assumes that bacteria require a time to acclimatize to a change in temperature (the lag phase) and that no acclimatization had occurred during display. If this rather optimistic assumption was not made, then up to 4.2 generations of *Pseudomonas* and growth of both *Salmonella* and *Listeria* were predicted. Very small increases in bacterial numbers (< 0.4 generations: Table 3) were predicted when the insulated box was used, due to the lower product temperatures.

Chilled foods spend a period between a few minutes and many days stored in domestic refrigerators. The average food temperature measured in a survey of refrigerators in 252 UK households was approximately 6 °C (Figure 5a). However, in over 15% of the refrigerators the average food temperature was above 8 °C. In a typical UK refrigerator, a chilled food would spend over 35% of its time in an air temperature above 7 °C (Figure 5b).

Quality and Economic Considerations

S James, University of Bristol, Langford, North Somerset, UK

Introduction

Quality and economic considerations are often the most important factors that govern the choice of a chilling system and the subsequent chilled chain for a particular foodstuff. Since the microbiological aspects are covered elsewhere, quality considerations in this chapter relate to organoleptic and nutritional changes. Chemical and biochemical changes within foods cause modifications in the appearance, taste, or texture that can limit its high quality shelf life. These changes are not always detrimental to the eating quality of the food. For example, biochemical changes, referred to as 'conditioning' or 'aging', that occur in meat after slaughter lead to improvements in both its texture and taste.

In general with meat- and fish-based foods, the longest high-quality shelf life is achieved by rapidly reducing the temperature of the food and then maintaining it at a temperature very close to its initial freezing point. However, this is not true of all foods. For example, tropical fruits such as bananas suffer discoloration at temperatures below 12 °C, whereas salad vegetables such as cucumbers lose their textural properties at temperatures below 6 °C. Different cultivars of tomato suffer damage, called watersoaking and softening at temperatures below 7 or 10 °C, pitting, and russeting occur in beans below 7 °C and brown core in apples below 2 °C.

Primary and Secondary Chilling

Quality Considerations

In the majority of foods, fast cooling is beneficial, but there are instances where excessively rapid chilling rates cause quality problems in particular foods. For example, a serious defect known as 'woolly texture' can be produced in rapidly cooled peaches. Biochemical constraints lead to toughening if the lean tissue of beef or lamb is reduced to 10 °C or below within 10 h of slaughter. Due to differences in the biochemistry of pork muscle, the same temperature has to be achieved within 3 h to cause toughening. (*See* **Meat**: Preservation.)

Different foodstuffs exhibit particular quality advantages because of rapid chilling. In meat, the pH starts to fall immediately after slaughter, and protein denaturation begins. The result of this denaturation is a pink, proteinaceous fluid, commonly called 'drip', often seen in pre-packaged joints. The rate of denaturation is directly related to temperature, and it follows therefore that the faster the chilling rate, the less the drip. With both pork (Table 1) and beef, the use of rapid rates of chilling can halve the amount of drip loss. Fish passing through rigor mortis above 17 °C are largely unusable because the fillets shrink and become tough. A relatively short delay of an hour or two before chilling can demonstrably reduce shelf life. In a different commodity area, freshly harvested sweetcorn loses 5, 20, or 60% of its sugar content after 24 h in air at 0, 10, and 30 °C, respectively. Prompt cooling is clearly required if this vegetable is to retain its desirable sweetness. Similarly, the ripening of fruit can be controlled by rapid cooling, the rate of ripening declining as temperature is reduced and ceasing below about 4 °C. (*See* **Fish**: Processing; **Ripening of Fruit**.)

Rapid cooling is also often desirable with cooked products to maintain quality by eliminating the overcooking that occurs during slow cooling. For vitamin retention, the time taken to reduce the center temperature from 80 to 15 °C is a critical factor. The vitamin C content in nonpasteurized meals is reduced by 1 to 12% if cooling is carried out in 0.5 h, by 2 to 17% if the time is increased to 2 h, and by 10 to 38% when cooling takes 5 h. (*See* **Ascorbic Acid**: Properties and Determination.)

Vacuum-cooling is a very effective method of cooling cooked beef joints and hams. However, the process results in high weight losses and some reduction in eating qualities of the meat. Intermittent spraying to replace the water loss is practiced in vacuum-cooling of vegetables. It could have an application with meat.

Table 1 Drip loss after 2 days' storage at 0 °C, from leg joints from different breeds of pig cooled at different rates

Breed	*Drip loss (percent by weight)*	
	Slow	*Quick*
Landrace	0.47	0.24
Large White	0.73	0.42
Wessex × Large White	0.97	0.61
Pietrain	1.14	0.62

Economic Considerations

It is clear from restrictions already detailed that attempts to increase chilling rates are complicated by many factors, but there are a number of clear advantages in production economics if faster cooling can be achieved. Most foods are of high value, and any increase in rate of product throughput will improve cash flow and utilize expensive plants more efficiently. For example, the cooling time of 400-g pies can be reduced by 10 min if the air velocity is raised from 6 to 10 m s^{-1}. In high-throughput baking lines (> 1000 items per hour), the 7% increase in throughput could justify the higher capital and running costs of larger fans. The power required by the fans to move the air within a chill room increases with the cube of the velocity. A fourfold increase in air velocity from 0.5 to 2 m s^{-1} results in a 4.4-h (18%) reduction in chilling time for a 140-kg beef side, but requires a 64-fold increase in fan power. Increasing air velocity to 3 m s^{-1} only achieves an extra 6% reduction in chilling time. In most practical situations, where large items (e.g., meat carcasses, tuna, bins of vegetables) are being cooled, it is doubtful whether an air velocity greater than 1 m s^{-1} can be justified.

Efficient chilling produces a reduction in weight loss, which results in a higher yield of saleable material. Most foods have a high water content, and the rate of evaporation depends on the vapor pressure at the surface. Vapor pressure increases with temperature, and thus any reduction in the surface temperature will reduce the rate of evaporation. The effect of air temperature and velocity on evaporative weight loss during chilling is dependent upon the endpoint of the chilling process (Figure 1a and b). When chilling for a set time, weight loss increases as the temperature decreases and velocity increases. The opposite effect is found when chilling to a set temperature.

If specified cooling schedules are to be attained, refrigeration machinery must be designed to meet the required heat extraction rate at all times during the chilling cycle. Heat enters a chill room via open doors, from personnel, through the insulation, from lights and cooling fans, and from the cooling

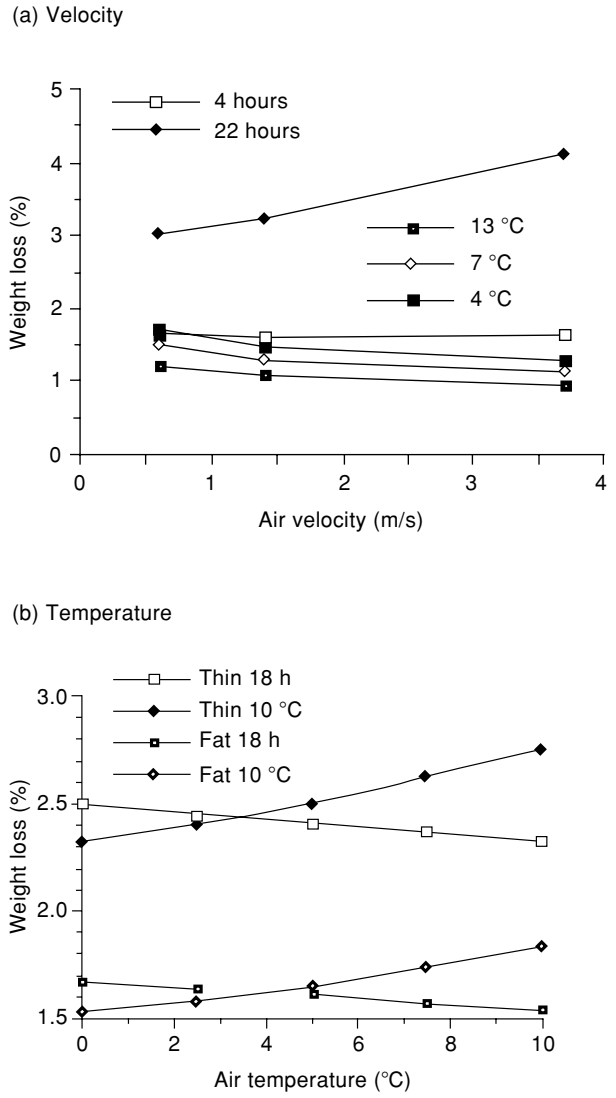

Figure 1 Relationship between weight loss and (a) air velocity for lamb carcasses and (b) air temperature for beef sides when chilling either for a set time or to a final temperature.

products. The product load is the major component of the total heat to be extracted from a fully loaded chill room. The rate of heat release from a food varies with time. It is at a peak immediately after loading and then falls rapidly.

The peak value is primarily a function of the environmental conditions during chilling. In commercial systems, the peak load imposed on the refrigeration plant is also a function of the rate at which hot food is introduced into the chill room. Increasing the air velocity, decreasing the air temperature, or shortening the loading time increases the peak heat load. In beef-chilling, for example, there is a fourfold difference in peak load between a chill room operating at 8 °C, 0.5 m s^{-1} loaded over 8 h and the same room operating at 0 °C, 3 m s^{-1} and loaded over 2 h.

Alternative chilling treatments can produce large increases in throughput and reductions in weight loss over conventional treatments (Table 2). The cash savings that result from the reduced weight losses can substantially increase the overall profits of many slaughtering operations (Table 2).

Commercial Storage, Retail Display, and Domestic Storage

Packaged Food

Most packaging systems substantially reduce evaporative weight loss from the surface of the product, and many retard the rate of chemical degradation. The use of modified atmospheres or opaque packaging can limit color changes during the chilled storage of meat, fish, and fruits.

Losses in vitamin content tend to be reduced at lower storage and display temperatures. Vitamin C losses from lettuce average 4.8, 5.6, and 6.6% per day at temperatures of 1, 5, and 10 °C, respectively.

Table 2 The weight loss, saving (£) over conventionally chilled controls, total work done at 24 h post mortem, cooling time to 10 °C for each treatment, drip loss from loin chops and annual saving for each treatment compared with the conventional chill used as a control for an abattoir slaughtering an average of 1000 pigs per week (74 kg dead weight at £0.90 kg^{-1})

[a]Measured at intersection of lean and fat.

Larger effects of temperature are found in French beans with equivalent losses of 1.9, 3.0, and 5.1% per day. No losses were reported in carrots at the three temperatures.

Oranges and pineapples are examples of foods that have an optimum temperature for vitamin C retention. In oranges, a 10% loss per month at 10 °C increases to 12% at 5 °C and 26% at 0 °C. Raising the storage temperature above 10 °C also increases the rate of loss to 13% at 15 °C and 22% at 30 °C. A similar optimum at 10 °C is found in pineapples.

Vitamin B_6 retention is also a function of both storage temperature and species. Loss from lettuce and French beans increases twofold and threefold, respectively, as the temperature is increased from 1 to 10 °C. No change was reported in parsley or carrots. (*See* **Vitamin B_6**: Properties and Determination.)

Unwrapped Food

Changes in appearance are normally the criteria that limit storage and display of unwrapped foods, commercial buyers or domestic consumers selecting fresh or newly loaded product in preference to that displayed or stored for some time. Deterioration in appearance has been related to degree of dehydration in red meat (Table 3), and similar changes are likely to occur in other foods. Apart from any relationship to appearance, weight loss is of considerable importance in its own right. The direct cost of evaporative loss from unwrapped foods in chilled display cabinets in the UK is in excess of £5 million per annum.

In the equation that governs weight loss, already described, the mass-transfer coefficient, m, is a function of air velocity. Typical values range from approximately $2 \times 10^{-8}\,\mathrm{kg\,m^{-2}\,s^{-1}\,Pa^{-1}}$ at $0.25\,\mathrm{m\,s^{-1}}$ to $14 \times 10^{-8}\,\mathrm{kg\,m^{-2}\,s^{-1}\,Pa^{-1}}$ at $1.5\,\mathrm{m\,s^{-1}}$. The vapor pressure difference ($P_s a_w - P_m$) is a function of surface temperature and dryness, and the temperature and relative humidity of the air.

In storage rooms at temperatures in the range of 0–2 °C, 76–90% RH, the average weight loss from cauliflower, French beans, and green peas is in the range of 0.1–0.4% per day. Under conditions typical of domestic refrigeration, 4–8 °C and 70–90% RH, weight losses from the same products range from 0.3 to 3.0% per day. In a nonrefrigerated ambient, 16–24 °C and 50–70% RH, losses are even higher in the range of 1.0–4.0% per day.

The relative effects of air temperature, velocity, and humidity on weight loss in retail display are demonstrated in Figure 2. Changes in relative humidity have a substantial effect with a reduction from 95 to 40%, increasing weight loss over a 6-h display period by a factor of between 14 and 18. The effect of air velocity on weight loss is confounded by that of relative humidity. Raising the air velocity from 0.1 to $0.5\,\mathrm{m\,s^{-1}}$ has little effect on weight loss at 95% RH but

Table 3 Relationship between change in appearance and evaporative weight loss ($\mathrm{g\,cm^{-2}}$)

Evaporative loss	*Change in appearance*
Up to 0.01	Red, attractive, and still wet; may lose some brightness
0.015–0.025	Surface becoming drier; still attractive but darker
0.025–0.035	Distinct obvious darkening; becoming dry and leathery
0.05	Dry, blackening
0.05–0.10	Black

increases the loss by a factor of between 2 and 2.4 at 60% RH. A temperature change from 2 to 6 °C has a far smaller effect on weight loss than changes in either relative humidity or velocity.

In further work, a model developed to predict the rate of weight loss from unwrapped meat under the range of environmental conditions found in chilled retail displays showed that it was governed by the mean value of the conditions. Fluctuations in temperature or relative humidity had little effect on weight loss, and any apparent effect was caused by changes in the mean conditions.

There is a conflict between the need to make the display attractive and convenient to increase sales appeal and the optimum display conditions for the product. High lighting levels increase the heat load, and the air temperature in the cabinet rises. This rise increases the temperature difference across the evaporator coil, and the air entering the cabinet is dehumidified. Consequently, the rate of evaporative weight loss from foods on display is increased.

Studies have shown that changing a lighting combination of 50 W sons and 100 W halogen lights to 100 W sons and a colour 83 fluorescent significantly increased the weight loss (Figure 3). The increase was similar in magnitude to that produced by 20% reduction in relative humidity. On average, the rate of weight loss under the combination of 50 W sons and 100 W halogen (spot) lights was approximately 1.4 times less than the 100 W sons and colour 83 fluorescent lighting.

Microbiological Considerations

S J Walker, Campden & Chorleywood Food Research Association, Chipping Campden, Gloucestershire, UK

Background

During storage, many foods and their raw materials will deteriorate and become unacceptable to the end user. Food preservation techniques aim to prevent or retard this deterioration. Chilled storage can be rarely relied upon to prevent spoilage, but can be used to extend the time until this becomes apparent. Such storage has major effects on the rates of biochemical and biological changes in foods, although this article will focus on microbiological issues in chill stored foods and ingredients.

Foods or ingredients intended for chilled storage may initially contain a wide variety of microorganisms derived from the material itself or contaminants arising from harvesting, storage, and processing. The organisms that spoil chilled foods will be those that are best adapted to these temperatures.

Effects of Chilled Storage on Microorganisms

If the temperature of chilled storage is below the minimum growth temperature for a microorganism, no growth will occur. However, microbial growth has been reported for a number of microorganisms at temperatures below 0 °C. Consequently, chilled storage cannot be relied upon for microbial stability. The major effects on microbial growth are to extend the time until an increase in numbers is apparent (the lag time) and to reduce the rate of growth when this occurs.

Cardinal Temperatures

Microorganisms may be characterized by their abilities to grow at specific temperatures, commonly referred to as the cardinal temperatures.

With chilled foods, the factor of most concern is the *minimum growth temperature* (MGT), which represents the lowest temperature at which growth of a particular microorganism can occur. If the MGT of a microorganism is greater than 10 °C, this microorganism will not grow during chill storage. Care is needed with published MGT values. For example, if the time period for the investigation reporting this value were too short, the resultant value would be overestimated. As the MGT is affected by other factors, including the pH, salt, preservatives, and previous heat treatments, a true estimate can be determined only when other factors are optimal for growth.

Although gradual death may occur if a microorganism is stored below its MGT, this should not be considered to be a lethal process, as, in many cases, growth will resume if the temperature is subsequently raised.

The *optimum growth temperature* represents the temperature at which the biochemical processes governing growth of a particular microorganism are overall operating most efficiently. At this temperature, the lag phase before growth is minimized and the growth rate maximized. As the temperature rises above the optimum, the rate of growth decreases until the *maximum growth temperature* is reached. In general, the maximum growth temperature is only a few degrees higher than the optimum. At temperatures just above the maximum for growth, cell injury starts to occur. However, if the temperature is subsequently reduced, growth may resume, although a period of time may be required to permit cell repair. At higher temperatures, the inactivation of one or more critical enzymes in the microorganism becomes irreversible, and cell damage occurs, leading to cell death.

Based on the relative positions of the cardinal temperatures, microorganisms can be divided into four main groups, viz. psychrophiles, psychrotrophs, mesophiles and thermophiles (Table 1). With chilled foods, the groups of most concern are the psychrophiles and psychrotrophs. Whilst these terms have been used synonymously in the past, it is now accepted that the major spoilage microorganisms of chilled foods are psychrotrophic in nature. True psychrophiles are rare in food microbiology and generally limited to some microorganisms from deepsea fish. The minimum growth temperatures for many of the microorganisms relevant to chilled foods are given in Table 2.

Microbial Growth in Chilled Foods

Whilst microbiological spoilage of chilled foods may take diverse forms, it generally manifests itself in a change in the sensory characteristics. In the simplest form, this may be due to the production of visible

Table 1 Cardinal temperatures for microbial types

	Temperature (°C)		
	Minimum	*Optimum*	*Maximum*
Psychrophiles	< 0–5	12–20	20–22
Psychrotrophs	< 0–5	20–35	30–40
Mesophiles	10	30–40	40–45
Thermophiles	30–40	45–65	60– > 80

Table 2 Minimum growth temperatures of microorganisms (Adapted from Martens, 1999)

Microorganism	*Minimum temperature (°C)*[a]
Bacillus cereus	
Mesophilic	15
Psychrotrophic	4
Bacillus species (spoilage)	0–15
Brochothrix thermosphacta	4
Campylobacter jejuni	32
Clostridium botulinum:	
Mesophilic (proteolytic)	10
Psychrotrophic (nonproteolytic)	3
Clostridium perfringens	12
Coliforms	2–8[b]
Escherichia coli	4
Escherichia coli O157	6.5
Lactobacillus species	0–10[b]
Listeria monocytogenes	0
Micrococcus species	1–10[b]
Pseudomonas species	−3
Salmonella	7
Staphylococcus aureus	6 (10 for toxin)
Vibrio parahaemolyticus	5
Yeasts	−10
Yersinia enterocolitica	−1

[a]Under otherwise optimal conditions. These figures are indicative only and not necessarily representative of all strains of microorganisms in foods, and will also depend on the composition of the food and the storage conditions.
[b]Depending on the strain.
From Martens T (1999) *Harmonisation of Safety Criteria for Minimally Processed Foods: Rationale and Harmonisation Report. European Commission FAIR CT-96-1020*.

growth, and this is common in molds that produce large, often pigmented colonies. Bacteria and yeasts also may produce visible (sometimes pigmented) colonies on foods. Other forms of spoilage include the production of gases, slime (extracellular polysaccharide material), diffusible pigments, and enzymes that may produce softening, rotting, off-odors and off-flavors from the breakdown of food components.

When only a few spoilage microorganisms are present, the consequences of growth may not be apparent. If, however, the microorganisms multiply during storage, the production of deleterious compounds or deterioration in structure in the food may become unacceptable. Some of the enzymes produced by spoilage bacteria may remain active, even when a thermal process has destroyed the causative microorganisms in the food.

The relationship between microbial numbers and food spoilage is complex and depends on the number, type, and activity of the microorganisms present, the type of food, the intrinsic properties of the food (e.g., pH, water activity, preservatives) and the extrinsic conditions (e.g., temperature of storage, atmosphere).

Spoilage is often most rapid and pronounced in proteinaceous chilled foods such as red meats, poultry, fish, shellfish, milk, and some dairy products. These products allow relatively good microbial growth as they are highly nutritious and have a high moisture content and relatively neutral pH value. However, care is needed to distinguish between those microorganisms present in spoiled food and those responsible for the spoilage defect (often called specific spoilage organisms), which may be only a fraction of the total microflora. Consequently, the relationship between sensory spoilage and microbial numbers is often only poorly correlated.

Spoilage Microorganisms

For this article, spoilage microorganisms have been arbitrarily divided into six categories: Gram-negative (oxidase positive) rod-shaped bacteria, coliform/enteric bacteria, Gram-positive spore-forming bacteria, lactic acid bacteria, other bacteria, and yeasts and molds.

Gram-negative (oxidase-positive) rod-shaped bacteria This group generally comprises the most common spoilage microorganisms of fresh, chilled proteinaceous products stored in air. The minimum growth temperatures are often −3 to 0 °C, and they grow relatively rapidly at 5–10 °C. Although they may represent only a small proportion of the initial microflora, they may grow and rapidly dominate the microflora of fresh, proteinaceous, chilled, stored foods.

Within this general group, the genus *Pseudomonas* is most common, although other genera include *Acinetobacter*, *Aeromonas*, *Alcaligenes*, *Alteromonas*, *Flavobacterium*, *Moraxella*, *Shewanella*, and *Vibrio* species. These microorganisms are common in the environment, particularly in water, and so may easily contaminate foods. Often, they may proliferate on inadequately cleaned surfaces of food processing plant or equipment.

These organisms may spoil products by the production of pigments, slime material on surfaces, and enzymes that result in food rots, off-flavors and off-odors. Some of the enzymes produced by *Pseudomonas* species are extremely heat-resistant and may produce long-term defects (e.g., rancidity or age gelation) in thermally processed (i.e., sterile) products.

Although this group is well adapted to grow at chill temperatures, it tends to be sensitive to other factors such as the presence of salt or preservatives, lack of oxygen, low pH (< 5.5) and a low water activity (< 0.98). Should these conditions prevail in a food, these bacteria will compete less well, and so other

microbial groups may cause spoilage. Overall, this group is not heat-resistant and is readily removed by mild thermal treatments. Consequently, their presence in heat-processed chilled foods is usually as a consequence of postprocess contamination.

Coliform/enteric bacteria This bacterial group also consists of Gram-negative rods, but these may be distinguished from the above group by a negative oxidase reaction. Traditionally, microbiologists have tended to examine for these groups separately, as their sources, significance, and factors affecting growth may differ. This group is frequently used as an indicator of postprocess contamination, inadequate processing or potential fecal contamination.

Compared with the Gram-negative (oxidase positive) rod-shaped bacteria, the coliform-enteric group is generally less well adapted to growth at temperatures of less than 5–10 °C, although some may grow at lower temperatures. However, they often dominate the flora of foods stored at temperatures of 8–15 °C and are less sensitive to changes in pH compared with the previous group. They are, however, generally sensitive to low water activity, preservatives, salt and thermal treatments. The coliform/enteric group does not necessarily require the presence of oxygen for growth.

This group may break down carbohydrates to give acids, which may result in souring of milk and other foods. Other types of spoilage include the production of pigmented growth, gases, slime, off-odors and off-flavors; these have often been described as 'grassy,' medicinal, unclean, and fecal.

Typical spoilage genera include *Citrobacter*, *Escherichia*, *Enterobacter*, *Hafnia*, *Klebsiella*, *Proteus*, and *Serratia*. These microorganisms are widely disseminated in the environment, including in animals. For animal products, poor slaughter and dressing practices may contribute to their presence in foods.

Gram-positive spore-forming bacteria These are of particular significance as they can produce heat-resistant spores that can survive many thermal processes that destroy vegetative cells, leaving these organisms to grow and dominate the microflora. The minimum growth temperatures are often quoted as 0–5 °C, although growth is frequently slow below 8 °C.

The genera of concern in this group are *Bacillus* and *Clostridium*. Again, these are common in the environment, and spores may survive for tens and possibly hundreds of years. The most common form of spoilage is the production of large quantities of gas that may result in pack or product blowing. The heat resistance of psychrotrophic strains is considered to be lower than that of mesophilic strains, but the former group may be of concern in chilled pasteurized foods.

Lactic acid bacteria At chill temperatures, lactic acid-producing bacteria grow more slowly than many of the bacterial groups mentioned previously. Consequently, they are only responsible for spoilage if growth of most other bacterial species is inhibited. This group is more tolerant of low pH than other spoilage bacteria and may multiply at pH values below 4.0. The lactic acid bacteria are also more resistant than the previously discussed spoilage bacteria to slight reductions in the water activity (a_w), and some strains are salt-tolerant. Lactic acid bacteria usually predominate in vacuum-packed products and in some modified-atmosphere-stored foods.

This bacterial group comprises both rod- and coccus-shaped Gram-positive bacteria, and typical genera include *Carnobacterium*, *Lactobacillus*, *Leuconostoc*, *Pediococcus*, and *Streptococcus*. Spoilage is generally by the production of acid, which results in souring, with or without concomitant gas production.

The presence of lactic acid-producing bacteria is not necessarily a problem, as some strains are deliberately added during the manufacture of some chilled foods (e.g., cheese, yogurts, and some salamis) and are essential for the development of the desired product characteristics. In addition, there is much interest in their potential use as a novel preservation system, as many produce natural antimicrobial compounds in addition to acids.

Other bacteria Depending on the food type and preservation system operating, other microorganisms also may cause problems in specific chilled foods. For example, *Brochothrix thermosphacta* is occasionally present on raw meats but does not normally create a spoilage problem. However, it can grow in atmospheres with a low oxygen level and/or high carbon dioxide concentration and so may cause problems in vacuum-packed or modified-atmosphere-packed meat products and produces an objectionable pungent 'cheesy' odor.

Micrococcus species are Gram-positive cocci that can grow in the presence of high salt concentrations. They grow more slowly than many other spoilage bacteria at chill temperatures but can cause souring and slime production when growth of competing organisms is inhibited.

Yeasts and molds Yeasts and molds generally grow more slowly than bacteria in foods, permitting good growth and so are generally out-competed.

Therefore, this group is seldom responsible for the spoilage of fresh proteinaceous foods. When the conditions in the food are altered to restrict bacterial growth, the role of yeasts and molds may become more significant. They are generally more resistant than bacteria to low pH, reduced a_w values, the presence of preservatives and low temperatures. Molds tend to require oxygen for growth, whereas many yeasts can grow in the presence or absence of oxygen. Most yeasts and molds are not heat-resistant and are readily destroyed by a thermal process, although some (e.g., *Byssochlamys*) may produce relatively heat-resistant ascospores that may survive food pasteurization treatments.

Air movements may be an important vector of transmission, especially with mold ascospores and so result in widespread contamination.

Typical spoilage yeasts include *Candida*, *Debaryomyces*, *Hansenula*, *Kluyveromyces*, *Rhodotorula*, *Saccharomyces*, *Torula*, and *Zygosaccharomyces* species. Molds that may be isolated from spoiled chilled foods include *Aspergillus*, *Cladosporium*, *Geotrichum*, *Mucor*, *Penicillium*, *Rhizopus*, and *Thamnidium* species. Fungal spoilage may be characterized by the production of highly visible, often pigmented, growth, slime, fermentation of sugars to form acid, gas or alcohol, and the development of off-odors and off-flavors, often described as yeasty, fruity, musty, rancid, and ammoniacal.

As with the lactic acid bacteria, yeasts and molds are sometimes deliberately added to food products (e.g., mold on ripened cheeses such as Brie).

Pathogenic Microorganisms

Foods may be considered to be microbiologically unsafe owing to the presence of microorganisms that may invade the body (e.g., *Salmonella*, *Listeria monocytogenes*, *E. coli* O157:H7 and *Campylobacter*) or those that produce a toxin that is ingested with the food (e.g., *Clostridium botulinum*, *Staphylococcus aureus*, and *Bacillus cereus*). The growth of pathogenic microorganisms in foods may not necessarily result in spoilage, and so the absence of deleterious sensory changes cannot be relied upon as an indicator of microbial safety. Furthermore, some toxins are resistant to heating and so may remain in a food after viable microorganisms have been removed.

In general, with human pathogens, the greater the number of cells consumed, the greater the chance of microbial invasion, as a larger number of cells may be able to evade/swamp the body's defense mechanism. Consequently, control, and preferably inhibition, of growth in foods is essential. However, with some invasive pathogens (e.g. *Campylobacter*), growth in the food may not be necessary as the infectious dose is low.

For discussion in this article, the pathogenic bacteria of concern for chilled foods can be arbitrarily divided as follows.

Microorganisms capable of growth at temperatures below 5 °C

These microorganisms are potentially of greatest concern as they continue to multiply, even with 'good' refrigeration temperatures. Although growth may continue, temperature control is critical, and the growth rate becomes increasingly slow as the temperature is reduced. In addition, temperature control can interact effectively with other factors (e.g., pH, salt, preservatives) to prevent or greatly limit growth.

Listeria monocytogenes A wide range of foods including meat, poultry, dairy products, seafoods and vegetables have been reported to be contaminated with *L. monocytogenes*. Although the total absence of *L. monocytogenes* from raw meats, poultry, and vegetables is difficult to ensure, the bacterium has been isolated from products that have undergone a thermal process designed to eliminate this bacterium. Such isolations are of concern, as many of these chilled foods may be consumed without further heating. The presence of *L. monocytogenes* on cooked foods suggests that postprocess contamination may have occurred. Several studies have shown that this bacterium has been isolated from a wide range of sites in several types of factory and may even be spread by poorly controlled cleaning procedures. Environmental control of *Listeria*, particularly in key areas of production (e.g., after cooking), is crucial to the prevention of product contamination.

The major concern with *L. monocytogenes* is its ability to grow at low temperatures, and a minimum growth temperature of −0.4 °C has been reported. Temperature control will, however, retard the rate of growth. Conversely, temperature abuse during storage of a food can exacerbate problems. *Listeria monocytogenes* is more resistant than many other vegetative bacteria to some, but not all, of the preservation mechanisms used in food manufacture (e.g., chilling, reduced water activity). Whilst resistance may be noted to these preservation systems when examined individually, foods are complex, and the combined effects of two or more preservation factors may effectively prevent growth.

L. monocytogenes is not considered to be a classically heat-resistant bacterium. It is generally accepted that conventional high-temperature, short-time milk pasteurization (71.7 °C/15 s) eliminates this

microorganism when freely suspended in milk. In other foods, a minimum process of 70 °C for 2 min (or the thermal equivalent) ensures the effective elimination of this bacterium.

The symptoms of disease are protean and range from a mild flu-like illness to meningitis, septicemia, stillbirths, and abortions. In general, the major symptoms of disease are restricted to the pregnant mother, fetus, elderly, and immunocompromised, and with these groups, the mortality level can be high.

Yersinia enterocolitica Outbreaks of disease caused by *Y. enterocolitica* are relatively rare, but have implicated milk, tofu, and chocolate milk. Although the reported incidence of *Y. enterocolitica* in gastrointestinal samples is generally low, it has increased, but this may be due not only to a true underlying increase but also to a greater awareness of this bacterium, recognition of symptoms, and improved methods. In some European countries, disease cause by *Y. enterocolitica* has surpassed that of *Shigella* and even rivals that of *Salmonella*.

A wide variety of foods have been reported to be contaminated with *Y. enterocolitica*, including many chilled products, i.e., raw and cooked meats, poultry, seafoods, milk, dairy products, and vegetables. Care is needed as the isolates responsible for disease generally belong to a few specific (bio-sero) types, whereas those from foods and the environment belong to a wide range of (bio-sero) types. Therefore, the pathogenic significance of food isolates should be ascertained before the food is considered as a health risk. The types responsible for human disease may be isolated from pigs and occasionally pork products.

The minimum reported growth temperature for *Y. enterocolitica* is −1.3 °C, and the bacterium grows relatively well at chill temperatures. Storage at refrigeration temperatures interacts with other preservation factors present in foods and help prevent growth of this bacterium. *Y. enterocolitica* is a heat-sensitive bacterium and can be readily eliminated from foods by heating. It has, however, been isolated from cooked meats, seafoods, and pasteurized dairy products, which is indicative of postprocess contamination. Greater attention is required for the environmental control of *Y. enterocolitica* in food-manufacturing establishments.

The symptoms of human yersiniosis are also variable. Overall, acute gastroenteritis is the most common symptom, particularly with children, and is characterized by diarrhea, abdominal pain, fever, and, less commonly, vomiting. With adolescents, abdominal pain may be localized and misdiagnosed as appendicitis. The mortality rate from human yersiniosis is low, and, other than cases involving appendectomies, the symptoms are generally self-limiting and rarely require treatment. In some cases, secondary symptoms may occur several weeks after the typical gastrointestinal symptoms disappear, e.g., postinfectious polyarthritis and erythema nodosum.

Aeromonas hydrophila The role of *A. hydrophila* as an agent of foodborne disease is still a matter of controversy. This bacterium, however, does possess many of the characteristics of other pathogenic bacteria. Incidents of foodborne disease implicating *A. hydrophila* have included oysters and prawns.

The minimum reported growth temperature for *A. hydrophila* is −0.1 to 1.2 °C. The bacterium is considered to be heat-sensitive and so may be readily eliminated from foods. Little has been published on the presence of *A. hydrophila* in the processing environment, but it is likely to be isolated particularly from wet areas.

Bacillus cereus The role of *B. cereus* as a spoilage bacterium of chilled foods is well recognized, and some strains may grow at temperatures as low as 1 °C. The minimum reported growth temperatures of pathogenic strains is usually considered to be 10–15 °C, although some isolates from outbreaks that involved chilled products have been able to grow and produce toxins at 4 °C. In addition, psychrotrophic, presumptively enterotoxigenic strains have been isolated from pasteurized milks and some cook–chill meats.

Bacillus cereus may be of particular significance in foods that have been heated or pasteurized, as the heat treatment may have eliminated other competitor microorganisms. During subsequent chilled storage, spores that survive the heat treatment may germinate and grow. Although relatively little published information is available, the heat resistance of psychrotrophic *B. cereus* (and other related species) is generally lower than that of the mesophilic strains.

Clostridium botulinum Human botulism is caused by the ingestion of a potent neurotoxin preformed in the food. Based on the antigenic analysis of this, seven types can be distinguished (named A–G). The strains responsible for disease can be divided into two main groups. First, mesophilic types A and some strains of B and F are proteolytic and so often cause putrefaction of foods if substantial growth occurs. Second, psychrotrophic types E and others of B and F are nonproteolytic, and so the consequences of growth and toxin production can occur with no discernible change to the food's appearance or smell. The

minimum growth temperature of the mesophilic proteolytic strains is considered to be 10 °C, and so these are of limited significance with chilled foods. Type E *C. botulinum* is able to grow and produce toxin after incubation at 3.3 °C for 32 days. It is now recognized that nonproteolytic strains of types B and F are also capable of growth and toxin production at 5 °C or less. Therefore, these nonproteolytic strains may grow, albeit slowly, in chilled foods.

'Sous vide' processing consists of packing foods under vacuum in impermeable sealed bags that are then heat-processed and stored chilled for extended periods. Whilst the time and temperature of cooking are specific to the food type, it will destroy vegetative microbial cells but may not be sufficient to destroy bacterial spores. The growth of nonproteolytic *C. botulinum* is of particular concern, because in the absence of air, spores may germinate and grow during storage if temperatures are not carefully controlled below the minimum for growth (3 °C).

It should be noted that the heat resistance of the psychrotrophic nonproteolytic strains is considerably lower than that of the mesophilic proteolytic strains. The risk of botulism from the former group can be minimized by the use of appropriate heating, controlled chilled storage and/or alterations in the product formulation to prevent growth.

Microorganisms capable of initiating growth at temperatures of 5–10 °C

These are a number of other pathogenic bacteria, which, although unable to grow at temperatures below 5 °C, may grow if temperature abuse occurs. These include *Salmonella* species, *Escherichia coli*, and *Staphylococcus aureus*, with generally accepted minimum growth temperatures of 5–7 °C. Even at temperatures up to 10 °C, the growth rate of these bacteria is generally slow, but these bacteria do, however, cause foodborne disease, frequently implicating chilled foods. Psychrotrophic strains of salmonellae have very occasionally been reported.

Several types of *E. coli* are well recognized as agents of foodborne disease. At present, the type of most concern is *E. coli* 0157:H7 and other verocytotoxigenic *E. coli*, which may produce severe hemorrhagic colitis. Limited growth of some strains may occur at 5–10 °C.

Whilst *Staphylococcus aureus* may grow at temperatures as low at 6 °C, disease is caused by the ingestion of a preformed toxin. The minimum temperature for toxin production is greater than for growth and is considered to be 10–14 °C.

Overall, the above bacterial species do not grow at temperatures below 5 °C, but may survive at these temperatures. Pathogens, and spoilage bacteria, often survive adverse conditions (e.g., low pH or high salt) better at refrigeration temperatures compared with higher temperatures. Therefore, if the infectious dose of the bacterium is low and/or growth of the pathogen has already occurred (e.g., during slow cooling), growth during chilled storage may not be a prerequisite for disease.

Microorganisms capable of initiating growth at temperatures above 10 °C

These species include mesophilic *C. botulinum*, mesophilic *B. cereus* and other *Bacillus* species, *C. perfringens* and *Campylobacter* species. In general, these do not grow below 10 °C, and growth is limited at temperatures between 10 and 15 °C.

Of particular concern in this bacterial group are the *Campylobacter* species that comprise the most commonly reported cause of gastrointestinal disease in many developed countries. Although many of the reported cases are sporadic, outbreaks have frequently implicated the consumption of raw milk and undercooked chicken. This bacterial group is unusual, as the minimum temperature for growth is 25–30 °C, and so it will not grow on most foods. However, as the infectious dose of the microorganism is very low, growth may not be necessary for disease to occur.

Whilst disease caused by the mesophilic spore-forming bacteria has implicated chilled foods, this is usually as a consequence of poor temperature control during cooling after cooking. These bacteria may grow extremely rapidly during a long slow cooling regime after cooking and then persist during chilled storage.

Conclusions

Chilled foods cover a wide range of commodities, containing a large number of ingredients. The number and types of microorganisms present are affected by the indigenous microflora, microorganisms contaminating before and after processing, the growth rates and abilities of the microorganisms present, the intrinsic properties of the food, the effects of processing and packaging, and the time and temperatures of storage. Consequently, the microbial safety and spoilage of chilled foods is very complex. Considerable efforts have been made by the food chain to minimize these effects through careful raw-material selection, product design and formulation, processing and packaging conditions, and good temperature control from processing through distribution, retail display, and even consumer storage. All of these have helped ensure the safety and quality of this important food sector.

Definition of Terms

'Modified atmosphere packaging' (MAP) is the term applied to different packaging technologies that use an internal atmosphere composition that has a different composition to air (20.6% oxygen/78% nitrogen) to increase the shelf-life of food products. The internal atmosphere is usually made up of mixtures of oxygen (O_2), carbon dioxide (CO_2) and nitrogen (N_2), with the possible addition of very small amounts of other gases such as carbon monoxide (CO), ethanol, sulfur dioxide (SO_2) and noble gases (e.g., argon). An alternative often used to describe MAP is 'gas packaging.'

'Controlled atmosphere packaging' is sometimes used incorrectly to describe modified atmosphere packages, as it is not possible to control the atmosphere inside a primary package (the package that is directly in contact with the product), but it could be used to describe the controlled storage conditions inside specialist shipping containers.

'Vacuum packaging (VP)' involves the 'complete' removal of air from the package, usually resulting in O_2 levels of below 1%. The product is placed in an oxygen barrier film, the air evacuated, and the product sealed. The evaluated pack collapses around the product. In the case of 'skin packaging' systems, the packaging material forms a second skin around the product. Skin packaging involves placing a product on to a substrate material such as a thermoformed plastic tray. A specialized polymer film is heated to the required softening temperature then draped over the product and tray, and a vacuum draws the film down and around the product and the tray to make a secure and attractive product. This packaging system has been used very successfully to retail shelled shellfish and marinated steak products.

'Active packaging' is the inclusion of specific additives into the packaging film or within the packaging to modify the headspace atmosphere and extend the product shelf-life. Active packaging systems include oxygen absorbents, carbon dioxide adsorbents or emitters, ethanol emitters, and ethylene absorbents. This is a developing technology and will gain more acceptance as system costs are reduced, although the use of oxygen absorbents is well established in Japan.

Although the benefits of MAP can be numerous, it is important that the microbiological safety considerations of using anaerobic conditions are understood. Anaerobic conditions can promote the growth of pathogens, and hurdles must be in place to insure the safety of the products. This is especially true of high-moisture foods, meat, fish, and ready-to-eat meals, where temperature control is critical to insure safe MAP foods. The use of good manufacturing practices, to insure that the packaged product has a low initial microbial count, and the use of MAP can provide a useful extension to the product shelf-life. The control of the temperature during the storage and distribution cool chain is equally important to MAP fruit and vegetables where temperature abuse can cause increased biochemical activity, thereby also increasing the rate of product-quality deterioration.

Principal Factors in MAP

The principal factors in a successful MAP operation are the selection of:

1. a gas or gas mixture to minimize the selected deteriorative reactions in the food to insure the required shelf-life;
2. a suitable packaging material to maintain the desired gas composition; and
3. an appropriate packaging machine.

For MAP to provide the stated shelf-life, the critical factor is control of the chill chain (refrigeration systems in the processing, storage, distribution, and retailing chain) to insure that no temperature abuse (i.e., temperatures outside the specified range for a particular product) occurs.

Choice of Gas

The choice of gas, or gas mixture, used to replace the air in the package requires knowledge of the nature of the food and its principal mode(s) of deterioration. Oxidative reactions and the growth of microorganisms are the two common deteriorative modes, and both are affected by the oxygen present in the package atmosphere. Reduction or removal of oxygen will reduce the oxidation reactions and prevent the growth of some microorganisms, whereas addition of CO_2 will inhibit the growth of other microorganisms. However some microbes, including some pathogens are not affected by high CO_2 and low O_2 levels and must be controlled by good manufacturing practices to insure low microbial numbers and temperature control.

Oxygen is a key component of oxidative degradation reactions occurring in food, combining readily with fats and oils causing rancidity, and other food components causing color, flavor, and odor changes. Oxygen is, however, a necessary requirement for normal respiration metabolism of whole and minimally processed fresh fruit and vegetables. Oxygen levels below the minimum required (as low as 1–2%) by the produce can result in anaerobic respiration and the development of off-flavors and aromas.

Carbon dioxide is present in the atmosphere in very low levels (~0.03%). It is highly soluble in water, and will be absorbed by the food until equilibrium is attained. For example, at 0 °C and a partial pressure of 101 kPa of CO_2, the solubility of CO_2 is 3.4 g per kilogram of water. The absorption of the CO_2 by the food in a sealed package creates a partial pressure difference between the inside and outside of the packaging, resulting in partial or complete collapse of the package around the food. This CO_2 absorption can also result in off-flavors, excess purge by muscle foods, and discoloration of fresh produce.

Nitrogen is used to purge air from a package to achieve sufficiently low levels of oxygen to prevent aerobic microbial spoilage. It is also used as a filler gas in MAP to reduce the concentration of other gases in the package and to keep the pack from collapsing as the CO_2 is absorbed by the product. The percentage of N_2 used in gas mixtures in combination with CO_2 often has to be determined experimentally to obtain the necessary positive effects of the CO_2 while maintaining the appearance of the pack with the level of N_2.

Packaging-material Selection

Most MAP relies on the correct choice of packaging material. A low water-vapor transmission rate and a high gas barrier are usually required to maintain the modified atmosphere, except for fresh produce where specific barrier properties are required to maintain the specified gas mixture, often using quite permeable materials. Most MAP are based on monolayer or multilayer thermoplastic polymers, and/or polymer trays to maintain the product and atmospheric integrity. High barrier multilayer films will often incorporate either metalized film or an aluminum foil layer, and the cost of the film usually increases with the increasing barrier properties. These films will still allow some gas transmission, even at chill temperatures. Thus, over the shelf-life of the MAP food, there will be movement of gases across the package. The movement of these gases can be mathematically modeled to allow accurate prediction of this gas movement, although there is a comparative lack of gas permeability data for thermoplastic polymers over the range of temperatures 0–40 °C and at the high humidity levels common in chilled food storage conditions.

The packaging material needs to have the necessary tensile strength to withstand machine handling, and subsequent storage, distribution, and retailing. The package must also be designed so that the end user can open, heat (if required), and consume the food easily.

Applications of MAP

Red Meats

Fresh red meat undergoes both oxidation, resulting in color and flavor changes, and microbial deterioration. The color of the meat is determined by the oxidation state of the pigment myoglobin. The oxygenated state, oxymyoglobin, is a bright red color associated by the consumer with fresh, high-quality red meat, whereas the reduced form, deoxymyoglobin, is a purple color. The surface of the meat is contaminated during the slaughtering process with microorganisms, and the presence of O_2 encourages the spoilage bacteria, especially the *Pseudomonas* species, which will produce putrid, unpleasant smelling compounds. The systems used for MAP of fresh meat can be classified into the following groups:

- VP involves the exclusion of air from the pack atmosphere, so the lack of oxygen prevents the oxidation deteriorative reactions and suppresses the growth of spoilage bacteria, especially the *Pseudomonas* species. The delay of these forms of deterioration through packaging significantly extends the shelf-life of chilled fresh meat. VP has been used for 2–9-kg primal cuts and subprimal cuts of meat for international and local distribution to retail outlets. These packs use high-gas-barrier films that often include shrink characteristics. The meat cut is placed into the bag, with any necessary protection to prevent the bone piercing the bag, vacuum-sealed, and then passed under a hot-water spray to shrink the bag tightly over the cut. Shrinking the bag produces a second skin effect on the product, eliminates folds and capillaries, improves seal strength and oxygen barrier, and reduces purge or drip from the meat. However, VP without the shrink will still provide a useful extension to fresh chilled meat shelf-life, for beef (10–12 weeks) and lamb (6–8 weeks).
- High-oxygen MAP systems have atmosphere gas mixtures of about 30% CO_2 and up to 70% O_2 to extend the color stability and delay the microbial spoilage of display packaged meat. This system is very suitable for centralized production of retail display meat packages where the oxygen insures that the meat has the required red color of fresh meat. These systems are not suitable for long storage times, where the high levels of oxygen can lead to off-odors and rancidity.
- Low-oxygen MAP includes mixtures of CO_2 and N_2, with less than 1% oxygen, and achieves a shelf-life similar to that of VP. One-hundred percent nitrogen flush can be used and has been shown to be as effective as VP with reduced purge.
- High-CO_2 MAP has very high levels of CO_2, and in some commercial operations includes 100% CO_2 atmosphere. The absence of O_2 retards the formation of brown metmyoglobin in the meat, and the CO_2 suppresses the growth of spoilage bacteria. However, because CO_2 is very soluble in both water and fat, especially at chiller temperatures, excess CO_2 must be added to the package to allow for solubility. Thus, the package must be overflushed with CO_2, then allowed to remain in the chiller for 24 h to allow for the CO_2 adsorption and pack-size reduction, before the final cartoning operation can be completed. These 100% CO_2 packages have resulted in a chilled shelf-life for lamb and beef of up to 16 weeks.

Poultry

Poultry are usually contaminated with large bacterial populations that consist primarily of spoilage bacteria but can include significant numbers of pathogens. Poultry has a higher pH compared with red meat and so provides an ideal environment for the growth of these bacteria. Vacuum packages are difficult to form around whole dressed birds because of their irregular shape. Thus, the shelf-life of vacuum-packed poultry is usually short, limited to about 2 weeks. There are now an increasing range of cut-up portions (e.g., breasts, wings, fillets) and other further processed products, both raw and cooked, available. High-CO_2 atmospheres will increase the product shelf-life. For chicken meat, 20% CO_2/70% N_2 can be as effective as 80% CO_2/20% N_2 mix over 1 week's storage at 2 °C and thus is very useful for retail packs. However, if a longer shelf-life is required, as in bulk packs, higher levels of CO_2 are needed. A storage life of up to 35 days has been achieved under certain closely controlled conditions, although commercially, 10–21 days at −1 to +2 °C would be expected using an 80–100% CO_2/0–20% N_2 mixture.

Fish and Shellfish

Fish encompasses a great diversity of species and habitats. Fish differ from terrestrial foods in that the

interior of their muscles is not sterile, they undergo rapid enigmatic breakdown of their proteins, even in low-oxygen environments, and they often grow in uncontrolled environments. Thus, fish are only as clean as the water from which they are taken. Thus, the commercial use of MAP to extend the shelf-life of fish has been limited by the potential of *Clostridium botulinum* nonproteolytic types B and E, *Vibrio parahaemolyticus*, and *Listeria monocytogenes* growth and toxin production in refrigerated MAP fish, without any evidence of spoilage.

The gas mixtures used vary according to the fish species, with low oxygen concentrations being used with fatty fish to suppress oxidative rancidity. Vacuum and MAP using high CO_2 have been used to extend the short shelf-life of various kinds of fish, e.g., gas mixtures of 30% O_2, 40% CO_2 and 30% N_2 for nonfatty fish and 40% CO_2 and 60% N_2 for smoked and fatty fish.

As inhibition of normal spoilage bacteria of fish is limited, extensions of shelf-life are not usually as dramatic as that which can be achieved with meat, and the need to maintain low temperatures throughout processing, storage, distribution, and retailing is not diminished. If the effort that is widely applied to controlling temperatures and turnover during production, distribution, and storage of MAP had been applied to earlier packaging systems, these may have provided similar shelf-life extensions as the MAP system.

Fruits and Vegetables

Fresh, whole, and minimally processed fruits and vegetables are living, respiring tissue, and therefore, under MAP conditions, care must the taken to insure that the gas mixture in the atmosphere does not become depleted of oxygen or contain too much CO_2. The increased shelf-life or storage time for produce comes with a combination of lower temperatures and lower O_2 levels, thereby slowing down the rate of respiration. Reduced respiration leads to a reduced depletion of carbohydrate reserves, hence less weight loss, slower ripening, and longer storage times. This suppression of the rate of respiration continues down to 2–4% O_2, depending on the produce species and storage temperature. At lower levels, the respiration becomes anaerobic, resulting in fermentation metabolism producing off-flavors, off-odors, and undesirable volatiles. The increasing CO_2 level in the gas mixture also helps suppress the rate of respiration in some produce. Reduced O_2 levels and increased CO_2 levels together can reduce respiration more than either alone. The lower limits for O_2 and the upper limits of CO_2 vary between different fruit and vegetable species and can vary within one produce species as a result of different growing and handling conditions. Temperature control of fruit and vegetable MAP is very important because the rate of change in the gas permeability of the polymeric films and the rate of respiration of the produce are different with the same temperature changes. The produce will use up the available oxygen very rapidly and start anaerobic respiration. To increase the complexity of fresh produce MAP, the selection of the packaging film is difficult as it has to release CO_2 at a rate similar to the production and let oxygen into the pack at the rate at which it is used by the produce. Thus, different produce will require a film with different gas transmission rates to insure the correct maintenance of the desired gas mixture. Despite almost 60 years of research and hundreds of publications reporting many experiments that have been conducted in this area, there is surprisingly little commercialization of MAP for horticultural produce. Current areas of research and commercialization include the development of models to aid the design of perforated film packaging to minimize weight loss (moisture loss) while controlling the development of a modified atmosphere. The use of high-oxygen 30–80-kPa atmospheres and noble gases, specifically argon modified atmosphere to extend the produce shelf-life. Current research indicates that exposure to superatmospheric O_2 concentration may stimulate, have no effect on, or reduce the rates of respiration and ethylene production, depending on the commodity, maturity and ripeness stage, O_2 concentration, storage time and temperature, and concentrations of CO_2 and C_2H_4 present in the atmosphere. The rapid growth of fresh-cut or minimally processed produce including retail salads, baby peeled carrots, apple slices, and many fruit and vegetables prepared for the service industry has been possible due to the improved quality and shelf-life of cut produce in MAP.

There are two methods of creating modified atmosphere (MA) conditions within packages of fruit and vegetables: passive MA and active MA. Passive MA involves sealing the produce in the bag and letting the product respiration and the film gas transmission rate develop the required gas mixture. Alternatively, the desired gas mixture can be added during bag sealing, and the respiration and film gas transmission rates will maintain this gas mixture. However, it is the produce respiration rate, package oxygen and carbon dioxide gas transmission rates, and storage temperature that determine the composition of the pack atmosphere, not the initial gas mixture used in the bag.

Ready-to-eat Meals, 'Meal Solutions,' Delicatessen Foods

Ready-to-eat meals, or prepared food products, are a rapidly increasing supermarket category involving chilled meals that only require the minimum of preparation, if any, before consumption. These products can be referred to as 'delicatessen' and include multicomponent food products. For a product to be eaten hot, the only preparation is heating, whereas for products like salads and sandwiches, no preparation is required. These ready-to-eat meals can range in quality from cheap meals, or snacks to expensive gourmet-style food dishes, and include pasta, pizza, precooked meats, sandwiches, precooked French fries, complete dishes, meat based dishes, pasta based dishes, and chilled bakery products, and includes 'sous vide' or cook/chill products. MAP is being used to increase the shelf-life of these products, along with control of the storage, distribution, and retail chill chain to prevent temperature abuse.

The shelf-life of these products is usually limited by two factors: microbial growth and oxygen sensitivity of the product. Thus, the packaging system used for ready-to-eat products should exclude O_2 and provide some microbial suppressing action, and usually involves a mixture of CO_2 and N_2. These atmospheres provide several advantages, including reduction of oxidative rancidity, lack of growth of aerobic spoilage organisms, suppression of mold growth by CO_2, minimal moisture loss through the package, and reduced oxidative breakdown of flavor and aroma volatiles.

Prepackaged sandwiches have grown in popularity over the last decade, and their sale has extended from large retail outlets to snack bars, lunch bars, and petrol service stations. An increase in shelf-life would be of great advantage in allowing more flexibility in the distribution of these products. The hygiene and safety of these MAP products during manufacture and the use of good manufacturing practices, combined with the use of good refrigeration practice, are critical. Typical gas compositions include 30% CO_2/70% N_2, 5% CO_2/95% N_2 or a minimum of 70% CO_2. The higher rate of of CO_2 can cause pack collapse, as the gas is absorbed by the product, hence the use of higher levels of N_2. The specific combination used will be a compromise, delaying microbial growth without causing collapse of the packs.

'Sous Vide' involves vacuum packaging of a prepared food in a multilayer composite polymer film pouch, cooking the packaged product, followed by rapid cooling, and then chilled storage. These products can have a shelf-life of 2–3 weeks under optimum chiller conditions. An alternative style of high-quality ready-to-eat meals involves precooking the individual food components and then assembling these components into the package before gas packaging with the desired atmosphere of CO_2/N_2 and chilling.

Modified atmosphere packaging for fresh pasta products is common. Typical gas compositions include 100% N_2 or 70–80% CO_2 and 20–30% N_2 mixtures resulting in a shelf-life, if stored under 4 °C, of up to 4 weeks.

Packaging Under Vacuum

M Rossi, Packaging Technical Center, Sealed Air s.r.l., Passirana di Rho, Milano, Italy

The Role of Oxygen in Food Spoilage

The presence of oxygen is one of the major factors of spoilage of foods and causes:

1. oxidation reactions, damaging vitamins, fatty substances, pigments, flavoring substances that are often catalyzed by enzymes;
2. growth and activity of aerobic microorganisms (aerobic bacteria, yeasts, molds). (*See* **Oxidation of Food Components**.)

It is therefore essential, in order to prolong the freshness of foodstuffs, to eliminate the presence of oxygen in contact with the foodstuff itself and to prevent further access of oxygen during storage. Vacuum packaging is one of the simplest and most widely used systems to achieve this objective. This type of packaging has enjoyed increasing success since the late 1950s, in parallel with the development of the technology of plastics owing also to the changes in the distribution chain of perishable foods requiring increased hygiene and storage life.

This article outlines the principles of vacuum-packaging technology and the features of the packages utilized, and describes the main fields of application of vacuum packaging to chilled foods.

Vacuum Packaging: A Definition

'Vacuum packaging' is a term improperly but commonly used to define a packaging system that implies the reduction of the partial pressure of atmospheric gases (oxygen being 20% of them) inside a package. A vacuum inside a package can be obtained mainly through two systems:

- steam flushing of the headspace;
- sucking of air from the package headspace by means of equipment (vacuum chamber, nozzle) based on a vacuum pump.

The former system is mainly utilized in hot packaging of shelf-stable products, which are generally packaged in rigid containers. The elimination of air is achieved by means of a steam flush that replaces atmospheric gases inside the package; steam condensation in the package headspace after chilling reduces the inner gaseous pressure. The latter system is commonly utilized for packaging of perishable foodstuffs that have to be stored in chilled conditions. In this case, packaging equipment based on a vacuum pump is generally utilized in combination with flexible packages, which, after evacuation, are closed hermetically (by means of a seal or sometimes a tight clip) and collapse on the packaged product once the package is exposed to atmospheric pressure. Depending on the type of equipment employed, a residual pressure of atmospheric gases as low as 500 Pa can be obtained in the package.

Figure 1 illustrates the main systems utilized for evacuating flexible packages:

1. nozzle (Figure 1a);
2. single vacuum chamber (Figure 1b);
3. divided vacuum chamber (Figure 1c).

Packaging Materials Utilized for Vacuum Packaging

Plastics are the main raw material utilized for manufacturing the flexible materials employed in vacuum packaging of chilled foods. These materials must have the following properties:

- flexibility;
- mechanical resistance to various forms of abuse (abrasion, puncture, flex cracking);
- gas-barrier properties adequate to the application requirements (generally expressed as gas permeation rates);
- thermosealability or clippability;
- good optics (haze and gloss);
- printability;
- suitable dimensional behavior (dimensional stability to heat, formability after heating, shrinkability after heating).

To combine and balance to the required level the above properties, it is often necessary to mix different types of individual materials. Different resins can be mixed together (resin blends), resin additives (such as plasticizers, pigments, stabilizers, slip agents, etc.) can be used, and, more commonly, a multilayer material is produced, each layer being composed of a distinct individual material that imparts its properties to the overall structure.

Individual components most commonly used in manufacturing flexible materials utilized for vacuum packaging are listed below, together with their abbreviations and main properties:

- polyethylene (PE): sealability, formability, moisture barrier, low cost;
- polypropylene (PP): moisture barrier, thermal resistance, dimensional stability;

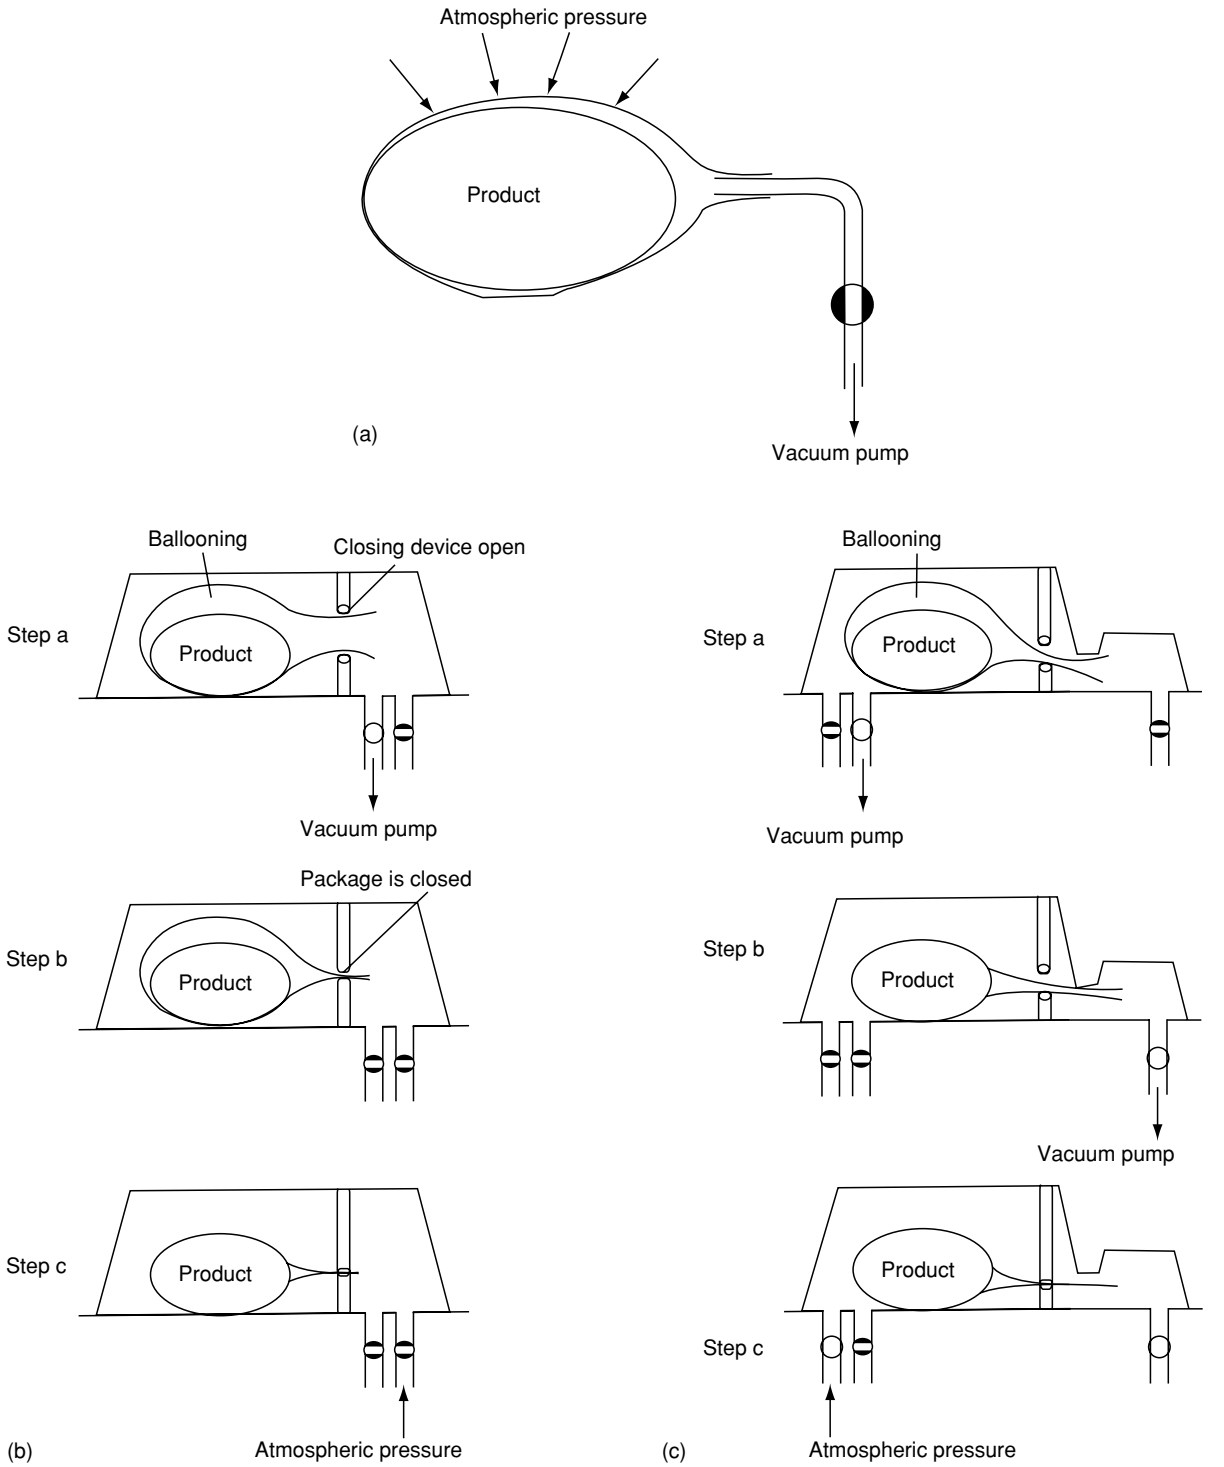

Figure 1 Main systems utilized for obtaining vacuum packages. (a) Nozzle system. Air is extracted from the package (a bag or a pouch) through a nozzle, and then the package is closed. This is the simplest way of extracting the air, but it does not allow high levels of vacuum in the package. (b) Most common system utilized for evacuating bags, pouches, and thermoformed packages. (c) Divided vacuum chamber. This allows a better evacuation of the package headspace by using two separate chambers where a vacuum is applied sequentially. Reproduced from Chilled Storage: Packaging Under Vacuum, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

- ethylene–vinylacetate copolymer (EVA): easy sealability, thermal shrink properties;
- ionomers: mechanical strength, easy sealability, grease resistance, formability;
- polyamides (PA): mechanical strength, gas barrier, formability;
- polyesters (PET): mechanical resistance, heat resistance, gas barrier;
- ethylene–vinylalcohol copolymer (EVOH): gas barrier, easy processability in coextrusion;
- polyvinylidenechloride (PVDC): gas barrier, grease barrier.

PE, PP, EVA, and ionomers are classified in the wide family of resins called polyolefins. Aluminum foils and vacuum-metallized plastic films are also utilized because of the excellent gas-barrier properties of aluminum.

Multilayer materials are manufactured using various techniques:

1. coextrusion: the molten resins are combined in the final structure by extruding them through a round or flat extrusion die, which keeps them separate in discrete layers;
2. lamination: previously extruded plastic films and, sometimes, aluminum foil, are joined together by means of glues (glue lamination) or with resins that have adhesive properties (extrusion lamination);
3. coating: pre-extruded films are coated with a layer of molten or dissolved resin (a latex).

Package Configurations Used for Vacuum Packaging of Chilled Foods

These can be classified into four main categories: shrink bags such as Cryovac*, pouches, thermoformed packages, and skin packages such as Darfresh*.

Shrink Bags

Shrink bags are available in the form of premade bags that can be prepared in different packages (e.g., taped bags) to allow their utilization on automatic equipment. The main feature of these bags is their ability to shrink when exposed for a short time to heat (for instance, a few seconds at 90 °C). This behavior is the consequence of treatment imparted to the packaging material during its production (oriented polymeric chains that retain a built-in tension, making them able to shrink when relaxed by heating).

Shrinking increases the packaging material thickness (which varies between 40 and 120 μm), improving mechanical resistance and gas-barrier properties, determines a tighter package around the product, limiting dripping out of juices in moist products such as meat, and improves the appearance by eliminating excess of packaging material around the product. Shrink bags, at the onset of their introduction on the market in the 1950s, were monolayer PVDC materials, but subsequent technological evolution gave rise to complex coextruded multilayer structures having polyolefins as the main components and gas-barrier layers made of PVDC or EVOH.

Some materials are electronically cross-linked to improve mechanical properties.

Shrink bags are used for vacuum packaging of industrial units of fresh meat, processed meat and cheese, and for consumer units of processed meat and cheese.

Pouches

Pouches can be utilized in two forms:

- premade plastic envelopes of different sizes that are loaded with the product, then evacuated and sealed in vacuum chambers;
- in-line prepared pouches from machines using rollstock material (horizontal form fill seal and vertical form fill seal machines).

The above machines, starting from a flat web, produce a film tubing that can be either horizontal or vertical (hence the different definitions), which is filled with the product, sealed transversely, and cut into final packages.

The machines can be equipped with a vacuum chamber to evacuate the pouch before final sealing. Form fill seal machines are widely employed in food packaging; however, their utilization for vacuum packaging of perishable foods is rather limited as thermoforming is preferred whenever a high packaging output and automation of packaging operation are required.

Premade pouches are commonly utilized for vacuum packaging of industrial units of fresh red meat such as whole primal cuts, processed meat (ham, bacon, salami, bologna) and cheese. Typical structures of materials for pouches, obtained by means of glue or extrusion lamination, are based on bioriented PA6 or PET (biorientation plus heat setting enhances dimensional stability and mechanical resistance), which can be coated with PVDC to increase the gas-barrier properties and are laminated to suitable sealing layers (PE, EVA, or PP and ionomers when heat resistance for pasteurization or cooking in the package is requested). For long storage-life

Cryovac* and Darfresh* are registered trademarks of Cryovac Inc., a subsidiary of Sealed Air Corporation.

applications (pasteurized cooked ham or sausages) where maximum gas-barrier properties are needed, aluminum foil is also used.

The total thickness of the above materials varies between 70 and 250 μm, the higher thickness being employed for heavy and hard products.

Thermoformed Packages

These are obtained on continuous thermoforming machines, which use rollstock materials. Two rolls are used, one for the bottom web, which is unwound, heated by a warm plate and formed into cavities where the product to be packaged is subsequently loaded, and a second one, the top web, which is sealed onto the bottom web inside a vacuum chamber from which the air has been removed. Thermoforming is widely applied to packaging of perishable foodstuffs because of the flexibility of the process, the packaging speed, and the ease of automation.

A wide variety of packaging materials is utilized. Bottom webs are generally based on PA laminated or coextruded with all types of polyolefins. PVDC or EVOH are used when high gas-barrier properties are needed. Some bottom webs are also heat-shrinkable after thermoforming.

Top webs are generally laminated structures similar to those used for pouches, the thickness of which seldom exceeds 100 μm. Metallized materials are often used in the top web formulation.

Thermoforming is utilized for packaging many kinds of perishable products, both consumer and industrial units, including whole ham and fresh meat primal cuts, with the exception of the biggest units of cheese and processed meat.

Skin Packages

Skin packaging represents an evolution of thermoforming where the top web is softened by means of heat and subsequently formed onto the packaged product.

The bottom web can be either flexible or rigid and can be preformed into a tray or a product-sized cavity into which the product to be packaged is loaded.

In skin packaging, the top film conforms tightly to the product shape with advantages in terms of appearance, limited product crushing due to vacuum, and the possibility of contour sealing around the product, limiting the exudation of liquids from the product. Because of its appealing appearance and the high cost of the packaging materials, skin-packaging utilization is limited to consumer or family units of meat (both fresh and processed), fish, prepared meals, and cheese.

Top webs are usually based on ionomeric resins or on coextruded structures of polyolefins. PVDC or EVOH provides the necessary gas barrier.

Bottom webs are generally either laminated or coextruded structures similar to those used for thermoforming.

When a rigid tray is required, polyvinylchloride (PVC), polystyrene (PS) or PET is employed.

Influence of Vacuum Packaging on the Storage Behavior of Chilled Foods

Fresh Meats and Poultry

Meats contain an abundance of nutrients necessary for the growth of microorganisms; they are particularly rich in soluble organic substances such as carbohydrates, amino acids and nucleotides. Therefore, spoilage of fresh meat and poultry during chilled storage is mainly due to the growth of aerobic psychrophyllic bacteria belonging to the Pseudomonadaceae family and to the *Moraxella–Acinetobacter* group. Growth of these bacteria results in development of off-odors (due to hydrogen sulfide, ammonia, amines, and indole) and bacterial slimes, which contribute to meat discoloration. (*See* **Spoilage**: Bacterial Spoilage.)

Vacuum packaging in oxygen-impermeable materials limits oxygen supply to the typical aerobic spoilage microflora, providing conditions suitable only for the slower-growing lactic acid bacteria, which, in chilled conditions, require several weeks to produce off-odors. (*See* **Lactic Acid Bacteria**.)

In addition, vacuum packaging has an impact on meat color, which is mainly due to the presence in the muscle tissue of myoglobin, a conjugated protein where the protein moiety (globin) is bonded to a heme group.

The iron atom of the hematin nucleus can form complexes with different ligands and can be in either the ferrous (Fe^{2+}) or ferric (Fe^{3+}) oxidation state. The globin can be in either the native or denatured state. Among the different complexes of heme, globin and ligands, three are important in fresh meat.

- oxymyoglobin, with oxygen as the ligand and iron in the ferrous state, characterized by a bright red color;
- myoglobin, with water as the ligand and iron in the ferrous state, characterized by a purplish red color;
- metmyoglobin, with water as the ligand and iron in the ferric state, characterized by a brown color.

Oxymyoglobin is the pigment normally present on the surface of meat exposed to air, and gives the meat its bright and attractive color.

During storage, as a consequence of the growth of aerobic bacteria that reduce the availability of oxygen on the meat surface, and of the reduction in the capability of the meat to reduce its own metmyoglobin level, metmyoglobin tends to predominate, imparting its brown color to the meat surface, which contributes to consumer rejection of the product.

In vacuum-packaged meat, as a consequence of preventing oxygen access to the meat surface, the pigment is of the myoglobin color, and the meat appears darker than a sample exposed to air or packaged in modified atmospheres. Displaying of vacuum-packaged consumer units of fresh meat can create problems of consumer acceptance because of the purplish color of the meat surface. In this case, proper consumer warning has to be given to explain the origin of the color and the advantages of vacuum packaging in terms of prolonged storage life. (*See* **Controlled-atmosphere Storage**: Applications for Bulk Storage of Foodstuffs.)

The storage life at 0–2 °C of fresh primal meat vacuum packaged in bags or pouches is 4–8 weeks, allowing full aging of meat types such as beef that require maturation. Consumer units in the form of meat slices have a storage life of 2–3 weeks.

Processed Meats

It is useful to classify the many existing types of processed meats into two main categories of products:

- products having high-activity water, the production processes of which often imply cooking (frankfurters, patties, bologna, fresh sausages, cooked ham, luncheon meats);
- cured products with low-activity water (raw ham, salami, bacon).

The spoilage of the former category of products can be due to surface drying, fat oxidation, discoloration or to microbiological factors (sliminess, souring, greening). The latter category of products is less susceptible to spoilage caused by bacteria. Rancidity, discoloration and mold growth are the most common limiting factors for storage life. (*See* **Meat**: Structure; **Spoilage**: Molds in Spoilage.)

All the above products can benefit from vacuum packaging, which avoids surface drying, mold growth and greatly slows down the oxidation of fat and pigments. Pasteurizable packages are also commonly used for microbial stabilization of some products (cooked ham, patties, and frankfurters). Furthermore, cook-in-the-package technology has been developed for production of cooked ham, allowing optimization of the production process, hygienic quality and yield.

The chilled storage life of vacuum-packaged processed meats is very variable, depending primarily upon product composition and packaging material characteristics and can vary from a couple of weeks (certain types of fresh sausages) to several months (cured products and pasteurized or cook-in-the-package products).

Cheese

Vacuum packaging is mainly applied to hard and semihard types of cheese, for both industrial and consumer units, and its effect in storage-life extension is due mainly to:

- elimination of surface drying;
- slowing down of fungal growth;
- limitation of oxidation of fatty substances.

An interesting application of vacuum packaging is the curing in the package technology that is utilized for certain types of cheeses (Emmenthal, Gouda, Edam). The cheese is vacuum-packaged at an early curing stage and cured inside the package. This technique improves yield (limiting rind formation and water loss) and allows a certain product standardization. Curing in the package is particularly demanding in terms of gas transmission properties of the packaging material; a good compromise is necessary between a sufficiently high carbon dioxide permeability to allow the escape of gas formed inside the cheese during curing and a sufficiently low oxygen transmission rate to avoid mold growth. The gas-transmission rate requirements can vary from cheese type to cheese type and also depend upon production conditions, which are often variable among different dairies. (*See* **Cheeses**: Cheeses with 'Eyes'.)

Fish

Wet fish is probably the most perishable type of foodstuff because of the high content of soluble substances in the flesh, many of which contain nitrogen, and triglycerides characterized by polyunsaturated fatty acids (in fatty types of fish such as clupeids, salmonids and scombroids). In addition, fish flesh is characterized by a high level of enzymatic activity, which plays a major role in the early stages of spoilage. (*See* **Fish**: Spoilage of Seafood.)

Vacuum packaging retards the growth of aerobic spoilage bacteria and limits the oxidation of fat. However, vacuum-packaged fish is very perishable and has to be carefully stored at temperatures below 2 °C, the normal storage life being 5–7 days. Prepackaged consumer units of wet fish, utilizing skin packages, have recently been introduced at a commercial level due to the need for a distribution system capable of handling in a relatively easy way a product

characterized by bad smells, dripping out, and hygienic and preparation problems at the consumer level. For processed fish (smoked, salted, pickled), vacuum packaging is commonly utilized because it limits the spoilage factors of this kind of product (mainly fat oxidation and mold growth). The storage life of vacuum-packaged processed fish depends upon the water activity level, ranging between 2 and 3 weeks for slightly salted fish and a few months for highly salted fish.

Prepared Foods

Vacuum packaging is also utilized for a wide range of prepared foods (delicatessen products, cooked meats and poultry, prepared meals, salads).

The spoilage mechanism and perishability of these products are related to their chemical composition (pH, additives) and heat treatment (pasteurization), and therefore, their storage life is very variable, ranging from 2 weeks to several months.

An interesting application of vacuum packaging to prepared foods is the cook-in-the-package technique, which implies packaging under vacuum of raw or partially cooked foods that are cooked inside the package, pasteurized (when required), chilled and stored, and reheated and unpackaged at the time of consumption. This technology allows the rationalization of meal preparation in central units (e.g., in institutional kitchens and restaurant chains) because of the storage life of the prepared meal (1 week or more) and it has also been introduced to food-processing plants to prepare meals to be distributed chilled at the retail level.

CHLOROPHYL

H G Daood, Central Food Research Institute, Budapest, Hungary

Introduction

The green color in nature results from the presence of chlorophyll pigments that occur in the chloroplasts of plant tissues. The chloroplasts hold chlorophylls close to the cell wall and carry out photosynthesis on biomembranes. In coordination with other pigments like carotenoids, chlorophylls play an important role in the metabolism of light energy and catalyze synthesis of carbohydrates, the key metabolites of the metabolism of living cells.

Because of their widespread occurrence in a variety of plant products, chlorophylls play a vital role in the acceptability of food commodities. Chlorophyll-containing products have the potential to be used as a natural food colorant and nutritional supplement. The changes in chlorophyll content and composition can be used as an indication for some physiological process and orders. Recently, biological studies have postulated the anticarcinogenic and antimutagenetic effect of chlorophyll-related compounds. This article covers topics concerning biosynthesis, biochemical conversion, response to technological factors and the antioxidant–oxidant role of food chlorophylls.

Biosynthesis

Chlorophylls in plant foods are synthesized from δ-aminolevulinic acid (ALA), whose role is demonstrated in the biosynthesis of the tetrapyrrole nucleus. Once ALA is formed, two molecules condense to form porphobilinogen (PBG) by converting an aliphatic compound into an aromatic one. The head-to-tail condensation of four molecules of PBG results in the formation of the first tetrapyrrole intermediate,

a linear hydroxymethylbilane porphyrin. This linear molecule is enzymatically closed to form the first cyclic tetrapyrrole, uroporphyrinogen III. By the action of decarboxylase-catalyzed decarboxylation of the acetic acid groups on the pyrrole rings A, B, C, and D, uroporphyrinogen III is converted to coproporphyrinogen III. Propionic acid group oxidation and aromatization of the oxidized intermediate forming protoporphyrin IX follow the last step.

The next phase of chlorophyll biosynthesis starts with the chelation of protoporphyrin IX, mediated by Mg chelatase. This is followed by methylation of one of the propionic acid residues to form Mg-protoporphyrin-*n*-monomethyl ester (Figure 1). The last phase is characterized by the conversion of Mg-protoporpyrin-Me to protochlorophyllide and the protochlorophyllide to chlorophyllide through reduction of the vinyl substitutuent in the side chain of the pyrrole ring B, followed by oxidation and photoreduction of the D ring. The final step is esterification of the propionate substituent on pyrrole ring D with geranyl geraniol, which is then reduced to phytyl.

The first enzyme involved in tetrapyrrole synthesis, aminolevulinic acid synthetase, regulates chlorophyll biosynthesis. During maturation of some plant seeds chlorophyll biosynthesis may be stimulated by ethylene in the dark.

Concerning biosynthesis of chlorophyll b, old and more recent investigations gave convincing evidence that chlorophyll b is formed from chlorophyll a. The kinetics of ^{14}C pulse labeling indicate that chlorophyll a is the precursor of chlorophyll b. In light pulse experiments, chlorophyll b formation was shown to take place stoiciometrically at the expense of chlorophyll(ide) a. In homogenate of plant leaves, in the presence of NADP+, labelled chlorophyll b is formed from [^{14}C]chlorophyll a. The label locates in the tetrapyrrole and the phytol portion of the chlorophyll b, ruling out the possibility that the only carbon transfer is by transphytylation reaction.

Biochemical conversion

Degradation of chlorophyll usually happens all the way from ripeness to processing and storage of plant-derived foods. Although the mechanism of degradation is fragmentary, chlorophylls are degraded to colorless products.

Initially, chlorophylls are degraded to the phytyl-free chlorophyllides by the enzyme chlorophyllase

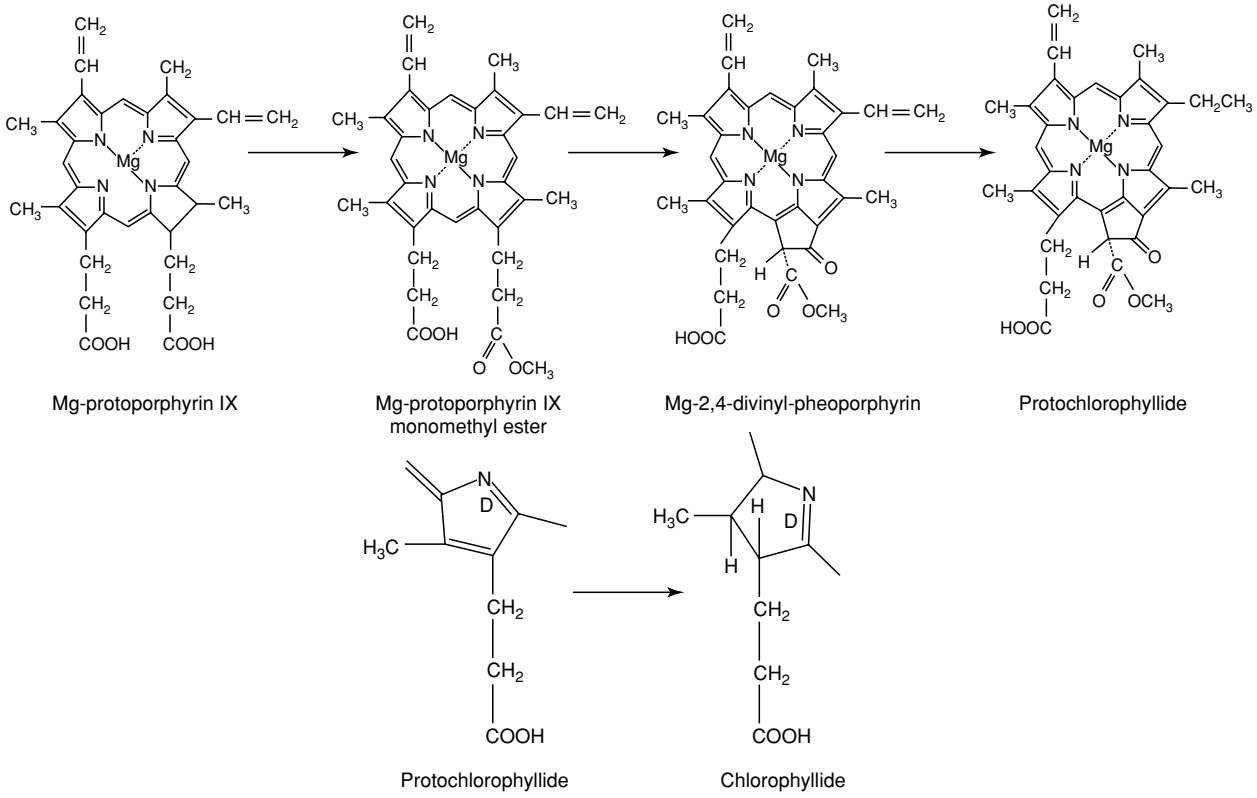

Figure 1 Last steps of chlorophyll biosynthesis in higher plants. Adapted from Castelfranco PA and Beale SI (1981) Chlorophyll biosynthesis. In: Hatch MD and Boardman NK (eds) *The Biochemistry of Plants*. New York: Academic Press.

(chlorophyll chlorophyllide hydrolase, EC3.1.1.14). The enzyme is located in the lipid envelope of the thylakoid membranes as an intrinsic membrane glycoprotein. Although chlorophyllase activity increases during ripening of some fruits and vegetables and parallels the respiratory climacteric, it is not affected by the endogenous ethylene. The enzyme activity remains even during storage and after processing of some plant products such as green tea. Generally, enzyme activity reaches a maximum at both the beginning and end of the vegetative growth phase.

Small amounts of chlorophyllide a and b can be found during the initial growth period, which coincides with a phase of great chlorophyll synthesis. Later, the synthetic and degeneration mechanisms may overlap, making the detection of phytyl-free compounds impossible. In ripening fruits and vegetables, the presence of allomerized chlorophyll derivatives suggests that, in addition to dephytylation by chlorophyllase, chlorophylls can be degraded by other oxidative systems involving active oxygen.

A chlorophyllide a-degrading enzyme is present in green tissues. It catalyzes the breakdown of chlorophyllide a in the presence of H_2O_2 and 2,4-dichlorophenol.

Biochemical conversion of chlorophylls to pheophytins or pheophorbides is initiated by the coordinating function of Mg-dechelatase (the enzyme catalyzes dechelation of Mg ion from chlorophyllins to form different pheophytins) and decarbomethoxylase. It is evident from the occurrence of 13-2-hydroxy-chlorophylls, hydroxy-lactone-chlorophylls, and unknown intermediates in fresh or stored green-colored plant products that more than one enzyme system is involved in the chlorophyll degradation mechanism.

Of the biological oxidants, lipoxygenase (EC1.12.13.11) contributes to the oxidative degradation of chlorophyll. The enzyme is well known to have pigment-bleaching activity of its isoenzyme-1 and isoenzyme-2, with the former being more active. Lipoxygenase cooxidizes chlorophylls through the oxidation of 1,2-pentadiene containing unsaturated fatty acids and results in the rapid formation of free radicals and, in the presence of molecular oxygen, in the creation of very reactive peroxy radicals. The results of many biochemical studies confirm that the chlorophyll-bleaching reaction requires an intermediate formed during peroxidation of polyunsaturated fatty acids by the isoenzyme. This type of degradation is responsible for the low storage stability of a variety of plant products. Furthermore, lipoxygenase-catalyzed chlorophyll bleaching is a characteristic change in some legumes and cereal products.

Due to various bioconversions of chlorophylls, the dephytylated polar intermediates, chlorophyllides, pheophorbides, and probably hydroxy chlorophylls appear and disappear during the ripening and storage of food commodities. The results of several investigations suggest that chlorophyll is first degraded to chlorophyllide by chlorophyllase, followed by oxidative degradation by peroxidase, lipoxygenase, or chlorophyll oxidase. The simultaneous action of dechelase may raise the diversity of chlorophyll extract by producing the corresponding Mg-free derivatives of the aforementioned chlorophyll degradation products. It should be noted that further degradation of chlorophylls and their derivatives to colorless compounds of low molecular weight is a function of oxidation processes which is not yet well described.

Degradation during Processing

Except for enzymatic conversions, chlorophylls undergo light-, heat-, and acid-catalyzed alterations that lead to a marked shift in the greenness of stored and processed foods.

Acid-catalyzed removal of Mg ion upon release of endogenous acids (in case of mechanical injuries and processes), acid formation via fermentation (brining, pickling, etc.), and dressing with an acidic ingredient are responsible for chlorophyll-to-pheophytin conversion. The acids produced in the fermentation that occurs naturally and spontaneously in brined or pickled fruits induce degradation of chlorophylls and chlorophyllides to the corresponding pheophytins and pheophorbides. Although physically acid-catalyzed conversion occurs inside the chloroplast, the media in which it takes place is the fermentor, since it is the diffusion across the membranes by osmosis that leads to fermentation. The intracellular pH is thus altered by the pH of the brining solution. The change in content of chlorophylls and pheophytins as a function of fermentation time and pH of the brine of green olive fermentation is shown in Table 1. The kinetic equation describing the degradation of the pigments is:

$$-\mathrm{d}c/\mathrm{d}t = k[\mathrm{H}^+]^n[\text{pigment}]^n \qquad (1)$$

In brining starting with alkaline treatment, when the interior of the fruit reaches a pH of 8, the concentration of chlorophylls is greater than that of hydrogen ions. In this case, if pheophytinization occurs, its kinetics would be of second order. When the concentration of hydrogen ions in the fermentation media, compared with the existing chlorophyll, is in excess and can thus be considered to be constant, the kinetic reaction is of pseudoorder and can be expressed as:

Table 1 Rate constant (k) for degradation of chlorophyll a, chlorophyll b, and total chlorophyll content in broccoli juice due to a thermal or a combined pressure–temperature treatment

Pressure (MPa)	*Temperature (°C)*	*Chlorophyll a* k (10^{-2} *min*$^{-1}$)	*Chlorophyll b* k (10^{-2} *min*$^{-1}$)	*Total chlorophyll* k (10^{-2} *min*$^{-1}$)

$$-\mathrm{d}c/\mathrm{d}t = k'[\text{pigment}]^n \qquad (2)$$

where $k' = k[\mathrm{H}^+]^n$.

At the first step of brining, when the pH is suitable for chlorophyllase activity a portion of the chlorophyll is converted to chlorophyllides, followed by acid-catalyzed formation of the corresponding Mg-free derivatives (pheophytins and pheophorbides). The decrease in the concentration of chloropyll a and b as well as the accumulation of Mg-free forms as a function of time follows first-order kinetics. A rapid accumulation of pheophytins in cooked or canned foods is a result of the combined action of heat and acid release after cell rupture.

At neutral or alkaline pH values, high-temperature short-time heat treatment, as in blanching, often results in an epimerization on carbon-10 of chlorophyll molecule, giving rise to the formation of the so-called a′ and b′ epimers that are a brighter green color than their original pigments. With an extended period of thermal treatment the rate and final products of chlorophyll degradation are changed. In canning the function of time, temperature, and pressure determines the kinetics of chlorophyll degradation. Chlorophyll degradation during thermal processing is frequently described as a first-order reaction. For such kinetics, the integrated form of eqn (2) for a decay process at constant temperature and pressure is given by:

$$X/X_0 = \exp(-kt) \qquad (3)$$

where X_0 is the response value at $t = 0$ (i.e., the concentration of chlorophyll at $t = 0$) and X is the residual response value after treatment (i.e., the residual concentration of chlorophyll).

The temperature dependence of the degradation rate constant (k) at atmospheric pressure can be adequately described using activation energy E_a, as given in the Arrhenius relationship:

$$k = k_{\mathrm{ref}}\exp[E_a/R(1/T_{\mathrm{ref}} - 1/T)] \qquad (4)$$

where k_{ref} is the rate constant at reference temperature T_{ref}, E_a is the activation energy, and R is the universal gas constant.

The pressure dependence of the rate constant (k) at a certain temperature is commonly described as an activation volume V_a, as given in the Eyring relation:

$$k = k_{\mathrm{ref}}\exp[V_a/RT(P - P_{\mathrm{ref}})] \qquad (5)$$

where k_{ref} is the rate constant at reference pressure P_{ref}, V_a is the activation volume at a certain temperature, T is the absolute temperature, and R is the universal gas constant.

In order to interpret the validity of a first-order reaction of chlorophyll degradation, eqn (3) is linearized using a logarithmic data transformation [ln (X/X_0)]. A log linear plot of relative chlorophyll a and b retention versus degradation time is depicted in Figure 2. These plots show that the rate of chlorophyll degradation follows a first-order kinetic model.

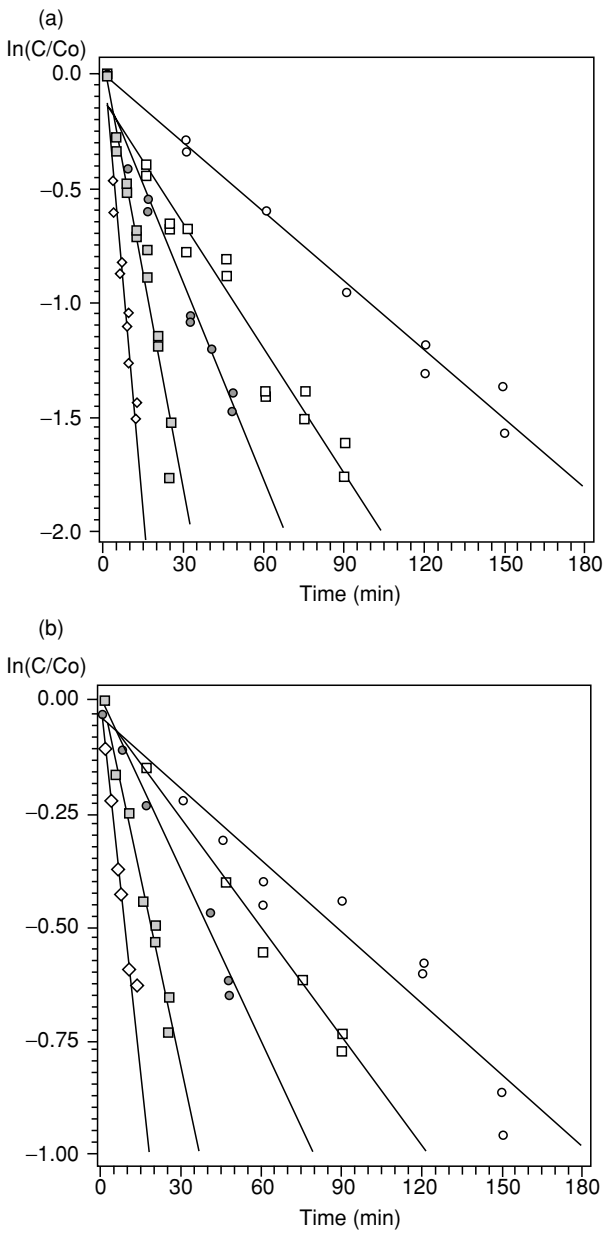

Figure 2 First-order thermal degradation of (a) chlorophyll a and (b) chlorophyll b in broccoli juice at (○) 80, (□) 90, (⊙) 100, (⊡) 110, and (◇) 120 °C. Reproduced from Weemaes CA, Ooms V, Van Loey M, Handrickx ME (1999) Kinetics of chlorophyll degradation and color loss in heated broccoli. *Journal of Agriculture and Food Chemistry* 47: 2404, with permission.

With regard to the ranking in heat stability of chlorophylls a and b, it is evident that chlorophyll a is less heat-stable than chlorophyll b, and hence the former degrades more quickly. The higher thermal stability of chlorophyll b is attributable to the electron-withdrawing effect of its C-3 formyl group.

Chlorophyll exhibits an extreme stability toward pressure processing at ambient or relatively low temperatures (not higher than 50 °C). This can be ascribed to the stability of the covalent structure of chlorophyll to high pressure and to the slight compressibility of covalent bonds.

From semilogarithmic plots of chlorophyll retention in broccoli juice as a function of treatment time at constant pressure and temperature, it can be seen that the pressure–temperature-induced degradation process follows a first-order kinetics. Rate constants for chlorophyll degradation due to thermal or combined pressure–temperature treatment are shown in Table 2.

Severe heat processing enhances the decarbomethoxylation reaction, leading to formation of pyro derivatives of chlorophylls. Heat treatment of 121 °C for more than 15 min is required for the appearance of pyropheophytin a and b. The rate of decarbomethoxylation reaction as a function of time and temperature follows first-order degradation kinetics.

Chlorophyll to pheophytin conversion has been recognized for more than 50 years in frozen foods stored at lower than −18 °C. This conversion is responsible for color change from a bright green to a dull olive green in freeze-stored fruits and vegetables. The rate of such a conversion is shown to be a first-order model with respect to acid concentration. A linear relationship is expected between the appearance and pheophytin formation for frozen plant products.

In drying processing, the rate of chlorophyll degradation is affected by some factors, including drying temperature and time, water activity (a_w), and the storage conditions of dried foods. At a_w values greater than 0.32 and ambient storage with nitrogen gas, pheophytins are expected to be the predominant pigment of green-colored dry vegetables. It is well demonstrated that chlorophyll a undergoes degradation more rapidly than does chlorophyll b by a factor of 2.5–3.0. A linear relationship between a_w and log time for a 20% loss of chlorophyll is recognized for dry fruit and vegetables. Recent studies indicate that the main reason for chlorophyll degradation in heat-dried foods (sweet peppers, kidney beans, Chinese onions, etc.) is the free radicals initiated in the food system, particularly in the presence of unsaturated fatty acids. It is recommended to increase the content of effective scavengers in the product before drying to neutralize free radicals and prevent pigment degradation.

Formation of pheophytins in edible oils during extraction and refining is a well-known photo-catalyzed degradation. At different temperature and luminous energies, this conversion follows first-order kinetics. From the Arrhenius plot display, it appears that the

incident luminous energy does not change activation energy, but increases the reaction frequency factor.

Effect of Controlled Storage and Atmosphere

Storage in controlled or ethylene-containing atmosphere can affect, to a considerable extent, the chlorophyll content of food commodities. Recently, such storage has been widely applied in food technology either to speed up chlorophyll loss in some fruit (citrus fruits, bananas, mangoes, pears, etc.) or to maintain the greenness of stored crops.

Ethylene can be used directly as gas to treat the product in the package or in closed stores. Also it is indirectly applicable either by treating trees or immersing fruit in diluted solutions of ethylene, releasing plant growth regulators such as ethrel and hydrel (150–250 p.p.m.). To accelerate the ripening of some pears, a combination of 500 p.p.m. ethylene and 100 p.p.m. acetylene gas is recommended.

Ethylene treatment enhances degreening of the peel of some fruit via *de novo* synthesis of chlorophyllase and chloroplast-dependent enzyme that regulates chlorophyllase activity. However, in spinach leaves accelerated color loss by ethylene is not associated with increased content of dephytylated derivatives. This difference may be due to differences in the degradation pathway in the different products. It is stated in the literature that ethylene treatment can also enhance the synthesis of chlorophyll-oxidative enzymes in cotyledons held in the dark. An inverse correlation between the content of chlorophyll of ethylene-stored radish cotyledons and the activity of chlorophyll-oxidizing enzymes indicates that chlorophyll oxidation is an important step in the degreening process.

Storage under controlled atmosphere (CA) retards chlorophyll decomposition in a wide variety of agricultural crops. CA of 10% O_2 and 10% CO_2 is very effective in reducing the rate of chlorophyll degradation to the extent that the shelf-life would be extended about 20% longer than that in air-held samples (**Figure 3**).

Low O_2 (3%) and high CO_2 (20%) treatment, as in CA of tomato storage, maintains firmness, reduces chlorophyll loss, and slows lycopene and carotenoid development. In CA storage, ethylene-mediated responses are impaired by low O_2 and high CO_2 and exogenous ethylene and low O_2/high CO_2 concentrations act antagonistically. Controlled storage may include vacuum cooling and prestorage treatment with ethylene-reducing and respiration rate-lowering agents. Of these agents, ethanol vapor is used to maintain freshness and keep the chlorophyll

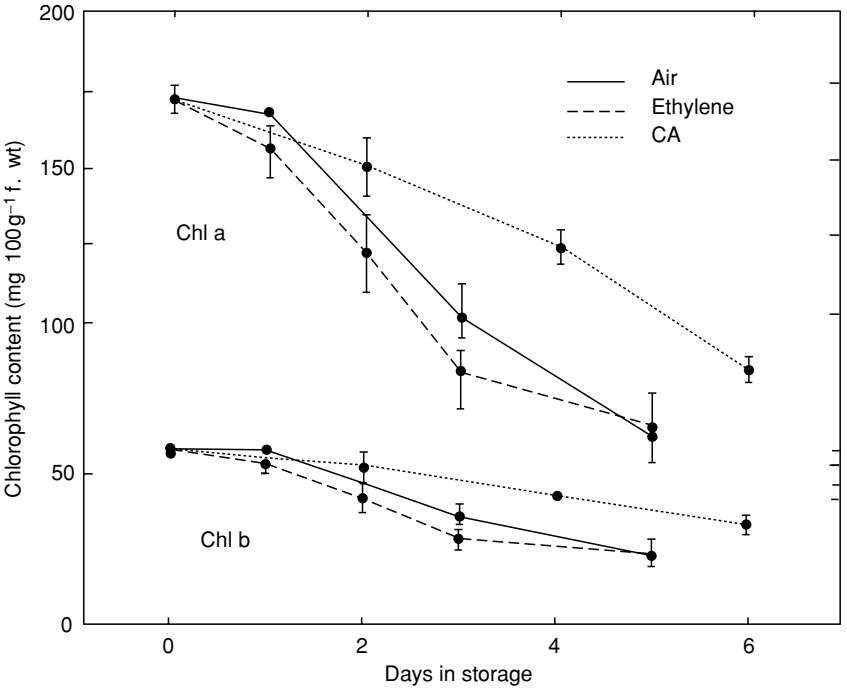

Figure 3 Change in content of chlorophylls of parsley leaves stored in air with or without 10 p.p.m. C_2H_4 or controlled atmosphere of 10% O_2 and 10% CO_2. content at high levels in some horticultural crops. A prestorage treatment of special interest is the short-term immersion of broccoli florets in ozonated water (10 p.p.m.)for 10–50 min. Although the treatment significantly reduces ethylene formation and total soluble proteins by the end of cold storage, it causes the vegetables to lose their green color rapidly.

Antioxidant–Oxidant Role

Due to their chemical nature and hydrophobic properties, chlorophylls are able to interfere with the chains of lipid oxidation in foods. From industrial practices and *in vitro* experiments, chlorophylls and their degraded products can play the role of either antioxidants or prooxidants. Factors which are most likely to determine the antioxidative or oxidative activity of chlorophylls include variety, ripeness stage, and chemical composition of food where they exist, the presence or absence of effective oxidants or antioxidant, and the climate.

When tested by ferric thiocyanate and other assays, chlorophylls and their derivatives exhibit marked antioxidant activity. Recent studies show that acidic fractions from plant containing pheophytins and related compounds have an antioxidant effect which is higher than that of α-tocopherol and comparable to that of BHT (butylated hydroxytoluene) (Figure 4).

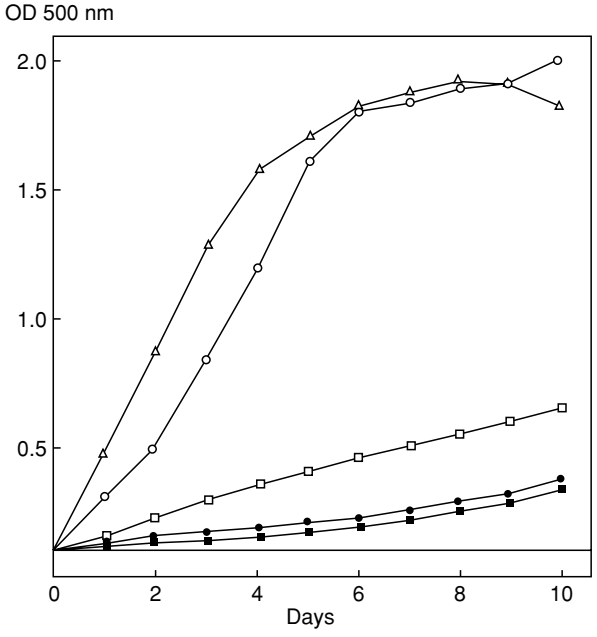

Figure 4 Antioxidative effect of fractionated extracts from marine algae by the ferric thiocyanate method. Sample concentration 0.02%; BHT concentration 0.01%. □, neutral fraction; •, weakly acidic fraction; ■, strongly acidic fraction; △, basic fraction; continuous line, BHT; ○, control. Reproduced from Cahyana AH, Shuto Y, Kinoshita Y (1992) Pyropheophytin a as antioxidative substance from the marine alga, arame (Eisenia bicyclis). *Bioscience Biotechnology Biochemistry* 56: 1533, with permission.

The antioxidant activity of chlorophyll-derived compounds is attributable to their interference with free radical cycles as scavengers to neutralize highly reactive oxygen-free forms such as superoxides. The porphyrin ring system of chlorophylls seems to be important for the antioxidant activity.

Treating some foods with oil containing chlorophyll between 200 and 800 mg% significantly reduces peroxide value during storage in the dark. This gives convincing evidence on the antioxidant effect of chlorophylls. In dry, oiled, and toasted laver, for example, the high lipid oxidative stability is ascribed to the presence of chlorophylls in the oil used. A positive correlation between oil stability and chlorophyll content is recognized in the processing of virgin oil.

The antioxidant activity of chlorophylls can be enhanced by ascorbic acid and α-tocopherol which exists at low level as 10^{-6} mol l^{-1} for each in the food system. This suggests that synergism between chlorophylls and other effective bioantioxidants is possible and of great importance from the point of view of oil oxidative stability.

Cooling green colored vegetables modifies their antioxidative ability due to chlorophylls. In cooked juices from broccoli, cabbage, green pepper, and leek, the superoxide scavenging ability is higher than that of the original raw materials. Moreover, the antioxidant effect of cooked spinach containing considerable amounts of chlorophyll a and b is much lower than that estimated for other vegetable extracts having no chlorophyll remains. It is, therefore, convincingly evident that Mg-free derivatives of chlorophylls have greater chemical capacity and ability as oxidation barriers than their origins. Also, as many recent *in vitro* studies have indicated, the antioxidant effect is more marked for chlorophyll a than chlorophyll b.

In oil-in-water food emulsions which have been stored in the dark, the addition of chlorophylls from plant sources such as dried leaves insures oxidation prevention equal to that provided by 80 p.p.m. of propyl gallate. However, the effect of green plant extract on the stability of oil-in-water emulsions is not the same when the emulsions are exposed to light. In contrast, under various conditions the prooxidant effect of chlorophylls is recognized.

As a practice in the processing of rapeseed oil, the chlorophyll content of raw oil should not exceed 25 mg kg^{-1} to maintain top-grade oil and extend shelf-life. The oxidation stability of the refined oil is reduced as the preprocessing content of pheopytins exceeds 30 p.p.m. The prooxidant effect of chlorophyll-derived compounds is increased, to a high extent, when the oil is stored in the light.

The degree of unsaturation of oil is another factor which modifies the prooxidant ability of chlorophylls. In highly unsaturated marine oil, the addition of chlorophylls from green tea extracts at less than 25 p.p.m. impairs oil oxidative stability and, moreover, removing chlorophylls from the tea extract gives it an antioxidant effect which is even higher than that of synthetic antioxidants at the same concentration. It can therefore be concluded that, in highly unsaturated oils, the prooxidant capacity of chlorophyll-related compounds is so high that oxidation is scarcely inhibited by spontaneous antioxidants like flavonoids and tocopherols.

Another type of chemical decay in foods is the photo-catalyzed oxidation of unsaturated lipids. Chlorophylls contribute to photooxidation of oils exposed to light or irradiation via a photosensitization reaction. The mechanism of light-induced photosensitization may involve free radical initiation and incorporation of singlet oxygen.

Fat-soluble oxygen quenchers and free radical scavengers such as carotenoids, ascorbyl palmitate, and tocopherols can interfere to minimize chlorophyll-sensitized oxidation of fatty acids and oils. Ascorbyl palmitate is recommended to be applied as an antioxidant with photo-oxidation-preventive properties (total quenching rate = 10^{-8} mol s^{-1}) in fatty foodstuffs. Tocopherols are efficiently used to minimize chlorophyll-sensitized oxidation. The activity of tocopherol analogs to prevent photosensitization is in the order of $\delta > \gamma > \beta > \alpha$. Carotenoid-type pigments actively interfere with photosensitized oxidation in food systems. The antiphotosensitization ability of carotenoids is attributed to the rapid transfer of radicals from chlorophyll to carotenoid molecules as well as the ability of carotenoids to quench oxygen free forms. In photosensitized reactions, carotenoid pigments undergo *trans*-to-*cis* isomerization on their structure. This may explain the presence of *cis* carotenoids in photosynthetic tissues.

It should be noted that all chlorophyll-derived compounds are able to induce photoisomerization of carotenoids in light-exposed food systems. Different carotenoids vary in their rate and capacity of interaction with photosensitizing agents. When tested by the headspace and rancimat methods, capsanthin has the highest rate and ability to minimize chlorophyll-induced photosensitization, followed by β-carotene and lutein.

Metal–Chlorophyll Interaction

Bright green color in drastically heat-processed vegetables is associated with the formation of metal–chlorophyll complexes. Copper and zinc, present as

contaminants in processing solutions, are the most familiar metals reacting with chlorophylls during the thermal processing and storage of processed foods. Such metal complexes can be found in canned green beans, Brussel sprouts, spinach and pea purées, table olives, candies, and chewing gum. The formation of Zn–chlorophyll complexes is of greater interest because of the toxicity nature of copper complexes.

The formation of green-colored metal complexes of chlorophyll derivatives is the basis of efforts by processors to preserve the desired green color of canned vegetables. This process is called regreening. Spontaneous regreening of vegetables during processing, which has long been known by canners as a nonuniform defect, is attributed to Zn-containing pigments.

Copper–chlorophyll complexes are formed more rapidly than Zn complexes. Clorophyll a-related derivatives form metallocomplexes more rapidly than chlorophyll b derivatives. Furthermore, pyropheophytins and pheophorbides have a markedly high tendency to react with metal ions. Steric hindrance due to the lack of a carbomethoxy group at C-10 is one possible reason for the rapid interaction of pyropheophorbides and metals. The other explanation is that the distribution of charge in the aromatic system is affected by the carbomethoxy group, which is strongly electron-withdrawing. In the absence of a carbomethoxy group, the pyrrole nucleus could become slightly more negatively charged, resulting in an increased reaction rate with positively charged ions. The kinetic parameters of Zn–chlorophyll reaction are shown in Table 3.

Food additives such as sugars, salts, and other preservatives may influence metal complexes of chlorophylls. While sucrose, glucose fructose, chlorides, sulfates, lactates, acetates, and propionates have no influence on metal–chlorophyll complex formation, malate, tartarate, citrate phosphate, and other metal-chelating agents such as ethylenediaminetetraacetic acid significantly decrease the rate of metal–chlorophyll reaction. In contrast, thiocyanate, benzoate, oleate, and caprylate ions accelerate the chemical interaction of chlorophyll with Cu and Zn.

The presence of active anionic compounds in canning solutions facilitates the formation of metal complexes of chlorophyll-derived compounds by adsorbing on to chloroplast membranes, thereby increasing the negative surface charge and giving rise to a higher affinity to bind positively charged ions. Increasing cation concentration in the food promotes the complex formation of chlorophylls. The mechanism for this promotion includes a direct common ion effect, which increases the rate constant

of the reaction of cations and chlorophylls, and an indirect pH-lowering effect of cation.

The pH of the media is an important factor affecting chlorophyll–metal complex formation. The rate of Zn–complex formation increases between pH 4.0 and 8.0, reaching a maximum between 6.0 and 8.0. Raising the pH to values higher than 8.0 decreases the amount of metal–chlorophyll complexes formed. At high pH values, chlorophyll a and b are very stable and the amount of derivatives available for the reaction is reduced.

Physiology

Properties and Determination

D C Woollard, AgriQuality NZ, Auckland 1, New Zealand
H E Indyk, Anchor Products, Waitoa, New Zealand

Physical Properties

Cholecalciferol (9,10-seco(5Z,7E)-5,7,10(19)-cholestatriene-3β-ol), commonly referred to as vitamin D_3, exists in the pure form as white crystalline needles. Referred to as a 'fat-soluble' vitamin, it is insoluble in water but is readily soluble in most organic solvents, notably hydrocarbons, chlorinated hydrocarbons, and alcohols. A closely related substance, ergocalciferol (9,10-seco(5Z,7E)-5,7,10(19),22-ergostatetraene-3β-ol), will also be occasionally referred to in the text. Described more simply as vitamin D_2, it is physically, chemically, and nutritionally similar to cholecalciferol. The term 'vitamin D' usually implies collectively both cholecalciferol and ergocalciferol together with any other active isomers and metabolites. Relevant physical properties are listed in **Table 1**.

Table 1 Physical properties of the calciferols

	Cholecalciferol	*Ergocalciferol*
Molecular weight	384.62	396.63
Empirical formula	$C_{27}H_{44}O$	$C_{28}H_{44}O$
Melting point (°C)	84–85	115–118
λ_{max} (nm)	264.5	264.5
Extinction coefficient, $E^{1\%}_{1cm}$ in hexane	485	459
Optical rotation in chloroform	+52°	+52°

Chemical Properties

Cholecalciferol is described in terms of steroid nomenclature and numbering (Figure 1). The '9,10-seco' prefix is added to denote the bond cleavage and the opening of the typical steroidal ring structure, an essential feature necessary to impart antirachitic activity. This cleavage is generally induced by ultraviolet (UV) irradiation of the precursor compound, 7-dehydrocholesterol (provitamin D_3), and occurs in the skin during exposure to sunlight. The previtamin D_3 so formed subsequently undergoes temperature-dependent equilibration to vitamin D_3. This process, along with the requirement for further hydroxylation challenges its original classification as vitamin; it is currently more accurately regarded as a prohormone.

Any homolog which possesses antirachitic activity is referred to as a D vitamin and each of the several compounds sharing this property elicits a unique and selective biological response (Figure 1). Common structural features of these substances are the β stereochemistry of the 3-hydroxy substituent and the *cis* conformation of the double bond at C5. While the 3-hydroxy substituent does not have an overwhelming influence on biological activity, other structural features, such as the A ring configuration and side-chain length, appear to be more critical. Thus, while alterations to the side chain result in diverse activity, only vitamins D_2 and D_3 are of prominence therapeutically and commercially. They are usually obtained via chemical synthesis, although vitamin D_3 has traditionally been extracted from fish liver oils.

It is widespread practice to express vitamin D concentration in food in international units (IU), rather than on a weight basis (1 IU is equivalent to 0.025 μg of either calciferol, although this equivalence in humans is occasionally challenged). This can be a useful concept because it reflects the nutritional status where several components of different biopotency coexist within a product. Nevertheless, there is some move back to mass units, particularly in supplemented foods where the contribution of cholecalciferol is dominant.

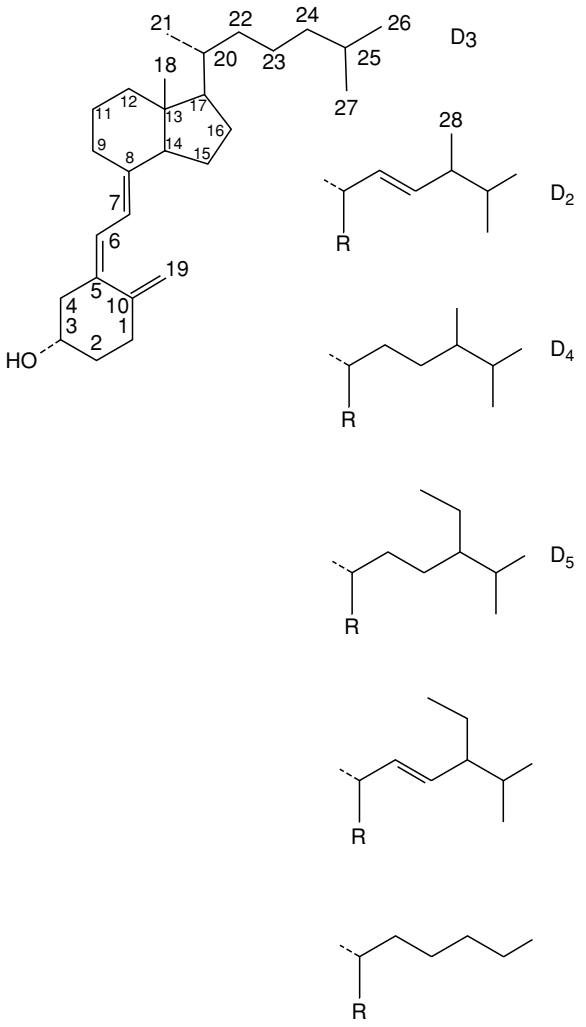

Figure 1 The chemical structure of cholecalciferol (vitamin D_3), indicating the carbon-numbering system of the molecule. Related calciferols with different side-chain configurations are also given, including ergocalciferol (vitamin D_2).

The stability characteristics of cholecalciferol have received considerable attention because they play a major part in the shelf-life of marketable products. Under conditions of low thermal, photochemical, and oxidative stresses, cholecalciferol is stable for several years. When added to foods and exposed to industrial and domestic processes, degradation is minimal. However, excessive light (UV) causes significant losses through the production of inactive substances such as toxisterol, suprasterol, lumisterol, and tachysterol, in a process which is accelerated by heating (Figure 2). Cooking temperatures above 100 °C, even in the absence of light and air, will cause isomerization through ring closure to the pyrocholecalciferols. Cholecalciferol is also sensitive to low pH and, if subjected to an acidic environment, will irreversibly

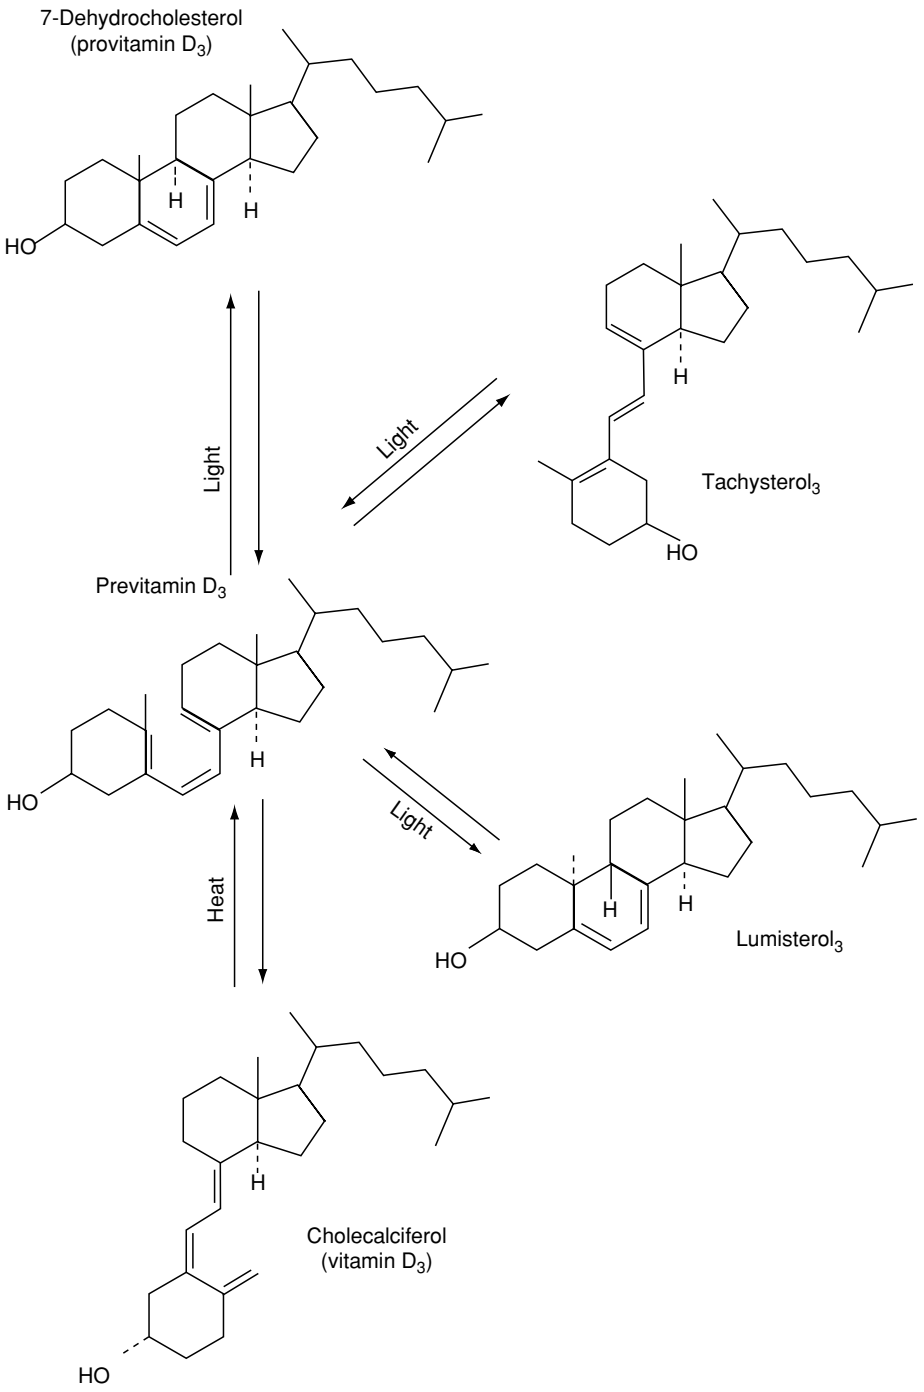

Figure 2 The major photochemical reactions of cholecalciferol. Ergocalciferol undergoes similar reactions. Overirradiation products are not shown.

rearrange to the inactive isotachysterol via the 5,6-*trans* isomer. These reactions (illustrated in Figure 3) are complex and will occur to an extent determined by the overall environment to which cholecalciferol is exposed. The reactions largely involve alterations to ring structure and so affect ergocalciferol and other D vitamins in a similar manner. It is generally acknowledged that ergocalciferol is less stable than cholecalciferol. This may imply that the double bond in the side chain of ergocalciferol imparts additional lability to the molecule.

Losses during storage are also known to occur in foods, and vary considerably between food types and conditions of storage. Thus, low temperatures and

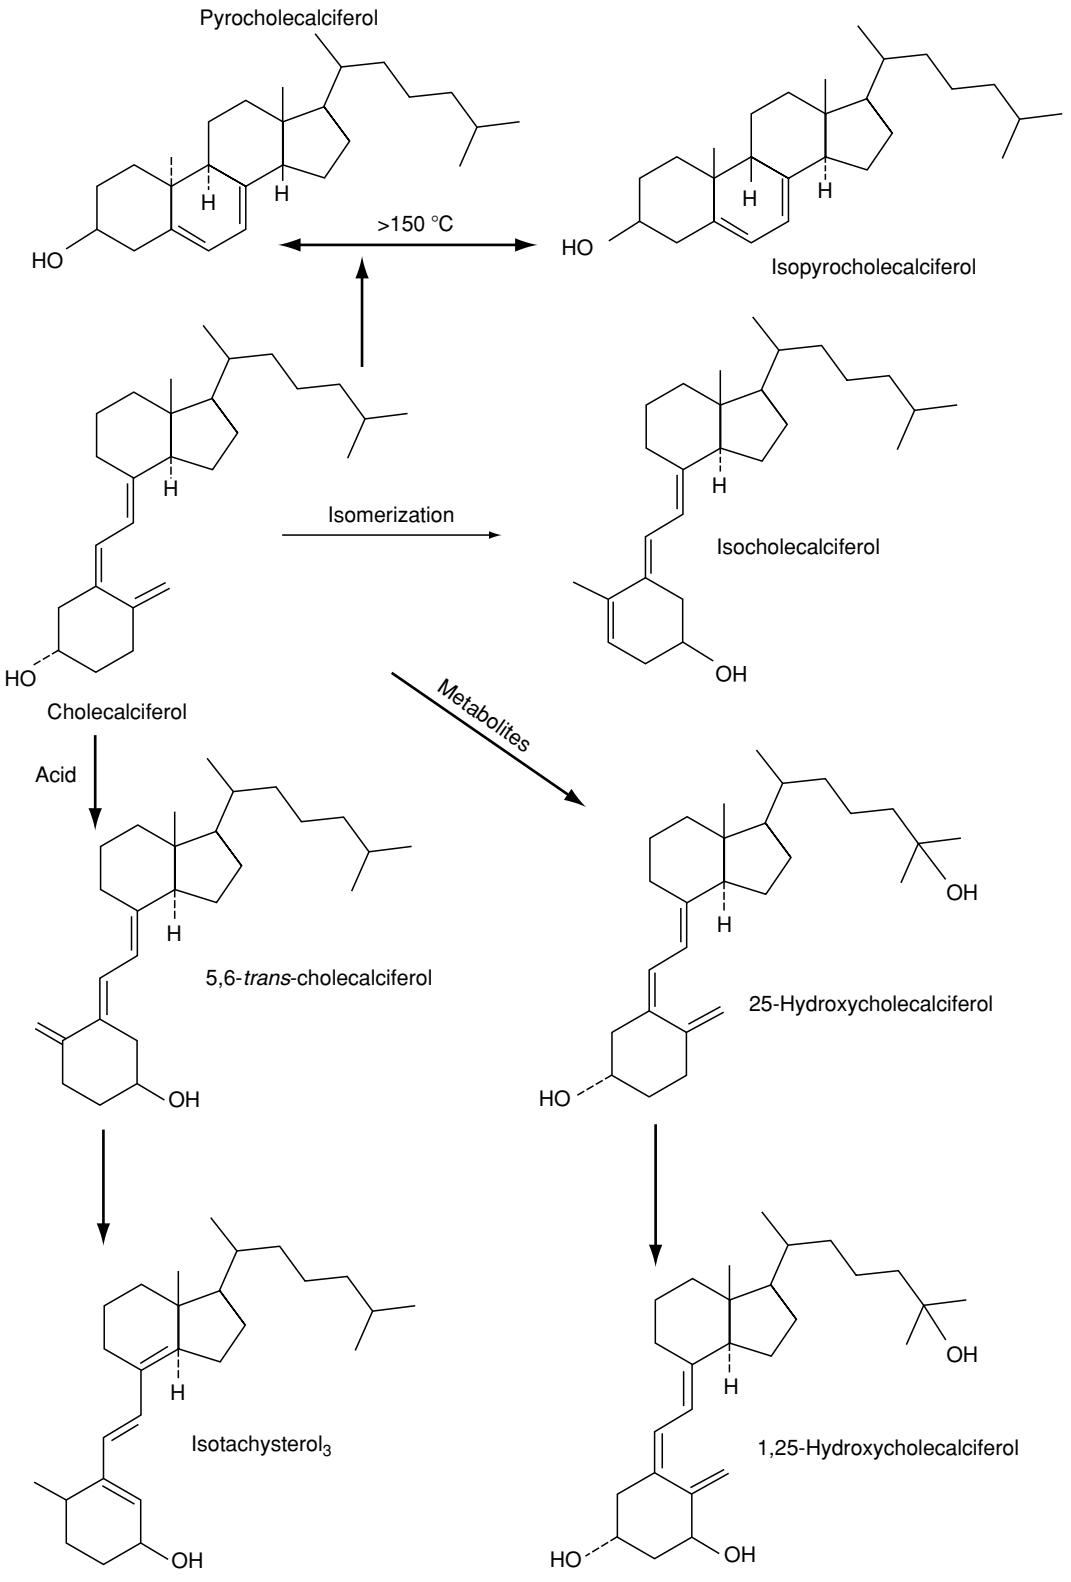

Figure 3 The major degradation reactions of cholecalciferol as relevant to foods.

absence of light will minimize losses in manufactured foods, as will vacuum packaging or nitrogen flushing. Foods containing natural, or added fat-soluble antioxidants such as vitamin E and carotenoids will, in general, exhibit superior cholecalciferol conservation. (*See* **Antioxidants**: Natural Antioxidants; **Antioxidants**: Synthetic Antioxidants.)

Occurrence and Forms in Foods

Most natural foods are limited in their content of active vitamin D components. 7-Dehydrocholesterol (provitamin D_3) and ergosterol (provitamin D_2) are widely distributed within the animal and plant kingdoms and supply a potentially good dietary source of vitamin D for humans. In particular, provitamins are abundant in fish, eggs, yeast, liver, milk, and some vegetables such as cabbage. It has been suggested that ergosterol only enters the food chain following fungal contamination. Consequently, mushrooms are good sources of ergosterol, particularly in the wild.

Vitamin D itself is generally present at low levels in unfortified foods derived from animal sources. Eggs, fish, and fish liver oils possess significant amounts, while meat and dairy products contain lesser quantities. Plants and vegetable oils contain negligible levels (< 2% recommended dietary allowance). Table 2 provides a list of the richest food sources of vitamin D and their approximate concentrations.

In addition, previtamin D isomers invariably coexist with cholecalciferol and ergocalciferol. Previtamin concentrations are proportional to the calciferols and are influenced by thermal conditions during food processing and storage. Higher temperatures increase the previtamin-to-vitamin ratio. Although the previtamins are biologically active precursors, they are not always accounted for in nutritional tables due to analytical difficulties in their determination.

Some foods also contain small but significant quantities of hydroxylated metabolites. These compounds are highly bioactive and are found in edible tissues (meat, liver) and fluids (milk) as a result of their biosynthesis within the live animal. The most predominant and biologically important compounds are 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D, while other trihydroxy metabolites may also be present.

Table 2 Typical vitamin D content of various foods

	Vitamin D content of edible portion (μg per 100 g)[a]
Natural food products	
Fish liver oils	150–3800
Fish	2–30
Egg yolk	5–8
Mammalian liver	0.5–4
Mushrooms (cultivated)	1–3
Mushrooms (wild)	10–30
Butter	1.5–2
Meat	0.2–2
Cheese	0.1–1
Liquid whole milk (raw)	0.05–0.15
Green vegetables (typical)	0.005 (approx.)
Supplemented food products	
Dietary formulae (milk- and soya-based)	3–14
Whole-milk powders	6–12
Margarine	8–10
Infant formulae	5–9
Liquid milk	0.75–1.25

[a]To convert to IU per 100 g, multiply by 40.

Use in Food Fortification

The supplementation of food products with vitamin D is a contentious issue because of the toxicological consequences of overdose. While adequate exposure to sunlight will generally negate the need for this practice, modern western lifestyles (including the recent trend to reduce the intake of dietary fat) and climatic variables justify its continuation. (*See* **Food Fortification**.)

As many diets will not supply the 10 μg (400 IU) of vitamin D required per day, some additional source is generally recommended by nutritionists. The balance of vitamin can be obtained from specially prepared natural sources (concentrated fish oils) or from consumption of artifically fortified food products. In this way, the onset of diet-induced bone disease is minimized, particularly in infants, the sick, and the elderly. Legislation in many countries governs fortification strategies.

Cholecalciferol is the most common D vitamin additive, ergocalciferol being less frequently used for human nutrition. Difficulties potentially arise in delivery of the vitamin to the consumer as a consequence of its intrinsic hydrophobic and labile nature. Common vehicles are margarine, milk, and milk powders, while a number of cereal products and various dietetic formulations contain vitamin D as part of their primary purpose.

Cholecalciferol can be easily incorporated into fat and oil-based foods by simple dissolution. It is common to add both vitamin D and vitamin A (retinol) to these foods. A protective phenolic antioxidant (e.g., 3-tert-butyl-4-hydroxyanisole, tert-butylhydroquinone, tocopherol) is usually incorporated at the same time. For powdered foods, cholecalciferol is added in an encapsulated 'beadlet' form, protected by a gelatine or acacia barrier and incorporating

stabilizers and carrier. If the blending of the vitamin and food is performed by dry mixing, then cholecalciferol is maintained in its protected environment, ensuring enhanced shelf-life. However, attaining uniform dispersion remains a problem and particle sizes must be carefully controlled to avoid redistribution during packaging, transport and storage. Alternatively, these difficulties can be overcome using 'wet-blending' procedures, but the vitamin is inevitably released from within its stabilized form into direct contact with the bulk food. Consequently, the receiving environment must be designed to minimize the potentially rapid degradation of the cholecalciferol supplement. (*See* **Retinol**: Physiology.)

Analytical Considerations

While it is clinically important to measure the hydroxylated metabolites, food scientists have been largely concerned with vitamin D itself, at both endogenous and supplemental levels.

The quantification of the parent secosteroid in foods is complicated by several factors, including low concentration, overwhelming excesses of other lipophilic components, limiting spectral properties (nonselective λ_{max}, low absorptivity), absence of native fluorescence, thermal instability, and the requirement to differentiate cholecalciferol from ergocalciferol.

Historically, curative and prophylactic bioassay techniques, based on the antirachitic quality of vitamin D-containing food, have been used extensively and have the advantage of estimating the true (species-specific) physiological response. Although sensitive, disadvantages of time, cost, and poor precision moderate against the use of bioassays in routine food analysis.

Competitive protein-binding radioassay techniques, utilizing a vitamin D receptor, have been exploited more recently, especially in clinical assays. Such biochemical recognition methods offer advantages in sensitivity and specificity, but extensive sample purification is mandatory in order to avoid endpoint interference from food artifacts. Lack of binding discrimination between vitamins D_2 and D_3 as well as the need for radioactive tracers and lengthy incubation periods remain problematic within the food industry. (*See* **Immunoassays**: Radioimmunoassay and Enzyme Immunoassay.)

Physicochemical determination by UV spectrophotometry or colorimetry without prior separation is clearly impracticable except for highly simplified food matrices, since the spectral properties of the parent or derivative calciferol species are insufficiently characteristic. Even high-potency pharmaceutical preparations still require scrupulous clean-up procedures in order to minimize spectral interference.

The development of instrumental chromatographic techniques has revolutionized the task of vitamin D estimation in both food and clinical samples. Although novel detection methods exploiting selective UV, fluorescence derivatization, or electrochemical techniques are presently under investigation, contemporary UV approaches still require the inclusion of rigorous purification procedures, since this detection mode remains inherently nonspecific.

Isolation, Extraction, and Clean-up

Vitamin D is vulnerable to oxygen, light, low pH and is also subject to reversible isomerization when heated. Therefore, adequate precautions are essential throughout any analytical procedure to avoid loss of the target analytes.

All chemical extraction techniques exploit the inherent lipophilic property of this vitamin and a vitamin-rich fraction is separated from other food components either by saponification or by total lipid extraction.

Saponification

Alkaline hydrolysis is a convenient way to eliminate the bulk of neutral lipids and is particularly favored in high-fat foods and those of an intractable nature. This popular technique is also advantageous for products containing encapsulated supplements and when relatively large sample quantities are needed for reasons of assay sensitivity or analyte heterogeneity.

While some authors report the use of high-temperature saponification, strategies such as direct measurement or use of conversion factors are then needed to account for the consequent elevated levels of previtamin D. These concerns can significantly complicate the assay and may be avoided through the use of overnight hydrolysis at ambient temperature, which additionally offers operational simplicity. It is considered mandatory during extraction to include a protective antioxidant and to purge with inert gas. Vitamin D, along with the other fat-soluble vitamins, sterols, carotenoids and hydrocarbons, remains in the nonsaponifiable fraction.

Enzymatic hydrolysis with lipase has been suggested as an alternative to saponification, thereby minimizing possible degradation and facilitating concurrent recovery of the alkali-unstable vitamin K, if required.

The nonsaponifiable fraction containing the calciferol is rapidly and conveniently partitioned into a solvent mixture of hexane and diethylether with good recovery, although other solvent systems have

also been cited in the literature. Following washing to remove hydrophilic remnants and excess alkali, the organic phase is dried and evaporated to recover an enriched crude extract. This will generally require further clean-up prior to quantification, dependent on the vitamin D concentration and level of coextractives.

Total Lipid Extraction

The risks of thermal equilibration with previtamin D and potential degradation of vitamin D may be avoided through an initial total lipid extraction. A variety of solvent systems have been recommended depending upon sample type and fat content. A consequence of employing such a technique for foods is the need to isolate the vitamin components from high-molecular-weight fractions (triglycerides, phospholipids) by gel permeation and/or adsorption chromatography. Various protocols have been advocated which, while successful, contribute complexities to the assays which are difficult for most quality control laboratories to manage.

This extraction route has been commonly applied to low-fat clinical specimens (such as plasma), and fat-reduced fortified foods (e.g., skim milk). It is also useful when vitamin D and its metabolites are to be estimated concurrently. The literature consensus seems to support the view that saponification is more appropriate when complex and poorly characterized foods are to be assayed.

The concentrations of cholecalciferol are generally low, even after isolation of the crude extracts. Further clean-up to remove substantial quantities of sterols and other unsaponifiable material is usually incorporated prior to analysis. Such strategies may be as simple as cholesterol precipitation or as complex as multistage semipreparative chromatography, depending on both sample type and the sophistication of subsequent analytical techniques. Often at this stage, analysts may expediently utilize the convenience of prepacked solid-phase extraction cartridges. Usually, the adsorption mode with activated silica is selected, producing an extract of higher vitamin D content and fewer potential interferences. These disposable cartridges are now widely replacing the earlier techniques of open-column or thin-layer chromatography (although the latter is still occasionally used for clean-up or qualitative 'spot testing').

Chromatography

Quantification of enriched vitamin extracts is achievable by applying gas–liquid chromatography (GLC) techniques, although the thermal instability of vitamin D at operating temperatures results in formation of pyro and isopyro peaks of both parent or derivative forms. This problem has been successfully avoided by prior conversion to the thermostable isotachysterol isomers. Modern GLC now benefits from the use of capillary columns and ultrasensitive mass-selective spectrometric detectors, but the extensive manipulative procedures still make GLC less attractive than other technologies for routine food analysis. (*See* **Chromatography**: Gas Chromatography.)

High-performance liquid chromatography (HPLC) has led to continuing improvements in the assay of vitamin D (and its metabolites) in foods and has now superseded GLC. While additional clean-up is not always unavoidable, derivatization procedures are unnecessary in the majority of schemes. Furthermore, the ambient and nondestructive features inherent in HPLC are more compatible with the lability properties of this, and other, vitamins. Recently, variants of micellar capillary electrophoresis (CE) have been applied to fat-soluble vitamin separations. Although representing an alternative to HPLC techniques, the application of CE to the hydrophobic vitamins is currently in its infancy. (*See* **Chromatography**: High-performance Liquid Chromatography.)

In the absence of useful native fluorescence or stable electrochemical viewing modes and the current infancy of commercial online liquid chromatography–mass spectroscopy (LCMS) interfaces, the use of UV spectrophotometric detection is universal.

The modest spectral properties of vitamin D often require a semipreparative HPLC fractionation step before an analytical HPLC stage can be undertaken. Spectral selectivity is further gained by the judicious use of either wavelength rationing or full-spectrum (e.g., diode array) detection. Alternative choices to attain additional specificity and selectivity include the use of offline competitive protein-binding assay or the precolumn conversion of cholecalciferol to its bathochromically shifted isotachysterol.

In view of the differing selectivities of normal-phase and reversed-phase HPLC, many researchers have concluded that the assay benefits by combining the two modes. This multidimensional technique exploits the fact that cholecalciferol and ergocalciferol are unresolved on silica columns yet are completely separated using C_{18} reversed-phase columns. There are a number of reported methods which employ reversed-phase chromatography during clean-up, either low-pressure or HPLC, followed by normal-phase quantitation. This regimen is generally of use where both calciferols are known to coexist in the sample or where the sample is not well defined in terms of its vitamin D content. Alternatively, normal-phase silica chromatography can be used during the preparative step and the two vitamins

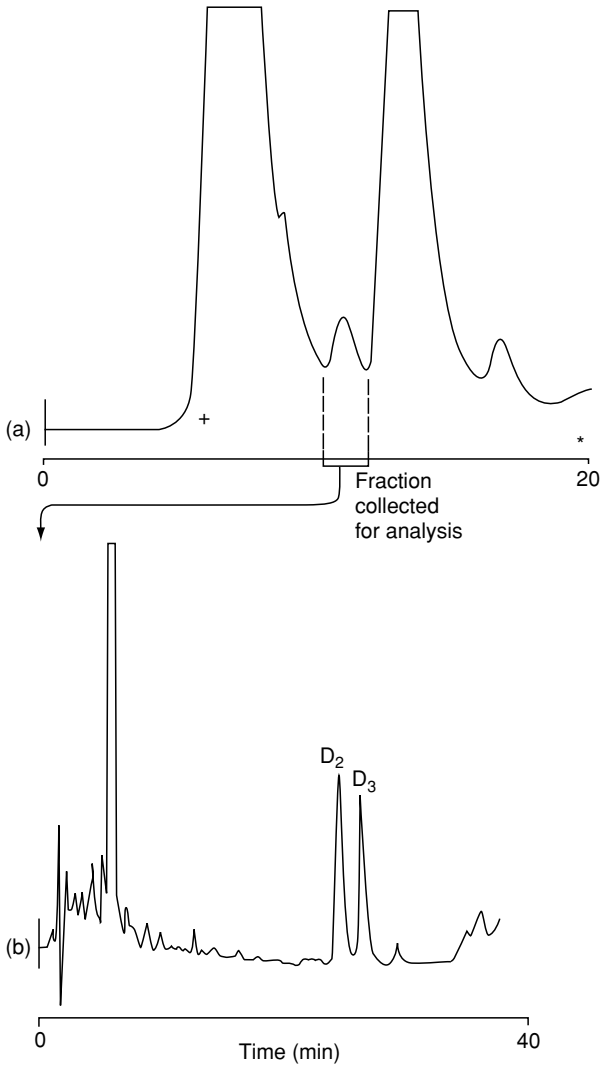

Figure 4 High-performance liquid chromatography (HPLC) chromatograms showing the analysis of cholecalciferol in halibut liver oil. An internal standard of ergocalciferol (D_2) was used throughout the analysis. (a) The semipreparative clean-up stage. A Brownlee (25 cm × 10 mm) silica column was used with a mobile phase of 1% 2-propanol in hexane, flowing at 3 ml min^{-1}. Detection was by ultraviolet at 280 nm (0.04 aufs). The unsaponifiable fraction from 2.5 g of fish oil was dissolved in 1.0 ml of mobile phase and injected. The fraction collected and evaporated for quantitative analysis is shown. The elution positions of previtamin D_3 (+) and provitamin D_3 (*) are shown. (b) A reversed-phase C_{18} column (Waters 5 µm Radial-PAK) was used for analyte quantification. A mobile phase of methanol:water:tetrahydrofuran (90:8:2 v/v/v) at a flow rate of 2.0 ml min^{-1} was used. The injection volume was 100 µl, representing the cholecalciferol (D_3) content of 0.25 g of oil. Detection was at 280 nm (0.005 aufs).

collected in a single fraction before application to a reversed-phase column. This allows one vitamin to be used as an internal standard for the other, greatly decreasing the cumulative assay errors introduced though potential isomerization and manipulative losses. The method can be used where only one vitamin is present, as is usually encountered in the food industry. Chromatograms of a fish oil taken through this analytical procedure are shown in Figure 4. The endogenous vitamin is cholecalciferol, allowing internal standardization with ergocalciferol.

The elution positions of previtamin D_3 and provitamin D_3 are shown in Figure 4a. They are well separated from vitamin D_3, thus allowing potential differentiation of the species. Other calciferols shown in Figures 2 and 3 can be similarly resolved. On silica columns, using hydrocarbon/alcohol mobile phases, the major isomers elute in the sequence previtamin D_3 < *trans*-vitamin D_3 < lumisterol$_3$ < isotachysterol$_3$ < vitamin D_3 < tachysterol$_3$ < provitamin D_3 < hydroxymetabolites. The pyrocalciferols elute close to lumisterol$_3$. The most likely interfering isomer is tachysterol$_3$ which elutes close to vitamin D_3 in both normal and reversed-phase analyses. Interestingly, the retention sequence of previtamin D_3, vitamin D_3, and provitamin D_3 is the same, regardless of which separation mode is used.

Background

Vitamin D is essential for life in higher animals. Classically, it has been shown to be one of the most important biological regulators of calcium homeostasis. It has been established that these important biological effects are only achieved as a consequence of the metabolism of vitamin D into a family of daughter metabolites, including the two key kidney-produced metabolites $1\alpha,25(OH)_2$-vitamin D_3 ($1\alpha,25(OH)_2D_3$) and $24R,25(OH)_2$-vitamin D_3 ($24R,25(OH)_2D_3$). $1\alpha,25(OH)_2D_3$ is considered to be a steroid hormone and there is increasing evidence that $24R,25(OH)_2D_3$ is also a steroid hormone.

It has become increasingly apparent since the 1980s that $1\alpha,25(OH)_2D_3$ also plays an important multidisciplinary role in tissues not primarily related to mineral metabolism, e.g., the hematopoietic system, effects on cell differentiation and proliferation including important interactions with keratinocytes and cancer cells, and participation in the processes of parathyroid hormone and insulin secretion. The purpose of this chapter is to provide a succinct overview of our current understanding of the important nutritional substance vitamin D and the mechanisms by which its daughter hormone $1\alpha,25(OH)_2D_3$ mediates biological responses.

Historical Review

The first scientific description of rickets, which is the hallmark of a vitamin D-deficiency, was provided in the seventeenth century by both Dr. Daniel Whistler (1645) and Professor Francis Glisson (1650). The major breakthrough in understanding the causative factors of rickets was the development of nutrition as an experimental science and the appreciation of the existence of vitamins. Considering the fact that now we accept that the biologically active form of vitamin D is a steroid hormone, it is somewhat ironic that vitamin D, through a historical accident, became classified as a vitamin. It was in 1919/20 that Sir Edward Mellanby, working with dogs raised exclusively indoors (in the absence of sunlight or ultraviolet light), devised a diet which allowed him to establish unequivocally that rickets was caused by a deficiency of a trace component present in the diet. In 1921, he wrote, 'The action of fats in rickets is due to a vitamin or accessory food factor which they contain, probably identical with the fat-soluble vitamin.' Furthermore, he established that cod-liver oil was an excellent antirachitic agent; this ultimately led to the antirachitic factor being classified as a vitamin.

The chemical structures of the vitamins D were determined in the 1930s in the laboratory of Professor A. Windaus at the University of Gottingen. Vitamin D_2, which could be produced by ultraviolet irradiation of ergosterol, was chemically characterized in 1932. Vitamin D_3 was not chemically characterized until 1936, when it was shown to result from the ultraviolet irradiation of 7-dehydrocholesterol. Virtually simultaneously, the elusive antirachitic component of cod-liver oil was shown to be identical to the newly characterized vitamin D_3. These results clearly established that the antirachitic substance vitamin D was chemically a steroid, more specifically a seco-steroid (see below).

The modern era of vitamin D began during the period of 1965–70 with the discovery and chemical characterization of $1\alpha,25(OH)_2D_3$ and its nuclear receptor, the VDR_{nuc}.

Chemistry of Vitamin D

Vitamin D_3 is the naturally occurring form of vitamin D and is produced from 7-dehydrocholesterol (see **Figure 1**). Vitamin D_2 is a synthetic form of vitamin D that is produced by irradiation of the plant yeast steroid, ergosterol.

The structures of vitamin D_3 (cholecalciferol) and its provitamin 7-dehydrocholesterol are presented in **Figure 1**. Vitamin D is a generic term and indicates a molecule of the general structure shown for rings A, B,

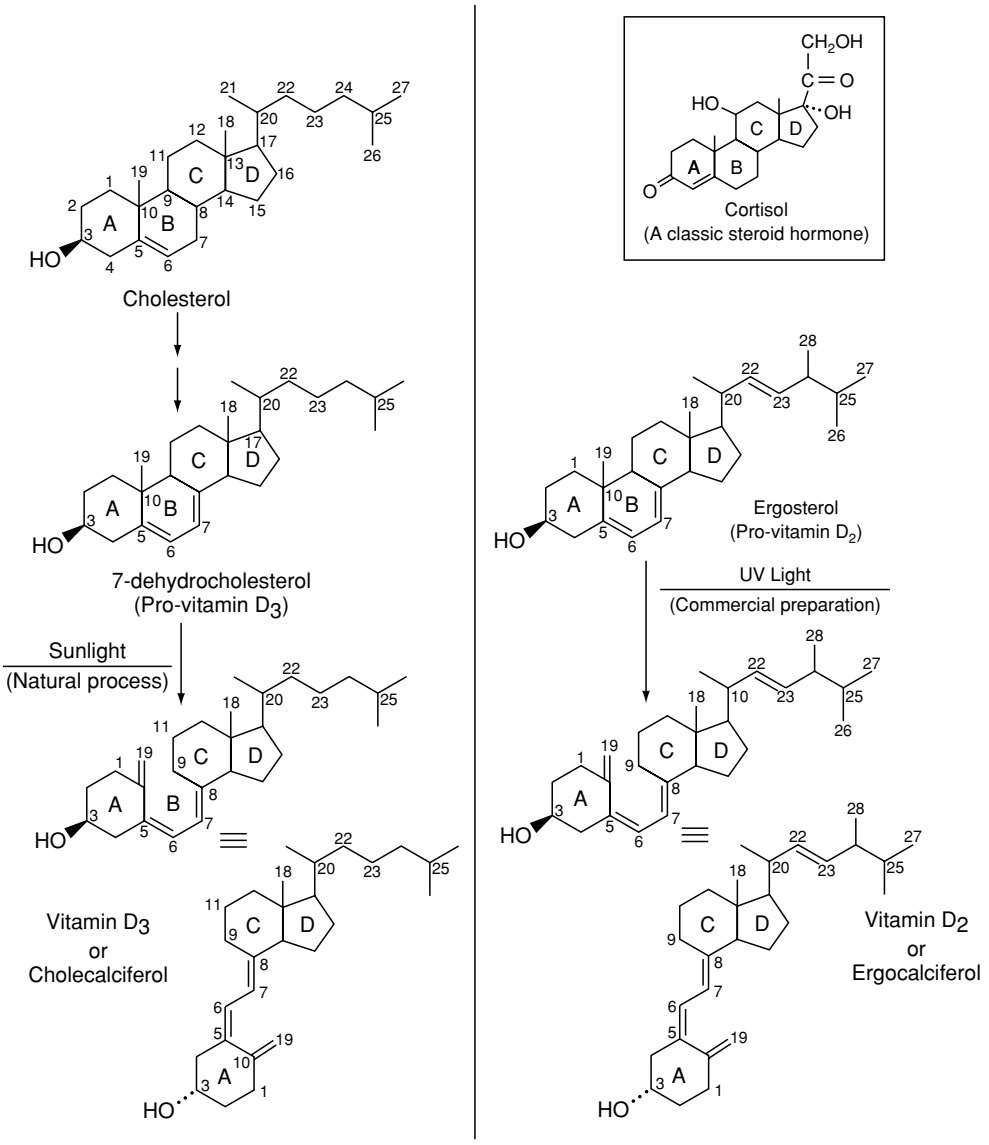

Figure 1 Structural relationship of vitamin D_3 (cholecalciferol) and vitamin D_2 (ergocalciferol) with their respective provitamins (7-dehydrocholesterol and ergosterol), cholesterol, and a classic steroid hormone, cortisol (see inset box). The two structural representations presented at the bottom for both vitamin D_3 and vitamin D_2 are equivalent; these are simply different ways of drawing the same molecule. It should be noted that vitamin D_3 is the naturally occurring form of the vitamin; it is produced from 7-dehydrocholesterol, which is present in the skin, by the action of sunlight. Vitamin D_2 (which is equivalently potent to D_3 in humans and many mammals, but not birds) is produced commercially by the irradiation of the plant sterol ergosterol with ultraviolet light.

C, and D with differing side-chain structures. The A, B, C, and D ring structure is derived from the cyclopentanoperhydrophenanthrene ring structure for steroids. Technically, the steroid vitamin D is classified as a seco-steroid. Seco-steroids are those in which one of the rings has been broken; in vitamin D, the 9,10 carbon–carbon bond of ring B is broken, and it is indicated by the inclusion of '9,10-seco' in the official nomenclature.

Vitamin D (synonym calciferol) is named according to the revised rules of the International Union of Pure and Applied Chemistry (IUPAC). Because vitamin D is derived from a steroid, the structure retains its numbering from the parent compound cholesterol (see Figure 1). Asymmetric centers are designated by using the R,S notation; the configuration of the double bonds is indicated as E for 'entgegen' or *trans*, and Z for 'zusammen' or *cis*. Thus, the official name of vitamin D_3 is 9,10-seco (5Z, 7E)-5,7,10(19)cholestatriene-3β-ol. Vitamin D_2 differs from D_3 by virtue of the presence of a 22-ene and 24-methyl group in the side-chain. The official

name of vitamin D_2 is 9,10-seco(5Z,7E)-5,7,10(19),22-ergostatetraene-3β-ol.

Vitamin D_3 can be produced photochemically by the action of sunlight or ultraviolet light from the precursor sterol 7-dehydrocholesterol that is present in the epidermis or skin of most higher animals. The chief structural prerequisite of a provitamin D is that it be a sterol with a Δ5–7 diene double bond system in ring B (see Figure 1). The conjugated double bond system in this specific location of the molecule allows the absorption of light quanta at certain wavelengths in the UV range; this can be readily provided in most geographical locations by natural sunlight. This initiates a complex series of transformations (partially summarized in Figure 1) that ultimately result in the transformation into vitamin D_3. Thus, it is important to appreciate that vitamin D_3 can be endogenously produced and that as long as the animal (or human) has access on a regular basis to sunlight, there is no dietary requirement for this vitamin.

Physiology and Biochemistry

Vitamin D Endocrine System

Vitamin D_3 is not known to have any intrinsic biological activity itself. It is only after vitamin D_3 is metabolized first into 25(OH)D_3 in the liver and then into 1α,25(OH)$_2D_3$ and 24R,25(OH)$_2D_3$ by the kidney, that biologically active molecules are produced. *In toto*, some 37 vitamin D_3 metabolites have been isolated and chemically characterized. Figure 2 illustrates the concept of the vitamin D endocrine system. The elements of the vitamin D endocrine system include the following: (1) in the skin, photoconversion of 7-dehydrocholesterol to vitamin D_3 or dietary intake of vitamin D_3; (2) metabolism of vitamin D_3 by the liver to 25(OH)D_3, which is the major form of vitamin D circulating in the blood compartment; (3) conversion of 25(OH)$_2D_3$ by the kidney (functioning as an endocrine gland) to produce the two principal dihydroxylated metabolites,

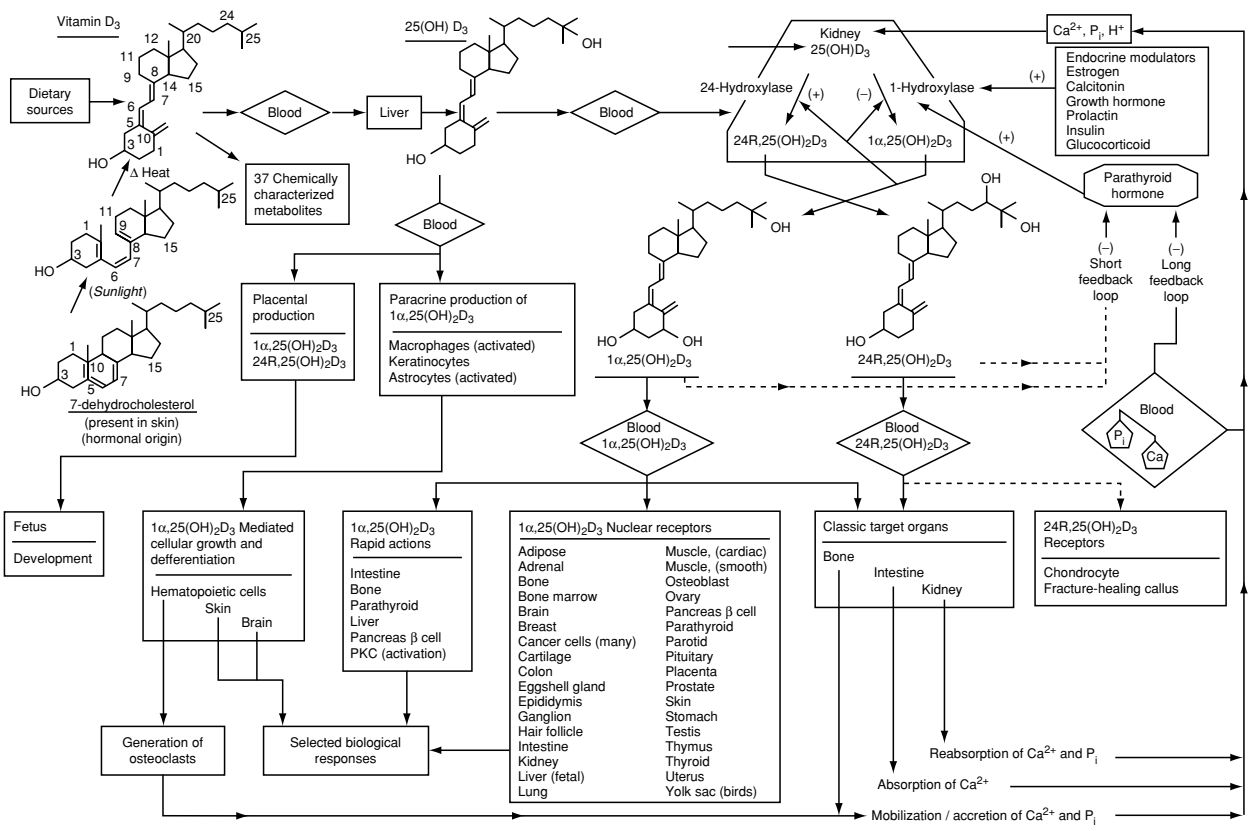

Figure 2 Summary of the vitamin D endocrine system. In this system, the biologically inactive vitamin D_3 is activated, first in the liver to generate 25(OH)D_3, which is then converted by the endocrine gland, the kidney, to the hormones 1α,25(OH)$_2D_3$ and 24R,25(OH)$_2D_3$. P_i, inorganic phosphate. There is currently much research being conducted to understand structure–function relationships with respect to chemical synthesis of analogs of 1α,25(OH)$_2D_3$ and their interaction with the vitamin D endocrine system. The objective is to develop new drug forms of 1α,25(OH)$_2D_3$.

$1\alpha,25(OH)_2D_3$ and $24R,25(OH)_2D_3$; (4) systemic transport of the dihydroxylated metabolites $24R,25(OH)_2D_3$ and $1\alpha,25(OH)_2D_3$ to distal target organs; (5) binding of the dihydroxylated metabolites, particularly $1,25(OH)_2D_3$, to either a nuclear receptor or membrane receptor at the target organs followed by the subsequent generation of appropriate biological responses (see also **Figure 3**). An additional key component in the operation of the vitamin D endocrine system is the plasma vitamin D binding protein, which carries vitamin D_3 and all its metabolites to their various target organs.

The three enzymes responsible for the conversion of vitamin D_3 into its two key daughter metabolites include the hepatic vitamin D_3-25-hydroxylase and the two kidney enzymes, the $25(OH)D_3$-1α-hydroxylase and the $25(OH)D_3$-24R-hydroxylase. All three enzymes have been demonstrated to be cytochrome P450 mixed-function oxidases. Both renal enzymes are localized in mitochondria of the proximal tubules of the kidney. The $25(OH)D_3$-1α-hydroxylase has been cloned and the specific site of mutations (which result in the appearance of vitamin D-resistant rickets, type I) identified. Also, the $25(OH)D_3$-24R-hydrodroxylase and vitamin D_3-25-hydroxylase have been cloned.

The most important point of regulation of the vitamin D endocrine system occurs through the stringent control of the activity of the renal $25(OH)D_3$-1α-hydroxylase. In this way, the production of the hormone $1\alpha,25(OH)_2D_3$ can be modulated according to the calcium and other endocrine needs of the organism. The chief regulatory factors are $1\alpha,25(OH)_2D_3$ itself, parathyroid hormone (PTH), and the serum concentrations of calcium and phosphate. Probably the most important determinant of the 1α-hydroxylase is the vitamin D status of the animal. When the circulating concentration of $1\alpha,25(OH)_2D_3$ is low, production of $1\alpha,25(OH)_2D_3$ by the kidney is high; when the circulating concentration of $1\alpha,25(OH)_2D_3$ is high, the output of $1\alpha,25(OH)_2D_3$ by the kidney is sharply reduced.

The process of nuclear receptor-mediated regulation of gene transcription is exquisitely dependent upon the complimentary relationship between the unoccupied receptor and its cognate ligand. Thus, the unoccupied receptor is largely incompetent to engage in a productive fashion with the

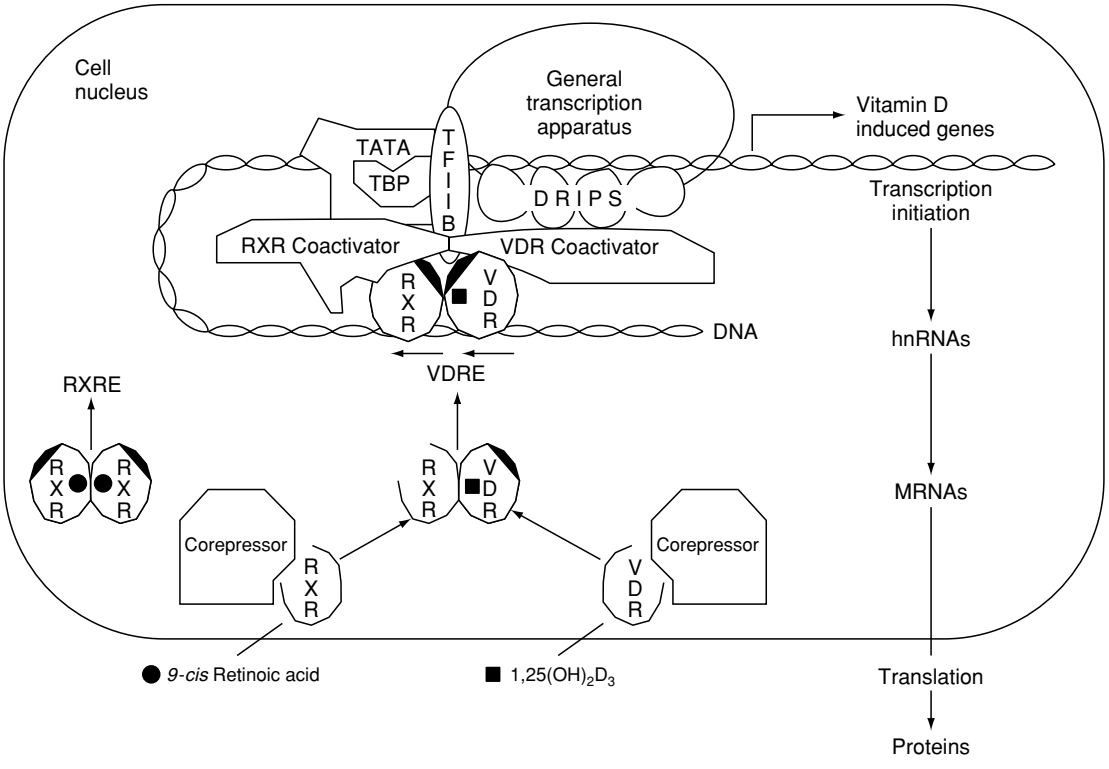

Figure 3 Model of $1\alpha,25(OH)_2D_3$ and VDR_{nuc} activation of transcription. The VDR, after binding its cognate ligand $1\alpha,25(OH)_2D_3$, forms a heterodimer with the retinoid X receptor. This heterodimer complex then interacts with the appropriate vitamin D response element on the promoter of genes (in specific target cells) which are destined to be up- or downregulated. The heterodimer – DNA complex then recruits the necessary coactivator proteins, such as TATA, TBP, TFIIB and other proteins to generate a competent transcriptional complex capable of modulating mRNA production.

transcriptional machinery to effect meaningful regulation of gene transcription. It is only after the ligand–receptor complex has formed (which results in conformational changes in the receptor protein) that a functional receptor protein is generated. Thus acquisition of a detailed understanding of the complementarity of the ligand shape with that of the interior surface of the nuclear VDR receptor ligand binding domain is believed to be the key not only to understanding the structural basis of receptor action and its formation of heterodimers and interactions with coactivators (see **Figure 3**), but also to designing new drug forms of the various hormones, including $1\alpha,25(OH)_2D_3$.

The receptors for all steroid hormones (estrogen, progesterone, testosterone, cortisol, and aldosterone) and the nuclear receptors for $1\alpha,25(OH)_2D_3$, retinoic acid, and thyroid hormone are all members of the same super gene family (*See* **Hormones**: Steroid Hormones, Figure 5); accordingly, there is a high level of conservation in their amino acid sequences, particularly in their DNA and ligand binding domains. The X-ray crystallographic structures of the ligand-binding domains (LBD) of the thyroid hormone receptor, the retinoic acid receptor, the estrogen receptor, the ligand binding and coactivator assembly of the peroxisome proliferator-activated receptor-γ, and the progesterone receptor have all been determined with their respective ligands bound. Also, the crystal structure of the nuclear receptor for vitamin D bound to its natural ligand $1\alpha,25(OH)_2D_3$ has been determined at a 1.8-Å resolution. The VDR_{nuc} LBD structure, like the other nuclear receptors, consists of 12 α-helices that are arranged to create a three-layer sandwich that completely encompasses the ligand $1\alpha,25(OH)_2D_3$ in a hydrophobic core. The secondary and tertiary structural features of this group of proteins have been found to be remarkably similar.

Nutritional Aspects

Recommended Dietary Allowance

The World Health Organization (WHO) has responsibility for defining the International Unit (IU) of vitamin D_3. Their most recent definition, provided in 1950, stated that 'the International Unit of vitamin D recommended for adoption is the vitamin D activity of 0.025 μg of the international standard preparation of crystalline vitamin D_3.' Thus, 1.0 IU of vitamin D_3 is 0.025 μg, which is equivalent to 65.0 pmol. With the discovery of the metabolism of vitamin D_3 to other active seco-steroids, particularly $1\alpha,25(OH)_2D_3$, it was recommended that 1.0 Unit of $1\alpha,25(OH)_2D_3$ be set equivalent in molar terms to that of the parent vitamin D_3. Thus, 1.0 Unit of $1\alpha,25(OH)_2D_3$ has been operationally defined to be equivalent to 65 pmol.

The vitamin D requirement for healthy adults has never been precisely defined. Since vitamin D_3 is produced in the skin after exposure to sunlight, the human does not have a requirement for vitamin D when sufficient sunlight is available. Man's tendency to wear clothes, to live in cities where tall buildings block adequate sunlight from reaching the ground, to live indoors, to use synthetic sunscreens that block ultraviolet rays, and to live in geographical regions of the world that do not receive adequate sunlight all contribute to the inability of the skin to biosynthesize sufficient amounts of vitamin D_3. Thus, vitamin D does become an important nutritional factor in the absence of sunlight. It is known that a substantial proportion of the US population is exposed to suboptimal levels of sunlight. This is particularly true during the winter months. Under these conditions, vitamin D becomes a true vitamin, and therefore must be supplied in the diet on a regular basis.

Since vitamin D_3 can be endogenously produced by the body and since it is retained for long periods of time by vertebrate tissue, it is difficult to determine with precision the minimum daily requirements for this seco-steroid. The requirement for vitamin D is also known to be dependent on age, sex, degree of exposure to the sun, season, and the amount of pigmentation in the skin.

In the USA, adequate amounts of vitamin D can be readily obtained from the diet and/or from casual exposure to sunlight. The UV exposure can be as little as three 20-min periods of exposure of the face and hands to ambient sunlight per week. However, in some parts of the world where food is not routinely fortified and sunlight is often limited during some periods of the year, obtaining adequate amounts of vitamin D becomes more of a problem. As a result, the incidence of rickets in these countries is higher than in the United States.

Many countries as well as the WHO have prepared recommendations on the daily intake of essential nutrients, including vitamin D. The current 'adequate intake' allowance of vitamin D recommended in 1998 by the Food and Nutrition Board of the US Institute of Medicine is 200 IU per day (5 μg per day) for infants, children, and adult males and females up to age 51. For males and females aged 51–70 or >70, the adequate indicated level is set at 400 IU per day (10 μg per day) or 600 IU (15 μg per day), respectively. The adequate allowance for pregnancy and lactation is set at 200 IU per day (5 μg per day). The recommendations of the UK and Canada for adults are about 50% lower than of the USA. Australia, which is generally

sunny, does not recommend daily supplements of vitamin D.

Food Sources

Animal products constitute the bulk source of vitamin D that occurs naturally in unfortified foods. Marine fish, such as herring, salmon, and sardines, and fish liver oils are good sources of vitamin D_3. Small quantities of vitamin D_3 are also derived from eggs, veal, beef, butter, and vegetable oils, while plants, fruits, and nuts are extremely poor sources of vitamin D. In the USA, artificial vitamin D_3 fortification of foods such as milk (both fresh and evaporated), margarine and butter, cereals, and chocolate mixes help in meeting the recommended dietary allowance. Vitamin D_2 was used in the period of 1940–60 as a food supplement for vitamin D activity.

Functions of Vitamin D

Classical target tissues In the classical target tissues such as intestine, bone, and kidney, $1,25(OH)_2D_3$, largely in conjunction with PTH, serves to regulate mineral homeostasis such that serum calcium and phosphorus levels are maintained within a physiological range that can support normal mineralization of bone.

In the intestine, $1,25(OH)_2D_3$ primarily stimulates the active transport of Ca^{2+} and inorganic phosphate, P_i, via mechanisms that involve a calcium-binding protein, termed calbindin D. Available evidence suggests that calbindin D may be involved in protecting the cell (as a buffer) against large fluxes of Ca^{2+} which result from active transport induced by $1,25(OH)_2D_3$.

In addition to the genomic effects of $1,25(OH)_2D_3$, recent studies have shown that $1,25(OH)_2D_3$ can stimulate the rapid (2–4 min) transport of calcium, termed transcaltachia, via a receptor-mediated process, albeit one independent of gene activation.

In the kidney, $1,25(OH)_2D_3$ functions in concert with PTH to enhance renal Ca^{2+} reabsorption, besides regulating its own biosynthesis by feedback inhibition of renal 1-hydroxylase.

$1\alpha,25(OH)_2D_3$ plays an important role in bone growth, development, and differentiation, and supports bone mineralization indirectly by supplying the minerals calcium and phosphorus via their enhanced intestinal absorption. In addition, $24,25(OH)_2D_3$ has been shown to promote the bone-mineralization process and to participate in the process of fracture-healing.

Nonclassical target tissues The $1,25(OH)_2D_3$ hormone promotes differentiation of cells in the hemopoietic system. Such effects of $1,25(OH)_2D_3$ offer a therapeutic prospect for leukemia.

In the immune system, $1,25(OH)_2D_3$ acts as an immunomodulator, regulating the functional performance of cells involved in the immune response.

Insulin production by the endocrine pancreas is influenced by vitamin D status in that the blunted secretion of insulin and impaired glucose tolerance seen in vitamin D-deficient conditions are corrected by treatment with vitamin D_3 and/or $1,25(OH)_2D_3$.

Myopathy and abnormalities in muscle contraction seen in patients afflicted with metabolic bone disease are amenable to correction with vitamin D therapy.

$1\alpha,25(OH)_2D_3$ induces differentiation of keratinocytes in skin and exerts antiproliferative effects on these epithelial cells. Such an effect of $1,25(OH)_2D_3$ in the skin has prompted the use of $1,25(OH)_2D_3$ analogs for treatment of psoriasis, which is a hyperproliferative disease of the skin.

Disease States in Humans Related to Vitamin D

In humans, diseases related to vitamin D can arise because of (1) altered availability of vitamin D; (2) altered hepatic conversion of vitamin D_3; (3) impaired renal metabolism of $25(OH)D_3$, or (4) variation in end organ responsiveness to $1,25(OH)_2D_3$ (see Figure 4).

Renal Disorders

Chronic renal failure, also known as renal osteodystrophy, is characterized by impaired renal production of $1,25(OH)_2D_3$ and intestinal malabsorption of calcium, which can often lead to derangements in skeletal metabolism and hyperparathyroidism. These symptoms are alleviated by $1,25(OH)_2D_3$ administration. In 1977, in the USA, the Food and Drug Administration approved the prescription use of $1,25(OH)_2D_3$ (calcitriol or Rocaltrol®) for renal osteodystrophy.

Vitamin D-resistant Rickets

Also known as familial X-linked hypophosphatemic rickets, vitamin D-resistant rickets is characterized by a primary phosphate leak in the kidney, skeletal deformities, and hypophosphatemia. A combination of oral phosphate and $1,25(OH)_2D_3$ is effective in treating these patients.

Vitamin D-dependent Rickets

Vitamin D-dependent rickets is also referred to as hereditary hypocalcemic vitamin D-resistant rickets, and is classified into Type I and Type II disease states.

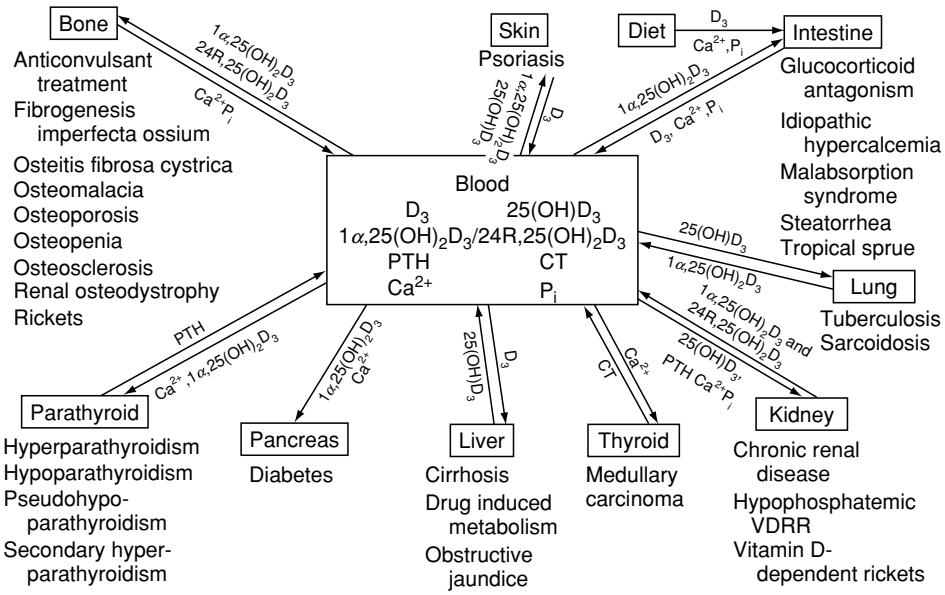

Figure 4 Human disease states related to the vitamin D endocrine system. Under the boxed headings (e.g., parathyroid, liver, bone, etc.) are listed disease states occurring in man which have been shown, or are believed, to have some functional linkage between some aspect of the vitamin D endocrine system and that particular organ. The information associated with the arrows indicates the direction of flow of calcium, phosphate or the calcium-regulating hormones (CT (calcitonin), PTH (parathyroid hormone), vitamin D_3, 1α, $25(OH)_2D_3$, 24R, $25(OH)_2D_3$). Ca^{2+}, calcium; P_i, inorganic phosphate; VDRR, vitamin D-resistant rickets.

Type I rickets is believed to arise as a result of an inborn error in the renal 1-hydroxylase enzyme. The clinical features include hypocalcemia, hypophosphatemia, and several rachitic lesions. These symptoms can be treated with pharmacological doses of vitamin D_3 or low doses of $1,25(OH)_2D_3$.

Point mutations in the vitamin D receptor gene have been shown to be responsible for the defective receptors seen in these children with Type II rickets. The clinical manifestations are defective bone mineralization, decreased intestinal calcium absorption, hypocalcemia, and increased serum $1,25(OH)_2D_3$ levels. To date, a point mutation in a steroid receptor gene resulting in the loss of functional activity has been demonstrated only for the vitamin D receptor and is therefore unique in this respect.

Diseases of Parathyroid

Hypoparathyroidism Hypoparathoidism exhibits hypocalcemia as a major clinical consequence and is corrected with large doses of vitamin D or physiological doses of $1,25(OH)_2D_3$.

Hyperparathyroidism Increased $1,25(OH)_2D_3$ levels, enhanced intestinal absorption of calcium (contributing to hypercalciuria), and nephrolithiasis are typical of this disorder.

Pseudohypoparathyroidism Pseudohypoparathyroidism results from a state of resistance to PTH. The biochemical abnormalities are hypocalcemia, hyperphosphatemia, elevated serum PTH, and decreased serum $1,25(OH)_2D_3$ levels.

Bone disorders Clinically, a deficiency in vitamin D manifests as rickets in children and osteomalacia in adults. Hypocalcemia, hypophosphatemia, increased serum alkaline phosphatase, and decreased serum $25(OH)D_3$ levels are some of the salient biochemical abnormalities, all of which can be ameliorated by vitamin D administration.

Conclusion

Current evidence supports the concept that the classical biological actions of the nutritionally important fat-soluble vitamin D in mediating calcium homeostasis are supported by a complex vitamin D endocrine system which coordinates the metabolism of vitamin D_3 into $1α,25(OH)_2D_3$ and $24R,25(OH)_2D_3$. It is now clear that the vitamin D endocrine system embraces many more target tissues than simply the intestine, bone, and kidney. Notable additions to this list include the pancreas, pituitary, breast tissue, placenta, hematopoietic cells, skin, and cancer cells of various origins. Key advances in understanding the mode of action of the $1α,25(OH)_2D_3$ have been made by a thorough study of nuclear receptors as well as emerging studies describing a membrane receptor for this steroid hormone. Integral to

these observations are efforts to define the signal transduction systems, which are subservient to the nuclear and membrane receptors for $1\alpha,25(OH)_2D_3$, and to obtain a thorough study of the tissue distribution and subcellular localization of the gene products induced by this steroid hormone. There are clinical applications for $1\alpha,25(OH)_2D_3$ or related analogs for treatment of the bone diseases of renal osteodystrophy and osteoporosis, psoriasis, and hypoparathyroidism; other clinical targets for $1\alpha,25(OH)_2D_3$ currently under investigation include its use in leukemia, breast, prostate, and colon cancer as well as use as an immunosuppressive agent.

J A T Pennington, National Institute of Health, Bethesda, MD, USA

Background

Cholesterol is a well-known and commonly determined lipid component and an important intermediate in the synthesis of steroid hormones. It is a sterol ($C_{27}H_{45}OH$) that occurs notably in animal fats and oils, bile, gallstones, nerve tissues, blood, brain, plasma, and egg yolk. Cholesterol is the most common animal sterol and is also found in trace amounts in vegetable fats and oils, seaweeds, and green leaves. Cholesterol was first found in gallstones and derives its name from the Greek *kholé* (bile) and *stereos* (solid). The determination of cholesterol in serum and foods is of significance because of the implication of cholesterol in the etiology of arteriosclerosis and coronary heart disease. (*See* **Atherosclerosis; Coronary Heart Disease**: Intervention Studies.)

Structure

A systematic study of the chemistry of cholesterol began at the end of the nineteenth century. The classic work of Wieland, Vindaus, Diels, Rosenheim, and King led to the formulation of the structure of cholesterol in 1932. The fundamental carbon skeleton of the cholesterol molecule is the cyclopentanoperhydrophenanthrene ring. The structure of cholesterol is shown in Figure 1. The hydroxyl group on C3 is connected by a 'solid' bond (β orientation) and the hydrogen by a 'dashed' bond (α orientation), depicting the naturally occurring β-cholesterol. Atoms connected by solid bonds (β orientation) are regarded as projecting in front of the plane of the steroid ring, and those connected by dashed bonds (α orientation) as lying behind the plane. The molecular weight of cholesterol is 384.64. Cholesterol consists of 83.87% carbon, 11.99% hydrogen, and 4.145% oxygen by weight. The formal chemical name of the molecule is cholest-5-en-3β-ol. Because the cholesterol nucleus contains eight centers of asymmetry, approximately 240 isomers of the molecule are possible. However, only two carbon centers (C3 and C5) appear to be involved in naturally occurring cholesterol isomers. In some of the earlier scientific literature, cholesterol is referred to as 'cholesterin.'

Chemical Characteristics

Cholesterol is a glistening, white, soapy, crystalline substance that is practically insoluble in water (about 0.2 mg per 100 ml). It is slightly soluble in alcohol (1.29% w/w at 20 °C) and more soluble in hot alcohol (100 g of saturated 96% alcoholic solution contains 28 g of cholesterol at 80 °C). One gram of the compound dissolves in 2.8 ml of ether, 4.5 ml of chloroform, or 1.5 ml of pyridine. Cholesterol is also soluble in benzene, hexane, petroleum ether, oils, fats, and aqueous solutions of bile salts. It crystallizes easily from absolute alcohol, acetic acid, ether, and similar solvents as colorless rhombic plates with one or more characteristic notches in the corners. Because cholesterol has an unsaturated bond, it will accept up to two halogen atoms. Cholesterol is not saponifiable.

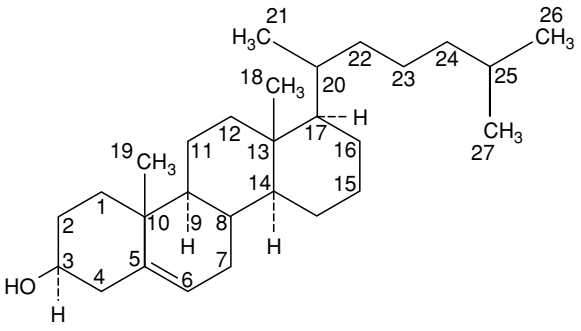

Figure 1 Structure of β-cholesterol showing carbon atom numbering. Reproduced from Cholesterol: Properties and Determination, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Cholesterol gives a number of color reactions that are useful to test for the molecule both qualitatively and quantitatively. The Salkowski reaction produces a series of colors when a chloroform solution of cholesterol is stratified over concentrated sulfuric acid. The acid assumes a yellowish color with a green fluorescence, whereas the chloroform layer first becomes bluish red and then gradually changes to a violet–red. If the chloroform layer is decanted into a porcelain evaporating dish, it changes from violet–red to violet, to green, and then to yellow. Another test, the Liebermann–Burchard reaction, which involves adding acetic anhydride and concentrated sulfuric acid (under conditions as nearly anhydrous as possible) to a chloroform solution of cholesterol, results in an initial blue to violet color that changes to emerald green. Under carefully controlled conditions, the intensity of the green color produced is proportional to the amount of cholesterol present.

Free cholesterol unites with digitonin, a glycosidic saponin, to form cholesterol digitonide; cholesterol esters do not form such compounds. Cholesterol digitonide is insoluble in petroleum ether; cholesterol esters are freely soluble in petroleum ether. This difference in solubilities is useful to test both qualitatively and quantitatively for free versus esterified cholesterol.

Fieser showed that the melting point of cholesterol, which had been purified by recrystallization from acetic acid, was 149.5–150.0 °C. Radin and Gramza indicated that the acceptable melting point of recrystallized cholesterol was 149.3–151.3 °C. The *Merck Index* indicates that the melting point of anhydrous cholesterol is 148.5 °C, and the boiling point is 233 °C at 0.5 mmHg and 360 °C at 1 atm (760 mmHg). At 360 °C, some decomposition occurs.

Primary Cholesterol Standard

The requirements for primary standards become progressively more stringent as methods are developed that are more sensitive and more compound-specific; such is the case for cholesterol. Primary standards are chemical substances that, by virtue of their purity, can be weighed directly for the preparation of solutions with known concentrations. Primary cholesterol standards are expected to be at least 99% pure.

Cholesterol stored at room temperature, unprotected by a nitrogen cover, will undergo autoxidation over an extended period. In addition, ultraviolet light will produce structural changes in cholesterol unless amber glass containers are used. Consequently, various amounts of cholesterol oxidation products may be present in what was initially pure cholesterol. Among the cholesterol oxides that have been identified in stored cholesterol are 7-ketocholesterol, 20-hydroxycholesterol, and 24-, 25-, and 26-hydroxycholesterol. Therefore, primary standards that have been stored must be checked and may need to undergo repurification before use. Crystalline standards should be stored in small amounts over a desiccant such as silica gel at $-20\,^{\circ}C$ in the dark.

Cholesterol may be recrystallized from ethanol or acetic acid, or as the dibromide. A cholesterol preparation may be added to absolute ethanol, which is gently heated until the cholesterol dissolves and is then cooled to room temperature. The precipitated cholesterol is collected on a filter, washed with a small volume of diethyl ether, dried overnight in air, and dried in an oven at $90\,^{\circ}C$ for 2 h. Cholesterol is recrystallized from boiling glacial acetic acid solution, which is then cooled to room temperature in an ice bath. The crystals are collected on a filter, washed with acetic acid and methanol, and dried as described above.

The recrystallization of cholesterol by the dibromide method (Schoenheimer) is a more arduous task than the recrystallization from either ethanol or acetic acid, but it produces a superior product. A bromine solution is added to the cholesterol solution. A white paste is produced that is then transferred to a filter and washed with acetic acid until the filtrate is colorless. Zinc dust is then added to a suspension of the white material in diethyl ether and glacial acetic acid (750:10 v/v); the reaction produces evolution of hydrogen. The resultant white precipitate of zinc salts is dissolved in water, and the ether solution is decanted. The water contains any excess solid zinc. The ether solution is washed in a separatory funnel with acid solution and neutralized with sodium hydroxide solution. Methanol is added to the ether solution, and most of the ether is evaporated on a steam bath as the purified cholesterol begins to crystallize. The crystallization proceeds more rapidly as room temperature is approached. The product is collected on a filter and dried as described above.

The cholesterol purified by the above methods may be characterized by the color reactions discussed above (Salkowski and Liebermann–Burchard). Other color tests, such as the formaldehyde–sulfuric acid test, may be used. In this test, formaldehyde–sulfuric acid solution is added to a solution of cholesterol dissolved in chloroform. The solution, which turns cherry red, is poured into another tube, and two to three drops of acetic anhydride are added. A blue color develops. These color tests have been adapted to form the basis of spectrophotometric measurements. The results of the purified products are determined by reference to a standard of known purity.

The purity of cholesterol standards may be assessed by using melting point and boiling point determinations, microscopic comparison of the crystals with a pure reference material, and infrared and ultraviolet–visible spectra. The spectrum of the cholesterol standard is compared with that of a pure crystalline reference material.

Classic colorimetric tests, microscopic examinations, and melting point determinations have been supplemented with more modern techniques, such as mass spectrometry, nuclear magnetic resonance spectrometry, gas chromatography (GC) and high-performance liquid chromatography (HPLC) for determining the purity of prepared crystalline cholesterol. No one test in itself is sufficient to determine purity. Confirmation of results requires a minimum of two tests, which should preferably be chemically or physically unrelated. (*See* **Chromatography**: High-performance Liquid Chromatography; Gas Chromatography; **Mass Spectrometry**: Principles and Instrumentation; **Spectroscopy**: Nuclear Magnetic Resonance.)

A serum reference material for determining serum cholesterol is normally used for both manual and automated methods. A serum reference material may be prepared by filtering pooled human serum through clarifying and 'sterilizing' filters. Stable serum preparations of cholesterol, with concentrations ranging from 100 to $400\,mg\,dl^{-1}$, may be made by adding an alcohol-precipitated cholesterol-rich protein from human serum to bovine, horse, or human serum. Aliquots of the preparation should be stored in sealed vials or ampoules at a temperature of $-20\,^{\circ}C$ or below. The stability of these preparations is similar to that of human serum. These sterile preparations may be shipped at room temperature for periods of up to 5 days. The concentrations of some commercial reference sera may vary considerably if the Abell–Kendall method is used as the reference assay. The Abell–Kendall procedure includes an initial step in which the serum is treated with alcoholic potassium hydroxide to liberate the cholesterol from the lipoprotein complexes and to saponify the cholesterol esters. The total cholesterol is extracted into a measured volume of petroleum ether. The cholesterol in an aliquot of the petroleum ether extract is measured by means of the Liebermann–Burchard color reaction. All commercial reference sera should be

checked against serum reference materials and standardized by the reference cholesterol method (Abell–Kendall method).

Colorimetry-based Analytical Methods

Routine lipid testing in clinical settings generally includes serum determination of triglycerides and cholesterol, and a more recent trend has been to include lipoprotein–cholesterol determination. The literature contains more than 200 methods or modifications for measuring serum cholesterol. This number is perhaps an indication of the difficulties of developing a reliable assay. Free cholesterol and cholesteryl esters may be determined separately, but it is common practice to determine the two together as 'total cholesterol.' (*See* **Spectroscopy**: Visible Spectroscopy and Colorimetry.)

The Liebermann–Burchard reagent has had a central role in much of the methodological development of cholesterol measurement systems. Since Grigant introduced a procedure for the quantitative estimation of cholesterol in 1910 by using the Liebermann–Burchard reagent (developed between 1885 and 1890), numerous modifications of the method have appeared in the literature. Most of the deviations from earlier methods consist of changes in extraction and color development.

The reaction of cholesterol with sulfuric acid in acetic anhydride (Liebermann–Burchard) to form a colored product has provided the basis for many subsequent methods. These methods may be categorized into three groups: (1) direct, in which the serum is added directly to the color reagent; (2) extraction, in which cholesterol is extracted into an organic solvent before it is added to the color reagent; and (3) hydrolysis, in which the esterified cholesterol is hydrolyzed before solvent extraction and color development. Many methods utilize acetic anhydride, acetic acid, or ferric chloride to develop color. Specificity is enhanced by prior extraction techniques. Values for cholesterol are usually higher by direct and automated methods than by manual, extraction, or hydrolysis methods. The color development of these various procedures obeys the Lambert–Beer law, which states that the absorbance is directly proportional to the concentration.

The direct methods are simple and convenient, but are subject to interference from compounds normally present in serum, such as bilirubin and proteins. Much of this interference is eliminated by extracting the cholesterol with a solvent before the color development reaction is initiated. Esterified cholesterol in serum should be hydrolyzed before a total cholesterol determination is made because more color is produced by esterified cholesterol than by free cholesterol. Failure to hydrolyze results in an overestimation of total cholesterol. Standard solutions of cholesterol must be reacted with the color reagent to determine when the color has developed its maximum intensity. Color reagents should be added to test solutions and standard solutions at fixed intervals, for example, every 30 or 60 s. When the color intensity of the standard solutions has reached its maximum, the color intensities of the test solutions should be read according to the preparation schedule, for example, every 30 or 60 s. The time required for the color to develop its maximum intensity is influenced by the ambient temperature and the composition of the individual batches of prepared reagents.

The American Association of Clinical Chemistry has suggested three methods for small laboratories that need a manual procedure for estimating total serum cholesterol. These procedures are an enzymatic method, the iron–uranyl acetate method (Parekh–Jung), and the Liebermann–Burchard reagent method. The modified Liebermann–Burchard reagent method, in both manual and automated forms, is widely used by small clinical laboratories. This discussion focuses on the manual manipulation of the method for clarity of the chemistry. The Liebermann–Burchard color reaction was discussed above with regard to primary standards. In the modified method, the cholesterol is extracted from serum test samples into 2-propanol to eliminate any interfering substances. A measured aliquot of the extract is evaporated before the Liebermann–Burchard color reagent is added. If the reagents are added directly to the extract, it is difficult to control the rate of color reaction under manual conditions. The heat produced from the exothermic reaction of 2-propanol with sulfuric acid cannot be controlled sufficiently to allow reproducible measurements. However, under stringent automated conditions, this problem can be circumvented. After a timed incubation and color-development period, the absorbance is measured at 630 nm. In this method, reference serum and serum test samples are treated in the same manner. According to the American Association for Clinical Chemistry, recoveries of cholesterol added to serum were 98–101% over a linear range of cholesterol concentrations of 0.8–4.0 g^{-1}. This method may be used to determine cholesterol in food and tissue extracts that have been cleaned in a separating funnel before being dried and redissolved in 2-propanol. Crystalline cholesterol is used as the primary standard for these test samples.

An estimation of the relationship of unesterified cholesterol to cholesterol ester can be made with another modification of the Liebermann–Burchard method. Unesterified cholesterol in serum is

precipitated as the digitonide from ethanol–ether solution. The solvent is evaporated, and the esters are extracted from the residue by adding petroleum ether, bringing the solution to a boil, cooling and centrifuging, and collecting the supernatant. The supernatant is processed as in a total cholesterol determination. The resultant value is a measure of the esterified cholesterol in the serum test sample.

The Parekh–Jung manual method is used in many clinical laboratories. This method is based on the precipitation of proteins and associated substances with ferric acetate–uranyl acetate reagent. The mixture is centrifuged, and the resultant supernatant is treated with sulfuric acid–ferrous sulfate color reagent. After a 20-min incubation and color-development period, the absorbance is measured at 560 nm.

The enzymatic method for the determination of total serum cholesterol is frequently used both manually and in an automated setting. The enzyme method is of limited value when either aqueous or pure alcohol standards are used. The method may be calibrated accurately with a homogeneous and stable serum pool. The method provides a direct measure of serum cholesterol. The enzymatic analytical determination is calibrated by using serum labeled with a target value assigned by an accepted reference method (e.g., the Abell–Kendall method). (*See* **Enzymes**: Uses in Analysis.)

Although cholesterol in serum is primarily free, cholesterol associated with lipoproteins is esterified. Cholesteryl esters are freed from the lipoproteins and enzymatically hydrolyzed by cholesterol-ester hydrolase to free cholesterol and fatty acids. The free cholesterol is then oxidized by cholesterol oxidase to cholest-4-en-3-one and hydrogen peroxidase. The peroxide, in the presence of peroxidase, oxidatively couples with phenol and 4-aminoantipyrine to produce a quinoneimine dye. The absorbance values at 560 nm are proportional to the concentration of total cholesterol in the serum test sample. The absorbance obeys the Lambert–Beer law over a wide concentration of up to about 5.5 g of cholesterol per liter. An estimate of the relationship of unesterified cholesterol to cholesterol ester is made by subtracting the free cholesterol value (the enzyme cholesterol esterase is withheld from the working test reagent) from the total cholesterol value. The enzymatic method has also been used successfully to determine the cholesterol content of foods. For this purpose, the cholesterol is extracted with a chloroform–methanol solvent, and crystalline cholesterol is used for calibration. A survey of the literature indicates that the coefficient of variation for this method is about 1–3%.

The Abell–Kendall method is generally accepted by clinical chemists as the total cholesterol reference method. The results obtained by other methods are nearly always compared with those obtained by the Abell–Kendall method. The method, however, does not lend itself well to analysis of large numbers of test samples. A saponification step generally precludes the development of an automated version of the method. The serum or plasma is saponified with alcoholic potassium hydroxide. The free cholesterol (from both unesterified and esterified cholesterol) is extracted into petroleum ether and dried; the cholesterol is determined photometrically by a modified Liebermann–Burchard reagent (acetic anhydride–sulfuric acid–acetic acid) at 620 nm. The results of this method are in good agreement with those obtained by the Schoenheimer–Sperry method.

No discussion of colorimetric cholesterol methodology is complete without a brief discussion of the separate determination of blood cholesterol and cholesterol esters that was originally developed by Bloor and Knudson in 1916. Practically all methods for separating free and esterified cholesterol emulate their work. Bloor and Knudson adapted the Windaus cholesterol digitonin precipitation method to separate cholesterol from its esters in small amounts of blood. The method consists of the determination of total cholesterol in an aliquot of an alcohol–ether extract of blood and the determination of cholesterol esters in another aliquot after precipitation of the free cholesterol by digitonin. The difference between the two values represents free cholesterol. The color reagent and color development were previously used by Liebermann–Burchard.

Gas Chromatographic (GC) Analysis

GC is used to measure cholesterol as free cholesterol, as the trimethylsilyl ether derivative, or as cholesteryl butyrate. Although colorimetric methods have been used in the past to measure the cholesterol content of foods, body fluids, and tissues, they have been, for the most part, cumbersome and not compound-specific in many applications. Agricultural chemists, biochemists, nutritionists, and food scientists began to explore the use of GC for measuring sterols in the mid-1970s. Although blood cholesterol determinations by GC can be fairly easy to accomplish, GC is not widely used as a routine clinical technique for determining cholesterol. The most probable reasons for this are the difficulties of automating the preparative stages and the fact that adequate colorimetric assays currently exist. Most chromatographic determinations of cholesterol are found in the research environment, in food and nutrition analytical laboratories, and in government regulatory laboratories.

All GC methods use a column stationary phase that is classified as nonpolar, typically methyl silicone (SE-30). In one method, the test sample is saponified, and the unsaponifiable materials are analyzed by GC. This method performs well for most products, but not for those that contain measurable amounts of α-tocopherol in addition to cholesterol. The retention times of α-tocopherol and cholesterol are nearly identical and, therefore, an analysis for either compound is not feasible in the presence of the other. The α-tocopherol may be present naturally, or may be added as a nutritional supplement or antioxidant. (*See* **Tocopherols**: Properties and Determination.)

Another approach is to saponify the test sample, extract the unsaponifiables, and derivatize the unsaponifiable compounds before GC analysis. The official method of the Association of Official Analytical Chemists (AOAC) uses this approach to form trimethylsilyl ethers (Punwar method). Another well-established method uses the classic butyric anhydride–pyridine reaction to attach a C_4 ester at position 3 on the A ring of the sterol to form cholesteryl butyrate. During GC analyses, both derivatives function equally with respect to response, reproducibility, and reliability. The trimethylsilyl ethers create problems over an extended series of analyses. The detector sensitivity drops drastically, and the detector must be disassembled, thoroughly cleaned, and reinstalled to restore sensitivity. The butyrate derivatives burn cleanly in the hydrogen flame ionization detector and do not degrade detector sensitivity. The procedure for preparing the trimethylsilyl derivative is somewhat less tedious than that for preparing the buyrates.

The GC official method of the AOAC determines cholesterol as the trimethylsilyl ether on a 2.4 m × 3 mm internal diameter silanized glass column packed with 0.5% Apiezon L on 80–100 mesh Gas-Chrom Q (Alltech Associates/Applied Science, Deerfield, IL). An alternative column may be used that consists of a 1.8 m × 4 mm internal diameter glass column packed with 1% SE-30 on 100–120 mesh Gas-Chrom Q (Alltech Associates/Applied Science, Deerfield, IL). In this method, one column is maintained at 230 °C, and the carrier gas flow is adjusted to elute the trimethylsilyl ether of cholesterol in 9–11 min. An internal standard of 5α-cholestane is used, and test samples containing 0.5–1 g of fat are extracted with chloroform–methanol–water (50:100:40 v/v/v).

A GC method based on steryl butyrates has been incorporated into a total-lipid analytical system (Sheppard–Hubbard system) for determining total lipids, fatty acid composition, and cholesterol in foods from extraction of a single test portion. The system is widely used in university, food quality control, commercial, and regulatory laboratories to determine the lipid components required for fatty acid and cholesterol labeling. The system has also been used to identify adulterated foods. This analytical system uses an aliquot of the fatty acid methyl ester preparation to prepare cholesteryl butyrate and other sterols. The fatty acid methyl esters are not affected by the reaction that forms the butyrate derivatives of the sterols. On the SE-30 column, the fatty acid methyl esters elute near the solvent front and before the appearance of the butyrates of the tocopherols and the sterols. In this system, external calibration is used. However, internal standards can be used if the internal standard peak is situated very close to the peak being measured and if there are no interfering peaks from compounds such as squalane, squalene, or cholestane in the test sample. Generally, in this system, there are too many peaks from the matrix to have a clear retention time available for internal standards.

The relative retention times for some sterols are 1.0 for cholesteryl butyrate, 1.15 for brassicasteryl butyrate, 1.3 for campesteryl butyrate, 1.4 for stigmasteryl butyrate, and 1.6 for sitosteryl butyrate. Free cholesterol and other sterols can be easily separated with a 15 m × 0.242 mm, SE-54, wall-coated, fused-silica capillary column operated at 250 °C with a helium flow rate of 0.74 ml min^{-1}. The sequence of compound appearance is the same as that for SE-30 packed columns.

High-performance Liquid Chromatography (HPLC)

HPLC is increasingly being used to determine cholesterol and other sterols in foods and tissue extracts. However, like GC, HPLC is not generally used in routine clinical analyses performed with automated clinical multiple analysis systems based on colorimetric or fluorometric assays. Sterols that can be separated by GC usually cannot be separated by an HPLC system. One HPLC system in widespread use determines the benzoate ester of cholesterol on a 300 × 3.9 mm internal diameter μBondapak C_{18} column with a 100% methanol mobile phase and a variable wavelength ultraviolet detector set at 230 nm. GC and HPLC determinations of cholesterol in a variety of foods show that the two techniques yield statistically identical results. Amounts as low as 10 ng of cholesterol benzoate can be determined using HPLC.

Absorption, Function, and Metabolism

D R Arnold and P O Kwiterovich Jr, Johns Hopkins University, Baltimore, MD, USA

Cholesterol Metabolism

Cholesterol metabolism in humans is complex. Cholesterol is either supplied from the diet (exogenous) or synthesized *de novo* by many cells of the body (endogenous). The major factors in the diet that may increase the blood cholesterol level are high intakes of cholesterol itself, or of saturated fats and excessive calories. The liver is one of the major sites of endogenous cholesterol synthesis. The pool of cholesterol in the liver is tightly regulated and reflects the input of cholesterol from the diet, the biosynthesis of cholesterol, the secretion and uptake of cholesterol from plasma lipoproteins, the conversion of cholesterol into bile, and the reuptake of biliary cholesterol and bile acids from the intestine to the liver. The metabolic exogenous and endogenous pathways of cholesterol metabolism are described in this chapter. The concentration of cholesterol in the blood in fasting normal humans is the result of the metabolism of cholesterol from exogenous and endogenous sources. Environmental factors such as dietary fatty acids, and metabolic perturbations such as diabetes and obesity as well as genetic factors also influence the level of cholesterol in blood. Consequently, after several decades, hypercholesterolemia causes atherosclerotic vascular disease. Dieting, exercise, and several drugs are available as tools to lower blood cholesterol levels, and the mechanisms by which these interventions lower elevated cholesterol levels are discussed here.

Cholesterol – Chemical Structure and Importance

Cholesterol (cholest-5-en-3-ol (3-beta) cholesterol) and cholesterol metabolites and esters are major components of the plasma membrane and of many other cellular organelles in animals. On average, 1.5 g of cholesterol is present per kilogram of body weight; some tissues like fat, brain, and liver contain higher amounts of cholesterol (e.g., liver contains 4.5 g kg^{-1}). Cholesterol is a water-insoluble lipid, made of a so-called sterol backbone with one hydroxy group and one double bond, together with a side-chain made up of eight carbon atoms. Cholesterol is chemically distinctly different from two other lipids, triacylglycerols and phopholipids. The steroid backbone of cholesterol also constitutes the fundamental structure of bile acids (with cholic acid and chenodeoxycholic acid being the primary bile acids), certain fat-soluble vitamins, such as vitamin D_3, steroid hormones (cortisone and aldosterone), and sex hormones (estradiol and testosterone, **Figure 1**).

Cholesterol is primarily transported through blood on low-density lipoproteins (LDL). When present in elevated amounts, LDL cholesterol causes 'hardening of the arteries' or atherosclerotic cardiovascular disease (ASCVD). The evidence for a causal relationship

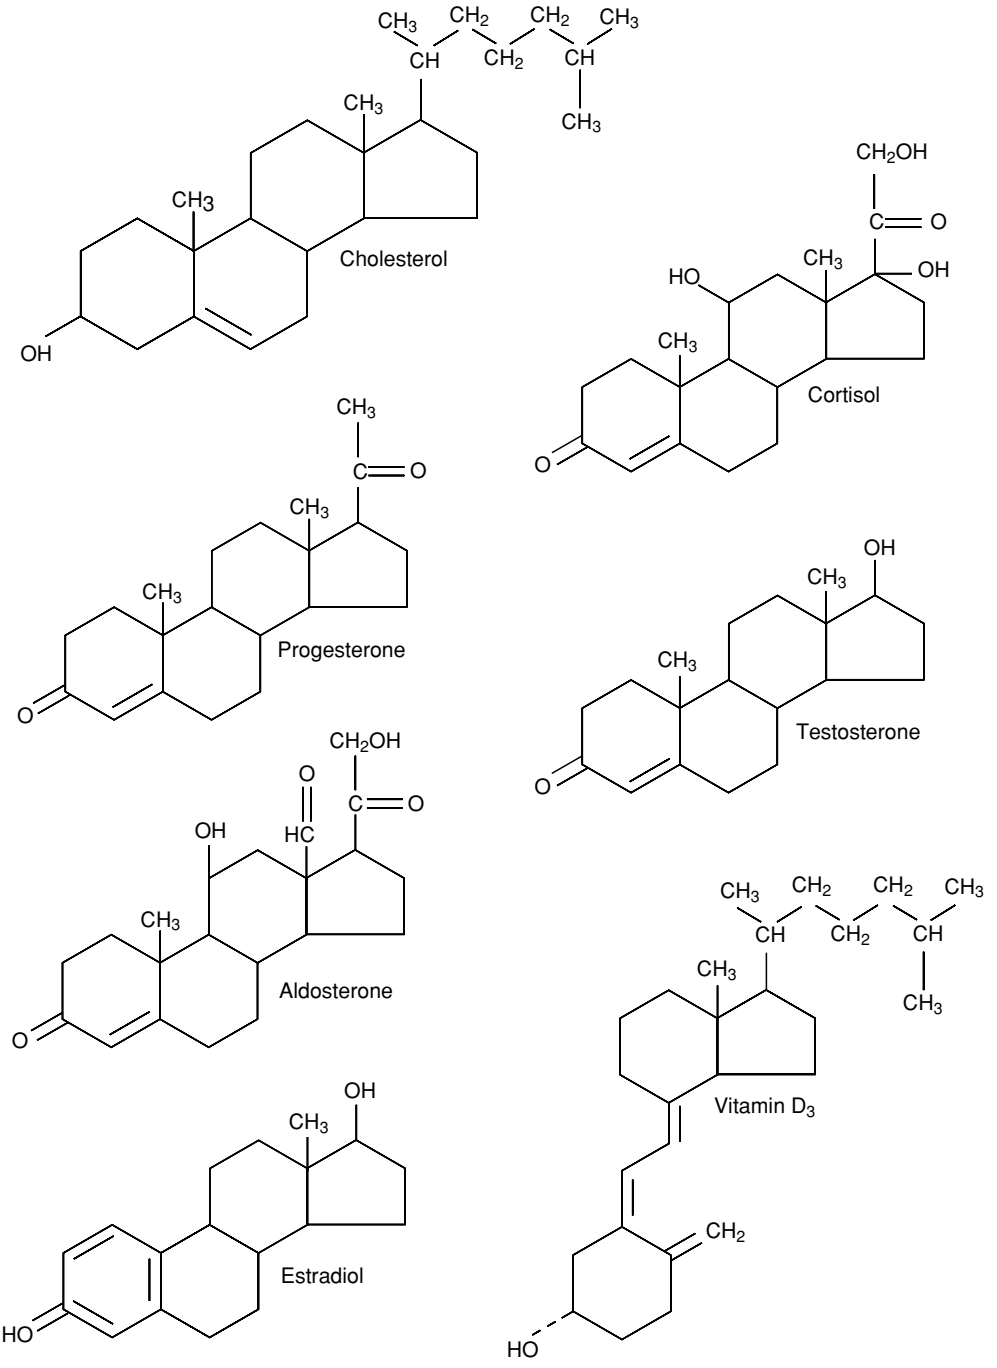

Figure 1 Biochemical structure of cholesterol in comparison with other hormones derived from cholesterol. Cholesterol is homologous to several steroid hormones: cortisol, a stress hormone, progesterone, testosterone and estradiol (sex hormones), aldosterone (important for blood pressure control and salt–fluid balance) and vitamin D_3 (important for calcium absorption in the gut and homeostasis).

between elevated blood LDL cholesterol and ASCVD comes from many research studies in various disciplines (feeding studies of animals, epidemiological surveys, studies of genetic abnormalities of lipid disorders, and large, placebo-controlled, double-blind clinical trials).

History

Poulletier de la Salle discovered cholesterol in gallstones in 1769, but Chevreul gave it the name 'cholesterine' in 1815. Ignatowsky first demonstrated in 1908 the connection between intake of cholesterol in

the diet of rabbits and the development of arteriosclerosis. Anitschkow demonstrated in 1913 that it was cholesterol feeding only that caused atherosclerotic changes in the blood vessels of rabbits.

Cholesterol De-novo Production

Cholesterol can be either absorbed from food or made *de novo* in multiple human tissues in varying amounts. The biosynthesis of cholesterol starts with acetyl coenzyme A (acetyl CoA). Three molecules of acetyl CoA are condensed to form 3-hydroxy-3-methylglutaryl CoA (HMG CoA). The conversion of HMG CoA to mevalonate by HMG CoA reductase is the rate-limiting step of cholesterol synthesis. A schematic diagram summarizing the *de-novo* biosynthesis of cholesterol is shown in Figure 2. While most of the sterol pool of the body is made *de novo* in extrahepatic tissues, the liver is a major organ involved both in the synthesis of cholesterol and

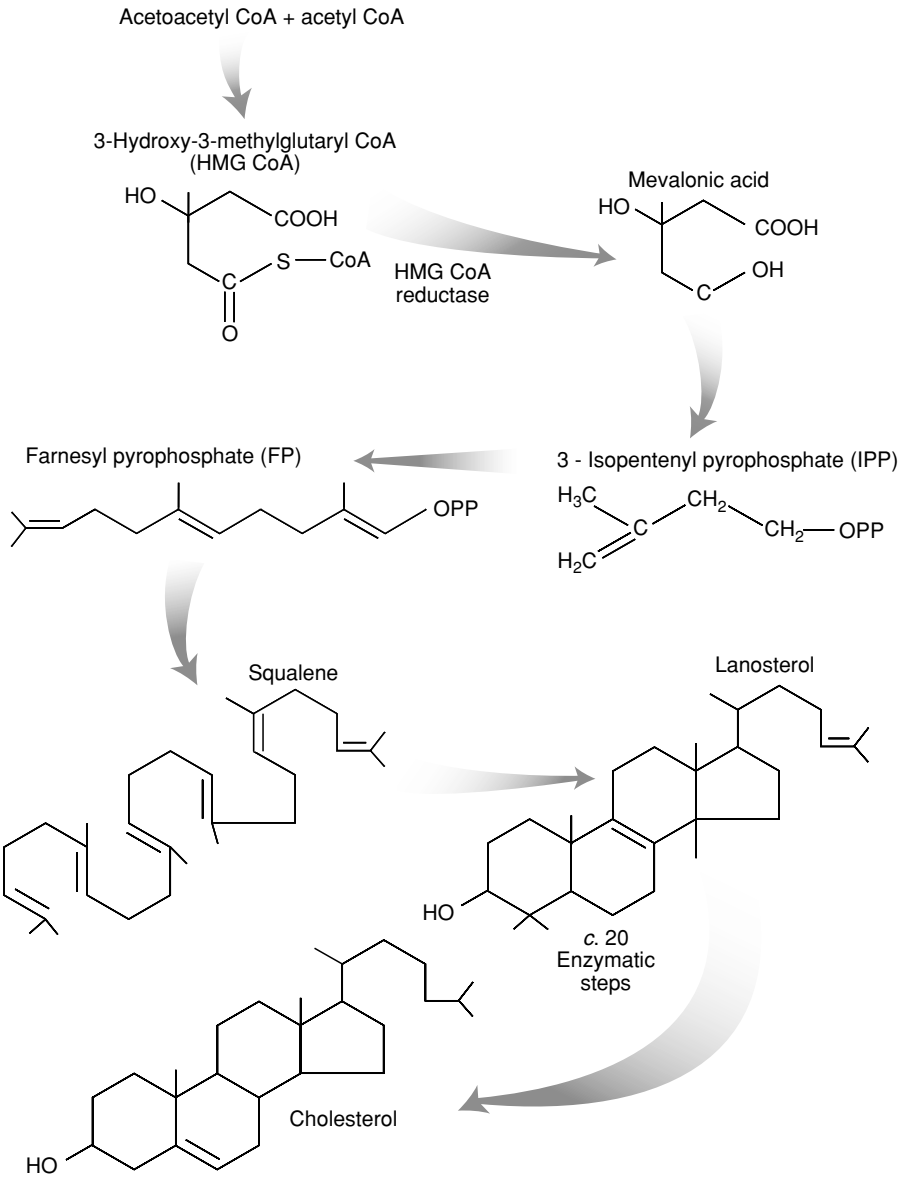

Figure 2 *De-novo* biosynthesis of cholesterol. The biosynthesis of cholesterol begins with the condensation of three acetyl molecules to form 3-hydroxy-3-methylglutaryl CoA (HMG CoA). The acetyl-CoA can be derived from glucose, fatty acids, or amino acids. Reduction of HMG CoA produces mevalonate, which gets further processed to isopentenyl pyrophosphate (IPP). Three molecules of IPP are condensed to make up farnesyl pyrophosphate (FP). Two molecules of FP are used to make up squalene, which gets converted by three enzymatic steps to lanosterol. Approximately 20 additional chemical steps are needed to make up cholesterol.

in the processing and repackaging of cholesterol and other lipids absorbed from the diet. By using H^3-labeled water, the average production of cholesterol in man has been estimated to about 9 mg per kilogram per day. Using this technique, the most active cholesterol processing tissue is the liver followed by the gastrointestinal tract, skin, striated muscle and bone marrow while minor amounts are made in the adrenal glands, and other endocrine organs like ovaries and testis.

Cholesterol from Diet and Factors Influencing Cholesterol Absorption/ *de novo* Synthesis

The amount of synthesis of cholesterol in mammalian liver is tightly controlled by multiple factors. Modulating dietary factors that affect plasma cholesterol levels include energy restriction in the form of decreased lipid and carbohydrate intake (diet), meal frequency, dietary fat type (saturated, unsaturated or trans), and cholesterol content of the food. Plants make sitosterol but not cholesterol, and an average American diet contains about 100–200 mg of this plant sterol per day. In the intestine, inhibition of the uptake of cholesterol occurs with intake of these so-called phytosterols, and this can lower the blood cholesterol level. Diseases of the liver, or exposure to drugs and toxins such as alcohol, can easily disturb the ability of the liver to handle cholesterol and other fats, and may result in the initiation of 'fatty degeneration,' thus demonstrating further the importance of the liver in the metabolic processing of lipids.

Cholesterol in the intestinal lumen comes either from the diet (250–500 mg) or the bile (*c.* 600–1000 mg). While bile acids, such as cholic acid and chendeoxycholic acid, are nearly completely recirculated, only about 50% of the dietary cholesterol is absorbed at an average intake of 300–600 mg per day. Formulas developed by Keys and by Hegstedt and coworkers predict the average increase in the blood cholesterol level that will result from a given change in the amounts of dietary cholesterol, saturated and unsaturated fatty acids. The Hegstedt formula is as follows:

$$< \text{Blood cholesterol (mg dl}^{-1}) = 2.16 < \text{S} - 1.65 < \text{P} + 0.068 < \text{C},$$

where < symbolizes a change in; S = dietary saturated fatty acids (% of total calories), P = dietary polyunsaturated fatty acids (% total calories) and C = dietary cholesterol (mg per day). Examples of polyunsaturated fats include linoleic acid (C18:2), linolenic acid (C18:3), and arachidonic acid (C20:4). Linoleic acid is the essential fatty acid, which can be elongated and desaturated to form other polyunsaturated fats. Fish oils include eicosapentaenoic acid (EPA: C20:5) and docosahexaenoic acid (DHA: C22:6).

Without drug treatment, dietary cholesterol and saturated fats, and the *de novo* production and removal of LDL, determine the blood LDL-cholesterol level. Saturated fatty acids, particularly with 14 and 16 carbons, suppress the receptor-mediated uptake of LDL and increase the LDL cholesterol level, whereas unsaturated fatty acids like 9-*cis* 18:1 increase receptor-mediated LDL uptake and lower the LDL cholesterol level.

Excretion of Cholesterol

The human does not have an enzyme that can degrade the sterol ring of cholesterol; the backbone/sterol ring of cholesterol thus has to be excreted in the bile and stool. All cholesterol metabolites, including hormones and vitamin metabolites, are excreted as bile acids or metabolites in the intestine, but they are partially reabsorbed in the intestine via the enterohepatic pathway. The sterol ring of hormones and vitamins are metabolized (hydroxylated/sulfonurated) by multiple enzymes in the liver to make the sterol more water-soluble, which promotes excretion in bile and the urine as well. The delicate balance of intake and excretion of cholesterol and cholesterol products is tightly regulated. Evolutionarily, excess cholesterol must be avoided inside cells as it can be toxic. Excess cholesterol in the bloodstream is also undesirable, as it causes hardening of the arteries (atherosclerosis) and consequently, ASCVD.

Lipoproteins

To make lipids soluble in blood, they usually are packaged inside a lipid-rich core, around which are wrapped amphipathic proteins, whose nonpolar amino acid groups are exposed to the lipid core, whereas their polar or charged amino acids are oriented to the outer surface, making the entire lipoprotein particle water-soluble. The proteins associated with lipoproteins are called apolipoproteins and act as surface components of the particle, as enzymes key to lipid metabolism in blood, or as ligands to cell-surface receptors promoting the binding and uptake of lipoproteins. A list of these apolipoproteins explaining their functions are listed in Table 1. Multiple apolipoproteins can be present on the surface of the lipoprotein particle and provide information about the tissue of origin and the function of the lipoprotein. For example, apoB-48, a

Table 1 Characteristics of apolipoproteins: their origins, functions and distribution in plasma lipoprotein classes

Apolipoprotein	*Origin*	*Function*	*Present in lipoprotein classes*	*Molecular weight (kDa)*
A-1	Liver, intestine	Activator of LCAT	CM, HDL	29 016
A-2	Liver, intestine	Inhibits HL and VLDL hydrolysis	CM, HDL	17 414
A-4	Liver, intestine	Activates LCAT	CM, HDL	44 465
B	B100 liver	Ligand for LDL receptor	B100→VLDL, LDL	512 723
	B48 intestine	Necessary for secretion of intestinal and hepatic fat	B48→CM	241 000
C-1	Liver	Cofactor for LCAT	CM, VLDL, HDL	6 630
C-2	Liver	Activates LPL, cofactor for LCAT	CM, VLDL, HDL	8 900
C-3	Liver, intestine	Inhibits LPL/inhibits binding of ApoE to the LDL receptor	CM, VLDL, HDL	8 800
D	Many sources	Reverse cholesterol transport	HDL	19 000
E (2,3, and 4)	Liver, peripheral tissues	Ligand for LDL receptor and LRP receptor	CM, VLDL, HDL	34 145

CM, chylomicron; LDL, low-density lipoprotein; HDL, high-density lipoprotein; VLDL, very-low-density lipoprotein; LPL, lipoprotein lipase; HL, hepatic lipase; LCAT, lecithin cholesterol acyltransferase; LRP, low-density lipoprotein receptor-like protein.

Table 2 Characteristics of key enzymes and transfer proteins of lipoprotein particles in the blood

Enzyme	*Origin*	*Function*	*Lipoprotein classes involved*	*Molecular weight (kDa)*
LPL	Capillaries of muscle and adipose tissue	Hydrolyzes triglycerides and phospholipids	CM, large VLDL	50 394
HL	Liver	Hydrolyzes triglycerides and phospholipids	Small VLDL, IDL, HDL	53 222
LCAT	Liver	Converts free cholesterol from cell membranes to cholesterol esters	HDL	47 090
CETP	Liver, spleen, adipose tissue	Transfers cholesteryl esters from HDL to ApoB containing lipoproteins	HDL, LDL, VLDL	74 000
PTP	Pancreas, adipose tissue, lung	Transfers the majority of phospholipids in plasma	HDL	81 000

CM , chylomicron; LDL , low-density lipoprotein; HDL , high-density lipoprotein; VLDL , very-low-density lipoprotein; LPL , lipoprotein lipase; HL , hepatic lipase; LCAT, lecithin cholesterol acyltransferase; CETP, cholesterol transfer protein; PTP, phospholipid transfer protein.

truncated version of apolipoprotein B, is only made in the intestine and is present only on chylomicrons and chylomicron remnants, whereas apoB-100 is made in the liver and is the major apolipoprotein on very-low-density lipoproteins (VLDL) and the products of VLDL catabolism, VLDL remnants and intermediate density lipoproteins (IDL), and LDL. Multiple enzymes are present on the capillary walls and on the lipoprotein particles that metabolize/transfer the lipids present in the particles (see Table 2 and also below).

There are principally five major classes of lipoprotein particles in the blood: chylomicrons (CM), VLDL, IDL, LDL, and high-density lipoproteins (HDL), based on their physicochemical properties. This classification is based on a separation via a salt density gradient (chylomicrons are the lightest particles, whereas HDL particles are the heaviest; see Figure 3 for further explanations).

Chylomicrons and Transport of Dietary (Exogenous) Fat

Dietary cholesterol and triacylglycerol are emulsified in the intestinal lumen by bile salts; the cholesteryl esters are hydrolyzed into unesterified cholesterol and free fatty acids (FFA), and the triacylglycerol into 2-monoglycerol and FFA. These constituents are absorbed into the intestinal epithelial cells where they are repackaged into chylomicrons. Chylomicrons are large (*c.* 1 μm) and their lipid-containing core is surrounded on the surface by apoproteins which are amphipathic molecules that allow the lipid core to be soluble in aqueous lymph fluid and blood. These particles contain the apolipoproteins B-48, A-1, A-2, and A-4. The secretion of the chylomicrons from the intestinal cells into the lymph requires the presence of apoB-48. The lymph from the gut collects in the thoracic duct and enters the blood stream via the right subclavian vein. Even before the chylomicrons reach the systemic circulation, the apoA-1 content is decreased, and apoE, apoC-1, apoC-2, and apoC-3 are acquired as a result of HDL particles interacting with chylomicrons in the intestinal lymph capillaries.

Chylomicrons then interact with endothelial cells in the arterioles lining a number of tissues. The triacylglycerols in the core of the chylomicrons, through the interaction of apoC-2 with the enzyme lipoprotein lipase (LPL) bound to the surface of endothelial

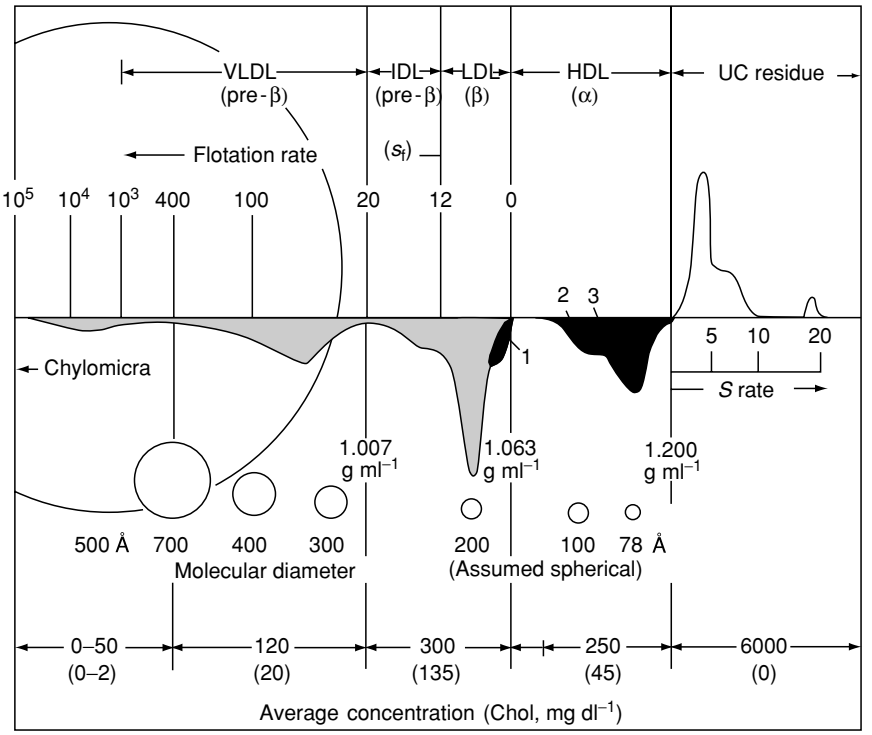

Figure 3 Characteristics of the major lipoproteins present in normal human plasma. Flotation rates are measured in S_f units. The flotation of VLDL, IDL and LDL is performed at a salt gradient of 1.063 g ml^{-1}, whereas a density of 1.200 g ml^{-1} is used for HDL. During ultracentrifugation at 200 000 g for 1 h, a light beam is directed through an aperture in the cell and the changes in diffraction recorded to outline the boundaries caused by the floating lipoproteins. The class of lipoprotein is indicated at the top, corresponding to abbreviations and a description given in the text. 'UC-residue' describes nonlipid plasma proteins that sediment at a density of 1.200 g ml^{-1}. The amount of each lipoprotein class is proportional to the area under each curve shown numerically at the bottom. There are three subclasses of HDL (1, 2, and 3), and these are indicated by numbers and colored black. HDL1 occurs only in hyperlipemic plasma. The approximate diameter of each lipoprotein class particle is shown in Ångströms (1 Å = 0.1 nm), and the average amount of plasma cholesterol present in each class of lipoprotein is shown in parentheses (for example, 45 mg dl^{-1} for HDL lipoproteins). From Olson RE (1998) Discovery of the lipoproteins: their role in fat transport and their significance as risk factors. *Journal of Nutrition* 128(Supplement 2): 439S–443S, with permission.

cells, are hydrolyzed into FFA and glycerol, which are then absorbed into adipocytes and other cells. During hydrolysis, phospholipids and apolipoproteins are removed from the surface of the chylomicrons and transferred to HDL. By removing apoC-2, an activator of LPL, the process starts to slow down. The resultant chylomicron remnant, which contains less triacylglycerols and relatively more esterified cholesterol, is removed rapidly from the circulation by its interaction with the chylomicron receptor (low-density, lipoprotein receptor-like protein (LRP)) on the surface of the liver cells. The LDL receptor and proteoglycans can also facilitate the uptake of chylomicron remnants into the liver. ApoE is the ligand that permits the binding and uptake of the chylomicron remnant.

Very-low-density Lipoproteins and Transport of Hepatic (Endogenous) Fat

In the liver, cholesterol, triacylglycerols, and other fats are packaged into the VLDL particle that is surrounded by apoB-100. Triacylglycerol and cholesteryl ester production is necessary for VLDL synthesis by the liver. The availability of apoB-100 affects both the assembly and secretion of the VLDL. The apoB-100 gene is constitutively expressed.

The amount of apoB-100 available is regulated by the rate of proteolysis of apoB-100. When excess lipid is available, proteolysis is decreased, and more apoB-100 is available for VLDL production. When lipid is depleted, apoB-100 proteolysis increases. The triacylglycerols and apoB-100 interaction requires the presence of the microsomal triacylglycerol transfer protein (MTP). MTP is a heteromer that consists of two subunits, a protein widely distributed in many cells, called disulfide isomerase, and a unique 97-kDa large subunit. A mutation in the 97-kDa protein prevents the association of lipid with apoB-100, leading to little, if any, secretion of VLDL and no production of IDL and LDL. At least a dozen mutations in the 97-kDa protein have been described in patients with the recessive disorder, abetalipoproteinemia.

VLDL is secreted from the liver into the bloodstream surrounded by apoB-100, apoE, and the apoCs. Once in the bloodstream, the apoC-2 on VLDL binds to the same LPL site as chylomicrons in the capillaries surrounding various tissues.

Intermediate-density lipoproteins

As the core triacylglycerol in VLDL is hydrolyzed, a remnant VLDL is formed, and the released FFA are taken up by tissues. Upon further hydrolysis of triacylglycerol, the final remnant, IDL, is formed. The liver takes up some IDL through the interaction of apoE with the LDL (B, E) receptor. The rest of the IDL is modified at the surface of the liver by hepatic lipase (HL), producing the cholesteryl ester-enriched LDL.

Low-density Lipoproteins – Production, Uptake, and Catabolism

The majority of LDL is formed from VLDL. The major apolipoprotein of LDL is apoB-100, which serves as the ligand for the binding of LDL to the LDL (B, E) receptor in clustered pits on the surface of liver and peripheral cells. The bound LDL and its receptor are internalized into the cell. LDL are taken up and degraded in the lysosomes, while the LDL receptor is released and recycled back to the cell surface. Cholesteryl esters in the core of LDL are hydrolyzed into unesterified (free) cholesterol and FFA. The enzyme acyl cholesterol acyl transferase (ACAT) controls the cellular levels of unesterified (free) cholesterol versus cholesteryl esters. Monounsaturated fat such as oleic acid is a preferred substrate for ACAT, whereas saturated FFA is not. In the presence of excess dietary saturated FFA, less cholesterol is esterified, and the excess cholesterol inhibits the release of the transcription factor from the nuclear membrane. Thus, less of this factor is available to go into the nucleus where it ordinarily upregulates the transcription of both the LDL receptor gene and the gene for HMG CoA reductase, the rate-limiting enzyme of cholesterol production (see below).

High-density Lipoproteins and Reverse Cholesterol Transport

HDL play a paramount role in the reverse cholesterol transport pathway, which mediates the removal of cholesterol from peripheral cells for transport back to the liver. HDL are secreted from the liver and intestine as nascent, disc-shaped particles that consist primarily of phospholipids and apoA-1, with very little cholesterol. The nascent HDL interacts with the ABCA1 transport protein on the surface of peripheral cells such as macrophages and removes unesterified cholesterol. In the bloodstream, the free cholesterol is esterified by lecithin cholesterol acyl transferase (LCAT) and its cofactor, apoA-1, producing a spherical HDL particle with a cholesteryl ester in its core. The core cholesteryl ester in HDL can be selectively taken up in liver and other steroidogenic tissues such as the adrenal gland, ovaries, and testes through the interaction of HDL with the SR-B1 receptor. Alternatively, the cholesteryl esters in HDL can be exchanged for the triacylglycerols in VLDL and IDL through the action of cholesteryl ester transfer protein (CETP). Such a cholesteryl ester is eventually removed by the interaction of IDL or LDL with the LDL receptor on the surface of liver or peripheral cells.

Important Enzymes Responsible for the Processing of Lipoprotein Particles in the Bloodstream and Peripheral Tissues

Apolipoproteins present on the surface of lipid particles serve as ligands for receptors as well as activators or inhibitors of enzymes important in the lipoprotein-processing pathway. The names and functions of enzymes playing a major role in the processing of lipid particles are summarized in Table 2. Functions of some of the important apolipoproteins and enzymes will be discussed briefly.

LPL catabolizes the triacylglyceride in the core of many lipoprotein particles. LPL converts chylomicrons into chylomicron remnants, and VLDL particles into VLDL remnants and IDL. LPL is bound to heparan sulfate proteoglycans on the surface of capillaries, and production of this enzyme is upregulated by insulin. Heparinase-induced proteoglycan deficiency (heparinase cuts off proteoglycans from the cells) impairs the function of LPL. Both chylomicrons and chylomicron remnants are cleared from the bloodstream by the liver through the binding of the ligand, apoE, either to the LRP receptor or to the LDL (B,E) receptor. This initiates internalization via coated pits and lysosomal degradation of the apoE-coated lipoprotein particles.

LCAT is made in the liver and is present on HDL particles. Initially, HDL has very little cholesteryl ester but is loaded up with cholesteryl ester by the action of LCAT. This HDL particle then undergoes exchange of cholesteryl esters for triacylglycerol on the triacylglycerol-rich lipoproteins through the action of the CETP. The triacylglycerol-rich lipoproteins are then processed by HL, present on the surface of liver cells. HL hydrolyzes triacylglycerols and phospholipids. HL is similar to LPL and belongs to the lipase superfamily. Both enzymes, CETP and HL, are needed for reverse cholesterol transport as

demonstrated by transgenic experiments/substitution experiments. Estrogen is an important negative regulator of HL. Phospholipid transfer proteins (PTP) are made in multiple tissues. PTPs play an important role in the maintenance of plasma HDL content and remodeling of HDL in the circulation.

Role of Transcription Factors in the Regulation of Cholesterol Metabolism

Recently, transcription factors (proteins that bind to DNA and control transcription of proteins important in lipid metabolism) have been described that tightly control the amount of cholesterol present inside the cell.

Uptake of cholesterol in liver cells is mediated by receptors such as the LRP receptor and the LDL receptor. Brown, Goldstein, and coworkers have described transcription factors called sterol regulatory element-binding proteins (SREBPs). SREBPs control the transcription of enzymes such as HMG CoA reductase, essential in cholesterol biosynthesis, and of the LDL receptor, which mediates the uptake of LDL by the liver. It has been known for years that cholesterol in the diet shuts down the synthesis of new cholesterol in the liver. It does so by downregulating the rate-limiting enzyme in the biosynthesis of cholesterol, HMG CoA reductase. It is now known that an increase in hepatic cholesterol levels inhibits the sequential release of an active form of SREBP by two proteases from the nuclear membrane. Conversely, a decrease in hepatic cholesterol levels promotes the proteolysis and release of SREBP, allowing its translocation into the nucleus where SREBP binds to the promoter of the LDL receptor gene and activates its transcription (Figure 4). The increased production of the LDL receptor molecule results in an increased uptake of LDL cholesterol by the cells. Also, SREBP interacts with the gene for HMG CoA reductase, enhancing its transcription and increasing the number of enzyme molecules. This increases the biosynthesis of cholesterol. Thus, both an increased uptake of cholesterol on LDL from the blood and enhanced production of cholesterol synthesis occur when the level of cholesterol in the liver is decreased. Conversely, as the cholesterol pool in the liver is increased, the release of SREBP is inhibited, the LDL receptor gene and HMG CoA reductase genes are downregulated, and an equilibrium is achieved (see Figure 4).

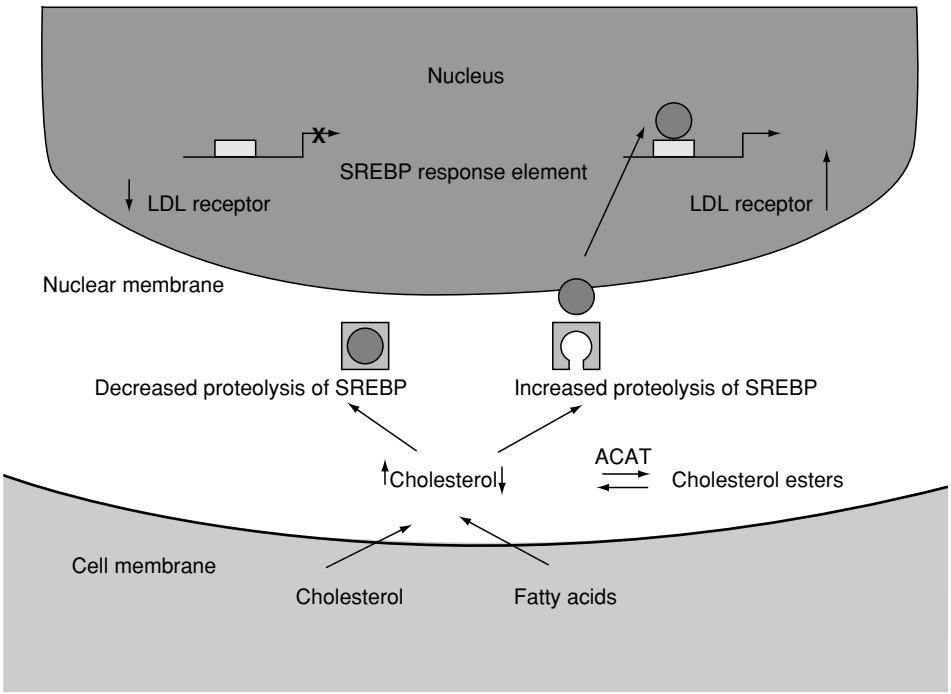

Figure 4 LDL-receptor/SREBP pathway. Liver cells adsorb cholesterol and fatty acids, and the amount of cholesterol versus cholesterol ester in the cell cytoplasm is controlled by the enzyme acyl cholesterol acyl transferase (ACAT). If the level of free cholesterol is decreased (on the right), a proteolytic process is activated to free the steroid response element-binding protein (SREBP) which then translocates to the cell nucleus and activates the transcription of the LDL-receptor gene. This leads to an increased expression of LDL-receptors on the surface of the liver cell and to enhanced clearance of LDL from the bloodstream. The reverse is true (on the left) if the intracellular cholesterol level is increased.

Other enzymes, such as the intracellular ACAT, also play a role in this regulatory pathway; for example, as ACAT converts free cholesterol into cholesteryl esters, less unesterified cholesterol is available to inhibit the proteolysis of SREBP, leading to increased release of SREBP and the upregulation of both the LDL receptor and HMG CoA reductase. If ACAT is less active, as might occur in the presence of saturated fats (which are not preferred substrates for the enzyme), more free cholesterol will be available to inhibit the release of SREBP, leading to a downregulation of LDL receptors and HMG CoA reductase. If the inhibition of the LDL receptors is greater than the inhibition of HMG CoA reductase, as occurs in about one in four humans, an increase in the blood cholesterol and LDL cholesterol occurs.

Another important protein involved in the control of cholesterol synthesis is the SREBP cleavage activation protein (SCAP). The NH_2-terminal protein domain of SCAP resembles the NH_2-terminal protein domain of HMG CoA reductase, and it is thought that both function as sterol-sensing domains. SCAP is a required activator of SREBP cleavage, as cleavage is usually abolished in the presence of sterols. The family of SREBP transcription factors also appears to be important in the regulation of fatty acid synthesis. acetyl CoA carboxylase, fatty acid synthase, stearyl CoA desaturase-1 (a necessary enzyme for the generation of unsaturated fatty acids), and even the enzyme LPL appear to be modulated by SREBP.

Inherited Mechanisms of Disorders of Lipid and Lipoprotein Disorders

Apolipoproteins are very important in cholesterol metabolism as they act as enzymes and ligands for receptors mediating lipid modification and absorption (see also above). Most apolipoproteins are made in the liver and intestine, but a small amount of apoB can be made in heart tissue and apoE is made by macrophages. All tissues can degrade apolipoproteins, but most of them are degraded in the liver.

One of the most serious inherited abnormalities of the cholesterol metabolism is a condition called familial hypercholesterolemia (FH). In FH, the LDL receptor is defective, and liver cells have a reduced capacity to bind and take up LDL cholesterol from blood. FH can occur in a severe homozygous form where patients have few, if any, functional LDL receptors. Homozygotes for FH are rare, about one in a million, whereas patients with one mutant allele and one normal allele for the LDL receptor, FH heterozygotes, occur in about one in 500 persons. The ligand for the LDL receptor, apoB-100, on the surface of LDL particle can also be defective, and this may also lead to inherited high total cholesterol and LDL cholesterol levels similar to those with FH.

More than 150 mutations in the LDL receptor gene have been described, and grouped into five different classes: the class I mutations do not permit the LDL receptor to be synthesized; class II mutations interfere with the transport of the receptor to the surface of the cell; class III mutations produce a receptor that does not bind normally to its ligand, apoB-100; in class IV mutations, the LDL receptor binds to LDL but it can not be internalized; and in class V mutations, the receptor cannot be reused by recycling.

Treatment of the homozygous FH individuals is problematic, since it is difficult in many patients to induce functional LDL receptors, either with a statin or with a bile acid sequestrant. Niacin and a high dose of statins may decrease the production of LDL by inhibiting to a degree the formation and secretion of VLDL in liver. FH homozygotes often die from ASCVD before the age of 20 years. The atherosclerosis also affects the aortic valve and can lead to life-threatening aortic stenosis. Transplantation of a liver with functional LDL receptors was once used but has fallen out of favor because of the significant morbidity and mortality associated with this procedure. LDL phoresis can often decrease the LDL levels by half; however, the procedure must be repeated every 2 weeks, and sufficient blood flow can be a problem in very young FH homozygoyes. There has been a strong interest in gene therapy as a potential successful treatment, but it is still experimental. Heterozygous FH individuals can be successfully treated by a combination of diet, exercise, and drugs.

Treatment of Lipid Disorders

Lipid disorders have traditionally been classified according to the increased amount of lipoprotein particles present in blood (Fredrickson's class I–V, Table 3).

With increasing knowledge, mutations in receptors, apolipoproteins, and enzymes have been identified as the cause of these abnormalities, but many defects are still not known, and often, their expression is modulated by environmental and genetic factors as well. Many lipid disorders are secondary to other diseases. For example, the LPL is upregulated by insulin, and diabetic patients who do not produce enough insulin often manifest a hypertriacylglycerolemia secondary to their diabetes and relative LPL deficiency. Other medical conditions such as hypothyroidism can cause an elevated LDL cholesterol level, and in such cases, the other medical condition must be treated first. Certain classes of drugs can also

Table 3 Classification of lipid disorders by phenotype (after Fredrickson)

Group	*Lipoprotein in excess*	*Plasma cholesterol*	*Plasma triacylglycerol*	*Plasma appearance*
I	Chylomicrons	Elevated or very elevated	Very elevated	Clear plasma with creamy layer on top
IIa	LDL	Elevated	Normal	Clear
IIb	LDL+VLDL	Elevated	Moderately elevated	Clear, turbid
III	β-VLDL, IDL	Elevated	Elevated	Turbid
IV	VLDL	Normal or moderately elevated	Elevated	Turbid
V	Chylomicrons+VLDL	Elevated or very elevated	Very elevated	Turbid plasma, creamy layer on top

Table 4 Intervention National Cholesterol Education Program (NCEP) guidelines

LDL-cholesterol level with	*Initiation of diet*	*Added drug therapy*
Less than two risk factors	$>160\,mg\,dl^{-1}$	$>190\,mg\,dl^{-1}$
More than two risk factors	$>130\,mg\,dl^{-1}$	$>160\,mg\,dl^{-1}$
ASCD		$>100\,mg\,dl^{-1}$
Diabetes mellitus		$>100\,mg\,dl^{-1}$

Patients with diabetes mellitus or ASVD have a treatment goal for LDL cholesterol of equal or less than 100 mg/dl independent of the presence or absence of risk factors.
From National Cholesterol Education Panel (NCEP) (1993) Adult treatment panel II. *Journal of the American Medical Association* 269: 3015–3023, with permission.

Table 5 Atheroclerotic vascular disease (ASVD) risk factors after the National Cholesterol Education Program (NCEP) guidelines

	Positive risk factor	*Negative risk factor*
HDL cholesterol value	$<40\,mg\,dl^{-1}$	$>60\,mg\,dl^{-1}$
Age	Men >45 years of age or older Women >55 years of age or older	
Family history of premature ASVD	Present	
Current cigarette smoking	Present	
Hypertension	Present	

Each person's risk factors are to be determined and used as a guideline for treatment. Patients with diabetes mellitus or ASVD have a treatment goal for LDL cholesterol of equal or less than $100\,mg\,dl^{-1}$ independent of the presence or absence of risk factors.
From National Cholesterol Education Panel (NCEP) (1993) Adult treatment panel II. *Journal of the American Medical Association* 269: 3015–3023, with permission.

contribute to lipid abnormalities and, if so, can be discontinued if medically feasible.

Elevated LDL-cholesterol levels are strongly correlated with development of ASCVD, whereas a high HDL-cholesterol level is usually protective against ASCVD. The National Cholesterol Educational Program (NCEP) uses measurements of LDL-cholesterol as guidelines for treatment with diet and drug therapy in addition to multiple risk factors (Tables 4 and 5).

The first step in treatment of a primary disorder of lipid and lipoprotein metabolism is a diet reduced in total fat, saturated fat, and cholesterol (NCEP step I and step II diets; see Table 6). Weight loss is particularly important, especially in those with hypertriacylglycerolemia, low HDL cholesterol, glucose intolerance, and insulin resistance. Drug treatment is usually based on the particular lipoprotein that is elevated starting with the atherogenic LDL. For every individual, positive and negative risk factors as outlined by the NCEP III guidelines determine whether the aim of treatment with diet, exercise, and drug treatment has been reached (Tables 4 and 5). Guidelines have also been proposed for hypertriacylglycerolemia and low HDL cholesterol. A plasma triacylglycerol level in adults above $400\,mg\,dl^{-1}$ is elevated, $200–400\,mg\,dl^{-1}$ is borderline, and below $200\,mg\,dl^{-1}$ is normal. An HDL cholesterol less than $40\,mg\,dl^{-1}$ is too low.

The drugs of choice to treat an elevated LDL cholesterol level are the HMG CoA reductase inhibitors, or the so-called 'statins.' Inhibition of this enzyme causes a reduction in the hepatic cholesterol pool, leading to an induction of LDL receptors and a fall in blood LDL cholesterol levels (see above). In 1976, a fungal metabolite, called mevinolin or mevastatin, was isolated, which inhibited HMG CoA reductase. Most of the currently available cholesterol-lowering drugs, which target these enzymes, are chemically modified fungal metabolites or completely synthetic analogs of this compound. These include: atorvastatin, fluvastatin, lovastatin, pravastatin, and simvastatin. When given in sufficiently high doses, these drugs can also produce a significant fall in triacylglycerols, presumably by decreasing hepatic VLDL production and by removing the IDL molecules. HDL levels often increase with statin therapy, but the mechanism is not currently known.

Other drugs that are given when the LDL cholesterol level is elevated are the bile acid sequestrants or resins (cholestyramine or colestipol) and niacin.

Table 6 Characteristics of step one and step two diets for patients with dyslipidemias

Nutrient	*Step one diet*	*Step two diet*
Total fat (% of calories)	Average of no more than 30	Same
Saturated fatty acids (%)	< 10	< 7
Polyunsaturated fatty acids (%)	Up to 10	Same
Monounsaturated fatty acids (%)	Remaining total fat calories	Same
Cholesterol (mg dl^{-1})	< 300	< 200
Carbohydrates (% of calories)	About 55	Same
Proteins (% of calories)	About 15–20	Same

From National Cholesterol Education Panel (NCEP) (1993) Adult treatment panel II. *Journal of the American Medical Association* 269: 3015–3023, with permission.

The bile acid sequestrants bind bile acids in the intestine promoting their excretion in the stool. This interferes with the reabsorption of the bile acids, causing more cholesterol to be converted into bile acids in the liver. The hepatic cholesterol level falls, and LDL receptors are induced, causing a fall in the blood LDL cholesterol levels.

Niacin is vitamin B_3 and is present in food at an average level of about 50 mg per day. When niacin is given in amounts 20- to 40-fold as much as this, it can decrease FFA mobilization, leading to a decrease in lipid in the liver, increased proteolysis of apoB-100, and decreased VLDL production. Thus, both the triacylglycerol-rich VLDL, and the product of VLDL catabolism, the cholesterol-enriched LDL, fall as the result of niacin treatment. Niacin has a separate effect on raising HDL cholesterol, presumably by decreasing the catabolism of HDL and its major apolipoprotein, apoA-1, in the liver. Niacin can be given as a regular short-acting preparation or in an extended or sustained release preparation.

Fibric acid derivatives, such as gemfibrozil and fenofibrate, are often used as drugs of choice for marked triacylglycerol elevations. They act by inducing the gene for LPL and repressing the gene for apoC-3. This leads to an increased hydrolysis of triacylglycerol by LPL and a decreased inhibition of LPL by apoC-3.

Combination therapy of HMG CoA inhibitors with fibrates can cause a serious side-effect, called myositis, which can lead to life-threatening rhabdomyolysis, and a specialist should carry out such combined therapy.

Knowledge of lipid disorders including abnormalities in cholesterol metabolism and the consequences of such has grown considerably, and many dyslipidemias are largely treatable with the proscribed means. It is expected that in the 21st century, ASCVD will be reduced considerably in developed countries, providing an increased quality of life and a prolonged life span to humans. In addition, greater attention will need to be paid to developing countries to prevent them from assuming the rates of ASCVD in developed nations.

Factors Determining Blood Cholesterol Levels

S M Grundy, University of Texas, Dallas, TX, USA

Introduction

A high blood (serum) cholesterol level is a major risk factor for atherosclerotic coronary heart disease (CHD). Consequently, there has been much interest in the causes of elevated serum cholesterol concentrations. Although the serum cholesterol can be measured as a single entity, in fact cholesterol is carried in the blood stream by several independent entities called lipoproteins. Each lipoprotein has its own characteristics and the concentrations of each are affected by different factors. Several of these factors are related to diet, i.e., dietary cholesterol, certain fatty acids, and energy imbalance resulting in obesity. Other factors also modify lipoprotein metabolism including advancing age, the postmenopausal state in women, and genetics. Consideration of each of the factors regulating serum cholesterol concentrations first requires a description of the different lipoprotein species.

Serum Lipoproteins

Lipoproteins are macromolecular complexes that consist of discrete particles and are composed of both lipids and proteins. The lipids include cholesterol, phospholipids, and triacylglycerols (TAG). A portion of serum cholesterol is esterified with a fatty acid; the remainder is unesterified. The protein components go by the name of apolipoproteins. The major forms of apolipoproteins and their functions are listed in **Table 1**. Four categories of lipoproteins that carry cholesterol in the serum include chylomicrons, very-low-density lipoproteins (VLDL), low-density lipoproteins (LDL), and high-density lipoproteins (HDL). The characteristics and metabolism of each lipoprotein will be reviewed briefly.

Table 1 Apolipoproteins of serum lipoproteins

Apolipoprotein	*Function*
A-I	Major apolipoprotein of HDL Activator of LCAT
A-I	Structural apolipoprotein of HDL (other functions unknown)
A-IV	Apolipoprotein of chylomicrons (other functions unknown)
B-48	Chylomicron assembly and secretion
B-100	VLDL assembly and secretion Ligand for LDL receptor unknown
C-I	Unknown
C-II	Activator of LPL
C-III	Inhibitor of LPL
E	Apolipoprotein of remnant lipoproteins Ligand for LDL receptor Promotes hepatic uptake of remnants

HDL, high-density lipoproteins; LDL, low-density lipoproteins; VLDL, very-low-density lipoproteins; LCAT, lecithin cholesterol acyl transferase; LPL, lipoprotein lipase.

Chylomicrons

Dietary cholesterol enters the intestine together with fat, which is predominantly TAG. The latter undergoes hydrolysis by pancreatic lipase and releases fatty acids and monoacylglycerols. In the intestine, these mix with bile acids, phospholipids, and cholesterol from the bile. The mixture of hydrolyzed lipids associates with phospholipids and bile acids to form mixed micelles. Fatty acids, monoacylglycerols and cholesterol are taken up by the intestinal mucosa. In the mucosal cells, the fatty acids and monoacylglycerols are recombined by enzymatic action to form TAG, which are incorporated with the cholesterol into lipoprotein particles called chylomicrons. Most of the cholesterol in chylomicrons as esterified with a fatty acid. The major apolipoprotein of chylomicrons is apo B-48; other apolipoproteins – apo Cs, apo Es and apo As – attach to the surface coat of chylomicrons and aid in metabolic processing. In the mucosal cells, microsomal lipid transfer protein (MTP) facilitates the transfer of TAG and cholesterol ester into chylomicron particles. The presence of MTP is required for the secretion of chylomicrons from mucosal cells.

Chylomicrons are secreted by intestinal mucosal cells into the lymphatic system. From here they pass through the thoracic duct into the systemic circulation. When chylomicrons enter the peripheral circulation they come into contact with an enzyme, lipoprotein lipase (LPL), which is located on the

endothelial surface of capillaries. LPL is activated by apo C-II on chylomicrons; this process is modulated by apo C-III, an inhibitor of LPL activity. None the less, most chylomicron TAG is hydrolyzed by LPL; a residual lipoprotein particle, named chylomicron remnant, is released into the circulation and is rapidly removed by the liver. Hepatic uptake of chylomicron remnants is believed to be mediated by binding of remnants with a glycoprotein on the surface of liver cells. Almost all newly absorbed cholesterol thus enters the liver in association with chylomicron remnants.

Very-Low-density Lipoproteins

The liver also secretes a TAG-rich lipoprotein called VLDL. Fatty acids used in the synthesis of TAG in the liver are normally derived from circulating nonesterified fatty acids (NEFA); even so, the liver has the capacity to synthesize fatty acids when the diet contains mainly carbohydrate. MTP inserts TAG into newly forming VLDL particles. The surface coat of VLDL contains unesterified cholesterol, phospholipids and apolipoproteins. The major apolipoprotein of VLDL is apo B-100. Other apolipoproteins, notably apo Cs and apo Es, are also present. As VLDL circulate they acquire cholesterol esters from HDL. Circulating VLDL particles lose TAG through interaction with LPL in the peripheral circulation; in this process, VLDL are transformed into VLDL remnants. The latter can have two fates: hepatic uptake or conversion to LDL. Hepatic uptake of VLDL remnants may occur via two mechanisms: interaction with glycoproteins or interaction with LDL receptors. Both glycoproteins and LDL receptors are located on the surface of liver cells.

Low-density Lipoproteins

Conversion of VLDL remnants to LDL appears to be largely the result of hydrolysis of remaining TAG by hepatic triacylglycerol lipase (HTGL). Normally about two-thirds of cholesterol is carried by LDL; most of this LDL cholesterol exists in the form of esters. The only apolipoprotein in LDL is apo B-100. LDL is removed from the circulation largely by hepatic LDL receptors. The level of expression of LDL receptors is a major determinant of serum LDL cholesterol concentrations. The synthesis of LDL receptors is regulated in large part by the liver's content of cholesterol. An increase in hepatic cholesterol content suppresses LDL receptor synthesis and raises serum LDL cholesterol; conversely, a decrease in hepatic cholesterol stimulates receptor synthesis and lowers serum LDL cholesterol. The mechanism whereby hepatic cholesterol controls LDL receptor synthesis is through a regulatory protein called sterol regulatory element-binding protein (SREBP). When hepatic cholesterol content falls, SREBP is activated and stimulates the synthesis of LDL receptors.

The regulatory form of cholesterol in the liver cell is unesterified cholesterol, not cholesterol ester. The hepatic content of unesterified cholesterol depends on several factors, including the amounts of cholesterol derived from chylomicrons and other lipoproteins, hepatic synthesis of cholesterol, secretion of cholesterol into bile, conversion of cholesterol into bile acids, esterification of cholesterol, and secretion of cholesterol into serum with VLDL. Factors that influence each of these processes can alter serum LDL cholesterol concentrations by modifying the hepatic content of unesterified cholesterol and thereby expression of LDL receptors.

High-density Lipoproteins

HDL consist of a series of lipoprotein particles of relatively high density, all of which contain apo A-I. A proportion of HDL particles also contain apo A-II. Some HDL species (HDL_3) are more dense than others (HDL_2). HDL particles are composed largely of byproducts of catabolism of TAG-rich lipoproteins. The surface coats of HDL particles contain phospholipids and unesterified cholesterol, apo A-I with or without apo A-II, and other apolipoproteins (apo Cs and apo Es). Their particle cores consist largely of cholesterol esters, although small amounts of TAG are also present. The cholesterol esters of HDL are formed by esterification with a fatty acid through the action of an enzyme, lecithin cholesterol acyl transferase (LCAT); the substrates for this reaction derive from either unesterified cholesterol released during lipolysis of TAG-rich lipoproteins or from the surface of peripheral cells. After esterification of cholesterol, the cholesterol esters of HDL are then transferred back to TAG-rich lipoproteins and eventually are removed by the liver through direct uptake of remnant lipoproteins or LDL. Whether whole HDL particles can be directly removed from the circulation is uncertain. Some investigators believe that the HDL components are dismantled and removed piecemeal.

Dietary Regulation of Serum Lipoproteins

A large body of research has shown that diet has a major impact on the concentrations and composition of serum lipoproteins, and hence on serum cholesterol concentrations. Three major factors affect cholesterol and lipoprotein concentrations: dietary cholesterol, the macronutrient composition of the diet, particularly dietary fatty acids, and energy

balance, as reflected by body weight. The influence of each of these factors can be considered.

Dietary Cholesterol

All dietary cholesterol is derived from animal products. The major sources of cholesterol in the diet are egg yolks, products containing milk fat, animal fats, and animal meats. Many studies have shown that high intakes of cholesterol will increase the serum cholesterol concentration. Most of this increase occurs in the LDL cholesterol fraction. When cholesterol is ingested, it is incorporated into chylomicrons and makes its way to the liver with chylomicron remnants. There it raises hepatic cholesterol content and suppresses LDL receptor expression. The result is a rise in serum LDL cholesterol concentrations. Excess cholesterol entering the liver is removed from the liver either by direct secretion into bile or by conversion into bile acids; also, dietary cholesterol suppresses hepatic cholesterol synthesis. There is considerable variability in each of these steps in hepatic cholesterol metabolism; for this reason the quantitative effects of dietary cholesterol on serum LDL cholesterol levels vary from one person to another. For every 200 mg of cholesterol per day in the diet, serum LDL cholesterol is increased on average by about 6 mg dl^{-1} (0.155 mmol l^{-1}).

Macronutrient Composition of the Diet

Dietary fat and fatty acids Most of the fat in the diet consists of TAG that are composed of three fatty-acid molecules bonded to glycerol. The contribution of TAG to total energy intake varies among individuals and populations, ranging from 15% to 40% of total nutrient energy. The fatty acids of TAGs are of several types: saturated, *cis*-monounsaturated, *trans*-monounsaturated, and polyunsaturated fatty acids. All fatty acids affect lipoprotein levels in one way or another. Table 2 lists the major fatty acids of the diet and denotes their effects on serum lipoproteins. Also shown are the effects of carbohydrates, which also influence serum lipoprotein metabolism. It should be noted that all lipoprotein responses are compared and related to those of *cis*-monounsaturated fatty acids which are widely accepted to be neutral, or baseline.

Saturated fatty acids The saturated fatty acids are derived from both animal fats and plant oils. Rich sources of dietary saturated fatty acids include butter fat, meat fat, and tropical oils (palm oil, coconut oil, and palm kernel oil). Saturated fatty acids are straight-chain organic acids with an even number of carbon atoms (Table 2). All saturated fatty acids that have from eight to 16 carbon atoms raise the serum LDL cholesterol concentration when they are consumed in the diet. In the USA and much of Europe, saturated fatty acids make up 12–15% of total nutrient energy intake.

The mechanisms whereby saturated fatty acids raise LDL cholesterol levels are not known, although available data suggest that they suppress the expression of LDL receptors. The predominant saturated fatty acid in most diets is palmitic acid ($C_{16:0}$); it is cholesterol-raising when compared with *cis*-monounsaturated fatty acids, specifically oleic acid ($C_{18:cis1\ n\text{-}9}$), which

Table 2 Macronutrient effects on serum lipoprotein cholesterol

Nutrient	*Symbol*[a]	*VLDL cholesterol*	*LDL cholesterol*	*HDL cholesterol*[b]
Fatty acids				
Saturated				
Palmitic	$C_{16:0}$	–[b]	↑↑	–
Myristic	$C_{14:0}$	–	↑↑↑	↓
Lauric	$C_{12:0}$	–	↑	–
Caproic	$C_{10:0}$	–	↑	–
Caprilic	$C_{8:0}$	–	↑	–
Stearic	$C_{18:0}$	–	–	– or ↓
trans-Monounsaturated	*trans* $C_{18:1\ n\text{-}9}$	–	↑ or ↑↑	↓
cis-Monounsaturated	*cis* $C_{18:1\ n\text{-}9}$	–	–	–
Polyunsaturated				
n-6[c]	$C_{18:2\ n\text{-}6}$	– or ↓	– or ↓	– or ↓
n-3[c]	DHA, EPA	↓↓↓	– or ↓	–
Carbohydrate		↑↑↑	–	↓↓

[a]First number denotes number of carbon atoms; second number denotes number of double bonds.
[b]The dash (–) indicates that there is no change in level compared to that produced by *cis*-monosaturated fatty acids (oleic acid) ($C_{18:1\ n\text{-}9}$). All the lipoprotein responses to oleic acid are considered 'neutral', i.e., no effect.
[c]The letter 'n' and number indicate at which carbon atom, numbered from the terminal methyl group, the first double bond appears.
VLDL, very-low-density lipoproteins; LDL, low-density lipoproteins; HDL, high-density lipoproteins; DHA, docosahexanoic acid ($C_{22:6\ n\text{-}3}$); EPA, eicosapentanoic acid ($C_{20:5\ n\text{-}3}$).

is considered to be 'neutral' with respect to serum cholesterol concentrations. In other words, oleic acid is considered by most investigators to have no effect on serum cholesterol or lipoproteins. Another saturated fatty acid, myristic acid ($C_{14:0}$), apparently raises LDL cholesterol concentrations somewhat more than does palmitic acid, whereas other saturates – lauric ($C_{12:0}$), caproic ($C_{10:0}$), and caprylic ($C_{8:0}$) acids – have a somewhat lesser cholesterol-raising effect. On average, for every 1% of total energy consumed as cholesterol-raising saturated, fatty acids, compared with oleic acid, the serum LDL cholesterol level is raised about 2 mg dl^{-1} (0.025 mmol l^{-1}).

One saturated fatty acid, stearic acid ($C_{18:0}$), does not raise serum LDL cholesterol concentrations. The main sources of this fatty acid are beef tallow and cocoa butter. The reason for its failure to raise LDL cholesterol concentrations is uncertain, but may be the result of its rapid conversion into oleic acid in the body.

Trans-monounsaturated fatty acids These fatty acids are produced by hydrogenation of vegetable oils. Intakes of *trans*-monounsaturates vary from one country to another depending on consumption of hydrogenated oils. In many countries they contribute between 2% and 4% of total nutrient energy intake. A series of *trans* acids are produced by hydrogenation; most are monounsaturated. For many years, it was accepted that *trans*-monounsaturated fatty acids were neutral with respect to LDL cholesterol concentrations. However, recent studies have shown that they raise LDL cholesterol concentrations to a level similar to that of palmitic acid when substituted for dietary oleic acid. In addition, they cause a small reduction in serum HDL cholesterol concentrations. Thus, *trans*-monounsaturates must be placed in the category of cholesterol-raising fatty acids.

Cis-monounsaturated fatty acids The major fatty acid in this category is oleic acid ($C_{18:cis1\ n\text{-}9}$). It is found in both animal and vegetable fats, and typically is the major fatty acid in diet. Intakes commonly vary between 10% and 20% of total energy. Oleic acid intake is particularly high in the Mediterranean region where large amounts of olive oil are consumed. Other sources rich in oleic acid are rapeseed oil (canola oil) and high-oleic forms of safflower and sunflower oils. Peanuts and pecans are also high in oleic acid. Animal fats likewise contain a relatively high percentage of oleic acid among all their fatty acids; even so, these fats also tend to be rich in saturated fatty acids. When high-carbohydrate diets are consumed, the human body can synthesize fatty acids; among these, oleic acid is the predominant fatty acid produced.

As indicated before, oleic acid is generally considered to be the 'baseline' fatty acid with respect to serum lipoproteins levels, i.e., it does not raise (or lower) LDL cholesterol or VLDL cholesterol concentrations, nor does it lower (or raise) HDL cholesterol concentrations. It is against this 'neutral' fatty acid that responses of other fatty acids are defined (Table 2). For example, when oleic acid is substituted for cholesterol-raising fatty acids, the serum LDL cholesterol concentration will fall. None the less, oleic acid is not designated a cholesterol-lowering fatty acid, but instead, this response defines the cholesterol-raising potential of saturated fatty acids.

Polyunsaturated fatty acids There are two categories of polyunsaturated fatty acids: n-6 and n-3. The major n-6 fatty acid is linoleic acid ($C_{18:2,n\text{-}6}$). It is the predominant fatty acid in many vegetable oils, e.g., corn oil, soya bean oil, and high linoleic forms of safflower and sunflower seed oils. Intakes of linoleic acid typically vary from 4 to 10% of nutrient energy, depending on how much vegetable oil is consumed in the diet. The n-3 fatty acids include linolenic acid ($C_{18:3,n\text{-}3}$), docosahexanoic acid (DHA) ($C_{22:6,n\text{-}3}$), and eicosapentanoic acid (EPA) ($C_{20:5,n\text{-}3}$). Linolenic acid is high in linseed oil and present in smaller amounts in other vegetable oils. DHA and EPA are enriched in fish oils.

For many years, linoleic acid was thought to be a unique LDL cholesterol-lowering fatty acid. Recent investigations suggest that earlier findings overestimated the LDL-lowering potential of linoleic acid. Even though substitution of linoleic acid for oleic acid in the diet may reduce LDL cholesterol levels in some people, a difference in response is not consistent. Only when intakes of linoleic acid become quite high do any differences become apparent. At high intakes, however, linoleic acid also lowers serum HDL cholesterol concentrations. Moreover, compared with oleic acid, it may reduce VLDL cholesterol levels in some people. Earlier enthusiasm for high intakes of linoleic acid to reduce LDL cholesterol levels has been dampened for several reasons: for example, its LDL-lowering ability does not offset potential disadvantages of HDL lowering; and other concerns include possible untoward side-effects such as promoting oxidation of LDL and suppressing cellular immunity to cancer.

The n-3 fatty acids in fish oils (DHA and EPA) have a powerful action to reduce serum VLDL levels. This action apparently results from suppression of the secretion of VLDL by the liver. The precise mechanism

for this action is not known. However these fatty acids do not reduce LDL cholesterol concentrations relative to oleic acid. They have been used for one treatment of some patients with elevated VLDL concentrations, although drug treatment is generally employed when it is necessary to lower serum VLDL levels.

Carbohydrate When carbohydrates are substituted for oleic acid in the diet, serum LDL cholesterol levels remain unchanged. However, VLDL cholesterol concentrations usually rise and HDL cholesterol concentrations fall on high-carbohydrate diets. Thus, a lack of difference in total serum cholesterol concentrations during the exchange of carbohydrate and oleic acid is misleading. The two categories of nutrients have different actions on lipoprotein metabolism. The differences in response to dietary carbohydrate and oleic acid provide a good example of how measurements of serum total cholesterol fail to reveal all of the changes that are occurring in the lipoprotein fractions.

Energy Balance

Obesity When energy intake exceeds energy expenditure, the balance of energy is stored in adipose tissue in the form of TAG. When the TAG content of adipose tissue becomes excessive (body mass index 30 or above), a state of obesity is said to exist. In some obese persons, excessive accumulations of TAG occur in other tissues than adipose tissue. Two such tissues are skeletal muscle and liver. High contents of TAG in muscle and liver arise due in large part to continuous leakage of excessive quantities of NEFA from adipose tissue. In the presence of desirable body weight, normal insulin levels are sufficient to suppress hydrolysis of TAG in adipose tissue, and NEFA release is low. On the other hand, in obese persons NEFA release is excessive and skeletal muscle and liver are flooded with high serum NEFA concentrations. The result is engorgement of these organs with TAG. When skeletal muscle is overloaded with TAG, insulin-mediated glucose uptake is impaired. This condition is called insulin resistance. When liver is packed with TAG, hepatic metabolism is altered and insulin action on the liver is deranged. As a result, there is an overproduction of VLDL; this leads to high VLDL cholesterol concentrations, and because LDL is a product of VLDL, to higher LDL cholesterol levels. In addition, obesity is accompanied by a reduction in HDL cholesterol concentrations. Thus obesity is responsible for multiple alterations in lipoprotein metabolism; it has significant effects on three major lipoprotein species – VLDL, LDL, and HDL. These changes appear to be the result of a combination of excessive hepatic TAG as a substrate for VLDL formation and failure of insulin to exert its usual action to curtail VLDL secretion.

Exercise Many of the adverse metabolic effects of obesity are reversed by exercise. Increased energy expenditure through regular and sustained exercise helps to prevent accumulation of excessive quantities of TAG in adipose tissue. In addition, increased muscle metabolism produced by exercise burns off NEFA and prevents TAG accumulation in the liver. Hence, increased and sustained energy expenditure favorably modifies the lipoproteins, particularly by lowering VLDL cholesterol concentrations and raising serum HDL cholesterol. The effects of exercise on LDL cholesterol concentrations are more modest, but in some people exercise produces a reduction.

Other Factors Affecting Serum Lipoproteins

Advancing Age

Between the ages of 20 and 50 years, there is a gradual rise in serum cholesterol concentrations. In the USA, for example, the serum cholesterol increases on average about $50\,\mathrm{mg\,dl^{-1}}$ ($1.295\,\mathrm{mmol\,l^{-1}}$). This change may be related in part to increasing obesity, according to the mechanisms described above. However, even in people who do not gain weight with advancing age, serum cholesterol concentrations usually rise to some extent. Available evidence indicates that this rise results from a decrease in expression of LDL receptors. The reasons for a decline in receptor synthesis with aging are not known, but may reflect 'metabolic' aging. However, in men, after age 50 years, there is little further rise in serum cholesterol. This observation suggests that the impact of weight gain, which occurs mostly between the ages of 20 and 50 years, may be greater than generally recognized.

Postmenopausal State in Women

In women, there is a further rise in serum cholesterol concentrations which occurs after age 50 years. This rise is believed to be due largely to loss of estrogens after the menopause. Estrogens are known to stimulate the synthesis of LDL receptors and, consequently, receptor expression declines after the menopause. This increment in cholesterol levels can be largely reversed by estrogen replacement therapy.

Genetics

Family studies and research in twins indicate that about 50% of the variation of serum cholesterol concentrations in the general populations can be explained by genetic polymorphisms. Presumably

this variation is related to factors that regulate lipoprotein concentrations. In some cases, specific genetic defects are severe, resulting in marked changes in lipoprotein concentrations. When this occurs, the affected individual is said to have a monogenic disorder. In other cases, multiple genetic modifications are present that combine to alter lipoprotein concentrations. When a few modifications are present, the condition is called oligogenic, but when many modifications combine to change lipoprotein concentrations, the condition is named polygenic. Several monogenic disorders have been identified; a few oligogenic conditions have been described; but there are very few instances in which complex polygenic traits have been unraveled. A question of great interest is whether nutritional and genetic factors ever interact synergistically to alter lipoprotein concentrations. Undoubtedly, dietary factors and genetic changes can be additive in their effects on serum lipoproteins; but synergistic interaction has been difficult to prove. In what follows, consideration will be given to the impact of modification of some of the key gene products regulating lipoprotein metabolism.

LDL Receptors The most severe elevations in LDL cholesterol levels occur in patients who have mutations in the gene encoding for LDL receptors. About one in 500 people are heterozygous for these mutations. Their condition is called heterozygous familial hypercholesterolemia. LDL cholesterol concentrations are essentially twice the normal level in this condition. Very rarely patients are homozygous for mutation in the LDL receptor gene, and thus have homozygous familial hypercholesterolemia. Their LDL cholesterol levels are approximately four times normal. Individuals with this condition develop severe, premature atherosclerosis.

Many other people appear to have a reduction in LDL receptor expression on a genetic basis, but they do not have as severe elevations of serum LDL cholesterol as occur in patients with familial hypercholesterolemia. Presumably, these people have genetic modifications in factors that regulate transcription of the LDL receptor gene. Although such genetic modifications may be relatively common, they are poorly defined. Again, an important but unanswered question is whether some people are genetically susceptible to the cholesterol-raising effects of dietary cholesterol and saturated fatty acids. If so, they may possess modifications in the genetic control of LDL receptor expression.

Apolipoprotein B-100 Structure About one in 500 people also have a mutation in the primary structure of apo B that interferes with its binding to LDL receptors. This mutation gives rise to the disorder called familial defective apolipoprotein B-100. The consequence is an elevation of LDL cholesterol concentrations, and the clinical pattern resembles that of familial hypercholesterolemia.

Apolipoprotein B Synthesis Rare patients have mutations in the gene encoding for apo B that impair the synthesis of this apolipoprotein. Such patients usually have very low LDL cholesterol concentrations. These individuals are said to have familial hypobetalipoproteinemia. In other rare cases, the intracellular TAG transport protein called MCT (medium chain triglyceride) is genetically absent; when this occurs, no lipoprotein particles containing apo B can be formed. LDL cholesterol is absent from serum, and the disorder is called familial abetalipoproteinemia.

Some researchers speculate that serum elevations in VLDL cholesterol and LDL cholesterol can result from excessive synthesis and/or secretion of apo B-containing lipoproteins by the liver. When this occurs on a genetic basis, the disorder is designated familial combined hyperlipidemia. However, a monogenic basis of this clinical phenotype has never yet been identified. Therefore, most investigators have concluded that familial combined hyperlipidemia most likely represents an oligogenic or polygenic disorder. In this disorder, lipoprotein elevations appear to be worsened by nutritional factors, particularly by obesity.

Apolipoprotein E This apolipoprotein is present on TAG-rich lipoproteins and it facilitates removal of remnant lipoproteins by LDL receptors in the liver. When apo E is affected by mutation, this enabling action is curtailed and hepatic uptake of remnant lipoproteins is impaired. The result is an accumulation of chylomicron remnants and VLDL remnants in the circulation. The accumulation is accentuated by the coexistence of other disorders of metabolism of TAG-rich lipoproteins. When remnant accumulation occurs on a genetic basis, the disorder is called familial dysbetalipoproteinemia.

Apolipoprotein C There are two forms of apo C – apo C-II and apo C-III. Apo C-II is required for activation of LPL; when it is genetically absent, affected patients develop severe elevations of TAG-rich lipoproteins. Apo C-III inhibits the activity of LPL. In certain metabolic disorders, notably insulin resistance, synthesis of apo C-III is increased; an elevated apo C-III can lead to impaired function of LPL and increases in serum concentrations of TAG-rich lipoproteins.

Apolipoprotein A-I This is the major apolipoprotein of HDL. Rare patients have mutations in apo

A-I which results in very low concentrations of HDL cholesterol. However, most people in whom HDL cholesterol concentrations are moderately reduced show increased catabolism of apo A-I. The mechanism for this change has not been fully determined, but one important cause may be an overexpression of HTGL.

Lipoprotein Lipase This enzyme is required for lipolysis of TAG in TAG-rich lipoproteins. Rare patients are homozygous for mutations in LPL that impair its function. In such patients, serum concentrations of chylomicrons are markedly increased. The accumulation of chylomicrons in serum is greatly accentuated by the presence of fat in the diet. Only by severe dietary fat restriction is it possible to prevent severe TAG elevations in serum.

Genetic Regulation of HDL Cholesterol Family and twin studies reveal that about 50% of the variation in serum HDL cholesterol levels in the general population is explained by genetic factors. However, the regulation of HDL cholesterol concentrations is complex, and HDL cholesterol levels are determined by many factors, e.g., serum TAG concentrations, activity of HTGL, production rates of apo A-I, and activities of cholesterol ester transfer protein (CETP) and LCAT. Genetic factors undoubtedly affect each of these regulating factors.

Role of Cholesterol in Heart Disease

R M Shireman, University of Florida, Gainesville, FL, USA

Background

The compound cholesterol (3β-cholest-5-en-3-ol) ($C_{27}H_{46}O$) (**Figure 1**) was first isolated from gallstones in the late eighteenth century. Its crystalline structure has been determined by X-ray diffraction.

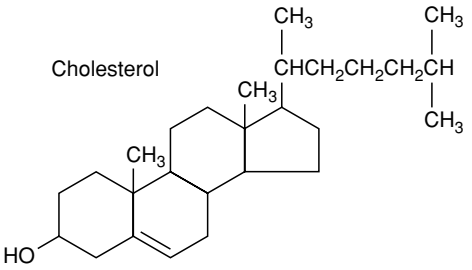

Figure 1 Structure of cholesterol.

More Nobel prizes have been awarded to scientists who worked on cholesterol synthesis, metabolism, and function than on any other compound. Much of the work on the complex biosynthetic pathway was done in the 1950s by Konrad Bloch, Feodor Lynen, John Cornforth, and George Popják, yet many questions remain unanswered. Vertebrates and most other animals can synthesize cholesterol *de novo*. Similar sterol compounds called phytosterols are synthesized by the same pathway in plant cells. Cholesterol is essential in all animal cells, and either too much or too little is detrimental. A familiar example of cholesterol accumulation occurs in the disease atherosclerosis, in which build-up occurs in the lining of the lumen of arteries. A less familiar example is Wolman's disease, a hereditary deficiency in an enzyme, cholesteryl ester hydrolase, in which cholesterol esters rapidly accumulate to very high levels in fetal cells, with ensuing mental retardation and other problems, leading to infantile death. Conversely, Smith–Laemli–Opitz syndrome is characterized by an inherited enzyme defect in the last step in cholesterol synthesis, resulting in very low cholesterol levels in cells, severe mental retardation, and abnormal skeletal development. The major consequence of these enzyme deficiencies that produce very high vs. very low intracellular cholesterol is severe mental retardation; this illustrates the importance of the strict regulation of cholesterol concentrations in cells. Cholesterol is present in high amounts in the brain and nervous system; in fact, about a quarter of the body's cholesterol is present in myelin. Table 1 lists some of the important functions of this sterol.

It is estimated that the adult human body contains about 100 g of cholesterol. The average adult requires approximately 1.1 g of cholesterol per day. About 15–25% of this is normally derived from the diet, while the rest is from endogenous synthesis, mainly in the liver and intestine. This explains why it is rather difficult to reduce blood cholesterol levels to any great extent by decreasing the intake of dietary cholesterol. Cholesterol absorption varies widely among individuals and also in the same individual,

Table 1 Major functions of cholesterol

Function	*Comments*
Membrane structure and integrity	Structural and protective functions; helps maintain the semipermeable barrier; especially important in myelin structure
Precursor to steroid hormones	Required for synthesis of progesterone, testosterone, estrogen, corticosteroids, and aldosterone
Precursor to vitamin D	Cholesterol in skin cells is converted to a precursor form under the influence of UV irradiation (sunlight)
Precursor to bile acids	Cholesterol and bile acids are emulsifiers in bile and aid in digestion and absorption of dietary fat

depending on other constituents in the diet. Cholesterol absorption is very high in about 20% of the population; these individuals have been referred to as 'hyper-responders.' Plant sterols are not absorbed well, but they do decrease cholesterol absorption. A number of factors have been reported to affect absorption besides phytosterols, including vitamin C, several different metal ions, and various types of protein or fiber, but there is little general agreement about the real physiologic effects, if any, of these agents. Unesterified cholesterol that enters the enterocyte (intestinal cell) is esterified before packaging into chylomicrons. Chylomicrons are large lipoprotein particles assembled in enterocytes and transported first in the lymph and then by the bloodstream to the liver. If insufficient cholesterol is absorbed to provide for the packaging of other absorbed fats into chylomicrons, enterocytes synthesize the needed cholesterol. Cholesterol biosynthesis is regulated somewhat differently in different cells, but feedback inhibition of synthesis occurs in most cells except enterocytes. The exact regulation of this process in enterocytes is still unclear, but it is evident that increased dietary fat absorption increases the intestinal biosynthesis of cholesterol.

Cholesterol Metabolism

Cholesterol is not metabolized for energy. It is removed from the body via desquamating cells and by the excretion of cholesterol and its products, including bile acids and steroid hormone catabolites. A relatively constant level is maintained in the body by controlling the rate of biosynthesis, rather than by conversion to products. Although most cells are capable of synthesizing cholesterol, the liver is responsible for much of the cholesterol subsequently delivered to cells such as neurons. Important clues to the synthesis of sterols came from the work of

Konrad Block in the early 1940s, when he fed (U)[^{14}C]acetate to rats and found all 27 carbons of cholesterol to be derived from acetate. The discovery that mevalonic acid is an intermediate allowed great progress in defining this pathway, which has a huge number of enzymatic steps. An abbreviated pathway is shown in Figure 2. Several important compounds in addition to cholesterol are synthesized in this pathway, commonly called the isoprenoid pathway.

Numerous genetic factors, as well as levels of hormones and nutrients, influence cholesterol homeostasis. Although the isoprenoid pathway may be controlled at several separate enzymatic steps, the key regulatory enzyme is hydroxymethylglutaryl-coenzyme A reductase (HMG-CoA). HMG-CoA reductase is an endoplasmic reticulum enzyme subject to a high degree of regulation by several and varied means. The enzyme is regulated acutely in response to extracellular signals through a cAMP-mediated phosphorylation cascade. Phosphorylation decreases the activity of this enzyme. Longer-term control depends on the regulation of transcription of the gene for reductase. Sterol accumulation normally decreases mRNA synthesis of reductase and may accelerate reductase degradation. A sterol regulatory element (SRE-1) is the recognition site for a specific DNA-binding protein whose activity is influenced by intracellular sterol levels. The SRE of the reductase gene promoter shares homology with those of HMG-CoA synthetase and low-density lipoprotein (LDL) receptor, suggesting coordinate control of these pathways by sterol effectors. Coordinate control of the three proteins allows very fine regulation of this synthetic pathway. Thus, when the intracellular concentrations of cholesterol or oxysterol become elevated, decreased transcription of two major genes in the cholesterol biosynthetic pathway leads to a decline in cholesterol biosynthesis by that cell, and decreased transcription of the LDL receptor protein leads to a decrease in cellular uptake of cholesterol via LDL. Reductase synthesis and activity are influenced also by hormones, especially insulin and glucagon.

The rate of synthesis of cholesterol is increased in proliferating normal tissues and tumors. Inhibition of cholesterol synthesis inhibits cell growth. In addition to the needs for cholesterol, other compounds from this pathway have important functions in dividing cells. For example, the farnesyl moiety activates some of the proteins involved in regulation of cell growth, and farnesyl and other prenyl groups are used in modifying certain membrane proteins. Inhibition of HMG-CoA reductase can affect the synthesis of all products of the isoprene pathway. A large number of pharmacologic inhibitors, mostly competitive inhibitors of reductase, are now on the market. Obviously, cholesterol-lowering drugs that inhibit reductase should be used with great caution in growing children, and not at all during pregnancy. *In vitro* studies have shown that compounds such as the monounsaturated fatty acid oleic acid inhibit reductase activity to some extent. Certain xenobiotic compounds, such as phenobarbital, which induce enzymes of the cytochrome P450 system, also affect some of the enzymes of cholesterol metabolism. Other enzymes affecting cholesterol metabolism are

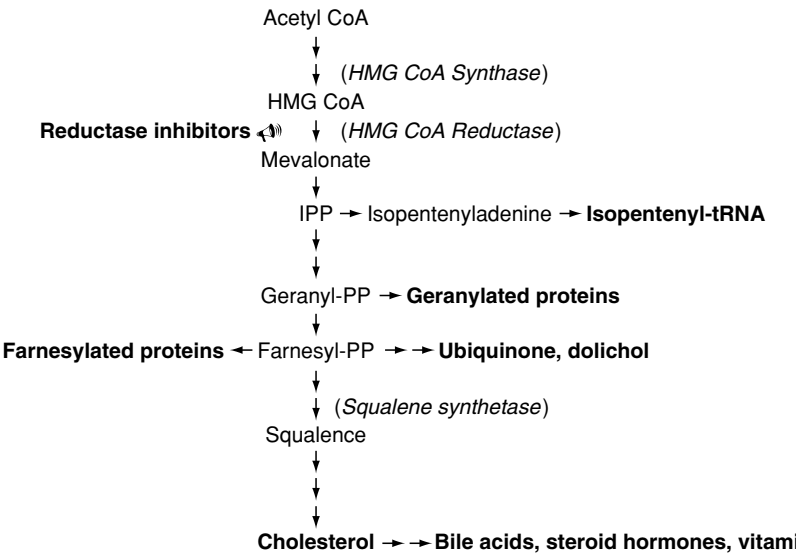

Figure 2 Major steps in the biosynthetic pathway for cholesterol. The major regulated enzymes are shown in italics.

7α-hydroxylase, acyl CoA cholesterol acyl transferase (ACAT) and lecithin cholesterol acyl transferase (LCAT). The 7α-hydroxylase catalyzes the first step in the conversion of cholesterol to bile acids, while ACAT and LCAT are responsible for esterifying cholesterol in cells and plasma, respectively.

Cholesterol and Lipoprotein Transport

Cholesterol is transported along with other lipids by the plasma lipoproteins. These are classified according to their size and density, which are functions of their compositions (Table 2). Each class is characterized by specific proteins (apoproteins), some of which have known important functions (Table 3). Mutations in apoproteins are involved in several types of hyperlipidemia. Although the liver contains a large amount of cholesterol because of immense amounts of membraneous organelles, it does not store extra cholesterol. Normal nascent (newly secreted by the liver) very-low-density lipoprotein (VLDL) has a cholesterol ester (CE)/triacylglycerol (TG) ratio of < 1:4, but CE-rich VLDL may have a ratio of 1:1. CE-rich VLDL is synthesized by the liver in some experimental animal models fed very high levels of dietary cholesterol. Such VLDL has extra apoenzyme E (apoE). This may be important because macrophages have not only the apoenzyme (apoB)/LDL receptor, but also a B/E receptor, which will bind apoB and/or apoE lipoproteins, as discussed below.

Circulating VLDL loses much of its triglyceride to tissues and some of its other components to high-density lipoprotein (HDL); in the process, VLDL becomes transformed to the cholesterol-rich LDL particle. LDL binds to its specific receptor on cells and is carried into the cell by receptor-mediated endocytosis. The major function of the LDL receptor is delivery of lipids to cells, but in the liver, it helps remove LDL and small VLDL from the bloodstream. The receptor is subject to transcriptional control in which high [cholesterol] leads to decreased receptor synthesis, thus downregulating the entry of apoB-containing lipoproteins. The LDL receptor is expressed in most cells and is basically the same in all tissues, but the number of receptors varies greatly between tissues. The greatest density of receptors occurs in the adrenal cortex, which requires enormous amounts of cholesterol for steroid hormone synthesis. It is expressed at low levels in nondividing cells, presumably because there is less need for cholesterol for membrane synthesis. Cholesterol that is not immediately used in the cell is esterified by

Table 2 Classification and composition of major human plasma lipoproteins

Class	*Density ($g\,ml^{-1}$)*	*Percentage protein*	*Percentage cholesterol*	*Percentage cholesterol ester*	*Percentage triacylglycerol*
Chylomicrons	< 1.00	2	1	3	85
Very-low-density lipoprotein	0.95–1.006	10	7	12	50
Low-density lipoprotein	1.006–1.063	23	8	37	10
High-density lipoprotein	1.063–1.210	55	2	15	4

The other major constituents of these lipoproteins are phospholipids; minor components are sphingolipids, carotenoids, and other hydrophobic compounds.

Table 3 Major human apolipoproteins

Apoprotein	*Associated lipoprotein*	*Function*
ApoA-1	HDL	LCAT activation; possibly involved with reverse cholesterol transport
ApoA-II	HDL	Transport of HDL lipids; unknown
ApoA-IV	HDL, chylo	Unknown; possibly antiatherogenic
ApoB-48	Chylo	Lipid transport
ApoB-100	VLDL, LDL	Lipid transport; LDL receptor interaction
ApoC-1	VLDL, HDL	Unknown; may function with A-I to activate LCAT
ApoC-II	VLDL, HDL, chylo	Activatation of lipoprotein lipase
ApoC-1II	VLDL, HDL, chylo	Inhibition of lipoprotein lipase
ApoD	HDL	Unknown
ApoE	VLDL, HDL, Chylo	Clearance of VLDL and chylomicrons from plasma; abundant in brain and cerebrospinal fluid, modifies risk of Alzheimer dementia

Apo, apoenzyme; chylo, chylomicron; HDL, high-density lipoprotein; LDL, low-density lipoprotein; VLDL, very-low-density lipoprotein.

ACAT, but normally, there are only small amounts of the ester within cells. Among the other factors thought to regulate LDL receptor expression are thyroid hormone, insulin, and platelet-derived and other types of growth factors.

Once LDL is delivered to cells, no degradation of cholesterol can occur in peripheral cells, and removal of cholesterol appears to be a function of another lipoprotein. HDL seems to function in 'reverse cholesterol transport,' in which it helps remove cholesterol from cells and return it to the liver for excretion in the bile. The exact mechanism and sequence of events are not yet understood. High levels of HDL cholesterol appear to indicate that more reverse cholesterol transport is occurring. This topic is discussed elsewhere in this volume.

Oxidation of LDL

The term oxidized LDL (oxLDL) encompasses a variety of particles, ranging from slight oxidation of LDL fatty acids to particles with oxidation of fatty acids, cholesterol and even apoB. LDL that has undergone certain modifications such as peroxidation or chemical acetylation or maleylation of apoB is taken up avidly by the modified-LDL receptor, also called the scavenger receptor. The expression of this receptor is independent of cell [cholesterol], and there is no downregulation of receptor number. Cholesterol accumulation can occur in macrophages and other cells that have this receptor. In addition, fatty acid oxidation fragments such as malondialdehyde may react with lysine residues of apoB, which may increase its ability to accumulate in macrophages. OxLDL is not a good ligand for the native LDL receptor, but it is more atherogenic than native LDL. After the discovery of the LDL receptor by Mark Brown and Joseph Goldstein in the mid-1970s, it gradually became evident that cholesterol accumulation in arterial lesions involves some processes other than uptake of native LDL by its receptors, since subjects with homozygous familial hypercholesterolemia, whose cells lack the receptors, accumulate cholesterol in 'foam' cells. Furthermore, 'foam' cells develop from macrophages/monocytes and smooth muscle cells, but *in vitro* experiments show that neither of these cell types accumulates much cholesterol from native LDL. Also, when native LDL delivers cholesterol and other lipids to cells via receptor-mediated endocytosis, feedback mechanisms decrease the number of receptors on the cell surface. This is called downregulation of the receptor, a process that normally helps maintain cholesterol homeostasis. Further experimentation has shown that the macrophages take up chemically modified LDL by a separate, nonregulated mechanism that allows accumulation and cellular damage (Table 4).

Table 4 Detrimental effects attributed to oxidized LDL

Avidly binds scavenger receptors, leading to accumulation of LDL lipids in arterial macrophages
Cytotoxic to arterial endothelial cells *in vitro* and possibly *in vivo*
Stimulates release of mitogenic factor(s) for macrophages and smooth muscle cells
Stimulates recruitment of additional monocytes/macrophages from bloodstream into intima
Is immunogenic and leads to autoantibody production
Antagonizes normal nitric oxide-induced vasodilation of arteries

It was soon learned that *in vitro* incubation of LDL with cultured endothelial cells creates oxidatively modified LDL that is readily bound and accumulated by the macrophages. Addition of antioxidants *in vitro* prevents this modification of LDL. We now know that the uptake of oxidized LDL occurs via a distinct receptor, called scavenger receptor A (SRA), on macrophages/monocytes and smooth muscle cells. Because this receptor is not downregulated, and LDL lipids accumulate in these cells, eventually they become 'foam cells.' Even slightly oxidized LDL, often called 'minimally modified,' can be recognized and taken up by the SRA. More than one type of scavenger receptor is present on macrophages, and other types of modification of LDL may also contribute to increased uptake by the macrophage. The sequence of events thought to be involved in atherogenesis is discussed below. Studies with experimental animals and *in vitro* cell-culture studies suggest that the use of antioxidants may help reduce or inhibit production of oxLDL and therefore may help inhibit atherogenesis. However, although epidemiologic data offer evidence of an inverse relationship between dietary antioxidant intake and risk of coronary heart disease (CHD), effectiveness in preventing atherosclerosis has not yet been conclusively demonstrated in humans.

Atherogenesis

Atherosclerosis (Greek athērē 'gruel' + sklērōsis 'hardness') occurs within major arteries when cholesterol-laden lesions build up in the lining and wall, eventually resulting in narrowing and sometimes occlusion of the lumen. In addition to decreasing the flow through the narrowed vessel, the lesions, called fibrous plaques, can cause thrombosis (blood clots), which may lead to CHD (also called myocardial infarction (MI) or heart attack), decreased oxygen delivery to the brain or other organs, or thrombotic

stroke. Atherosclerosis is usually described as a multifactorial disease with numerous risk factors (Table 5). Although genetics seems to be a predominant risk factor, attention has focused on those factors that can be changed, namely hypertension and blood cholesterol levels. Risk factors appear to be multiplicative rather than merely additive. Risk varies between races, and in America, blacks have a higher incidence of CHD than whites of the same age. Blood cholesterol levels do not differ between the two groups, and the higher incidence of CHD is attributed to the greater incidence of hypertension among blacks.

Theories on the etiology of atherosclerosis have gradually coalesced into the prevailing 'endothelial injury' hypothesis, which encompasses most *in vivo* and *in vitro* observations (Table 6). The endothelium lining of arteries plays a major role in the development of atherosclerosis. The response to endothelial injury is similar to the inflammatory response to injuries elsewhere. This may occur at the bifurcation of blood vessels where flow is turbulent; it may be in response to the constant insult of hypertension or to chemicals such as benzo(a)pyrene in cigarette smoke. White blood cells invade the area. If high levels of LDL are present, oxidation of LDL, possibly by endothelial cells, results in the formation of a modified (oxidized) LDL. OxLDL triggers a series of events: it causes more endothelial injury, and endothelial cells synthesize endothelial-leukocyte adhesion molecules (ELAMs). The latter attract monocytes and T lymphocytes that adhere to the endothelium. These move below the endothelium and not only engulf more oxLDL but also secrete cytokines and growth factors that stimulate movement of smooth muscle cells and macrophages to the area where all cells begin to accumulate increasing amounts of lipid, particularly cholesterol esters. Over a number of years, the process results in pronounced lesions (Table 7).

Table 5 Primary and secondary risk factors for coronary heart disease

Primary risk factors for CHD
Serum [cholesterol] $> 5.2\,\text{mmol}\,l^{-1}$
[HDL cholesterol] $< 0.9\,\text{mmol}\,l^{-1}$
Hypertriglyceridemia
Heredity
Hypertension
Smoking
Age (risk increases at 45 + years age for men, 55 + for women)
Diabetes mellitus
Obesity
Physical inactivity
Stress
Secondary risk factors for hyperlipidemia
Nephrotic syndrome
Alcoholism
Various drugs
Certain hormonal disorders (e.g., Cushing's disease)
Systemic lupus erythematosis
Pregnancy[a]

[a]A normal physiologic response to pregnancy.

Table 6 Likely sequence of events and relationship of LDL and atherogenesis

Dietary, genetic, and environmental factors
↓
Increased blood levels of LDL lipids (cholesterol, triglycerides)
↓
Greater adherence of monocytes to endothelial lining of arteries and more LDL entering lining of arteries
↓
Oxidative modification of LDL to MM-LDL by cells in the intima (lining)
↓
Stimulation of release of MCP-1 from endothelial cells by oxLDL; and simultaneous stimulation of release of MCSF
↓
Movement of more monocytes into the area from the bloodstream; differentiation of these cells into macrophages with increased SRAs
↓
Increased uptake of modified LDL by SRA and accumulation of cholesterol esters
↓
Recruitment of smooth muscle cells from arterial media to intima; induction of SRA expression in these cells
↓
Formation of lipid-laden foam cells from macrophages and smooth muscle cells
↓
Formation of fatty streaks
↓
Continuation of above sequence, leading eventually to localized cell necrosis, atheroma, and finally plaque formation

MCP-1, monocyte chemoattractant protein-1; MCSF, macrophage colony-stimulating factor; MM-LDL, minimally modified low-density lipoprotein; oxLDL, oxidized LDL; SRA, scavenger receptor-1.

Studies in molecular genetics are proving helpful in establishing the relationships between lipoproteins, lipids, apolipoproteins, membrane proteins, and numerous other factors involved in cholesterol metabolism and atherogenesis. Also, the use of transgenic technology has provided animal models for studying atherogenesis. There now exist transgenic animals (mice or rabbits) for overexpression of most of the apolipoproteins, as well as LCAT, cholesterol ester transfer protein, and scavenger receptor B-1 protein. In addition, 'knockout' animal models, in which certain apolipoprotein genes are missing, are being studied to help determine the functions of the proteins.

Intervention Trials and Current Status

While epidemiologic studies long ago suggested the relationship between high blood cholesterol levels and increased incidence of atherosclerosis and CHD, much of the progress in understanding the etiology, pathology, and relationships has been made in the last two to three decades. The positive correlation between blood cholesterol levels and risk of CHD-related deaths was established in the 1970–80s by the Framingham Heart Study and the Lipid Research Clinics Cornary Primary Prevention Trial. In the mid- to-late 1980s, health agencies in many countries published ranges of 'desirable' vs. 'undesirable' cholesterol levels, along with recommendations on modifying high levels of total and LDL-cholesterol levels (Table 8). But whether deliberately lowering cholesterol levels could decrease the risk of CHD-related events remained questionable until recent years. Several intervention studies have now provided good evidence that reducing plasma cholesterol levels in patients with established CHD with drugs and/or diet does in fact reduce the incidence of both fatal and nonfatal heart attacks. The efficacy of early studies with some of the statin drugs appeared questionable because, although the incidence of CHD deaths declined, overall mortality did not. Newer studies, however, have shown no increase in noncardiovascular disease deaths. Table 9 summarizes some of these studies.

Current thinking is that there should be aggressive cholesterol management in most patients with CHD, irrespective of the etiology of the condition. Very-low-fat diets diets help to reduce total plasma cholesterol levels in some hypercholesterolemic individuals, but recent studies have shown that HDL cholesterol is lowered by such diets, particularly in women. This is of concern and deserves further work. Cholesterol levels increase in older people, but the correlation of high [blood cholesterol] and CHD appears to be less prominent in the elderly population. Nevertheless, it has been reported recently that high total cholesterol levels do increase CHD risk in the elderly population. In the USA, current guidelines, supported by the American Heart Association and the American College of Cardiology, and based on experimental evidence and clinical trials, suggest that LDL cholesterol should be reduced to $\leq 100\,\mathrm{mg\,dl^{-1}}$. Since LDL cholesterol is a calculated value and since the measurement of total and HDL cholesterol may be subject to some error, the consensus opinion is that two or three fasting lipoprotein measurements on consecutive days should be made for an accurate baseline. All patients with CHD and LDL cholesterol $> 100\,\mathrm{mg\,dl^{-1}}$ should immediately reduce the daily intake of saturated fats to $\leq 7\%$ of total calories and of cholesterol to < 200 mg per day. In addition, weight loss is advised for those who are overweight, and appropriate physical activity is suggested. If baseline LDL cholesterol in those with CHD is $> 130\,\mathrm{mg\,dl^{-1}}$, drug therapy in addition to the diet is normally advised immediately.

Table 7 Stages in atherogenesis

Stage	*Age*	*Characteristics*
One	Childhood	Development of 'fatty streaks' in the aorta
Two	Early and Mid-adulthood	Fatty deposition under intima; migration of smooth muscle cells from arterial media to intima; macrophages and smooth muscle cells become lipid-laden 'foam cells'
Three	Middle age and seniors	Formation of frank plaques; calcification of plaques

Table 8 Classification of cholesterol levels

Type	*Desirable*	*Borderline high*	*High risk*
Total serum cholesterol	< 5.2 mM ($< 200\,\mathrm{mg\,dl^{-1}}$)	5.2–6.2 mM (200–239 $\mathrm{mg\,dl^{-1}}$)	> 6.2 mM ($> 240\,\mathrm{mg\,dl^{-1}}$)
Low-density lipoprotein cholesterol	< 3.35 mM ($< 130\,\mathrm{mg\,dl^{-1}}$)	3.35–4.1 mM (130–159 $\mathrm{mg\,dl^{-1}}$)	> 4.15 mM ($> 160\,\mathrm{mg\,dl^{-1}}$)
High-density lipoprotein cholesterol	> 0.9 mM ($> 35\,\mathrm{mg\,dl^{-1}}$)		< 0.9 mM ($< 35\,\mathrm{mg\,dl^{-1}}$

Based on recommendations of the USA National Cholesterol Education Program.

Table 9 Summary of recent intervention trials

Name of study	*Subjects, characteristics*	*Treatment*	*Outcome*
WOSCOPS (1995)	6500 males, [Ch] = 249–295 mg dl^{-1}, no CHD	Low fat diet plus statin drug or placebo	20% ↓ [total Ch] 31% ↓ CHD risk
AFCAPS (1998)	Healthy men and women with average [Ch] ~ 221 mg dl^{-1}	Low-fat diet plus statin drug or placebo	16% ↓ [total Ch] 40% ↓ MI risk
SSSS (1994)	Hypercholesterolemic patients with diagnosed CHD	Diet plus statin drug or placebo	24% ↓ in MI
CLAS (1991)	Middle-aged men with atherosclerosis (4 years)	Colestipol + niacin + diet vs. placebo + diet	16.2% of subjects had lesion regression compared to 2.4% of placebo group

AFCAPS, Airforce Coronary Atherosclerosis Prevention Study; Ch, cholesterol; CHD, coronary heart disease; CLAS, Cholesterol-lowering Atherosclerosis Study; MI, myocardial infarction; SSSS, 4S, Scandinavian Simvastatin Survival Study; WOSCOPS, West of Scotland Coronary Prevention Study.

The choice of drugs depends largely on the lipoprotein patterns (e.g., concomitant high [triglyceride], low [HDL-C], and baseline [LDL-C]). Drugs most often used individually or in combination are statins, bile acid sequestrants, and nicotinic acid. Sequestrants increase the excretion of bile acids in feces and reduce blood cholesterol levels by conversion of more cholesterol to bile acids. Statins inhibit HMG-CoA reductase and thereby decrease the synthesis of cholesterol and other products of the isoprenoid pathway. Nicotinic acid appears to decrease the synthesis of LDL and increase the synthesis of HDL. In patients with a [LDL-C] of 100–129 mg dl^{-1} and low [HDL-C] (< 35 mg dl^{-1}), nicotinic acid is probably the first-choice drug. The efficiency, cost, and side-effects of these drugs are usually important factors in decisions about therapy. Each of these groups of drugs may have undesirable side-effects in some patients, and compliance is often a problem, but recent advances in drug therapy have resulted in safer, but effective, pharmocologic reductions in blood cholesterol levels. Reports from many of the recent intervention trials have indicated that in addition to the decreases in risk, number of CHD deaths, and overall mortality, there was also a reduction in the need for bypass surgery or angioplasty. Furthermore, the interventions have proven effective in reducing high blood cholesterol levels in both genders, in middle-aged and elderly, and in those with or without established CHD.

CHOLINE

Contents
Properties and Determination
Physiology

Properties and Determination

S H Zeisel, University of North Carolina, Chapel Hill, NC, USA

Background

Choline is a common constituent of foods and is an essential component of the human diet. This quaternary amine is important for the structural integrity and signaling functions of cell membranes; it is the major source of methyl groups in the diet; it directly affects cholinergic neurotransmission; and it is required for lipid transport/metabolism. Most choline in human tissues is found in phospholipids such as phosphatidylcholine and sphingomyelin. In some components, such as human milk, the choline esters phosphocholine and glycerophosphocholine are the predominant forms of choline. Though representing a smaller proportion of the total choline pool, important metabolites of choline include platelet-activating factor, acetylcholine, choline plasmalogens, lysophosphatidylcholine, and betaine (Figure 1).

Measurement of Choline

Careful collection of biological samples to be analyzed for choline is exceedingly important. In blood samples, choline concentrations double every 15 min in the sample at room temperature, probably because membrane phosphatidylcholine is hydrolyzed. Therefore, it is important that blood be kept on ice until plasma is separated by centrifugation. For similar reasons, tissues and foods should be stored at −70 °C. At this temperature, samples are stable for at least one year. Acetylcholine is readily hydrolyzed by basic conditions, or by cholinesterases present in tissues. If acetylcholine is to be determined, rapid deactivation of tissue enzymes is essential, and microwave irradiation is commonly used. When acetylcholine is not an important analyte (e.g., for tissues other than brain), it is sufficient to freeze-clamp the tissue using tongs cooled in liquid nitrogen.

There are multiple forms of choline in biological tissues, as discussed above. Assay procedures are available for the most common forms. For all the assays, it is important to realize that purified choline salts are very hygroscopic, and this makes assessing the true weight of internal standards difficult. Unesterified choline can be measured in plasma and red blood cells using a radioisotopic procedure, but this difficult assay has largely been supplanted by a procedure that uses high-pressure liquid chromatography (HPLC), an enzyme reactor, and electrochemical detection after a simple sample pretreatment. An alternative method using HPLC and fluorometric detection has also been used. These methods are accurate, reliable, and inexpensive, but are only suitable for measurement of the choline (unesterified) and acetylcholine, and they do not permit the use of internal standards. A gas chromatography/mass spectrometry method requires much more expensive equipment, but has the advantage that it has been adapted to measure other choline esters. The original method has been enhanced by preseparation of the various aqueous soluble choline metabolites using HPLC. This procedure allows analysis of choline, acetylcholine, phosphocholine, and glycerophosphocholine in a single sample at minimum detection levels of 5–10 pmol applied to the GC/MS (e.g., the amount of choline present in 1 µl of plasma, but owing to the complex extraction and derivatization procedures, 25 µl of plasma is the minimum amount that can be analyzed). It is a demanding procedure and requires that the separate HPLC peaks be collected, the metabolite in question be converted to choline, and then this choline be injected on to the gas chromatogram/mass spectrometer. It does allow the inclusion of an isotopically labeled internal standard for each metabolite, thereby insuring a greater accuracy and reliability when widely divergent matrices are to be analyzed (e.g., tissues and foods).

Neither the electrochemical nor the mass spectrometric assays detect betaine. Betaine can be isolated using HPLC and derivatized with 4′-bromo-phenacyl triflate so that it can be detected and quantified using UV absorbance. Phosphatidylcholine and sphingomyelin can be isolated by thin-layer chromatography

Compound	*Chemical structure*	*Biologic function*
Choline		
Betaine		Methyl group donor; renal osmolyte
Acetylcholine		Neurotransmitter
Phosphatidylcholine		Necessary building block of biomembranes; very-low–density lipoprotein component necessary for hepatic very-low–density lipoprotein secretion
Platelet-activating factor		Hormone
Sphingomyelin		Necessary building block of biomembranes
Glycerophosphocholine		Intracellular storage pool of choline
Phosphocholine		Intracellular storage pool of choline

Figure 1 Biologically important metabolites of choline.

and quantified using choline or phosphorus determination, or isolated by HPLC and quantified with ultraviolet or fluorometric detection. The advantage of these last methods is the ability to differentiate phospholipids by fatty acid composition.

A method has recently been devised, using liquid chromatography/electrospray ionization/mass spectrometry (LC/ESI/MS), which greatly reduces the number of steps in the analysis (eliminates the transfer to the gas chromatograph), but the equipment costs still remain very high. This method requires no derivatization and allows the use of internal standards. After sample extraction, the aqueous and organic phases are separated and analyzed separately

using straight-phase liquid chromatography. This method requires 2 pmol of choline to be applied to the LC/MS (e.g., the amount of choline in 0.2 μl of plasma).

Dietary Sources of Choline

Many foods eaten by humans contain significant amounts of choline and esters of choline, but there is currently no comprehensive database of the choline content of foods. Some of this choline is added during food processing (especially when preparing infant formula). The average dietary intake of choline and choline esters in the adult human is estimated to be 7–10 mmol per day. When humans are switched from a diet of normal foods to a defined diet containing 5 mmol per day, plasma choline and phosphatidylcholine concentrations decrease in most subjects. Thus, the average dietary intake of choline seems to exceed this level in adults. Human, commercially available infant formulas and bovine and rat milk contain approximately 1–2 mmol per liter of choline and choline esters. Human milk has a significantly higher phosphocholine concentration, the same or lower glycerophosphocholine concentration, and similar phosphatidylcholine and sphingomyelin concentrations compared with either bovine milk or bovine-derived infant formulas. Soy-derived infant formulas have lower glycerophosphocholine and sphingomyelin concentrations and higher phosphatidylcholine concentrations than do either human milk or bovine milk-derived formulas. By assuming that a newborn infant drinks 150 ml of milk per kilogram per day, their choline intake would be approximately 200–250 μmol per kilogram per day, two to three times that ingested by the adult human.

Intestinal Absorption

The extent to which dietary choline is bioavailable depends upon the efficiency of its absorption from the intestine. In adults, some ingested choline is metabolized before it can be absorbed from the gut. Gut bacteria degrade it to form betaine and to make methylamines. The free choline surviving these fates is absorbed all along the small intestine. No other component of the diet has been identified as competing with choline for transport by intestinal carriers. Both pancreatic secretions and intestinal mucosal cells contain enzymes (phospholipases A_1, A_2, and B) capable of hydrolyzing phosphatidylcholine in the diet. The free choline that is formed enters the portal circulation of the liver.

In infants, there are differences in the bioavailability of the water soluble, choline-derived compounds (choline, phosphocholine, and glycerophosphocholine) and the lipid-soluble compounds (phosphatidylcholine and sphingomyelin) present in milk.

Metabolism of Choline

There have been several comprehensive reviews of the metabolism and functions of choline that describe its role in the synthesis of the phospholipids in cell membranes, methyl metabolism, cholinergic neurotransmission, transmembrane signaling, and lipid-cholesterol transport and metabolism. Choline can be acetylated, phosphorylated, or oxidized.

Choline, methionine, and folate metabolism interact at the point that homocysteine is converted to methionine (**Figure 1**). Betaine:homocysteine methyltransferase catalyzes the methylation of homocysteine using the choline metabolite betaine as the methyl donor. Elevated plasma homocysteine is an independent risk factor for cardiovascular disease and stroke in humans. Treatment with betaine or choline also lowers elevated plasma homocysteine in humans. In an alternative pathway, 5-methyl-tetrahydrofolate:homocysteine methyltransferase regenerates methionine. In addition, tetrahydrofolate is needed to scavenge one-carbon groups when betaine is metabolized. Perturbing metabolism of one of the methyl donors results in compensatory changes in the other methyl donors owing to the intermingling of these metabolic pathways. Rats ingesting a choline-deficient diet have diminished tissue concentrations of methionine and *S*-adenosylmethionine, doubled plasma homocysteine concentrations, and diminished hepatic methyl-folate content. These effects are reversible by refeeding choline. Rats fed diets deficient in both methionine and choline for 5 weeks have hepatic folate concentrations that are half of those present in controls. Rats treated with the antifolate, methotrexate, have diminished pools of choline metabolites in liver. Severe folate deficiency, induced in rats by feeding an amino acid-defined diet containing no folate and succinylsulfathiazole for 4 weeks have resulted in hepatic choline and phosphocholine concentrations that were 65 and 80% lower, respectively than in controls.

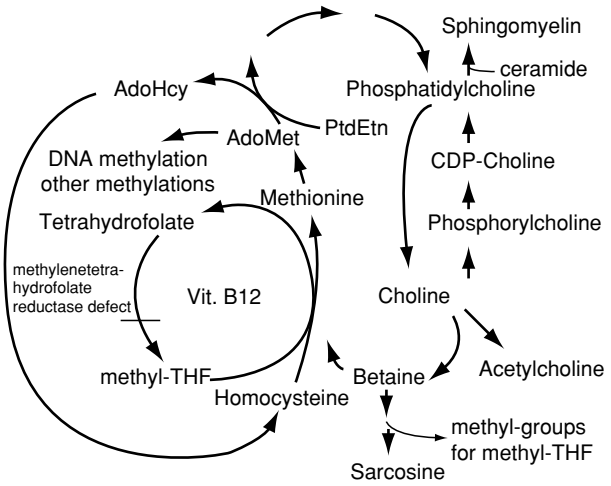

Figure 1 Choline, folate, and homocysteine metabolism are closely inter-related. The pathways for the metabolism of these three nutrients intersect at the formation of methionine from homocysteine. PtdEtn, phosphatidylethanolamine; AdoHcy, *S*-adenosylhomocysteine; AdoMet, *S*-adenosylmethionine

Dietary Requirements

Though there is a pathway (in all tissues, but most active in the liver) for the *de novo* biosynthesis of the choline moiety via the sequential methylation of phosphatidylethanolamine using *S*-adenosylmethionine

as the methyl donor (Figure 1), only some of the demand for choline can be met by using methyl groups derived from one carbon metabolism. Animals and humans fed a choline deficient diet deplete choline stores and develop liver dysfunction. Healthy male humans with normal folate and vitamin B_{12} status fed a choline-deficient diet have diminished plasma choline and phosphatidylcholine concentrations, and develop liver damage (elevated plasma alanine aminotransferase). Liver cell death occurs in choline deficiency, because hepatocytes initiate programmed cell death (apoptosis) when deprived of choline. Because methyl supplementation with betaine, methionine, folate, or vitamin B_{12} does not prevent apoptotic death induced by choline deficiency in hepatocytes, it must be that depletion of intracellular choline moieties rather than depletion of methyl groups is the critical parameter involved in induction of apoptosis. Some humans (male and female) fed with total parenteral nutrition solutions devoid of choline, but adequate for methionine and folate, develop fatty liver and liver damage that resolves when a source of dietary choline is provided. Fatty liver occurs because choline is required to make the phosphatidylcholine portion of the very-low-density lipoprotein particle. Animals fed a choline-deficient diet may also develop growth retardation, renal dysfunction and hemorrhage, or bone abnormalities. A metabolite of choline, betaine, is used in the kidney glomerulus as an osmolyte, and for this reason, choline-deficient animals have trouble excreting concentrated urine.

Human studies of choline requirements in women, children, or infants have not been conducted. Thus, we do not know whether choline is needed in the diet of these groups. Female rats are less sensitive to choline deficiency than are male rats perhaps because estrogen enhances females' capacity to form the choline moiety *de novo* from *S*-adenosylmethionine. Pregnancy may be a time when dietary supplies of choline are especially limiting. Though female rats are resistant to choline deficiency, pregnant rats are as vulnerable to deficiency, as are males. During pregnancy, large amounts of choline are delivered to the fetus across the placenta, and this depletes maternal stores of the various forms of this nutrient. At birth, humans and other mammals have plasma choline concentrations that are much higher than those in adults. Also, the need for choline is increased during lactation, because so much must be secreted into milk; lactating rats are more sensitive to choline deficiency than are nonlactating rats.

The Institute of Medicine (IOM) recently made recommendations for choline intake in the diet. There were insufficient data with which to derive an estimated average requirement for choline, and so only an adequate intake can be estimated. The IOM report cautioned, 'this amount will be influenced by the availability of methionine and methyl-folate in the diet. It may be influenced by gender, and it may be influenced by pregnancy, lactation, and stage of development. Although AIs are set for choline, it may be that the choline requirement can be met by endogenous synthesis at some of these stages.' The IOM recommendations are shown in Table 1.

Table 1 Institute of Medicine recommendations for choline intake in the diet

AI for infants	0–6 months	125 mg per day, 18 mg per kilogram
	6–12 months	150 mg per day
AI for children	1–3 years	200 mg per day
	4–8 years	250 mg per day
	9–13 years	375 mg per day
AI for males	14–18 years	550 mg per day
	19 and older	550 mg per day
AI for females	14–18 years	400 mg per day
	19 years and older	425 mg per day
AI for pregnancy	All ages	450 mg per day
AI for lactation	All ages	550 mg per day

AI = adequate intake level.

The recent report by Jacob that folate deficiency in humans exacerbates choline deficiency highlights why studies of choline–folate–homocysteine interrelationships in humans are important for the future refinement of these recommendations.

Plasma choline concentration varies in response to diet and can rise as much as twofold after a two-egg meal. Fasting plasma choline concentrations vary from 7 to 20 μM, with most subjects having concentrations of 10 μM. Individuals that have starved for up to 7 days have diminished plasma choline, but levels never drop below 50% of normal. Plasma phosphatidylcholine concentration also decreases in choline deficiency, but these values are also influenced by factors that change plasma lipoprotein levels. Fasting plasma phosphatidylcholine concentrations are approximately 1–1.5 mM.

Choline and Brain Development

Choline availability during embryogenesis and perinatal development may be especially important. There is a sensitive period in rodent brain development during which treatment with choline (about three times the dietary intake) produces long-lasting enhancement of spatial memory that is lifelong. This period occurs during embryonic days 12–17 in the rat (rats give birth on day 21; mice give birth one day earlier and probably have a slightly different period of susceptibility). Choline supplementation

during these critical days elicits a major improvement in memory performance at all stages of training on a 12-arm radial maze. Choline deficiency during the critical timeframe reduces memory performance. The choline-induced spatial memory facilitation correlates with changes in the birth, death, and migration of cells in the hippocampus during fetal brain development, with altered distribution and morphology of neurons, biochemical changes, and electrophysiological changes in the hippocampus. Human and rat brains mature at different rates; rat brain is comparatively more mature at birth than is the human brain, but in humans, hippocampal development may continue for months or years after birth.

Choline and Cancer

Dietary deficiency of choline in rodents causes development of hepatocarcinomas in the absence of any known carcinogen. Choline is the only single nutrient for which this is true. It is interesting that choline-deficient rats not only have a higher incidence of spontaneous hepatocarcinoma but also are markedly sensitized to the effects of administered carcinogens. Several mechanisms are suggested for the cancer-promoting effect of a choline-devoid diet. A progressive increase in cell proliferation that is related to regeneration after parenchymal cell death occurs in the choline-deficient liver. Cell proliferation and its associated increased rate of DNA synthesis could be the cause of the heightened sensitivity to chemical carcinogens. Methylation of DNA is essential to the regulation of expression of genetic information, and the undermethylation of DNA observed during choline deficiency (despite adequate dietary methionine) may be responsible for carcinogenesis. Choline-deficient rats experience increased lipid peroxidation in liver. Lipid peroxides in the nucleus are a possible source of free radicals that could modify DNA and cause carcinogenesis. Choline deficiency activates protein kinase C signaling, usually involved in growth factor signaling in hepatocytes. Finally, a defect in cell-suicide (apoptosis) mechanisms may contribute to the carcinogenesis of choline deficiency.

Summary

Choline in the diet is important for many reasons. As our understanding of the importance of folate and homocysteine nutrition increases, there should be increased interest in how choline interacts with folate and homocysteine metabolism. Recent findings about choline in brain development should stimulate comparable studies in humans. During the next few years, it is likely that food composition data will be available for choline, and this will make it possible to examine interactions between choline, folate, and methionine when considering epidemiological data. In addition, we should learn more about choline requirements in women. For these reasons interest in choline as a nutrient for humans should be sustained.

Background

Chromatography is a common name for techniques based on the partition of the molecules to be analyzed between a mobile and a stationary phase. Separation is the result of different partitions of molecules between the two phases. Because the best separation of any solutes can be obtained under equilibrium conditions, analytical chemists prefer to use chromatographic systems that are as near to the equilibium state as possible. However, in the case of preparative chromatography, where the main objective is not the optimal separation of solutes but the maximum yield of one or more solutes at a given purity, the situation is entirely different. Preparation chromatographic separations are generally not equilibrium processes. The high sensitivity, selectivity, and reproducibility of chromatographic methods have been extensively exploited in food and nutrition science and technology.

This chapter overviews the theoretical backgrounds, principles, and fundamental technical characteristics of chromatographic separation processes and instrumentations.

Basic knowledge of the principles of chromatography may help analytical chemists solve any separation problems, using chromatography as a tool.

Gas Chromatography

Principle

Gas chromatography (GC) is the common name for chromatographic methods in which the mobile phase is gas, and the stationary phase is solid or liquid (gas–solid chromatography (GSC) or gas–liquid chromatography (GLC)). There are limitations to the type of compound suitable for GC analysis. A compound needs to have an appreciable vapor pressure at temperatures below 350–400 °C and has to be vaporized rapidly without decomposing or reacting with the components of the stationary and mobile phase (instability at high temperatures usually renders a compound unsuitable for GC analysis).

The common GC equipment consists of a carrier gas system, injector, gas chromatographic column, detector, and data-processing unit (Figure 1). The carrier gas is generally a permanent gas with a low or negligible adsorption capacity, i.e., hydrogen, helium, argon, or nitrogen. The nature of the carrier gas may influence the separation characteristics of the GC system and can modify the sensitivity of the detection.

As the stability and reproducibility of the carrier gas flow rate are the prerequisites for a successful GC analysis, they have a considerable influence on both the efficacy of the separation and the quantification of the results.

Injectors deliver the sample to the head of the GC column and can be classified into two major groups: vaporization and on-column injectors. Vaporization injectors use high temperatures to rapidly vaporize a liquid sample. Usually, a syringe is used to introduce the sample into the thermostated injector. In this case, the sample rapidly vaporizes, mixes with the carrier gas, and is transported into the column. On-column injectors deposit the sample directly into the column without relying on vaporization of the sample and its subsequent transport into the column. Separation of volatile compounds of the injected sample is performed in the GC column.

The columns used for gas chromatography can be divided into two distinct groups: packed and capillary columns. A packed column is a rigid metal or glass column filled with small particles that are often

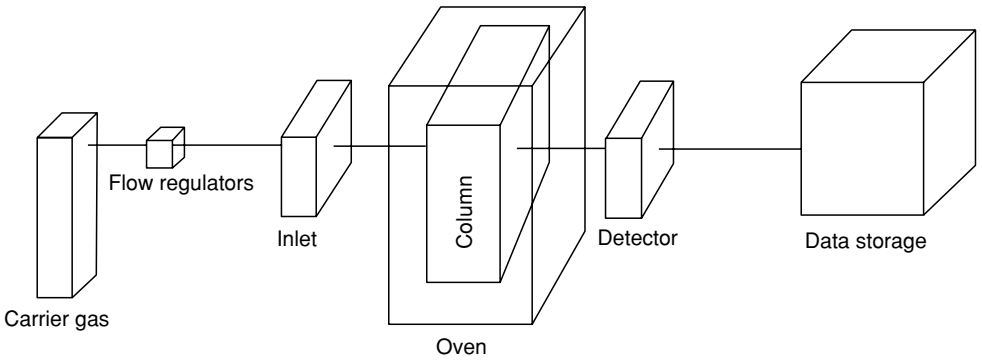

Figure 1 Block diagram of a typical gas chromatogram.

coated with a thin layer of high-molecular-mass polymer. The most common solid supports are diatomaceous earth, fluorocarbons, graphitized carbon black, and glass beads. The stationary liquid phase has to comply with the following requirements: low vapor pressure, high chemical stability, and relatively low viscosity at the temperature of analysis; selectivity for the sample components under investigation; and a good wetting capacity for the surface of the inert support or for the possibly inert wall of the column. A capillary (open tubular) column is a glass or fused-silica tube of very small internal diameter (generally between 0.20 and 0.53 mm). The inner surface of a capillary column is coated only with a thin layer of stationary phase, so it is still possible for the analytes to come into contact with the inner wall of the tubing. Stationary phases can be cross-linked and covalently bonded to the inner wall of the capillary. The stationary phase in a capillary column is characterized by its film thickness (0.1–5 μm). The advantage of capillary columns is the considerably higher separation capacity than that of packed columns. The decrease in lateral diffusion, easier availability of the separation liquid, and increase in column length account for the enhanced separation efficacy of capillary columns. Because of the better separation performance, capillary columns have been used more frequently in gas chromatography than packed columns.

In order to achieve effective and reliable separation, a gas chromatographic column has to be kept at a constant temperature (isothermal separation mode), or the column temperature can be changed according to a temperature program (temperature gradient). As linear temperature programs consisting of more than one step are usually sufficient for the effective separation of analytes, nonlinear temperature programs are rarely used in the analysis of food constituents. Detectors interact with the solute molecules as they exit the column. This interaction is converted into an electrical signal that is sent to a recording or data-storage device. A chromatogram, i.e., a plot of the intensity of the signal versus elapsed time, is then created. The primary differences between the detectors are in the lowest amount of a compound that is detectable (sensitivity) and the compounds that produce the strongest detector response (selectivity). Many different detectors (flame ionization detectors (FID), nitrogen–phosphorus detectors (NPD), flame photometric detectors (FPD), electron capture detectors (ECD), thermal conductivity detectors (TCD), atomic emission detectors (AED), electrolytic conductivity detectors (ELCD), chemiluminescence detectors, mass spectrometry (MS) detectors, etc.) and data-handling devices have been developed for the sensitive and selective detection and quantification of sample components. The FID uses a hydrogen flow mixed with the carrier gas. The mixture is ignited, the analytes are burned, and the ions formed during the burning process are collected in a cylindrical electrode at a high voltage applied between the jet of flame and the electrode. The resulting current is amplified and detected. The NPD is similar to the FID in its design. It contains rubidium or cesium beads inside a heater coil near the hydrogen jet. The partially combusted nitrogen and phosphorus molecules absorb on to the surface of the beads, thereby reducing the emission of electrons, which increases the current. The FPD especially detects sulfur and phosphorus compounds. Analytes are burned in the flame, and because of the excitation in the flame, light is emitted at 392 nm (sulfur) and 526 nm (phosphorus). A filter selects the wavelengths reaching a photomultiplier tube. The ECD employs a low-energy β-ray source for the production of electrons and ions. Electron-capturing molecules (halogenated compounds) entering the detector decrease the electron current, which can be amplified and registered. The TCD responds to the changes in thermal conductivity and specific heat, via a filament under a current applied to the carrier gas flow.

Changes in the thermal conductivity and/or specific heat of the current gas caused by the analytes change the potential across the filament. The AED is suitable for detecting selected atoms or groups of atoms, and the ELCD can be used for detecting Cl-, N-, or S-containing analytes. The chemiluminescence detector is used mainly for detecting sulfur compounds. The MS ionizes molecules at low pressures and then separates them to create a spectrum of ion intensity vs. mass-to-charge ratio. The good application parameters of capillary GC/MS using the temperature gradient is illustrated on the chromatograms of sterol esters and free sterols in rapeseed and sunflower oils (Figure 2). (*See* **Chromatography**: Gas Chromatography.)

Fundamentals

The distribution of solute molecules between the stationary and mobile phases is defined by the distribution constants (K_D), i.e., the ratio of the concentration of the solute molecules in the stationary phase to that in the mobile phase:

$$K_D = \text{compound concentration of stationary phase/compound concentration of mobile phase.} \quad (1)$$

The general expression describing retention in terms of column temperature and solute properties can be expressed by:

$$\ln K_D = -\Delta G^0/RT, \quad (2)$$

where, ΔG^0 is the change in Gibbs free energy for the evaporation of the compound from the stationary phase, T is the column temperature, and R is the ideal gas constant. Equation (2) shows that the differences in the Gibbs free energy for the evaporation of the solutes from the stationary phase result in different degrees of solute retention.

The amount of time that the compound remains in the stationary phase is called the retention time (t_R).

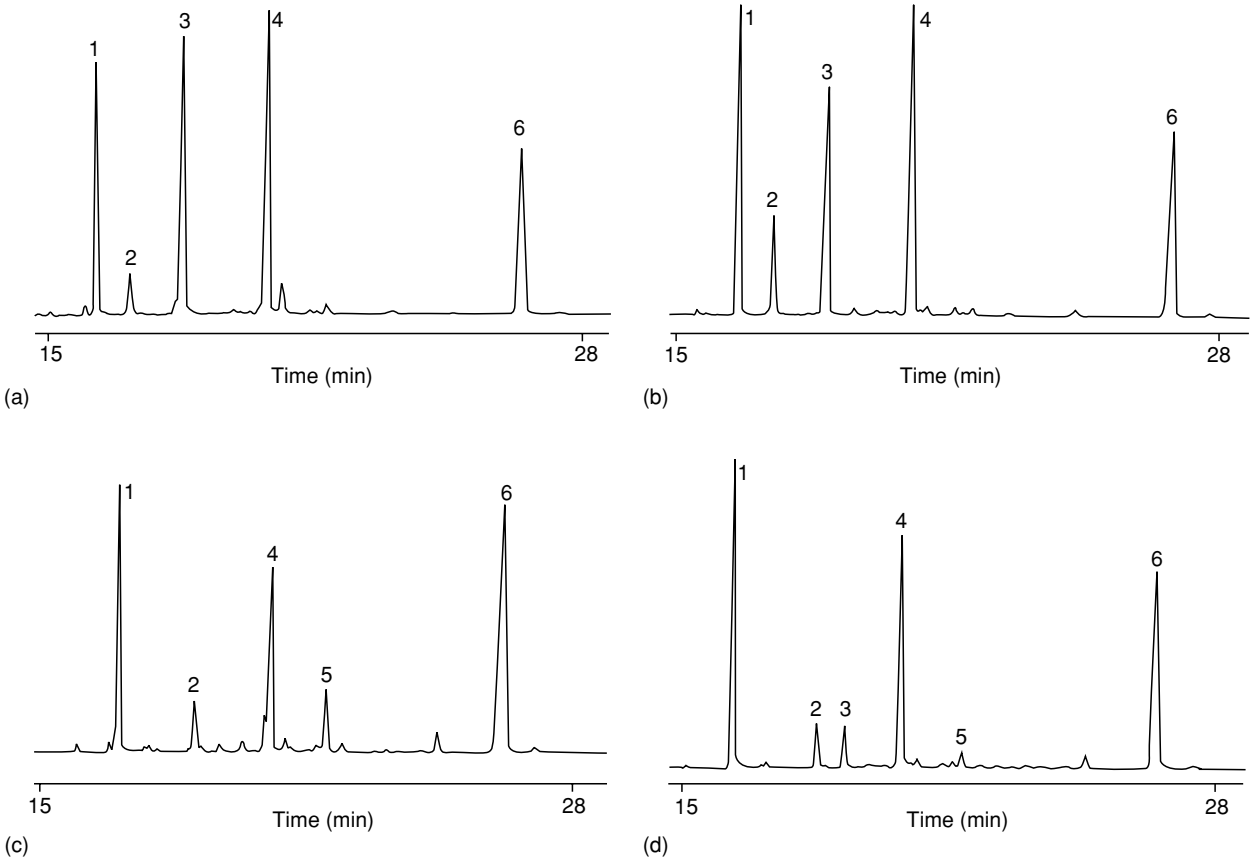

Figure 2 Gas chromatograms of sterol esters (a, c) and free sterols (b, d) in rapeseed (a, b) and sunflower oils (c, d). Peak identification: 1, cholesterol (internal standard); 2, brassicasterol; 3, campesterol; 4, sitostesterol; 5, Δ^7-stigmastenol; 6, betulin (secondary internal standard). Reprinted with permission from Kalo P and Kuuranne T (2001) Analysis of free and esterified sterols in fats and oils by flash chromatography, gas chromatography and electrospray tandem mass spectrometry. *Journal of Chromatography* 935: 237–248.

Dead time (t_0) is the time required for a nonretained solute to travel through a column.

The partition ratio, also known as the capacity factor (k') is the amount of time a compound remains in the stationary phase relative to the mobile phase.

$$k' = (t_R - t_0)/t_0. \quad (3)$$

The resolution number (R) is used to describe the efficacy of the separation of two peaks.

Resolution numbers can be calculated using either of two equations, as illustrated in Figure 3:

$$R = 1.18(t_{R2} - t_{R1})/(w_{h1} + w_{h2}) \quad (4)$$

$$R = 2(t_{R2} - t_{R1})/(w_{b1} + w_{b2}) \quad (5)$$

where t_{R1} and t_{R2} are the retention times of peaks 1 and 2, respectively, w_{h1} and w_{h2} are the peak widths at half height of peaks 1 and 2, respectively, and w_{b1} and w_{b2} are the peak widths at the base of peaks 1 and 2, respectively.

The theoretical plate number (N) characterizes the separation capacity of a chromatographic column. The number of theoretical plates is calculated by the following equation:

$$N = 5.545(t_R/w_h)^2. \quad (6)$$

Liquid Chromatography

The term liquid chromatography (LC) encompasses chromatographic methods in which the mobile phase is liquid and the stationary phase is organic or inorganic solid. According to the shape of the solid-phase support, liquid chromatographic methods can be divided into planar and column chromatography. Moreover, LC methods can be classified as normal (adsorption or direct) and reversed-phase (RP) separation modes. When the chromatographic system consists of a nonpolar mobile phase and a polar stationary phase, it is called normal chromatography. In the reversed-phase separation mode, the mobile phase is polar, and the stationary phase is nonpolar. (*See* **Chromatography**: High-performance Liquid Chromatography.)

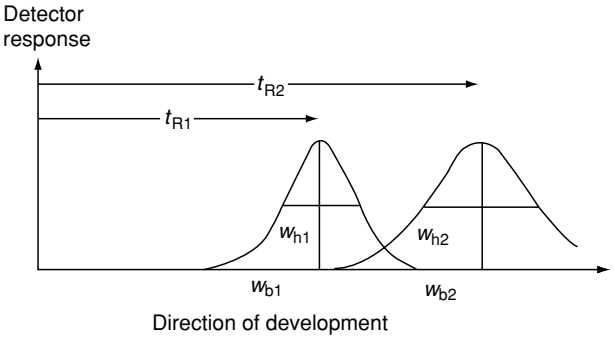

Figure 3 Schematic illustration of the mode of calculation of resolution numbers in gas and high performance liquid chromatography.

Thin-layer Chromatography

Thin-layer chromatography (TLC) is a planar chromatographic technique extensively used as a rapid and straightforward analytical tool. The success of TLC is due to its rapidity, cost-efficient optimization of separation (mobile and stationary phases can be changed easily), the high sample throughput in a short time, and the suitability for screening tests. A wide variety of inorganic and organic supports have been used for separation in TLC; however, silicas with different physicochemical characteristics (e.g., various surface pHs and pore diameters) and silicas with hydrophobic ligands covalently bonded to the surface (silanized silica, C_2, C_8, C_{18} alkyl bonded silica, amino, diol, cyano) are commonly used in TLC. Besides silica and modified silica stationary phases, other sorbents such as alumina (basic, neutral, and acidic), diatomaceous earth (Kieselguhr), celluloses and cellulose derivatives, polyamides have also been used in TLC, because their separation characteristics differ from those of silica-based layers.

Sample application Samples prepared for TLC are dissolved in an appropriate solvent and applied in the form of spots or narrow bands to the plates.

Development of chromatogram The most frequently used developing technique is ascending TLC, which is carried out in a chamber. Besides linear ascending development, linear horizontal development and anticircular development have sometimes been employed. The use of multistep gradient elution and two-dimensional development enhance the efficacy of TLC separation.

Detection in TLC is generally based on the visible or ultraviolet absorption of the solutes or on the use of various detection reagents. One of the main advantages of TLC is that a large number of detection reagents can be used that are more or less selective. In the last decade, many new instruments have been developed for the quantitative evaluation of TLC plates. Up-to-date chromatogram spectrophotometers (densitometers) are suitable for the determination of the visible, ultraviolet, and fluorescence intensity of solute spots. Characteristic densitograms obtained after TLC separation of cholesterol in liquid egg yolk are shown in Figure 4. (*See* **Chromatography**: Thin-layer Chromatography.)

Fundamentals The retention factor, R_f, characterizes the position of spots in TLC and is determined

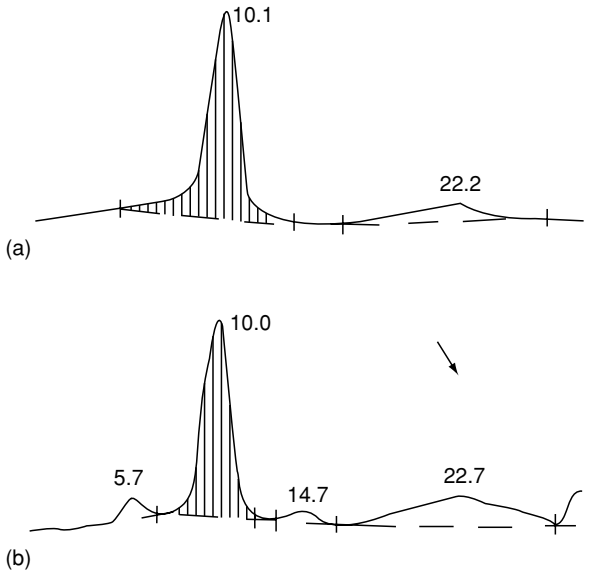

Figure 4 Typical densitogram obtained after TLC of cholesterol: (a) standard solution ($c = 400\,\mu g\,ml^{-1}$); (b) cholesterol from egg yolk. Reprinted with permission from Pozar M, Wondra AG and Prosek M (1999) TLC and HPLC determination of levels of cholesterols before and after its reduction in liquid egg yolk. *Journal of Planar Chromatography – Modern Thin-layer Chromatography* 12: 416–424.

by dividing the distance between the center of the spots and the start line (z_s) by the distance of the eluent front from the start line (z_f):

$$R_f = z_s/z_{f.} \qquad (7)$$

Other chromatographic parameters can be calculated, as described above.

High-performance Liquid Chromatography

High-performance liquid chromatography (HPLC) is the most frequently used liquid-chromatographic technique. Separation is carried out using a liquid mobile phase and a solid stationary phase filled in columns. Similar to TLC, normal-phase and reversed-phase separation modes can be employed. Supports with different separation mechanisms, such as ion exchange, size exclusion, gel-permeation chromatography, etc. can be used in HPLC.

Separation in ion-exchange HPLC is based on the interaction of the charged solute with the oppositely charged surface of the stationary phase. Ion-exchange chromatography has been increasing in popularity for the separation of inorganic species. Size-exclusion chromatography (SEC) is a common name for liquid-chromatographic methods that separate analytes based on their effective shape and bulkiness at relatively low pressures. SEC methods can be differentiated according to the character of the mobile phase.

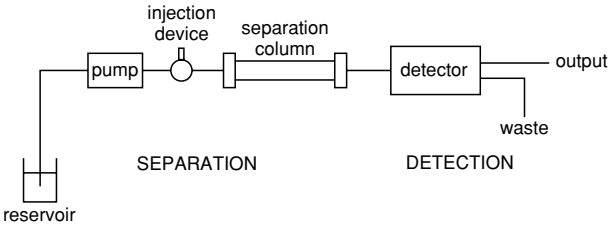

Figure 5 Schematic diagram of a typical HPLC system.

Gel-permeation chromatography (GPC) uses organic mobile phases, and gel-filtration chromatography (GFC) uses aqueous phases. The stationary phases applied in this separation mode are porous particles with closely controlled pore sizes. The molecules of the solute may be able to enter the pores of the particles of the stationary, depending on their size and shape. The choice of a mobile phase for this separation mode is simpler than for other HPLC techniques, because generally, only one solvent is required. HPLC systems can be divided into two different parts: one part is for separation, and the other part is for detection, including one or more detectors and a signal output device (Figure 5). The part of the HPLC responsible for separation consists of an injection device, a column, and the mobile-phase delivery system.

Injectors There are several approaches to injection, using a combination of a septum and syringe or valve injection.

Columns The stationary phases for adsorption HPLC are silica, alumina, porous graphitized carbon, porous glass, etc., the mobile phase generally being a mixture of relatively nonpolar organic solvents. The RP mode requires the combination of a polar mobile phase and a nonpolar stationary phase. Similar to TLC, mainly silica with hydrophobic ligands covalently bonded to the surface have been used as the stationary phase. The RP technique is popular because of the reproducibility associated with the use of the hydrocarbon-bonded phase. Octyl- and octadecyl-bonded silica stationary phases are relatively stable, with most aqueous eluents having a pH value below 8. RP HPLC uses less toxic solvents (water and an organic modifier miscible with water), thus causing less environmental pollution. Typical organic modifiers are methanol and acetonitrile.

The mobile-phase delivery system includes a pump with a filter, a degasser and transfer tubing. The pump delivers the mobile phase into the separation system with a constant, precise, and reproducible flow rate. Two different types of elution modes are used in

HPLC: isocratic and gradient elution. The isocratic elution mode uses a mobile phase of constant composition. The composition of the mobile phase is changed according to a predetermined program in gradient elution. The degasser removes the residue of gases from the mobile phase. Gases can form bubbles in the mobile phase, impairing separation and sometimes precluding the reliable detection of analytes.

Detectors The ideal HPL detector has a high sensitivity, a universal or specific response, a wide linear dynamic range, and a stable response with temperature and flow rate. The most commonly used detectors in HPLC are: ultraviolet-visible (UV-vis), fluorescence, refractive index, and electrochemical detectors.

The characteristic chromatographic parameters (separation factor, resolution, theoretical plate number) in HPLC can be calculated in the same way as in gas chromatography. (*See* **Chromatography**: High-performance Liquid Chromatography.)

Supercritical Fluid Chromatography

Principle

Supercritical fluid chromatography encompasses all chromatographic methods in which the mobile phase is supercritical under the conditions of analysis, with the solvating properties of the fluid having a measurable effect on the separation. The physical state of these conditions are illustrated in Figure 6 for CO_2, the most commonly used supercritical solvent. SFC has several advantages over GC and HPLC: it extends the molecular-weight range of GC, thermally labile compounds can be separated at lower temperatures, compounds without chromophores can be sensitively detected, and the use of open-tubular and packed columns is feasible. Figure 7 shows a schematic layout of a SFC system.

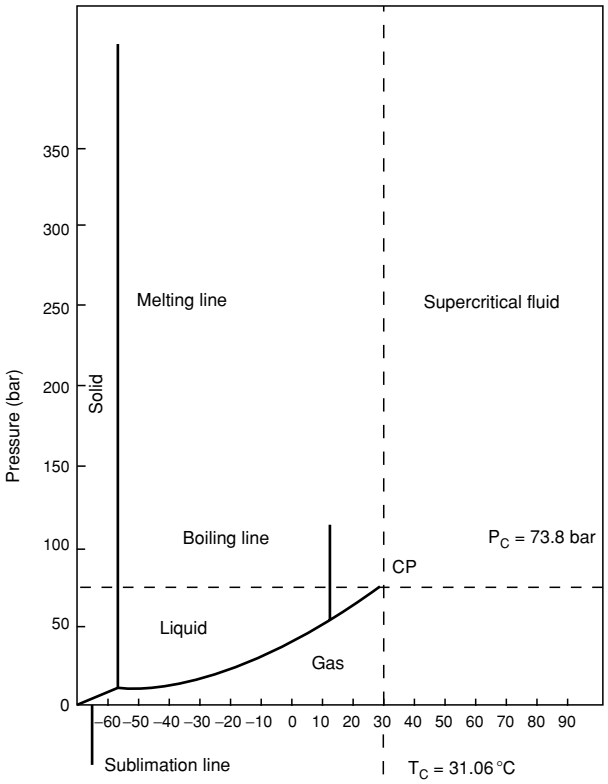

Figure 6 Phase diagram (pressure–temperature) for CO_2.

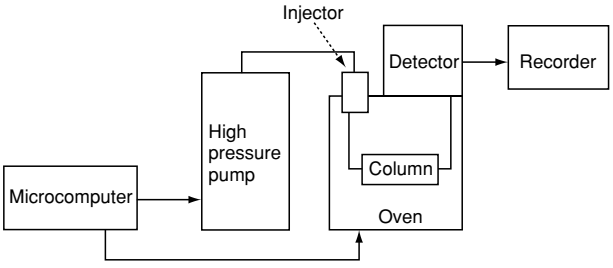

Figure 7 Schematic diagram of a SFC system.

Injectors

The most common injectors in SFC are high-pressure valve injectors similar to those used in HPLC. The method used for injection for open tubular columns is split injection. Several split-injection methods have been employed, dynamic flow split being the simplest and most popular.

Columns

Open-tubular coated capillaries (50–100 μm internal diameter (ID)), packed capillaries (100–500 μm ID), and packed columns (1–4.6 mm ID) have been used for SFC. Many types of stationary phases developed for either GC or HPLC have been adopted for use in SFC.

The separation process in SFC can be influenced by changing the pressure or the density (pressure or density programming). The programmed addition of mobile phase modifiers can also be used to change the solute retention. The mobile phase travels from the pump to the heated zone, where it becomes supercritical, and then to the injector and column.

Detectors

A major advantage of SFC over GC and HPLC is that SFC is 'detector-friendly.' Both HPLC and GC

detectors can be successfully interfaced to SFC. The most frequently used SFC detectors are flame ionization, electron capture, ultraviolet, and mass-spectrometric detectors. (*See* **Chromatography**: Supercritical Fluid Chromatography.)

Fundamentals

Carbon dioxide with or without a modifier is the mobile phase used preferentially in SFC. CO_2 is often used as the mobile phase in SFC, possibly because its physicochemical characteristics can be changed easily under moderate temperature and pressure conditions. The retention of solutes can be changed by an order of magnitude by increasing the fluid density during density programming.

The chromatographic parameters (separation factor, resolution, theoretical plate number, etc.) in SFC can be calculated in a similar way to that in GC.

Capillary Electrophoresis

Principle

Separation is based on the different electromigration velocities of ionic solutes under the influence of a high voltage in narrow-bore capillaries. The use of a capillary has numerous advantages, particularly with respect to the detrimental effects of Joule heating. The high electrical resistance of the capillary enables very high electrical fields (100–500 $\mathrm{V\,cm^{-1}}$) to be used, with only minimal heat generation. Moreover, the large surface area-to-volume ratio of the capillary efficiently dissipates any heat that is generated. The separation efficiency, which is often in excess of 10^5 theoretical plates number, is due in part to the plug profile of the electroosmotic flow, an electrophoretic phenomenon that generates the bulk flow of the solution within the capillary. This flow also enables the simultaneous analysis of all solutes, regardless of charge. The ideal properties of the capillary material are its chemical and electrical inertness, UV-visible transparency, flexibility, and low cost.

CE is characterized by its simple experimental setup. A schematic diagram of a basic CE instrument is shown in Figure 8. Both ends of a capillary filled with buffer are dipped into two buffer reservoirs that are maintained at the same level. A high voltage is then applied to this capillary.

Various modes of capillary electrophoresis can be performed using the same intruments, including capillary zone electrophoresis (CZE), capillary gel electrophoresis (CGE), micellar electrokinetic capillary chromatography (MEKC), capillary isoelectring focusing, and capillary isotachophoresis. Figure 9 shows the different modes of capillary electrophoresis. MEKC is the second most popular CE separation technique (after CZE), because it can separate neutral analytes too. A surfactant above its critical micellar concentration is added to the background electrolyte. Solutes with varying degrees of hydrophobicities partition between the hydrophobic core of the micelles and aqueous buffer. The interaction between the micelle and the neutral solutes leads to separation. The separation mechanism of neutral solutes in MEKC can be described using modified chromatographic relationships. The ratio of the total number of moles of solute in the micelle (that is in the pseudostationary phase) to those in the mobile phase, the capacity factor k', is given by:

$$k' = (t_r - t_0)/[t_0(1 - t_r/t_m)] = K(V_s/V_m), \qquad (8)$$

where t_r is the retention time of the solute, t_0 is the retention time of unretained solute moving at the EOF rate, t_m is the micelle retention time, K is the partition coefficient, V_s is the volume of the micellar phase, and V_m is the volume of the mobile phase.

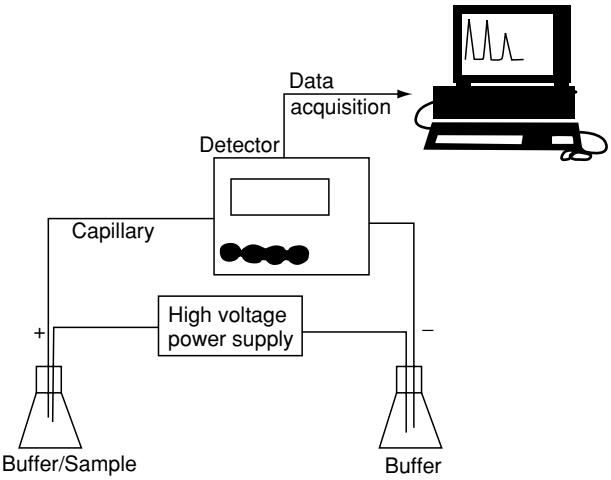

Figure 8 Schematic diagram of a CE system.

Injectors

Two different injection modes can be used: hydrodynamic and electrokinetic injections. With hydrodynamic injection, a pressure difference is applied for a short period of time between the two ends of the capillary. A pressure difference can be introduced, depending on the design of the instrument, by pressure, vacuum, or simply the height difference between the levels of the buffer and sample reservoirs. Electrokinetic injection is performed by replacing the injection-end reservoir with the sample vial and applying the voltage.

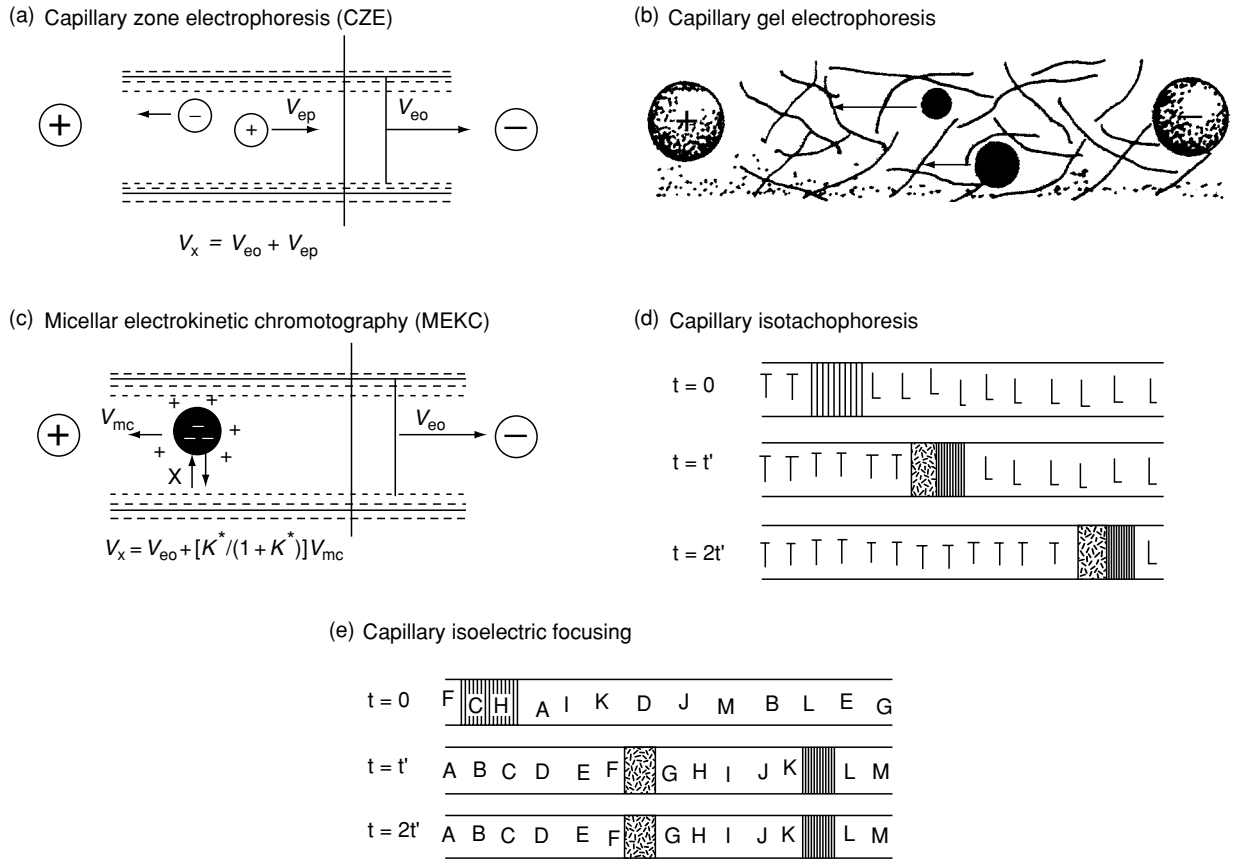

Figure 9 Different modes of capillary electrophoresis. In (a), V_x is the electromigration velocity, and V_{eo} is the electroosmotic velocity. In (b), there are obstructing strands of gel, and large ions move more slowly through the pores than the small ions. In (c), V_x is the electromigration velocity of the solute, V_{eo} is the electroosmotic velocity, V_{mc} is the migration velocity of the micelle, and K^* is the phase capacity ratio. In (d), L is the leading electrolyte, and T is the terminating electrolyte.

Detection

Detection is generally carried out by measuring the ultraviolet or visible absorbance at the end of the capillary. Other detection systems such as laser-induced fluorescence, mass spectrometry, and conductivity detection have also been employed.

Fundamentals

The basic phenomena in capillary electrophoresis are electroosmotic flow (EOF) and electrophoretic flow (μ_{ep}). Electroosmotic flow is bulk flow of a solvent in a capillary under an applied potential. Electrophoretic flow is the flow of ions due to a certain charge, with cations being attracted to the cathode and anions being attracted to the anode.

The magnitude of the EOF can expressed by

$$\mu_{EOF} = (\varepsilon \cdot \zeta)/\eta, \qquad (9)$$

where μ_{EOF} = EOF mobility; ε = dielectric constant; ζ = zeta potential; η = bulk viscosity.

According to eqn (9), the mobility is independent of the applied electric field. The zeta potential is essentially determined by the surface charge on the capillary wall. Since it is strongly pH-dependent, the magnitude of the EOF varies with pH. Depending on the specific conditions, the EOF can vary by more than an order of magnitude between pH 2 and 12. The zeta potential is also dependent on the ionic strength of the buffer.

The separation parameters of capillary electrophoresis can be described in similar terms to those for GC and HPLC.

The time required for a solute to migrate to the point of detection is called the migration time, and is given by the quotient of migration and velocity. The migration time and other experimental parameters can be used to calculate the apparent solute mobility, using

$$\mu_a = 1/tE = 1L/tV \qquad (10)$$

and

$$\mu_a = \mu_e + \mu_{EOF}, \qquad (11)$$

where l is the effective capillary length (to the detector), L is the total length, t is the migration time, and E is the electric field. In the presence of EOF, the measured mobility is called the apparent mobility (μ_a). The effective mobility (μ_e) can be calculated from the apparent mobility by independently measuring the EOF using a neutral marker that moves at a velocity equal to the EOF.

Thin-layer Chromatography

D R Tocher, University of Stirling, Stirling, UK

Introduction

Thin-layer chromatography (TLC) is a type of liquid chromatography performed on a stationary phase in the form of a thin layer usually on a glass, plastic, or aluminum support. A solution of sample is applied as a small spot or narrow band to the thin layer of adsorbent that has been spread uniformly over the support. The mobile phase (a solvent mixture) then passes through the adsorbent by capillary action, and the sample is resolved into discrete components. The separated components are then located by either physical methods or chemical staining reagents after the solvent has evaporated. Quantitation by methods such as densitometry may also then be possible, depending upon the precise conditions utilized. Although high-performance liquid chromatography (HPLC) and gas chromatography (GC) are often regarded as superior, especially with regard to quantitation, TLC has many advantages including low capital costs, simplicity of operation, the availability of many sensitive and selective reagents for detection and confirmation without interference of the mobile phase, and in-system calibration for quantitative analysis. Therefore, TLC should be regarded as highly complementary to the other techniques and particularly suited to low-cost screening of many samples.

Apparatus

TLC is very cost-effective as the basic apparatus required is simple and relatively cheap, and many samples can be analyzed on a single plate with low solvent usage. However, more sophisticated and expensive apparatus are available particularly for automated sample application and quantitation.

Adsorbents and Supports

The predominant adsorbent used in TLC is silicic acid, a partially hydrated silicon dioxide, often termed silica gel, but others are also available, including cellulose, aluminum oxide, celite (kieselguhr), magnesium oxide, and zeolites. Modified versions of these include C_8- or C_{18}- (reverse-phase) and 3-aminopropyl-silica gel, polyamide- and polyethylene imine (PEI)-cellulose. The particle size of the adsorbents is usually in the range 1–25 μm.

TLC plates were often made in the laboratory using specific apparatus. However, home-made plates could be variable, and commercially produced precoated plates, which are available in various sizes and supports with almost every adsorbent, are now the first choice due to their much greater reproducibility and consistent quality. Adherence of the adsorbent to the support is often enhanced in precoated plates by the inclusion of binders such as calcium phosphate ($\sim$10% w/w) or organic binders like polyacrylic acid.

Silica gel is the most commonly employed adsorbent in TLC, particularly that with a pore size of 6 nm. Precoated analytical plates frequently use silica gel of particle size 10–12 μm coated in a layer of 0.25 mm thickness. Plates coated with this type of silica provide 1000–2000 theoretical plates per 5 cm of migration. Modern high-performance TLC (HPTLC) uses silica gel of particle size 5–7 μm in layers of 0.20 mm thickness. The reduced particle size provides 5000–10 000 theoretical plates per 5 cm of migration distance and increases the separation efficiency. In comparison with conventional TLC, HPTLC is a more efficient, instrumentalized, and quantitative method. The narrower particle size distribution, thinner layers, and shorter development distances of HPTLC lead to a greater separation efficiency, faster separations, and enhanced sensitivity through improved detection limits such that quantitative HPTLC can produce results comparable with GC and HPLC when optimally performed. HPTLC plates cannot be prepared easily in the laboratory and are usually purchased ready-made.

The adsorption properties of silica gel can be modified by impregnation with various complexing reagents, including silver nitrate, urea, boric acid, oxalic acid, and ethylenediaminetetraacetic acid (EDTA) to aid the separation of particular classes of compounds. Reverse-phase plates can be produced by using silanized silica gel in which the surface silanol groups of the silica are silylated with chlorosilanes. Silanized silica has a low carrying capacity that can be increased by impregnating the silanized silica plates with hexadecane or paraffin oil. It is now more common to utilize ready-made reverse-phase plates with C_2, C_8, or C_{18} hydrocarbon chains, or diphenyl groups chemically bonded to the silica. Aminopropyl bonded silica gel plates are also available. Kieselguhr or celite, a diatomous earth, is used less often than synthetic silica gel on account of its natural variability. Other adsorbents include cellulose and its derivatives, such as diethylaminoethyl (DEAE)-cellulose for ion-exchange chromatography, magnesium oxide, and alumina (aluminum hydroxide), which is manufactured in three types, acidic, basic, and neutral, according to its pH.

Glass is the support employed most commonly for adsorbents on grounds of rigidity, flatness, and inertness. Layers of adsorbents can also be obtained precoated on flexible aluminum or plastic (polyester) sheets, which have the advantage of being able to be cut to smaller size, but care must be taken in insuring their compatibility with solvent systems and subsequent detection reagents. The standard sizes of TLC and HPTLC plates are 20×20 cm and 10×10 cm, respectively, although other sizes such as 10×20 cm are available (Figure 1).

Sample Applicators and Development Chambers

The application of the sample solution to the adsorbent layer is usually performed manually using microsyringes or disposable glass capillaries. However, a wide range of instruments, including microprocessor-controlled instruments, are available for the automated application of samples either as spots or streaks. Rectangular glass chambers with lids are usually employed for the linear development of chromatograms in solvent mixtures. Sizes are available for standard 20×20 cm plates and 10×10

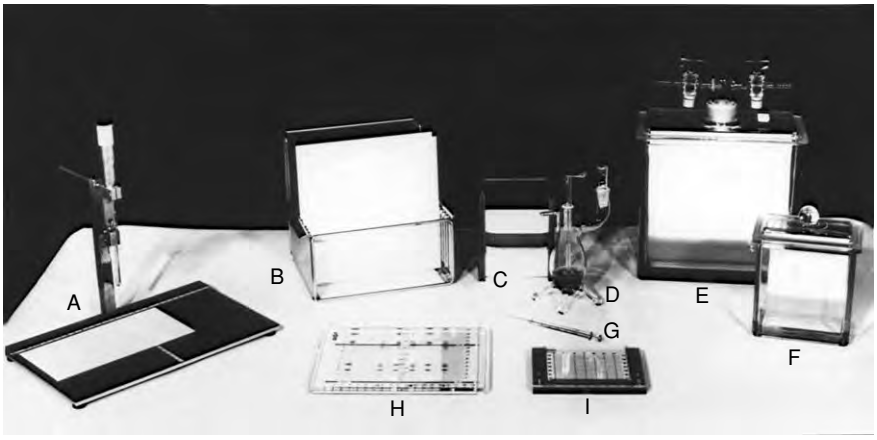

Figure 1 Typical apparatus used in TLC. (**A**) Applicator with micrometer-controlled syringe containing 10×20 cm HPTLC plate; (**B**) drying/storage rack containing standard 20×20 cm TLC plates; (**C**) 10×10 cm HPTLC plates in drying/storage rack; (**D**) atomizer for spraying plates; (**E**) 20×20 cm TLC plate being developed in a standard chamber; (**F**) 10×10 cm HPTLC plate being developed in HPTLC chamber; (**G**) glass microsyringe; (**H**) sample application template/R_f calculator overlayed on the standard plate; (**I**) HPTLC plate contained in the sample application template.

HPTLC plates. Chambers can be purchased with vertical grooves in the side and end walls to allow the simultaneous development of several plates (Figure 1).

Equipment for Detection and Quantification of Components

Atomizers operated by compressed air or hand bellows are required for spraying developed chromatograms evenly with detection reagents. An oven is necessary for heating plates sprayed with certain reagents. For the quantitation of separated components on developed chromatograms, modern computer-controlled scanning densitometers are available along with sophisticated software packages for evaluation and data storage. Densitometry is particularly useful for one-dimensional chromatography, but programs can be adapted for two-dimensional chromatograms. The location and quantitation of radiolabelled compounds can be achieved using specialized radioactivity detectors that can scan the whole chromatogram, although these instruments are rather expensive. However, less elaborate equipment is required for the location of radiolabelled compounds on chromatograms by autoradiography. Fluorography can be performed with similar equipment. New detection apparatus that may prove useful include the charge coupled device array detector for HPTLC and matrix-assisted laser desorption/ionization mass spectrometry.

Specialized Systems

Several techniques that rely on the same chromatographic principle as conventional TLC, but which require the use of specialized equipment, have been developed. The most durable of these specialized systems is probably TLC with flame ionization detection (TLC–FID), which was developed to ally the quantitative benefits of FID to TLC. In the 'Iatroscan' system, samples are applied to silica gel fused to thin quartz rods, which are then developed conventionally in mobile phase. After drying, the developed 'chromarods' are passed through a flame ionization detector to determine the mass of individual components by quantifying the amount of ionizable carbon. The 'Iatroscan' has been relatively successful, particularly in certain areas such as lipid metabolism. Another reasonably successful system is automated multiple development (AMD), which permits the multiple development of TLC plates in the same or different solvent systems. This repeated development of TLC plates can improve the resolution of components.

Other specialized systems have not had such a durable or widespread appeal but have had limited use. In over-pressured TLC (OPTLC), the TLC plate is held beneath a flexible membrane under hydrostatic pressure, and solvent is forced through the adsorbent using a pump. This system allows compounds to be eluted completely from the TLC plate for collection or detection using detectors normally associated with HPLC. Centrifugal TLC also involves the forced flow of solvent. In this case, solvent is fed into the center of a rapidly rotating TLC or HPTLC plate and is forced through the adsorbent by centrifugal force. In radial-development TLC, the sample is applied to the center of a plate and the solvent supplied through a hole in the plate via a wick that dips into a solvent reservoir. Another system allowed the application of solvent under pressure to HPTLC plates allowing very short development times. (*See* **Chromatography**: High-performance Liquid Chromatography.)

Methodology

Sample Application

In conventional TLC and HPTLC, the sample is applied as a small volume of solution on to the adsorbent near the bottom of the plate. The point of application is termed the origin. A maximum of about 80 or 10 μg for TLC and HPTLC, respectively, can be applied as a spot on adsorbent layers of silica gel G 0.20–0.25 mm thick. Samples can also be applied as a narrow streak along the origin. Standards are applied as separate spots on the same plate.

Development

The choice of solvent system depends on the components to be resolved and the type of adsorbent utilized (see Table 1). Regardless of the components, in conventional TLC, the solvent mixture is placed in the development chamber. In the case of solvent systems containing large proportions of polar solvents, the chamber can be lined with filter paper to aid saturation of the atmosphere. The plate is placed within the chamber so that the bottom edge is immersed in the solvent mixture, and the chamber is sealed with a lid (Figure 1). When the solvent has migrated to within 1 cm of the top edge of the plate, the plate is removed from the chamber. Although ascending chromatography, as described above, is the most common form of TLC, chromatograms can also be developed by descending chromatography using a wick to feed the solvent on to the adsorbent layer.

TLC plates can also be subjected to multiple development in which the plate is developed partially in one solvent system and removed from the

Table 1 Substances separated by selected one-dimensional TLC systems

Adsorbent	*Substances separated*	*Solvent system*[a]	*Detection reagent*
Alumina	*Alkaloids*	$CHCl_3$	Dragendorff reagent
	Amino acids (dicarboxylic)	2 M HAc	Ninhydrin
	Aromatic hydrocarbons	CCl_4	10% tetracyanoethylene in C_6H_6
	Carotenes	Hexane/C_6H_6/EtOH (100:100:1)	None required
	Food dyes (fat-soluble)	Hexane/EtAc (98:2)	None required
	Food dyes (water-soluble)	H_2O/EtOH/*n*-BuOH (1:1:5)	None required
	Neutral lipids	Hexane/Et_2O/HAc (94.5:5:0.5)	0.05% 2′,7′ dichlorofluorescein in MeOH
	Sterols	C_6H_6/EtOH (95:2)	10% phosphotungstic acid in 90% EtOH
	Steroids	$CHCl_3$/EtOH (99:1)	Anisaldehyde/H_2SO_4/HAc (1:2:100), UV
	Vitamins (fat-soluble)	Toluene	1.3% $FeCl_3$ in 2 M HCl/0.7% K_3FeCN_6 (1:1)
Cellulose	*Amino acids*	*n*-BuOH/Me_2CO/Et_2NH/H_2O (10:10:2:5)	Ninhydrin
	Antibiotics (water-soluble)	PrOH/pyridine/HAc/H_2O (15:10:3:12)	Ninhydrin
	Food dyes (fat-soluble)	*n*-PrOH/EtAc/H_2O (6:1:3)	None required
	Nucleotides	*n*-BuOH/Me_2CO/HAc/5% NH_4OH/H_2O (4.5:1.5:1:1:2)	20% $SbCl_5$ in CCl_4
	Nucleosides and free bases	H_2O	20% $SbCl_5$ in CCl_4
DEAE cellulose	*Amino acids*	*n*-BuOH/HAc/H_2O (4:1:5)	Ninhydrin
	Nucleotides	Isobutyric acid/NH_4OH/H_2O (33:1:16)	20% $SbCl_5$ in CCl_4
PEI cellulose	*Nucleotides*	0.25, 1.0, 1.6 M LiCl in H_2O (in successive developments)	20% $SbCl_5$ in CCl_4
Celite (Kieselguhr)	*Sugars*	EtAc/*iso*-PrOH/H_2O (130:57:23)	0.2% naphthoresorcinol in EtOH/10% H_3PO_4
	Oligosaccharides	*Iso*-PrOH/EtAc (65:35)	0.2% naphthoresorcinol in EtOH/10% H_3PO_4
	Food dyes (fat-soluble)	Cyclohexane	None required
Magnesium oxide	*Carotenoids*	Pet. ether/C_6H_6 (3:1) or pet. ether/Me_2CO (97:3)	None required
Polyamine	*Anthocyanins*	HAc/HCl/H_2O (10:1:3)	10% oxalic acid in Me_2CO/H_2O (1:1), UV
	Antioxidants	MeOH/Me_2CO/H_2O (6:1:3)	10% phosphomolybdic acid in EtOH
	Flavonoids	Me_2CO/95% EtOH/H_2O (2:1:2)	25% PbAc in basic aqueous solution
Sephadex	*Proteins*	0.5 M NaCl	1% naphthalene black in MeOH/H_2O/HAc (5:4:1)
Silica gel	*Alkaloids*	$CHCl_3$/Me_2CO/Et_2NH (5:4:1)	Dragendorf reagent
	Amino acids	*n*-BuOH/HAc/H_2O (4:1:1)	Ninhydrin
	Antibiotics		
	Macrolides	$CHCl_3$/MeOH/H_2O (80:20:2.5)	20% phosphomolybdic acid in EtOH
	Penicillins	Me_2CO/MeOH (1:1)	20% phosphomolybdic acid in EtOH
	Streptomycins	H_2O/Na citrate/citric acid (100:20:5)	20% phosphomolybdic acid in EtOH
	Tetracyclines	BuOH/HAc/H_2O (2:1:1)	20% phosphomolybdic acid in EtOH
	Antioxidants	$CHCl_3$	20% phosphomolybdic acid in EtOH
	Bile acids	Me_3pentane/*iso*-PrOH/HAc (60:20:0.5)	5% phosphomolybdic acid in EtOH/Et_2O (1:1)
	Food dyes (fat-soluble)	Hexane/Et_2O/HAc (70:30:1)	None required

chamber. After evaporation of solvent from the developed plate, the plate is developed fully or partially in another solvent system. Multiple developments enable improved resolution of components. Development of the chromatogram with the mobile phase in one direction only is known as one-dimensional TLC (Figure 2). In instances where one-dimensional TLC/HPTLC does not allow the complete resolution of all the components of a mixture, improved separation can be achieved with two-dimensional TLC/HPTLC. In this technique, the sample is applied as a spot at one corner and developed fully in one direction in the first solvent system. The plate is removed from the chamber and, after evaporation of the solvent, is then developed in a second solvent system in a direction at 90° to that of the first development (Figure 3).

Identification of Separated Components

Colored compounds are visible on developed chromatograms, but colorless compounds require detection by physical or chemical means. Detection by chemical means usually involves spraying the adsorbent layer of the developed chromatogram with a derivatizing reagent that reacts with the separated components to produce a colored derivative *in situ*. Nonspecific reagents such as sulfuric acid and iodine will detect a wide range of compounds. Specific reagents react with specific functional groups and will

only detect compounds containing the group, e.g., ninhydrin for amino groups. The use of specific reagents can be used as an aid to identification and characterization of components.

Physical methods of location commonly involve ultraviolet light. Commercial plates are available coated with adsorbents containing an indicator that absorbs light at 254 nm and reemits or fluoresces light at the green end of the spectrum. When separated on these plates, compounds that absorb ultraviolet light appear as dark spots on a green fluorescent background. Plates with adsorbents not containing fluorescent indicator can be sprayed with 2′,7′-dichlorofluorescein with similar results when viewed under ultraviolet light. Radiolabelled compounds can be located on TLC plates physically by autoradiography or *in situ* measurement of radioactivity using a radioscanner.

A useful aid to the identification of separated components is the R_f value, which is defined as the ratio of the distance traveled by the compound to the distance traveled by the solvent. Although the R_f value of a given compound in a defined mobile phase and adsorbent is very characteristic, many factors, including the thickness and moisture content of the adsorbent and development distance, affect the reproducibility of the value. For this reason, the R_f value is only an indication of the identity of a compound, and confirmation of identity should be obtained by other means. Identification of separated components can be aided by comparison with authentic standards run alongside the samples, if such standards are available, and by staining patterns to different reagents.

Quantification of Separated Components

Once located, it is often useful and necessary to quantify the components in a mixture, and this has been the most difficult aspect of TLC. However, various methods can be employed for the quantitation of separated components.

Areas of adsorbent that contain components can be scraped from the support and the compounds eluted from the adsorbent with suitable solvents. The recovered compounds can be estimated gravimetrically after evaporation of the solvent, or by using a

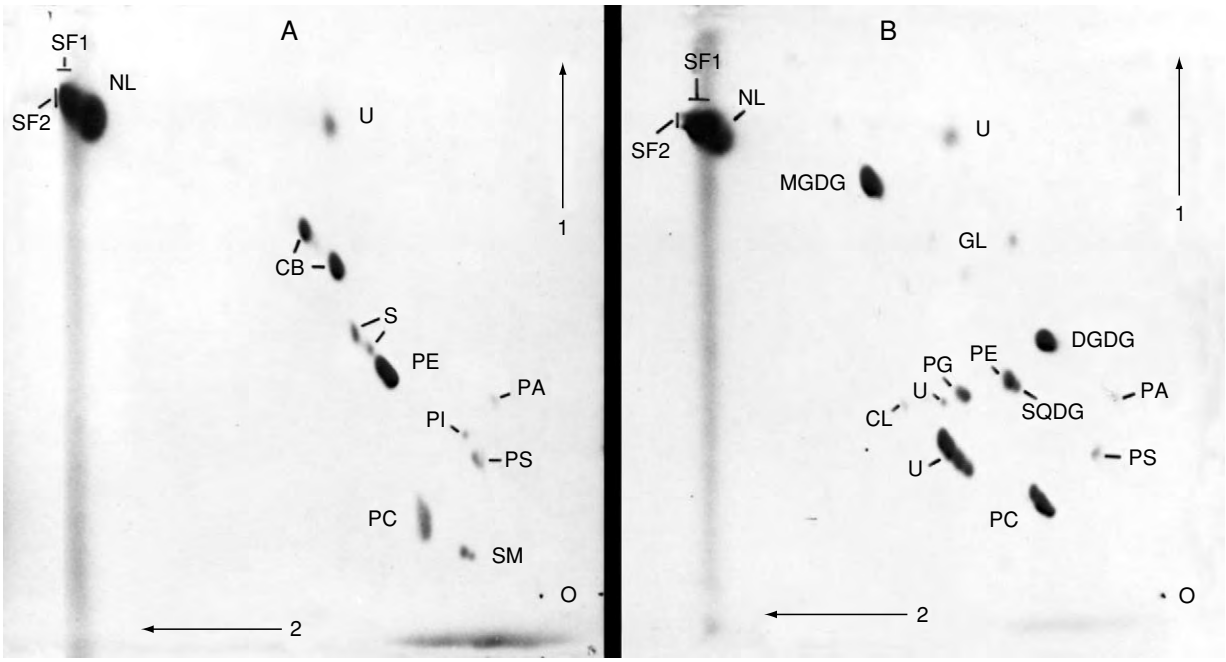

Figure 3 Two-dimensional HPTLC of total lipid from (**A**) rat brain and (**B**) the alga *C. salina*. Plates were first developed in direction 1 with MeAc/*iso*-PrOH/$CHCl_3$/MeOH/0.25% aqueous KCl (25:25:25:10:9, by volume) and then in direction 2 with $CHCl_3$/MeOH/7M NH_4OH (65:35:5, by volume). Developed chromatograms were stained by charring after spraying with 3% copper acetate in 8% orthophosphoric acid. Abbreviations: as in **Figure 2**.

specific assay such as the measurement of phosphorus or sugar content.

Developed chromatograms can be subjected to scanning densitometry and the separated components quantified on the basis of transmittance, reflectance intensity, or fluorescence, depending on the nature of the compounds and the detection reagent/stain used. Modern techniques of imaging in conjunction with sophisticated computer software packages for image analysis and data processing have increased the accuracy of these techniques. As well as locating radiolabeled compounds, radioscanners can also quantify the amount of radioactivity present in individual components. Alternatively, bands of adsorbent that contain compounds can be scraped from the support into scintillation vials and measured directly for radioactive content by liquid scintillation counting after addition of suitable scintillation fluid.

Preparative TLC

Although TLC is mostly used as an analytical technique, one-dimensional TLC can be scaled up to a preparative scale. To this end, sample can be applied as a streak across the origin of an analytical plate, the length of the streak being determined by the amount of sample. Special preparative TLC plates coated with thicker layers of adsorbent can be obtained, which can accommodate relatively large amounts of sample. However, these plates lack the resolving power of the analytical plates. After nondestructive visualization of the separated components, the bands of adsorbent containing the compound or compounds of interest are scraped from the support and eluted with suitable solvents.

Modes of Chromatography

TLC conforms to the basic principles of liquid chromatography. The most common mode of chromatography used in TLC is adsorption chromatography, although other modes of chromatography can be employed. With silica, celite, keiselghur, and cellulose, the mechanism is by adsorption chromatography if the adsorbent on the plate is completely free of water, and the solvent system is a nonpolar mixture. However, if water is present on the adsorbent or if the mobile phase contains a highly polar solvent, then separation will be by partition chromatography. In addition, reverse-phase TLC plates also separate by partition chromatography. TLC plates are also available precoated with reverse-phase silica gel that has been impregnated with a chiral reagent and copper ions. These can be used to separate optically active isomers, e.g., amino acids, by chiral chromatography on the basis of ligand exchange.

Alumina separates components by adsorption but, depending upon the nature of the surface and the solvent system, can also function as an ion exchanger.

Modified cellulose such as DEAE-cellulose can be used for ion-exchange separations on TLC. Separation by size-exclusion chromatography can be carried out with TLC plates coated with Sephadex gel but is slower and significantly more difficult than other forms of TLC. Polyamides such as polyhexamethylenediaminoadipate can be used as the adsorbent to separate components that interact with it by hydrogen bonding. (*See* **Chromatography**: Principles.)

Applications

The actual method employed for preparing samples from foodstuffs for analysis by TLC depends on the nature of the substances being investigated. Many methods involve the extraction of the food with a suitable solvent followed by precipitation and filtration steps to remove classes of compounds that are not of interest. (*See* **Analysis of Food**.)

The choice of adsorbent and solvent system used in TLC is dictated by the nature of the sample to be analyzed. Examples of broad groups of substances that have been successfully resolved by TLC methods are shown in Table 1, along with suggested solvent systems and detection reagents commonly used. However, for most substances, there can be a variety of different solvent systems and detection reagents that are suitable, depending on the precise composition of the samples to be resolved.

High-performance Liquid Chromatography

M V Moreno-Arribas and M C Polo, Instituto de Fermentaciones Industriales (CSIC), Madrid, Spain

Introduction

High-performance liquid chromatography (HPLC) is an instrumental form of liquid chromatography that employs stationary phases consisting of small particles, thereby achieving more efficient separations than those used in conventional liquid chromatography. Since its origin in the late 1960s, it has been known by several different names, including high-pressure liquid chromatography, because of the high pressures required to force the mobile phase or solvent through the stationary phase, and high-resolution liquid chromatography, because of the good resolution achieved using this technique.

This article describes the equipment needed to carry out HPLC and summarizes some of the applications of this technique in food analysis. Two techniques related to HPLC, fast-protein liquid chromatography (FPLC) and supercritical fluid chromatography (SFC), are also considered. The basic theory of the chromatographic process and the factors that affect separation efficiency are discussed in the section on Chromatography. (*See* **Chromatography**: Principles; Thin-layer Chromatography; High-performance Liquid Chromatography; Gas Chromatography; Supercritical Fluid Chromatography; Combined Chromatography and Mass Spectrometry.)

Separation Modes

There are many different stationary and mobile phases that can be used in HPLC, and for this reason there is a great variety of separation mechanisms. The treatises on HPLC use different criteria in their attempt to classify the modes of this technique: type of stationary phase, predominant separation mechanism, type of groups of compounds it is aimed at. These criteria sometimes overlap; that is to say, it is possible to work in several different chromatographic methods with the same stationary phase, and the same group of compounds can be separated using several different stationary phases, and for this reason it is not easy to classify HPLC techniques into specific groups. Generally speaking, it can be said that there are three large groups

that dominate the field of chromatographic separations: reversed-phase chromatography, ion exchange chromatography and size exclusion chromatography. There are also other types of chromatography that are rapidly gaining in importance and cannot be included exactly in any of these three groups: ion pair chromatography, affinity chromatography, and chiral separations.

Reversed-Phase Chromatography

This is the most commonly used method for chromatographic separations, so it could in fact be called 'normal-phase' except that it was developed later than the latter. In reversed-phase chromatography, the stationary phase is of a nonpolar nature and the mobile phase is more polar than the stationary one. Among the most widely used stationary phases are silica-based ones with cyano, phenyl, or alkyl functionality and those of a polymeric nature, above all polystyrene-divinylbenzene (PSDVB). The mobile phase is usually water with an organic modifier (methanol, acetonitrile, or tetrahydrofuran). Ternary or quaternary mixtures of these components can be used to improve selectivity.

There is controversy over the mechanism that controls reversed-phase separations. The three basic models are the partitioning model, the solvophobic effect, and the adsorption model. It is also necessary to consider the possibility that a mixed mechanism might exist.

In the partitioning mechanism it is accepted that the retention of a solute in reversed-phase liquid chromatography is due to its partitioning between the mobile phase and the stationary phase. This mechanism assumes that the stationary phase behaves in a similar way to a liquid, a situation that may occur in certain conditions, such as when working with monomeric phases and high percentages of water in the mobile phase, and the size of the hydrocarbonated chains is large enough for them to be associated. The adsorption mechanism accepts that retention takes place through the interaction of the solute to the organic molecules bonded to the surface of the packing matrix. The solvophobic effect theory accepts that the solute is expelled from the mobile phase towards the stationary phase.

Ion Exchange Chromatography

This is used for the analysis of electrically charged substances in working conditions. Stationary phases with electrically charged functional groups are used for this method of chromatography. The support can be silica or a polymer. The mobile phase contains a buffer which controls the loading of the solutes, and a salt that competes with the solutes in their interaction with the charges of the stationary phase. The charges permanently bonded to the chromatographic support are compensated by counterions, that is to say, by free ions with the opposite charge. Passage through the column of a sample or of the mobile phase with ions of the same sign as the counterions of the column may result in the displacement of the counterions and the retention of the ions of the sample or of the stationary phase.

The ion exchangers can be classified as cationics and anionics. Within each group it is possible to differentiate strong and weak exchangers. Strong cation exchangers (SCX) usually contain sulfonic groups, while weak ones have carboxylic groups. Quaternary ammonium salts are the most usual functional groups in strong anion exchangers (SAX), and primary amines are used in weak anion exchangers.

Size Exclusion Chromatography

This separation method is based on the size of the molecules. For many years it was known as gel permeation chromatography (GPC) or gel filtration chromatography (GFC). The retention of the molecules depends on their size: the larger molecules that do not enter the pores of the packing elute first, while the smaller molecules, whose diameter makes it possible for them to enter and exit the pores of the chromatographic packing, take a longer time.

Ion Pair Chromatography

This chromatographic method enables the separation of solutes that are ionized in separation conditions. On most occasions the separations are carried out on the same columns as those used in reversed-phase separations without the formation of ion pairs. The mobile phase is made up of a water buffer and an organic modifier, to which mixture is added a counterion with an opposite charge to that of the solute. Quaternary ammonium salts are often used as counterions for the analysis of anion substances, while *n*-alkyl sulfate salts are among the most commonly used for the analysis of cation substances.

Affinity Chromatography

This is based on the specific interaction between a molecule, or group of molecules, and a ligand, which is a molecule that is attached to the stationary phase to interact with those of the solute. The growing importance of affinity chromatography is due to the development of bioaffinity chromatography in which the interactions between ligands and molecules are based on recognitions of a biological type.

Chiral Separations

These can be approached mainly in two ways; by transforming enantiomers into chromatographically separable diasteroisomers, which does not necessitate the use of chiral phases, or by preparing chiral phases. Chiral phases can be obtained by covering the packings by making a solution pass through the column, or by ionic or covalent bonding of the chiral reagent with the column packing material.

Instrumental Configurations

The basic equipment consists of a column packed with a stationary phase, a driving force to propel the solvent through the column (pump), a system (injector) for introducing the sample on to the column, a system (detector) for measuring a physical property of the solutes being analyzed that differs from the properties of the solvent of a property of the mobile phase which is altered by the presence of the solute, and a system for recording the detector signals and converting them into graphic traces or chromatograms.

A single solvent is often used to carry out the separation (isocratic elution), but differing proportions of various solvents are also often used (gradient elution), in which case a gradient device is needed. A variety of accessories, such as pressure controllers, valves for switching solvents, valves for switching column, and ovens for heating the columns, are also commonly employed. Today most chromatographs are controlled by a computer, which is also used for data collection. This provides greater quality of quantitative data and enables automation of the system.

Solvents

The nature of the solvent will depend upon the mode of chromatographic separation employed, but a series of precautions that are common to all types of HPLC must be taken when preparing solvents. Because the columns have frits at the ends to hold the packing in place, the solvents must be devoid of particles and consequently must be filtered through membranes with a pore size of 0.5 μm or smaller, prior to use. Bubble formation must also be avoided, since bubbles may cause variations in the flow rate if they reach the pump or perturbations in the chromatogram if they reach or form in the detector cell. Solvents must therefore be degassed by immersing the bottle containing the solvent in an ultrasonic bath or by flushing the solvent with a stream of helium or nitrogen before delivering it to the chromatograph. A small stream of helium is commonly bubbled through the solvent during the chromatographic procedure to prevent uptake of air. To prevent bubble formation in the detector cell with depressurization, a restrictor is sometimes attached to the outlet of the detector cell.

Pumps

The pump is the system for delivering the solvent from the solvent reservoir to the column through the injector. Basically, two types of pumps are available: constant-pressure pumps and constant-flow-rate pumps. The latter are more frequently used in HPLC.

Constant-pressure pumps are less expensive and easy to operate, but the flow rate may vary with changes in the viscosity of the mobile phase caused by temperature fluctuations or by the accumulation of undissolved sample components in the column. These variations in flow rate affect retention times, and they may also affect resolution, increasing the difficulty of both qualitative and quantitative analysis.

Constant-flow-rate pumps afford the advantage of maintaining retention times irrespective of changes in solvent viscosity. This type of pump includes syringe pumps, which consist of a cylinder containing the mobile phase, which is expelled by a piston. The piston is driven by a motor, so as to supply a constant flow devoid of pulses. This type of pump can achieve relatively high pressures, but maintenance and changing solvents are complicated.

Reciprocating pumps, also a type of constant-flow-rate pump, are most commonly employed. Their price varies depending on their complexity of design, and their main drawback is that they generate pulses that may cause noise in the detector. Single-piston pumps are the least expensive and have a rotating eccentric cam, which drives the plunger, discharging the liquid through a one-way valve. Duplex pumps have two plungers driven by a single motor by means of a shared cam. This arrangement means that, while one of the plungers is in the discharge phase, the other is in the intake phase, thereby superimposing the two flow-rate profiles and considerably reducing pulsation. In this type of pump, delivery from the solvent reservoir is steepled and changing solvents is rapid.

Injectors

Introducing the sample on to the column is one of the most critical steps in HPLC. Ideally, the sample should reach the column in the form of a tiny droplet that does not undergo diffusion, which would broaden the chromatographic bandwidth and thus lower resolution.

Several methods are employed to deliver the sample on to the column. In on-column injectors the

sample is introduced through a syringe which traverses a septum and enables the desired quantity of sample to be deposited at the column inlet. In this method the mobile phase flows continuously through the column. The stop-flow injector is a variation of this type of injector. In this method the pump is stopped before the syringe is inserted in the injector, and injection is effected when column pressure has dropped to atmospheric pressure. The advantage of these injectors is that they are inexpensive and of simple construction, yet they do not lower efficiency. However, reproducibility is poor, they are not suitable for high working pressures, and they are complicated to operate.

Valve injectors are most commonly used. In these injectors the sample is delivered on to a pressurized column with no appreciable interruption in flow. The sample is deposited by a syringe into an external loop, the valve selector is turned, and the mobile phase passes through the loop on its way to the column. The valve thus has two positions, a load position and an injection position. High injection reproducibility can be achieved with these injectors. The band-broadening effect is comparable to or somewhat higher than that obtained using on-column syringe injectors. The drawback afforded by these injectors is that there is a split-second interruption in mobile-phase flow that may damage the column. To avoid this problem, a bypass may be attached, such that there is always a constant flow of mobile phase from the pump to the column.

Automatic injectors that are capable of running analyses on up to 100 samples without operator attention have been designed on the basis of the same mechanism as valve injectors. There are also injectors equipped with a system of valves connecting them to several columns, which enables columns to be switched without stopping the flow.

Columns

The columns most commonly utilized in HPLC consist of stainless-steel, plastic, or glass tubes, measuring 15–25 cm in length and packed with small-diameter particles (3–20 μm). Internal column diameter is normally between 2 and 5 mm.

The use of small-internal-diameter (microbore) columns has become increasingly important from the early 1980s; they are similar to the columns described above, but their internal diameter is between 0.5 and 2 mm, while they range in length from 10 to 25 cm. Packing particle size normally ranges from 3 to 5 μm. These columns are suitable for use when only small samples are available or when low solvent consumption is required.

The length of both conventional and microbore columns is mainly limited by the pressure needed to drive the solvent through the column, which is inversely proportional to the size of the particles used in the packing. Minimum column diameter is limited by column-wall effects that cause solute molecules flowing next to the wall to move more slowly than those flowing through the center of the column, resulting in an increase in chromatographic bandwidth.

Open capillary columns similar to those employed in gas chromatography are the most recent to have come into use. The column tube is made of glass and is 20–50 μm in diameter and several meters long. The stationary phase is chemically bonded to the wall of the tube. Capillary columns are also prepared by packing a tube with particles 5–30 μm in size and subsequently heating and drawing the tube to an internal diameter of 50–125 μm.

In addition to the column on which the separation is carried out, two other types of column are also utilized in HPLC to protect the analytical column. These are precolumns and guard columns. Precolumns are placed between the pump and the injector to saturate the mobile phase with the stationary phase and thus prevent dissolution of the stationary phase in the analytical column. Guard columns are placed between the injector and the main column in order to retain components in the sample that might otherwise become permanently adsorbed on the analytical column, thereby affecting column efficiency and permeability. Both precolumns and guard columns are normally made of a material similar to that used in the analytical column.

Chromatography is customarily performed at ambient temperature, but it may be necessary to regulate the column temperature or to carry out the separation at a temperature other than room temperature. In such cases thermostat-equipped compartments (ovens) and systems for heating or cooling the columns are required.

Detectors

In order to be suitable for use in HPLC, detectors must meet a number of requirements. First and foremost, detector design must prevent broadening of chromatographic bandwidth to insure that the separations achieved on the column do not deteriorate in the detector. In addition, response time must be short and the response must be linear over a sufficiently broad range of concentrations.

The detectors most frequently employed are the refractive index detector, the photometric detector, and the fluorescence detector.

Refractive index detectors measure the difference between the refractive index of the mobile phase and that of the column eluate. They are universal detectors that are highly sensitive to small changes in the mobile phase and even to small variations in temperature or pressure. This sensitivity means that to achieve a suitable signal-to-noise ratio they are only capable of detecting solute concentrations in the order of micromoles. In addition, they are unsuitable for working with gradient conditions.

Photometric detectors measure absorbance in the ultraviolet (UV) or visible regions of all the components in the column eluate. They are less universal than refractive index detectors but by the same token are more specific. This type of detector is normally capable of detecting nanomoles, provided that the compound contains a strong chromophore. The three types of photometric detector most frequently used are fixed-wavelength detectors, variable-wavelength detectors, and diode array detectors. This last type of detector is capable of performing complete spectral analysis of the column eluate on a continuous basis, i.e., without stopping the flow.

Fluorimeter detectors are more specific and more sensitive than photometric detectors, but their linear range is smaller. Detection limits are in the order of picomoles for suitably fluorescent compounds, and they are very useful in trace component analysis.

Electrochemical detectors are also widely employed in HPLC. These come in two types: amperometric and conductometric detectors. Amperometric detectors are highly sensitive but are only applicable to analyses that can be oxidized or reduced; conductometric detectors are moderately sensitive and are applicable for detecting anions and cations. This type of detector is the detector most commonly used in ion exchange chromatography.

Derivatization of the components being analyzed may sometimes be employed to increase the detection limit or specificity.

Mass spectrometry (MS) is being used more and more as an online detection system in HPLC. The use of HPLC-MS coupling has spread since 1980 due to the improvements introduced in the different types of interface used. Several coupled MS-HPLC systems are available commercially, and improvements are continually being introduced in existing equipment. At the same time, new equipment is appearing all the time. MS has been considered to be the ideal detector, since it furnishes information on component structure. Microbore HPLC is particularly useful for online HPLC-MS, which requires low sample volumes. MS in combination with HPLC may become a standard technique in a few years' time. (*See* **Mass Spectrometry**: Principles and Instrumentation.)

Selected Applications

The use of HPLC in food analysis is growing daily, and it is now routinely applied in many laboratories. The many different types of columns and detectors that are currently available commercially make it possible to apply HPLC in analyzing nearly all the nonvolatile components in foods, be they present naturally or added artificially. The techniques employed for certain groups of food components are summarized below by way of example.

Carbohydrates

Nearly all chromatographic modes may be used in separating carbohydrates. For example, ion exchange on strongly or weakly basic anionic resins or on cationic resins, and partition chromatography on ion exchange resins, on chemically bonded cyano, amino, propyl-amino, or combined amino-cyano phases, or on silica gel or gel permeation are all possible. Differential refractometry is the conventional detection system, although direct detection, using short UV wavelengths or by forming derivatives detectable at longer wavelengths or fluorescent derivatives, is also employed. (*See* **Carbohydrates**: Determination.)

Acids

A variety of chromatographic modes are also applied to this group of components. Certain workers have employed ion exchange chromatography on strongly acid cationic resins or strongly or weakly basic anionic resins. Reversed-phase chromatography and ion pair chromatography have also been used. Detection is carried out by refractometry, photometry using UV, or visible wavelengths, as in the case of carbohydrates. (*See* **Acids**: Properties and Determination.)

Amino Acids and Amines

Most separations of amino acids and amines are performed using reversed-phase chromatography of dansyl chloride, orthophthaldialdehyde (OPA), or phenyl dithioisocyanate derivatives. 9-Fluorenylmethyl chloroformate (FMOC) is a suitable reagent for the analysis of secondary amino acids. Detection is carried out by means of fluorescence or UV absorption. The derivatizing, highly fluorescent, reagent 6-aminoquinolyl-*N*-hydroxysuccinimidyl carbamate (AQC) reacts rapidly and easily with both primary and secondary amines and its use is currently spreading. (*See* **Amines**; **Amino Acids**: Determination.)

Peptides

Diverse techniques are used to separate peptides on account of the broad range of molecular weights

of these components. Conventional reversed-phase columns are applied for peptides with molecular weights of less than 3 kDa, while reversed-phase columns packed with particles with large pore sizes or size exclusion columns are used for larger peptides. Detection is performed at 214 nm. Figure 1 shows a chromatogram of the peptides with molecular weights higher and lower than 700 from a sparkling wine, as an example of this type of analysis. (*See* **Peptides**.)

Proteins

Practically all known modes have been used in the separation of proteins, e.g., separations based on molecule size (gel permeation chromatography), on charge (ion exchange chromatography), on hydrophobicity (reversed-phase chromatography and hydrophobic–interaction chromatography), and even combinations of these mechanisms. The combination of HPLC and MS analysis is commonly used for the sequence analysis of glycoproteins. Detection is carried out at 214 or 280 nm. (*See* **Protein**: Determination and Characterization.)

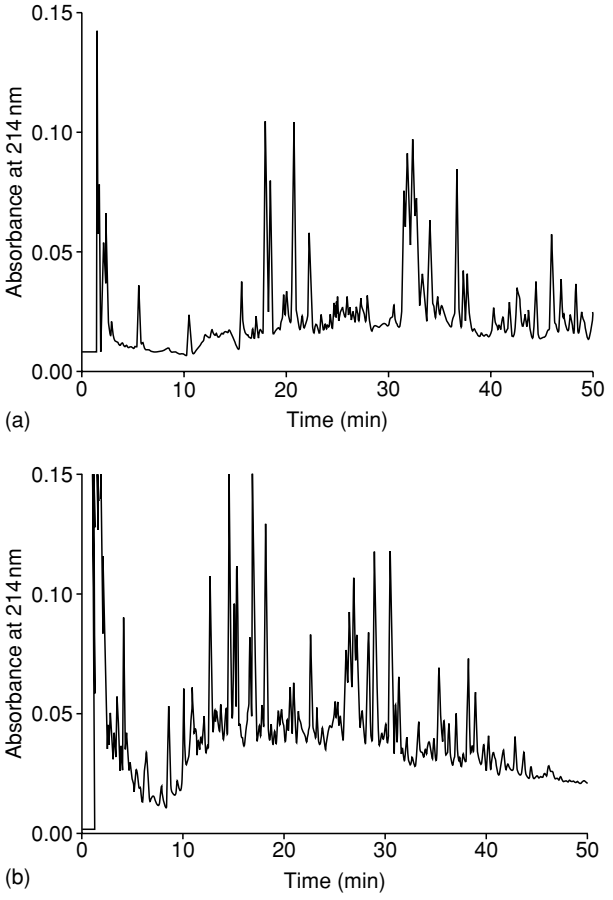

Figure 1 Chromatogram of peptides with molecular weights (a) higher and (b) lower than 700 Da from a sparkling wine. Column: Nova Pak C_{18}. Solvents: (a) TFA/water; (b) TFA/acetonitrile. Gradient elution. Detection at 214 nm. Other Compounds

In addition to the major groups of food components mentioned above, HPLC has found application in many other areas of food analysis, and details may be found in the relevant articles for the following compounds or groups of compounds: lipid components, phospholipids, triglycerides, vitamins, colors, pesticides, drug residues, polycyclic aromatic hydrocarbons, and nitrosamines. (*See* **Colorants (Colourants)**: Properties and Determination of Natural Pigments; Properties and Determinants of Synthetic Pigments; **Fatty Acids**: Analysis; **Nitrosamines**; **Pesticides and Herbicides**: Types, Uses, and Determination of Herbicides; **Phospholipids**: Determination; **Polycyclic Aromatic Hydrocarbons**; **Triglycerides**: Characterization and Determination; **Vitamins**: Determination.)

Related Techniques

FPLC designates a fast chromatographic method, developed by Pharmacia, which is similar to HPLC and yields high resolution. Since FPLC needs only a relatively low backpressure to drive the high flow rates at which the separations are performed, the risk of denaturation caused by shearing forces is reduced. Moreover, the mechanical components are resistant to corrosive buffers, and there is no contamination or inactivation or the components of interest.

Given the range of columns available in the market, a variety of separation modes can be applied using this technique: size exclusion, hydrophobic interaction, chromatofocusing, ion exchange, and reversed-phase chromatography.

This method was developed to separate and purify biomolecules and is very useful in separating isoenzymes and molecular species with similar charge characteristics. It is also used to distinguish between different types of meat or grains.

SFC is another technique, related to HPLC, which uses as the mobile phase a supercritical fluid, i.e., a fluid at a pressure and temperature above the critical point. The properties of supercritical fluids are intermediate between those of gases and those of liquid. Thanks to their higher diffusivity and lower viscosity as compared to liquids, high efficiencies are achievable with shorter analysis times than those customarily employed using HPLC.

The basic advantage of SFC with respect to gas chromatography (GC) is the possibility of analyzing

components that span a broad range of volatilities as well as heat-labile components. At the same time, SFC is also compatible with many of the detectors commonly used in GC or HPLC and SFC-MS coupling is easy to carry out.

The critical temperature of the supercritical fluids employed as the mobile phases between 0 °C and 200 °C and the critical pressure of these fluids should not be too high. Carbon dioxide, nitrous oxide, alkanes (such as *n*-pentane), and xenon, all of which are nonpolar, are most often used. Ammonia can be used to elute polar solutes, but mixtures of phases, e.g., a nonpolar mobile phase containing a small quantity of a polar organic solvent, known as a modifier are normally employed.

SFC can be performed on capillary, packed, and micropacked columns. Stationary phases should be cross-linked; otherwise the supercritical fluids, which are excellent solvents for polymers, could extract the stationary phase. Enantiomers can be resolved using chiral phases.

The equipment used in SFC is similar to that used in HPLC and basically consists of a high-pressure syringe pump, an injector, and a restrictor or post-column valve to keep the mobile phase in a supercritical condition inside the chromatographic column.

Fluid density is commonly programmed to adjust mobile-phase selectivity, in as much as the physicochemical properties of supercritical fluids (solvation strength, viscosity, diffusion) are all dependent upon density.

This method has been applied in food analysis (oils, cheeses, coffee, etc.) Some of the most interesting applications include separations of acids, alcohols, lipids, carbohydrates, vitamins, and terpenes. (*See* **Acids:** Properties and Determination; **Alcohol:** Properties and Determination; **Analysis of Food; Carbohydrates:** Determination; **Coffee:** Analysis of Coffee Products; **Vitamins:** Determination.)

Gas Chromatography

I Martínez-Castro, J Sanz and M V Dabrio, Instituto de Química Orgánica General (CSIC), Madrid, Spain

Background

Gas chromatography was born in 1951, when James and Martin developed a new separation technique in order to analyze a mixture of 17 fatty acids. This technique includes different chromatographic modes that use a gas as the mobile phase: the separation process takes place in a chromatographic column. Like other separation techniques, gas chromatography (GC) can be employed on the preparative scale, but more frequently, it is used as a powerful analytical technique.

Instrument

The analytical instrument consists of a mobile phase supply (usually a gas cylinder) regulated by a control system, a sample introduction system (usually called injector), a thermostatically controlled oven

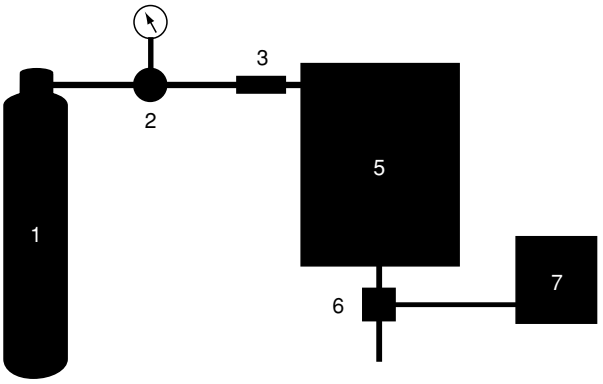

Figure 1 Scheme of a gas chromatograph. 1, gas cylinder; 2, pressure control system; 3, injector; 4, oven; 5, column; 6, detector; 7, recorder/data system.

containing the column, a detector, and a data-acquisition system (Figure 1).

Mobile Phase

The separation process is mainly based on the interaction of the analytes with the stationary phase; the mobile phase is called the 'carrier gas,' since its role is merely to transport the analytes through the column. Helium, nitrogen, hydrogen, and argon are usually employed as mobile phases. High-purity gases are necessary because traces of impurities, such as oxygen or water, can spoil the stationary phase or disturb the detector response. Helium is recommended to achieve faster separations, and nitrogen is a less expensive alternative, whereas the use of hydrogen requires special care.

Carrier gas pressure is between 5 and 700 kPa at the inlet (p_i), while the outlet pressure (p_o) is usually ambient pressure. The density, pressure, and velocity (u) of the carrier gas vary nonlinearly through the column, and it is necessary to specify at which column point they are measured or calculated. A factor that corrects for the mobile phase compressibility in the column can be calculated as:

$$j = \frac{3}{2}\frac{(p_i/p_o)^2 - 1}{(p_i/p_o)^3 - 1}. \quad (1)$$

The average linear carrier gas velocity can be obtained by dividing the column length (L) by the retention time of an unretained compound:

$$\overline{u} = L/t_M \quad (2)$$

t_M is called the 'hold-up time.'

The flow rate at the column outlet (F_c) can be easily measured and related to the average flow rate through $\overline{F} = jF_c$. It is also related to linear velocity:

$$\overline{F} = ku_o = k\frac{\overline{u}}{j}. \quad (3)$$

The retention time of a compound is defined as the length of time between sample injection and the emergence of the compound peak maximum. It is related to the volume of mobile phase entering the column during this time (V_R, retention volume) by the following equation:

$$t_R = V_R/F_c. \quad (4)$$

The net retention volume, V_N, takes into account the compression correction factor and the hold-up time:

$$V_N = jF_c(t_R - t_M). \quad (5)$$

The specific retention volume at the column temperature (V_g^θ) is the net retention volume per gram of stationary phase (W_S):

$$V_g^\theta = V_N/W_S. \quad (6)$$

The specific retention volume at 0 °C is:

$$V_g = \frac{V_N}{W_S}\frac{273.17}{T_c}. \quad (7)$$

The variation of efficiency with the carrier-gas velocity is described by the Van Deemter equation:

$$H = A + \frac{B}{u} + (C_S + C_M)u, \quad (8)$$

where C_S and C_M, respectively, represent the contribution of the stationary and mobile phases to the zone spreading caused by the resistance to mass transfer and other diffusion phenomena. When the column is an open capillary, Golay's equation can be used:

$$H = \frac{B}{u} + (C_S + C_M)u. \quad (9)$$

In most cases, C_S is negligible when compared with C_M.

Stationary Phase

Stationary phase type (solid or liquid) determines the two main gas chromatographic modes: gas–solid chromatography (GSC) and gas–liquid chromatography (GLC). System selectivity, which depends on the compounds to be separated and on the stationary phase, is estimated by the separation factor, α:

$$\alpha = V_{N2}/V_{N1} = (t_{R2} - t_M)/(t_{R1} - t_M). \quad (10)$$

Solid Phases

These consist of adsorbent particles; the separation mechanism is mainly physical adsorption. Since

sorption/desorption processes are usually faster than those of solution/vaporization (occurring in GLC), transfer kinetic constants are higher, and C_S values are lower in GSC, allowing better efficiencies. Selectivities can be high enough to separate stereoisomers and isotopes. Other characteristics of GSC are a wide temperature operation range, isotherms with a narrow linearity range, and high retention values. These characteristics make GSC the technique of choice for the separation of permanent gases and small polar molecules. Solid phases are formed by small particles of uniform size, with a high specific surface area. Commercial solid phases are based on silica (Spherosil, Porasil), graphitized carbon (Carbopack, Graphpac), or porous organic polymers (Porapak, Chromosorb Century series, Tenax).

Liquid Phases

These are usually inert and thermally stable polymeric molecules. When the stationary phase is a liquid, the main separation mechanism is partition, although other mechanisms like chirality, mesomerism, and complex formation may also contribute.

Partition Compounds dissolved in the liquid phase are in equilibrium (Henry's law) with the vapor; the elution order may be proportional to the boiling points or very different, depending on the activity coefficients.

Chiral interactions Enantiomer pairs always coelute when chromatographed on achiral phases. However, liquid phases possessing chiral groups can show a greater interaction with one of the pair members, which is then relatively more retained. As chiral interaction energies are small, α values are usually close to 1, and a high efficiency is required, such as that provided by capillary columns. Chiral phases are based on peptides, amide-substituted polysiloxanes, or substituted cyclodextrins.

Interactions with mesophases (liquid crystals) These are formed by elongated or planar molecules. In a temperature range from the melting point to the anisotropic transition, they are liquids ordered in a mono- or bidimensional orientation. These phases present a high selectivity for long or planar isomers.

Complex formation Organometallic compounds possessing metal ions are able to interact selectively with solutes having electron-donor groups.

Characteristics of liquid phases The liquids used as stationary phases have to be thermally stable over a wide temperature range. The lower limit is marked by the melting point, and the so-called maximum allowable operation temperature (MAOT) is determined by the increase in the detector signal caused either by an appreciable value of vapor pressure or by thermal degradation of the phase: in both cases, some molecules from the phase arrive continuously at the detector. The most important characteristic of a stationary phase is its polarity, which is usually defined by various empirical scales, the most popular being that of McReynolds, which uses as probes 10 solutes with different polar groups and a series of saturated, linear hydrocarbons. The molecular interactions are supposed to be additive and are described by several parameters (McReynolds constants) deduced from the retention observed in the studied phase and in squalane, which was defined as the zero on this polarity scale. Five McReynolds constants, which appear in most commercial catalogs, are directly related to phase polarity. Cross-linking improves the phase stability.

Table 1 shows some characteristics of the most commonly used liquid phases. Hydrocarbons (like squalane or apolane) are used to obtain reference data. Polysiloxanes (with methyl, phenyl, trifluoropropyl, or cyanoalkyl substituents, showing a wide polarity range) are commonly called 'silicones' and are nowadays the most popular liquid phases, since they have a good thermal stability and high permeability to solutes. Polyethylene glycols with different chain lengths (from a molecular weight of 150 to around 4.1×10^6) are another set of highly used phases.

Columns

Columns are usually classified as open or packed. Figure 2 shows a cross-section of the main types of columns.

In open columns, the stationary phase is distributed on the inner wall, and the mobile phase circulates through a central channel. Packed columns consist of a glass or metal tube packed with solid particles (100–250 μm), whose surface adsorbs the analyzed solutes (GSC) or is covered with a thin film of liquid stationary phase (GLC). Table 2 lists the main characteristics of the analytical columns.

Packed columns are mainly used for permanent gases analysis by GSC; they are cheap, robust, and easy to handle. The most frequently used GLC columns are open tubular and are usually referred to as 'capillary' since their diameter is very small. Since the system efficiency depends on the dimensions of the analytical columns, they should be chosen in order to achieve the desired resolution in the minimum time. Efficiency is always directly related to

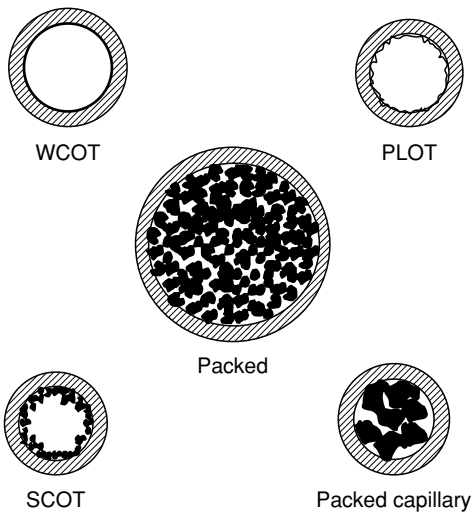

Figure 2 Cross-section of columns. PLOT, porous layer open tubular; SCOT, support-coated open tubular; WCOT, wall-coated open tubular. Adapted from Dabrio *et al*. (2000) *Cromatografia y electroforesis en columna*, p. 122. Barcelona: Springer with permission.

column length, as shown in eqn (2). The efficiency of a packed column is mainly related to the particle diameter, which appears in two terms (A and C_M) of the van Deemter equation (eqn (8)). Column diameter has a large influence on the efficiency of capillary columns, as Golay's equation (eqn (9)) shows. Open tubular capillary columns require more sophisticated equipment than packed columns, but their efficiency is very high, since it is possible to use very long columns with a moderate pressure drop (between 0.1 and 7 kg cm^{-2}).

Capillary columns with the inner wall covered by a porous layer open tubular (PLOT, Figure 2) or by a support-coated open tubular layer (SCOT, Figure 2), where the stationary phase is coated, have both a high sample load capacity and a high efficiency.

Operating Conditions

The flow rate and column temperature can be easily modified, enabling the best conditions to be selected for an adequate separation.

The *flow rate* is usually controlled through either a pressure regulator or a flow controller. According to eqn (4), t_R is inversely proportional to the flow rate for a given compound. A linear velocity of carrier gas close to the van Deemter optimum (eqn (8)) affords the best efficiency, but higher flow rates reduce the analysis time.

Temperature has a decisive influence on retention. When the temperature increases, V_R and t_R decrease (eqn (7)). The temperature operation should be selected in such a way that the retention factor (k) values lie between 1 and 15. When a mixture contains

compounds with very different volatilities, it is not possible to find an optimum temperature for separating all components. Since the oven temperature is easily controlled, it can be changed during the chromatographic run ('programmed') in such a way that each compound traverses the column within an optimum temperature range.

Sample Introduction

The objective of injection is to introduce the sample as a narrow band, whose composition should correspond closely to that of the original mixture. No universal system is available to handle all the different samples encountered. Permanent gases may be introduced with gas-tight syringes or using multiport valves. Liquid samples and solutions are usually introduced by microsyringe at the injection port, which is a heated chamber where the carrier gas enters under controlled flow or pressure. The sample is vaporized and transferred to the column inlet by the carrier gas stream. A schematic diagram of an injector is shown in Figure 3.

The chamber is provided with an inert glass or quartz liner to minimize sample contact with hot metallic surfaces. It is closed with a mechanical seal or, more usually, with an elastomer membrane called an septum, with can be pierced with a microsyringe to introduce the sample. Depending on the column dimensions, the quantity of sample can be varied from nanoliters to a few microliters, containing nanograms or micrograms of analytes. There are special devices capable of transferring several hundreds of microliters of very diluted samples, the solvent excess being discarded before it enters the analytical column.

Injection Modes

There are several different ways of injecting samples. The more common modes are detailed below.

Direct injection The sample is introduced through the septum in the hot injector, where the liquid

rapidly vaporizes; carrier gas sweeps the vapor into the column inlet.

Split injection This was designed for the introduction of samples into capillary columns. The basic design used for direct injection was modified as shown in Figure 3. The carrier gas, controlled by a pressure regulator or a combination of a flow controller and a back-pressure regulator, is divided into two streams: one is used to eliminate the possible impurities from the septum membrane; the other enters the vaporization chamber. This gas stream, after sweeping the vaporized sample, is split before it enters the column inlet to attain a high flow rate. The sample is also proportionally divided, so only a small part reaches the column. Since quantitative analysis presents some problems related to the split process, the use of internal standards is recommended.

Splitless injection When very dilute solutions need to be injected, the amount of sample entering the column can be increased, stopping the split process by using a solenoid valve. The split valve is closed, the sample is introduced, and after a controlled delay (usually 15–60 s), the split valve is opened again. Most of the sample enters the column while the split is closed, while the rest is purged out when the valve opens. Since the sample enters the column as a broad band, it is a necessary focusing step. Usually, the column is kept at a low temperature during injection, and sample vapors condense at the column inlet in a narrow band (*cryofocusing*); next, the temperature is raised in order to elute the solutes correctly. Sample solvent condensation can also be used (*solvent effect*) to retain the solutes as a narrow band at the column inlet.

Programmed temperature vaporizer (PTV) With the same basic design of a split/splitless detector, it can be heated and cooled very fast. The injector is cold when the sample is introduced and deposited on inert packing; then, the injector is heated to the desired temperature so that the vaporization is homogeneous, and sample discrimination is reduced.

On-column injection A liquid sample is deposited directly at the column head, without previous vaporization. The injectors are very simple, having a mechanical stop valve instead of a septum, and the microsyringes usually have very thin needles (less than 0.3 mm outer diameter). This system reduces the discrimination, thermal decomposition, and degradation of labile compounds. Its main drawback is possible column contamination with nonvolatile sample impurities.

External Sampling Devices

Pyrolysis A solid sample is thermally decomposed; the volatile fragments resulting from its breakdown can be chromatographically separated and detected, and their chromatographic pattern related to that of the original sample.

Headspace sampling The sample is thermostatized in a closed vial, and the vapor is sampled after equilibrium is attained. Usually, the process is automatic, under either atmospheric or high-pressure conditions, and the technique is frequently used for aroma analysis.

Purge and trap A stream of inert gas passes over or through the sample, and the stripped volatiles are trapped on a solid sorbent. These can be recovered either by a solvent or by thermal desorption (see below). The enrichment factors obtained are very high; matrix interferences are largely reduced. This technique is useful when very low concentrations of volatile substances have to be analyzed.

Thermal desorption The injector chamber can be ballistically heated to the desired temperature while it is purged with carrier gas. When a solid matrix is placed in this chamber, the volatile substances present are released and stripped towards the column; they can then be cryofocused before arriving at the column inlet. In the *direct* mode (DTD, direct thermal desorption), the solid matrix is a sample (e.g., a spice or a herb). In the *indirect* mode, volatiles have been previously stripped from the sample and trapped on an adsorbent.

Multidimensional Gas Chromatography

This usually refers to a combination of columns with different selectivity, where a small fraction from a complex sample is preseparated on the first column and introduced into the second column for further separation. Whereas the first column may be packed or may be a capillary, the second column is always a capillary and more selective. A special pneumatic switching arrangement is necessary in order to provide a sharp sample band.

Detectors

A high number of detectors have been designed for GC. The most frequently used detectors can be classified into four types.

Thermal Conductivity Detectors (TCD)

These are universal detectors, with a medium sensitivity, and are concentration-dependent. The column effluent passes through a chamber containing a hot filament. When a compound appears in the effluent, the thermal conductivity of the mixture solute/carrier gas, and hence the heat dissipation velocity, varies; this causes a temporal variation in filament temperature and a change in its electric resistance, which is very easy to measure. The best carrier gases for this detector are hydrogen and helium. TCD is appropriate for substances such as permanent gases, and can also be coupled in tandem with other detectors.

Ionization Detectors

These induce sample ionization by using thermal, chemical, electromagnetic, or radioactive energy. Solute ions in the carrier gas produce changes in the electric field between two electrodes. This is shown schematically in Figure 4.

Flame-ionization detectors These are the most commonly used detectors in GC and are almost universal, with a high sensitivity to organic carbon-containing compounds, a wide linear range, and an excellent baseline stability. They are also very reliable, with a negligible dead volume and a fast response time. The ionization energy is supplied by a flame, obtained by a hydrogen flow, which is mixed with the column effluent. The organic compounds are burnt, producing H_2O and CO_2; the response is proportional to the solute mass flow and is similar for most organic substances. Molecules with less C—H bonds than hydrocarbons give a lower response than hydrocarbons. These detectors can be used with all carrier gases and are easy to calibrate.

Electron capture detectors (ECD) These are very specific and sensitive to compounds with a high electron affinity. The ionization source is a foil (usually ^{63}Ni or ^{3}H), which emits β-radiation. Nitrogen and an argon/methane mixture are suitable carrier gases for ECD. A low potential is established between electrodes, producing a current that decreases when a solute capable of accepting ('capture') electrons appears in the effluent. The relative response is very different for compounds that have groups with different electronic affinities: e.g., a polychlorinated compound has a response 10^6 times higher than that of a saturated hydrocarbon. Thus, it is comparatively easy to detect less than 1 pg of polyhalogenated compounds in the presence of other molecules that have only C, H, and O atoms. Since the ECD response is dependent on the sample concentration and electron affinity of each analyte, calibration using standards is necessary for quantitative analysis.

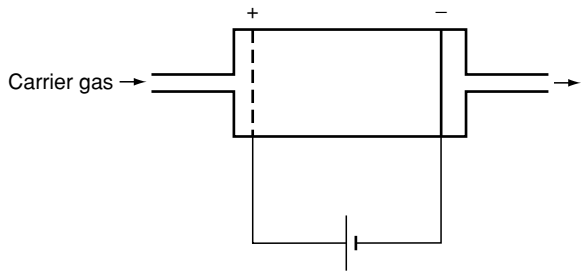

Figure 4 Scheme of an ionization detector.

Electrochemical Detectors

These are designed mainly for the environmental analysis of substances with heteroatoms like S, N, or halogens, and these detectors are very specific and sensitive.

Spectroscopic Detectors

Several spectroscopic devices can be coupled with GC in order to obtain structural information about the eluting peaks. The most commonly used detectors are those based on mass spectrometry (MS) (*See* **Chromatography**: Combined Chromatography and Mass Spectrometry; **Mass Spectrometry**: Applications; Principles and Instrumentation); and Fourier transform infrared (FTIR); *See* **Spectroscopy**: Infared and Raman.) The former have a high selectivity and sensitivity. The column effluent is continuously fed into the ionization chamber of a mass spectrometer, and a mass spectrum is recorded every few seconds. GC–MS coupling can be used in two modes: scan, in which all the ion fragments are collected and registered, giving structural information about all chromatographic peaks, and selected ion monitoring (SIM), in which only a few mass fragments are recorded, improving the signal-to-noise ratio and significantly reducing the detection limit.

Applications

GC has been used to analyze the main constituents of foods, such as lipids, carbohydrates, or amino acids, and it is especially useful in the study of minor constituents such as aromas or pollutants.

Food Constituents

Lipids GC has been the technique of choice for the study of fats. It is possible to study the degree of lipolysis by analyzing the free fatty acid (FFA) profile or the authenticity of fats and oils by determining the

glyceride fraction, the fatty acid composition, and the unsaponifiable fraction. FFAs can be studied using modified polar stationary phases, although fatty acids are usually determined as fatty acid methyl ester derivatives; these derivatives are volatile and easy to resolve on polar phases such as polyesters, polyethylene glycols and cyanoalkyl silicones. There is considerable interest in the separation of geometric isomers of unsaturated fatty acids: the use of very long capillary columns coated with cyanoalkyl silicones is the best choice. Direct analysis of triacylglycerols, initially problematic because of their low volatility, has improved since the development of fused silica capillary columns with a thin layer of stationary phase with high MAOT values; to date, very good separations have been reported, based on the number of carbon atoms and even on unsaturations. The injection of high-molecular-weight triacylglycerols requires the use of a cold-on column or PTV injection.

Carbohydrates GC is used to separate monosaccharides, disaccharides, and oligosaccharides. Although the preparation of volatile derivatives is necessary, the advantage that GC affords over HPLC is its greater sensitivity and higher resolution. The most popular derivatives are silyl ethers, oximes, methyl ethers, and acetates. Silicones ranging from methyl to cyanoalkyl are the preferred stationary phases. These methods have been used for juices, milk, molasses, honeys, and beverages.

Amino acids These have to be derivatized to achieve a sufficient volatility. The carboxylic group is usually esterified, and the amino group can be acylated or silylated.

Minor constituents Sterols are determined in order to assess food authenticity, especially with fats and oils, since the sterol composition is characteristic of each species. They can be analyzed, either as free sterols or as trimethyl silyl ethers, using packed columns (methyl or phenyl silicones), but they are better resolved on capillary columns. Naturally occurring wax esters (from C_{24} to C_{48}) have been analyzed using stable thin-film capillary columns.

Volatiles Volatile components are difficult to analyze because they are usually present as very complex mixtures at very low concentrations. Thus, the first requirement is the use of high-resolution columns: these are long, well-deactivated capillaries, coated with nonpolar (methyl or methyl vinyl silicones) or medium polar (polyethylene glycols) phases in order to elute hydrocarbons, alcohols, esters, pyrazines, aldehydes, acids, etc. High-resolution gas chromatography coupled with MS and sometimes with other spectrometric detectors like FTIR detectors allows the successful analysis of complex mixtures and the identification of many new compounds. A data-acquisition system is suitable for profile analysis and computer-based pattern recognition. A prior isolation and concentration step is usually necessary in order to suppress the matrix. Different off-line or on-line techniques can be used: these are based on extraction, static headspace, thermal desorption, and purge-and-trap devices.

Chiral compounds GC affords excellent separations of enantiomeric pairs, due to the high efficiency of capillary columns. Commercial columns are prepared with D- or L-valine *tert*-butylamide derivatives, metal complexes, or substituted cyclodextrins. They have been used to determine the racemization of amino acids, to detect adulterations in several food products by analyzing the enantiomeric purity of marker compounds, and to assess the aging or thermal processing of different foods.

Permanent gases CO_2 and SO_2, present in certain beverages or wines, can be determined using packed or SCOT columns and TCDs.

Pollutants

GC is the basic method used to detect and analyze the presence in foods of pollutant residues, such as pesticides, toxaphenes, polychlorinated biphenyls (PCBs), polycyclic aromatic hydrocarbons (PAHs), chlorinated solvents, polychlorodibenzodioxins (PCDDs), and polychlorodibenzofurans (PCDFs). Multiresidue procedures are used more frequently than specific methods. Analysis of these substances, which are present at p.p.b. or p.p.t. levels, requires several extraction, clean-up, and purification steps. High-purity solvents and reagents must be used, and glassware has to be cleaned with special care to avoid introducing new residues. High-efficiency capillary columns are recommended; this is especially true for PAHs, which can be resolved efficiently using liquid crystal phases, and for chiral PCBs. Selective detectors are required for all of these compounds. Chlorinated compounds are detected using ECDs; organophosphorus compounds are better detected using thermoionic or flame-photometer detection. MS detectors working in the SIM mode are useful for all pollutants. Those present at very low levels, such as PCDDs and PCDFs, require high-resolution MS or MS–MS systems to be selectively characterized. (*See* **Contamination of Food**; **Pesticides and Herbicides**: Residue Determination; **Pesticides and Herbicides**: Types of Pesticide.)

Other

GC allows analysis with very low detection limits of different substances such as illegal drugs used in cattle fattening, N-nitrosamines, residues in food deriving from plastic packaging, additives like antioxidants, preservatives, certain colorants, and other food ingredients

Supercritical Fluid Chromatography

J W King, Los Alamos National Laboratory, Los Alamos, NM, USA

Background

Supercritical fluids are unique substances that exhibit physical properties that are intermediate between those of a gas or liquid. Their density can be adjusted by regulating the pressure or temperature of the fluid, thereby allowing the fluid's density to range from that of a dilute gas to liquid-like values. Such a variation in density accounts for the adjustable, liquid-like properties that these fluids exhibit when used for extraction and for separation purposes. Mass transport properties of supercritical fluids (SFs) also exhibit values that are in between those of gases and liquids, but in general, properties like solute diffusion coefficients in SFs are more gas-like than liquid-like in magnitude. These favorable characteristics allow SFs to readily penetrate samples, thereby allowing for rapid dissolution and high flux rates of solutes into the SFs.

The supercritical fluid region is usually defined in the upper right region of a pressure and temperature phase diagram by a substance's critical points, the critical pressure (P_c) and critical temperature (T_c). This is shown in **Figure 1** for carbon dioxide (CO_2), the substance usually utilized in supercritical fluid extraction (SFE) and supercritical fluid chromatography (SFC). Above a pressure of 7.38 MPa (1070 psig) and a temperature of 31 °C, carbon dioxide will always be in its supercritical state (SC-CO_2) no matter what external pressure is applied to CO_2. This relatively low T_c, CO_2's high nonideality, and its relative environmentally benign nature, make CO_2 the fluid of choice for SFC and SFE.

The application of SFC to foods and nutritional analysis came about naturally owing in part to the early application of SC-CO_2 extraction in the food industry, i.e., for the extraction of coffee, hops, and similar food items used routinely by the consuming public. As will be demonstrated, SFC is particularly applicable for the analysis of lipid-containing

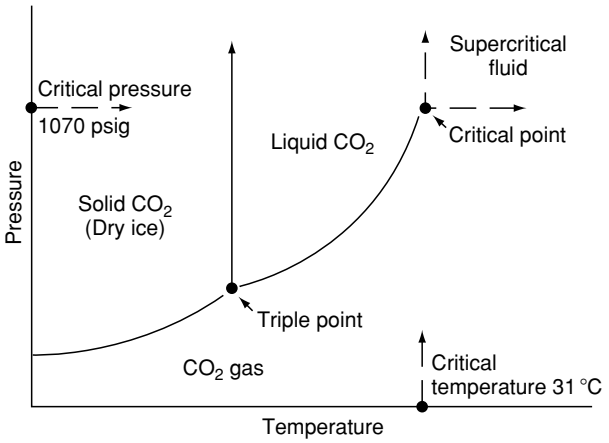

Figure 1 Pressure and temperature phase diagram for carbon dioxide.

materials, owing to relative high solubilities exhibited by these solutes (analytes) in SC-CO_2. Analysis and detection of ultratrace components in foodstuffs, e.g., pesticides or drugs, has not generally been successful owing to the problems in routinely interfacing and using sensitive detectors, such as the electron capture detector with SFC, owing to the change in mobile phase characteristics with respect to time during analysis. However, the ability to routinely use the flame ionization detector (FID) with SFC has provided the analyst with a useful technique to detect an array of components, or a specific moiety in a complex food matrix.

With respect to the chromatographic technique utilized, it was initially the capillary mode of SFC that was cited more often than packed column SFC for the analysis of foods. This has changed somewhat in recent years, however, particularly with the advent of using packed column SFC for the analysis of chiral compounds. This has created more opportunities for applying SFC using packed columns in food analysis, since a knowledge of the chirality of a compound can be of importance even in the food industry (e.g., flavor esters). Figure 2 shows the basic schematic for a capillary SFC (a) and a packed column SFC (b) instrument. The components making up the instrumentation for both modes of SFC are very similar: dual pumps for the SFs and cosolvent (or modifier), respectively; columns contained inside a thermostatted oven and detectors external to the oven. However, in the case of the capillary SFC, the fluid is depressurized directly into the detector, whereas in the packed column case, the detector is usually maintained under pressure, before it is discharged to waste (W). In the packed column mode, the SFC can be interfaced with a ultraviolet detector (UV), evaporative light-scattering detector (ELSD), or a mass spectrometer. In general, the coupling of analytical supercritical fluid extraction (SFE), on-line with SFC, has not been adopted to any considerable extent by food analysts, owing to the lack of an interface that permits routine coupling for use of the SFE/SFC mode. However, preparative and production-scale SFC have been utilized for specialized applications in the food-production industries and will probably see increased use owing to the current interest in producing high-value nutraceutical components, in a 'natural' and environmentally benign manner.

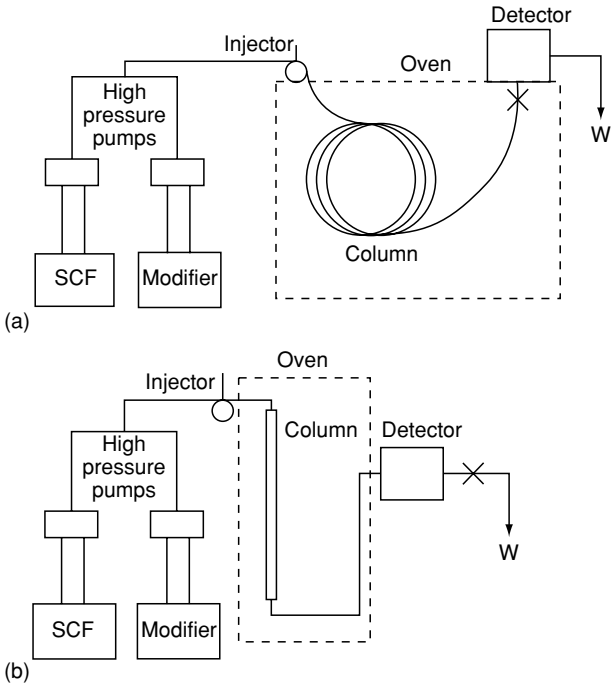

Figure 2 Schematic diagram of (a) capillary SFC, and (b) packed column SFC.

SFC is perceived as a niche technique in the food industry, so it is critical to recognize when and where it can be used to advantage relative to what can be achieved using other forms of chromatography, such as gas chromatography (GC) and high-performance liquid chromatography (HPLC). (*See* **Chromatography**: High-performance Liquid Chromatography; Gas Chromatography.) Some of these opportunities are as follows:

- reduction of the use of organic solvents relative to HPLC;
- direct analysis of samples avoiding sample preparation step;
- deformulation of commercial food products;
- detection of product adulteration or deterioration;
- support of food engineering extraction/reaction process development.

With respect to nonpolar solutes, pressure- or density-programmed SFC provides the capability to analyze compounds having molecular weights approaching 1200 Da using one chromatographic analysis. Separation of these compounds by SFC is a function of their solubility in the mobile phase, their respective vapor pressures, and the miscibility pressure/temperature of the solute in the fluid phase. For example, in Figure 3, a diverse number of components have been separated using the capillary SFC method, that traditionally would have required the use of either GC or HPLC, as well as derivatization of some of the analytes. Utilizing SFC allows the analyst to avoid using either of both GC or HPLC, and to directly analyze the sample, obtaining a 'snapshot' of the entire molecular composition of the sample. These characteristic elution patterns produced using a SFC can be used as means of identifying the presence

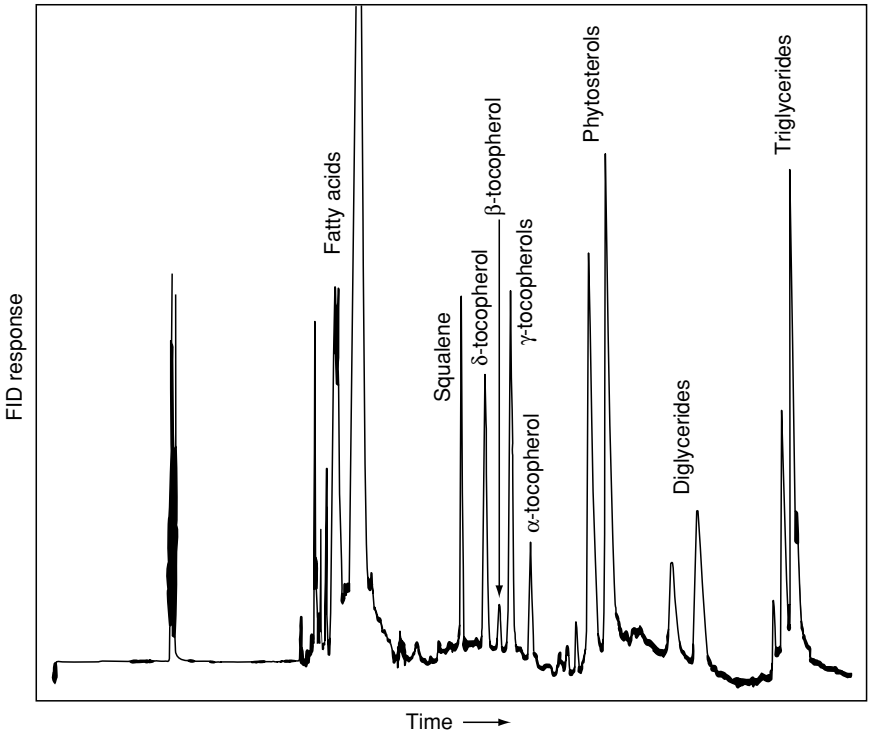

Figure 3 Supercritical fluid chromatography analysis of deodorizer distillate with a SB-octyl-50 column using flame ionization detection.

or absence of a particular analyte in a food sample, thereby providing valuable information for a food product formulator, to match or alter, in developing new and competitive food-related products.

Increasing concerns about minimizing or eliminating the use of hazardous organic solvents in the laboratory also bodes well for use in SFC. By incorporating SFC for the separation and detection of food-related solutes, one not only eliminates most of the traditional solvent needs associated with HPLC, but potentially solvents utilized in the extraction or sample workup steps prior to analysis. In this regard, SFC is an excellent tool for monitoring the end result of an extraction or reaction of a food component using supercritical fluid media. Also, by using SFC, food-related analytes that are thermally labile or susceptible to degradation via oxidation are not exposed to the harsh conditions that often accompany their analysis by GC or HPLC. Such an advantage can be attributed to the protective action of SC-CO_2, which excludes oxygen, and the low temperatures used when separating components via SFC.

Selecting and Optimizing SFC Separation Conditions for Food Components

For the SFC analysis of food-related samples, the analyst will undoubtly want to start with a general fluid programming sequence to separate as many components in the sample matrix as possible. These programs are executed for an extended time to assure optimum resolution and detection of the unknown or target analyte(s). Run times of 1.5 h in length are not unusual in this beginning stage of method development for SFC separations. After the target analyses have been identified by retention time matching with standards, or via an independent method such as mass spectrometry (MS), the original program can be modified to reduce the analysis time or improve the resolution within the chromatogram. Usually, changes in the mobile phase program will be executed to hasten the elution of early or late eluting components that are of no importance for the analysis.

Because of the molecular complexity exhibited by many food ingredients or compositions, it is not unusual to have a temperature gradient with respect to time, superimposed on the mobile phase pressure program during the SFC run. For example, separation of the like-carbon number triglycerides in soybean oil is not possible by pressure or density programming alone, but by superimposing a temperature gradient during the analysis, these oil components can be separated quite well. SFC analysis under isobaric conditions is limited in application when analyzing foods, but it should not be overlooked, since it can yield often the most precise and accurate results.

By far, the FID has been the most used detector used to date in SFC. FID sensitivity to food components is lower than that obtained using GC, since expansion of the mobile phase dilutes the detector signal substantially. However, the FID signal can be amplified to permit analysis down to the p.p.m. level, provided that baseline shifts can be compensated for. Analytes with chromaphoric properties are amenable to analysis using the ultraviolet (UV) detector in conjunction with SFC. The absorption maxima of components shifts as a function of fluid density or pressure, but most detector units constructed for operation at these elevated pressures allow for stop flow or *in situ*, on-the-fly scanning of peaks to determine absorbance maxima shifts. Bathochromic shifts of 15–20 nm have been recorded for carotenoids in SC-CO_2 over a 25-MPa pressure interval. The mating of the ELSD detector with SFC has been reported by several investigators, but the day-to-day stability is inferior to that obtained with HPLC–ELSD couplings when applied to food analysis. Heteroelement specific detectors, such as the electron capture or flame photometric detector, have been utilized mostly in research studies using SFC and have not been adopted for routine analysis. The detector sensitivity and stability under SFC conditions limit their sensitivity at best to the p.p.m. range.

Many of the promising applications of capillary SFC have utilized nonpolar bonded phases utilizing siloxane functionalities as methyl, octyl, phenyl, and biphenyl in a polymeric form. The weak elutropic strength of neat SC-CO_2 has favored the use of short-chain-length, monomeric silance-modified columns having C_1, C_4, C_{18}, phenyl, amino, and diol phases for packed column SFC. The choice of these phases is not so much related to their selective interaction with food-related solutes, but to their surface-modifying properties, which reduce peak tailing and solute interaction with the base silica matrix. Polymer resin columns have also been utilized, but they are susceptible to voiding unless specifically packed for use under supercritical fluid conditions.

Table 1 Food components separated and analyzed by SFC

Carbohydrates:	Derivatized corn syrups, mannose glycans
Chiral compounds:	Monoterpenes, pyrazines, clenbuterol
Drugs/antibiotics:	Caffeine, erythromycin, polycyclic ether antibiotics, sulfonamides, assorted steroids
Hydrocarbons:	Sesquiterpenes, squalene, waxes and wax esters
Lipids:	Fatty acids, fatty acid esters, monoglycerides, diglycerides, triglycerides, sterol esters, sterols (cholesterol), fat-soluble vitamins, tocopherols, phospholipids (lecithin), lipid hydroperoxides, glycolipids
Nutraceuticals:	Valeriana, gingolides, sawtooth palmetto berry
Oils/fats:	Celery oil, coconut, fish, soybean, wheat germ, palm oil, rice oil, milk/cheese triglycerides
Packaging/film components:	Polypropylene oligomers, polyvinyl chloride, phenolic antioxidants, low-molecular-weight polystyrene
Pesticides:	Halogenated, organophosphorus, carbamate, pyrethrins, acidic phenoxy herbicides, sulfonyl ureas
Pigments:	Carotenoids, xyanthophyls
Speciality ingredients:	Hops components
Spices/flavors:	Capsicum, cardoman, coumarin, curry, garlic components, marjoram, rosemary, vanillan
Terpenes/essential and fruit oils:	Grapefruit oil, limonenes, mint, lemon
Other toxicants:	Mycotoxins, nitrosamines, polycyclic aromatic hydrocarbons

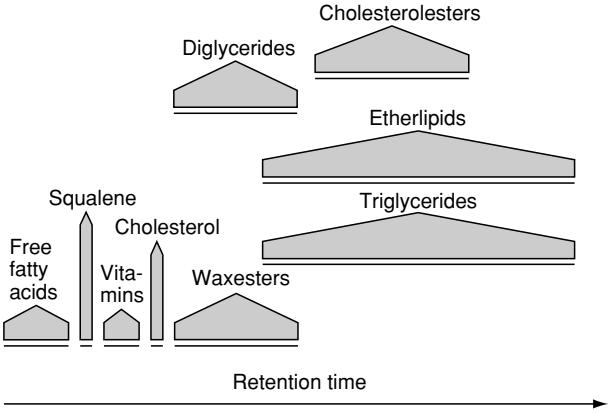

Figure 4 General elution order (retention time) of lipids in SFC on nonpolar stationary phases.

Types of food Ingredients Analyzed by SFC

A myriad of food-related components and matrices have been analyzed by SFC, as indicated by the partial listing in Table 1. These include naturally occurring ingredients such as fats/oils, spices, etc., minor unwanted constituents like pesticides, antibiotic drugs, and mycotoxins, and specific food components, including nutraceuticals and flavoring aids. Inspection of Table 1 indicates a preponderance of applications in the lipid analysis area. Indeed, SFC is tailor-made for lipid analysis, although somewhat lacking in the high-resolution capabilities demonstrated by high temperature GC. The retention pattern for typical lipid solutes in SFC as shown in Figure 4, follow a distinct pattern governed approximately by the solute's molecular weight/volatility characteristics. Elution of the following classes of lipids occurs in the following order: fatty acid methyl esters, free fatty acids, hydrocarbons, vitamins, sterols, wax esters, mono- and then diglycerides, followed by triglycerides and steryl esters. Although there is some

overlap between individual classes of the above solutes, owing to the overlapping molecular weight ranges (e.g., triglycerides and steryl esters), this solute separation pattern has proven very useful in tracking conversion of lipid species undergoing reactions, as well as in the quality control of food ingredients.

Triglyceride-based oils/fats are also readily amenable to analysis by SFC. Separation of the individual components is once again governed by molecular weight considerations, allowing SFC to facilitate the separation of the major triglyceride species, i.e., T_{50}, T_{52}, T_{54}, etc. For some oils, such as coconut oil, picturesque chromatograms result (Figure 5), as shown by the separation of the C_{18} to C_{54} saturated triglycerides as equally spaced peaks. For other oils such as soybean oil, there is some overlap between the saturated and unsaturated triglyceride species, requiring, as noted previously, a superimposition of a temperature gradient along with the pressure gradient program to achieve adequate resolution. However, even without high resolution, the rapid SFC analysis can be used to advantage in quality control, where speed, rather than optimal separation, is often desired.

Detection of minor components in foods is limited by the detector sensitivity and stability as noted previously, but those components that can be detected by using FID, UV, or ELSD, are often analyzed more rapidly by SFC, owing to the time savings afforded by avoiding elaborate preparation of the sample prior to analysis. In addition, SFC analysis provides a more detailed profile of the entire sample in addition to detecting the target analyte. This allows an accurate assessment of the total contribution of the minor constituent to the entire ingredient profile, e.g., the presence of sterol esters in sawtooth palmetto berry extracts, where the fatty acids and triglycerides are the major constituents.

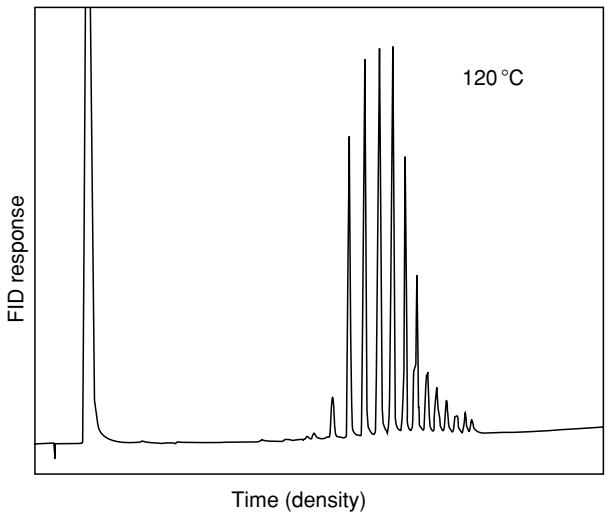

Figure 5 Capillary supercritical fluid chromatogram of coconut oil triglycerides.

Other food sample types that can be readily analyzed by SFC are the fat-soluble vitamins, essential and flavor oil ingredients, spice extracts, hop components, as well as functional food components, i.e., nutraceuticals. Some SFC-based separations require the use of a cosolvent (usually 5–20 vol.%), in addition to the SC-CO_2, to modify the mobile phase. For example, phospholipids are only sparingly-soluble in neat SC-CO_2, but these polar lipid compounds can be chromatographed successfully on packed silica columns by incorporating ethanol and/or water as a modifier into the mobile phase. Likewise, carbohydrate moieties, which exhibit limited or no solubility in SC-CO_2 or SC-CO_2 /cosolvent mobile phases, can be derivatized so that they can be analyzed by SFC.

Selected Applications of SFC in Food and Nutritional Analysis

In this section, several brief examples will be given to illustrate the utility and potential of SFC for food and nutritional analysis. As noted previously, both high and low resolution of solutes are possible using SFC. SFC separation and detection of α-tocopherol and cholesterol in a fish oil capsule can be achieved on a capillary SB-methyl column at 120 °C, using a density program with SC-CO_2 from 0.28 to 0.66 g ml^{-1} and a density programming rate of 0.0006 g ml^{-1}. Although the analysis took 90 min to perform, it allowed the analyst to avoid any sample preparation, other than diluting the oil from the capsule in small quantity of solvent, and injecting it into the SFC. Therefore, no derivatization of the sample was required, and there was sufficient resolution between the α-tocopherol and cholesterol to quantify these analytes. This was made possible by adjustment of the elution conditions, i.e., the background components (fish oil triglycerides), that were of no interest in this analysis, and were programmed off the column without resorting to a prefractionation of the sample prior to SFC analysis.

Not all applications of SFC require the above high-resolution separation. Packed column SFC (5 μm, C_8 – Deltabond) has been used to 'clean up' samples prior to other types of chromatographic analysis (GC). In this case, organochlorine- and phosphorus pesticides extracted by SFE with SC-CO_2 from a meat sample were separated from the coextracted fat moieties using the packed SFC column. Hence, by 'heart cutting' the appropriate elution fraction, a lipid-free, pesticide-containing fraction was provided for residue analysis by GC.

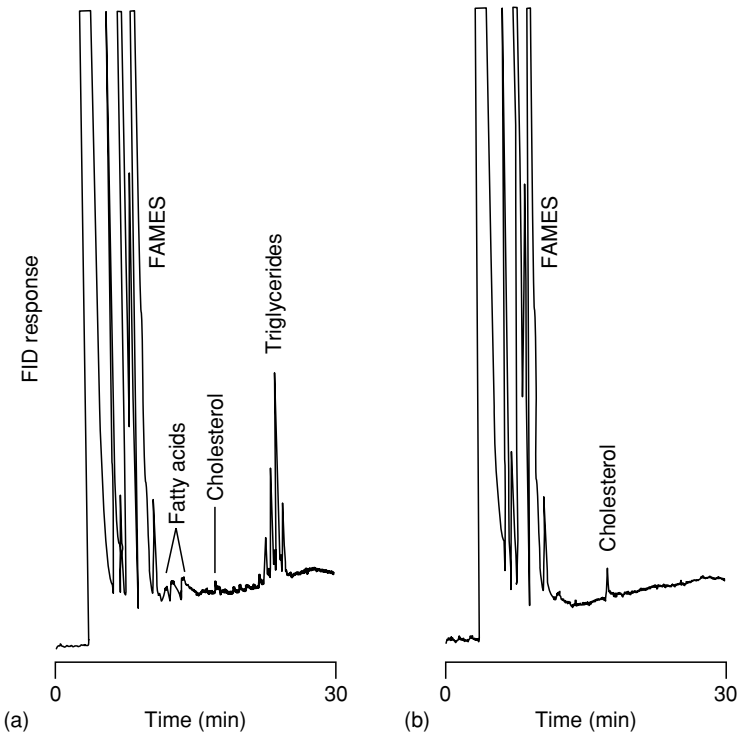

Figure 6 SFC analyses of reaction products from the transesterification of ground beef lipids: (a) neat ground beef sample; (b) freeze-dried ground beef sample.

SFC is an excellent technique to monitor reaction chemistry between lipid species, since it avoids the need to employ more than one analytical technique or analyte derivatization. Further, it permits the successful chromatography of all of the relevant reactants and products using one chromatographic analysis. Examples where SFC has been applied are for the esterification or transesterification of lipids, glycerolysis reactions, and randomization of fats/oils. Figure 6 shows two SFC profiles for the enzymatic-catalyzed transesterification reaction between the triglycerides from a ground beef sample and methanol, to produce the corresponding fatty acid methyl esters (FAMEs) for nutritional labeling analysis. The 30-min chromatograms show the effect of the moisture content of the ground beef sample on the yield of FAMEs, (a) being the yield from the neat ground beef sample, and (b) being the conversion attained by freeze-drying the sample matrix prior to methanolysis. Note that freeze-drying of the ground beef was crucial to obtaining a quantitative yield of FAMEs for fat analysis required in nutritional labeling. The transesterification reaction in this case was run in a flow extractor-reactor in which the ground beef triglycerides were extracted using SC-CO_2 and carried over a bed of supported lipase in the presence of methanol to produce the desired FAMEs.

Table 2 Analysis of lipid species in a soybean oil glycerolysis mixture

Method of analysis	*MAG*	*DAG*	*TAG*	*FFA*
SFC – FID	75.3	23.2	< 0.1	1.5
GC – FID	76.2	21.8	< 0.1	2.0

Table 2 shows the analysis of the glyceride content of a soybean oil glycerolysis mixture by both HPLC-FID and SFC-FID. The information desired was the relative amounts of free fatty acids (FFA), mono- (MAG), di-(DAG), and triacylglycerols (TAG) in the reaction mixture. A comparison of the SFC-FID results with those obtained by HPLC-FID shows a relatively good agreement between the two methods. However, the SFC method does not require the time and effort for sample preparation associated with the alternative technique, and in addition saves on the cost of solvents and chemical reagents.

Although mentioned previously, preparative or production-scale SFC is now being used as a separation technique in the food industry. Fractionation and isolation of food components, such as tocopherols and phospholipids, or the ω-fatty acids/esters from fish oils, have been cited in the literature.

Recently, a production plant for the separation of fish oil ethyl esters has been constructed in Spain to produce ≥95% pure polyunsaturated fatty acids for the nutraceutical market. The basic separation premise upon which this production scale plant is designed was based on chromatographic fractionations initially developed using analytical-scale, packed SFC columns.

Combined Chromotography and Mass Spectrometry

F A Mellon, AFRC Institute of Food Research, Norwich, UK

Introduction

Techniques of combined chromatography/mass spectrometry are widely used in food analysis and have been applied to the solution of a very diverse range of problems. These include flavor analysis, determination of vitamins and other biologically active naturally occurring substances in foods, analysis of lipids, amino acids, peptides and proteins, analysis of toxicants, and determination of pesticide and veterinary drug residues. These are a small sample of a very wide range of applications of combined gas chromatography–mass spectrometry (GC-MS), liquid chromatography–mass spectrometry (LC-MS), capillary electrophoresis–mass spectrometry (CE-MS), supercritical fluid chromatography–mass spectrometry (SFC-MS), and capillary electrochromatography–mass spectrometry (CEC-MS).

The general principles of combined chromatography–mass spectrometry are the same for all hyphenated mass spectrometry techniques: the chromatograph separates the mixture components and these are transferred to the mass spectrometer, often via a suitable interface (**Figure 1**). An analog detector (for example, diode array or fluorescence) may also be incorporated, particularly in LC-MS instruments. This may be placed in series with the mass spectrometer interface or the eluent flow can be spilt between the two types of detector. Many mass spectrometer data systems are capable of recording and displaying mass spectra and (for example) ultraviolet data simultaneously, adding an extra dimension to the information obtained.

The mass spectrometer is scanned continuously and cyclically (e.g., one scan per second), so that the spectra of all components, even minor ones, are recorded. The data are plotted as a total ion current (TIC) chromatogram or a mass chromatogram (**Figure 2**).

The TIC is simply the sum of the intensities of all the ions in each mass spectrum plotted against retention time and/or scan number. A mass chromatogram (e.g., *m/z* 270 in **Figure 2**) comprises a plot of the intensity of a particular ion in a mass spectrum against time. This technique is often useful in identifying particular molecular ions or fragment ions that are characteristic of particular structural features. For example, the ion at *m/z* 74 in **Figure 2** is a McLafferty rearrangement ion characteristic of fatty acid methyl

esters containing the moiety $-C(H)\text{-}CH_2\text{-}CH_2\text{-}COOMe$. Similarly, the ions at 270 and 284 are characteristic molecular ions of methyl palmitate and margaric acid (methyl heptadecanoate) and isomers of these molecules. A mass chromatogram is different from a selected ion-monitoring (SIM) trace (see below) because the ions of interest are part of a complete mass spectrum: the entire mass spectrum is still available for examination. In addition to TIC and mass chromatogram plots, ion intensities may be summed over a preselected mass range and plotted against time (for example, m/z 260 – 320 in Figure 2). This type of display is sometimes referred to as a Reconstructed ion chromatogram and is useful for eliminating intense background ions (for example, those that arise from solvent peaks during an LC-MS analysis), or for searching for characteristic ions that appear in a limited mass range.

Whichever chromatographic plotting techniques are used, each time point in the chromatogram represents a single mass spectrum that may be examined or processed either by the operator or automatically

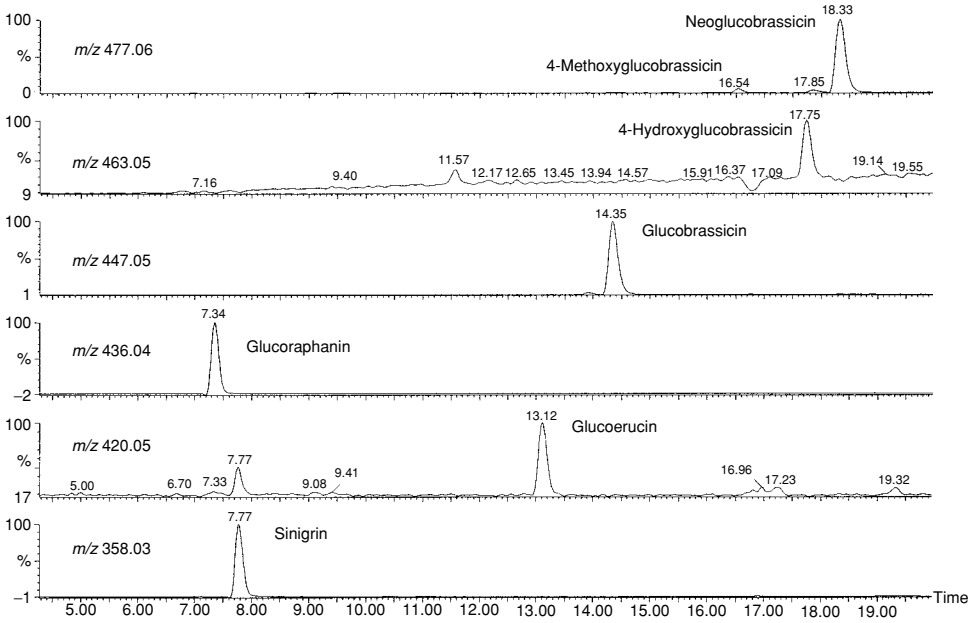

Figure 3 Negative-ion electrospray liquid chromatography–mass spectrometry (LC-MS) selected ion-monitoring (SIM) chromatogram of intact glucosinolates extracted from broccoli. Copyright Institute of Food Research, reproduced with permission.

using appropriate software (for example, library search or quantification routines).

In the special case of SIM, preselected masses are scanned in preference to the entire spectrum. This yields much greater sensitivity and is used for quantifying analytes. Figure 3 shows an LC-MS SIM chromatogram of the molecular anions of the glucosinolates glucoraphanin, glucoerucin, glucobrassicin, 4-hydoxyglucobrassicin, 4-methoxyglucobrassicin, and neoglucobrassicin extracted from broccoli.

Sinigrin (a glucosinolate not present in broccoli) is used as a quantitative spike. Peak areas are integrated and the ratios of these areas against that of the sinigrin internal standard are used to generate quantitative data by comparison with a calibration curve.

Gas Chromatography–Mass Spectrometry

GC-MS was the first combined chromatography–mass spectrometry technique to enjoy widespread acceptance in food science (one of the earliest published applications of GC-MS was in flavor analysis). GC-MS is still used widely in food science, particularly in flavor analysis. User-friendly and cheap benchtop instruments are now available for conducting these types of analysis. Despite their compactness and simplicity, these instruments are sensitive and equipped with powerful data systems that are used not only to control and acquire data from the gas chromatograph and mass spectrometer, but also to identify flavor components by automated matching against reference libraries of spectra of known flavorants. More sophisticated GC-MS instruments are also used in many other areas of food analysis, especially in the identification of toxic residues (e.g., dioxins). Advances in column technology (particularly the widespread use of flexible fused silica columns) and improved mass spectrometer vacuum pumps mean that coupling a gas chromatograph to a mass spectrometer is now routine and does not require any special form of interface. Capillary columns generally operate at helium gas flows of a few milliliters per minute, and modern turbomolecular vacuum pumps are easily able to cope with these flow rates and still maintain ion source pressures (for electron ionization (EI)) of $< 10^{-3}$ Pa. One of the main recent advances in GC-MS technology has been the introduction of 'fast' GC-MS techniques in which the speed of analysis available from some types of modern GC capillary columns have been complemented by fast-scanning mass spectrometers (time-of-flight instruments, for example). GC-MS techniques are now routine and will not be dwelt on at any length here. LC-MS is now providing some of the most interesting and versatile new methodologies in food analysis and food science generally and this article will focus mainly on this technology.

Liquid Chromatography–Mass Spectrometry

LC-MS presents far more technical problems than GC-MS because of the incompatibility of flowing

liquids with the high vacuum necessary for mass spectrometers to function. A typical liquid chromatograph eluent flow of 1 ml min^{-1} becomes over 1000 times this flow of gas when converted to a vapor, far in excess of the gas flow that a conventional mass spectrometer ion source can cope with and still maintain vacuum. Furthermore, the expansion from liquid to gas results in dilution of analyte molecules entrained in the solvent, potentially reducing sensitivity by a very large factor. Consequently, special interfaces and ion sources have been developed to remove excess solvent vapor and insure that the analytes are not diluted excessively.

LC-MS Interfaces and Ion Sources

Several different techniques, or interfaces, for combining liquid chromatography and mass spectrometry were developed in the 1970s and 1980s. These included the direct liquid introduction (DLI) interface, the moving belt interface, dynamic FAB (fast atom bombardment) or dynamic LSIMS (liquid secondary ion mass spectrometry), and thermospray ion source. All of these techniques had some disadvantages in terms of the range of compounds amenable to analysis, robustness and reliability, sensitivity and, in some cases, limited flow rates.

Electrospray and Atmospheric Pressure Chemical Ionization

The interfaces mentioned above have been superseded by electrospray (ESI) and atmospheric pressure chemical ionization (APCI) ion sources. Both of these ion sources can be coupled directly to liquid chromatographs, with very few restrictions on flow rate or solvent composition (*See* **Mass Spectrometry**: Principles and Instrumentation). Both techniques have been used very widely in food and nutrition studies. Examples of SIM chromatograms of 1 and 20 pmol of β-carotene (**Figure 4**) and a mass chromatogram (**Figure 5a**) and spectrum (**Figure 5b**) of quercetin 3′ glucoside are shown. These types of data are useful in quantitative and qualitative metabolic studies.

The Particle Beam Interface

A third type of interface, the particle beam, completes the trio of modern LC-MS technology, providing a suite of techniques capable of handling nearly all types of analysis. A schematic diagram of a particle beam interface is shown in **Figure 6**.

The incoming liquid stream (i.e., the high-performance liquid chromatography (HPLC) eluent) enters the device on the left of the diagram. The liquid is nebulized by helium gas flowing, forming a fast-moving spray of droplets that enter the heated desolvation chamber. Solvent begins to evaporate from the spray droplets which shrink, thus concentrating any dissolved sample molecules. The partially evaporated spray then passes through a narrow orifice (skimmer 1 in the diagram) and across a region that is maintained under vacuum by a rotary pump. A supersonic molecular beam is formed in this region and, because

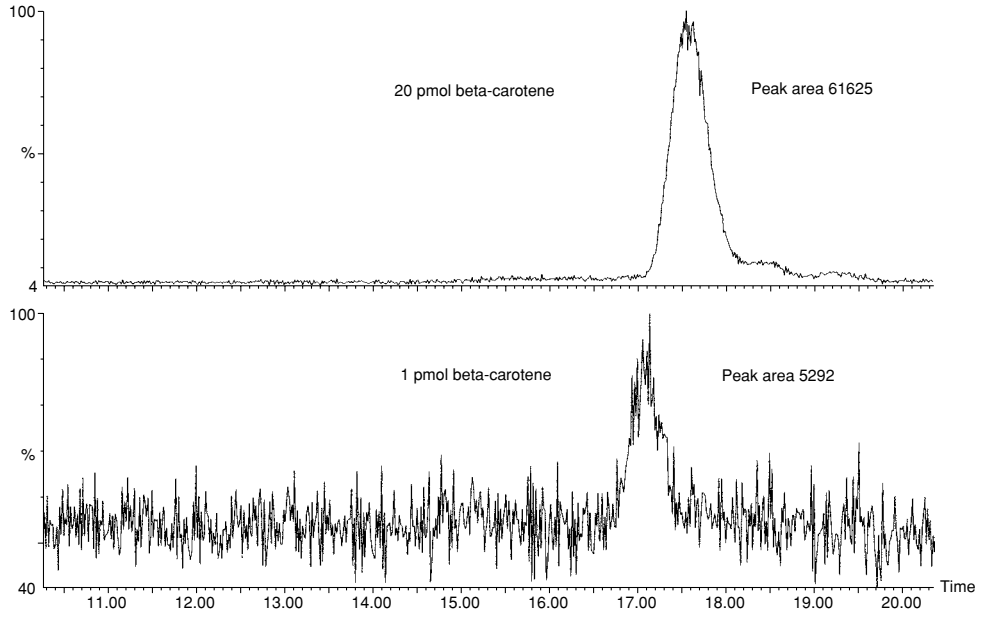

Figure 4 Positive-ion atmospheric pressure chemical ionization liquid chromatography–mass spectrometry selected ion-monitoring chromatogram of the molecular ion of β-carotene (1 and 20 pmol injections, respectively). The slight retention time shift between the two traces is caused by temperature drift affecting the chromatography. These types of data are useful for quantifying carotenoids in food extracts and in metabolic experiments. Copyright Institute of Food Research, reproduced with permission.

the solvent molecules and helium atoms are significantly lighter than sample molecules, they diffuse away more rapidly and are pumped out of the system preferentially. This leaves the heavier solute molecules concentrated in the beam. A second skimmer removes yet more solvent molecules and allows particles of sample to enter the EI or chemical ionization (CI) ion source. The interface can handle flows of between 0.1 and 1 ml min^{-1}, depending on the volatility of the solvent.

The great advantage of the particle beam system is that it can generate CI and, especially, EI spectra that are highly reproducible and comparable with spectra obtained by other types of EI and CI inlet systems. These spectra are therefore searchable against databases of known spectra. The major difference between the particle beam interface and other LC-MS systems is that the device processes the HPLC eluent in such a way that sample molecules can be ionized by the conventional mass spectrometric techniques of EI

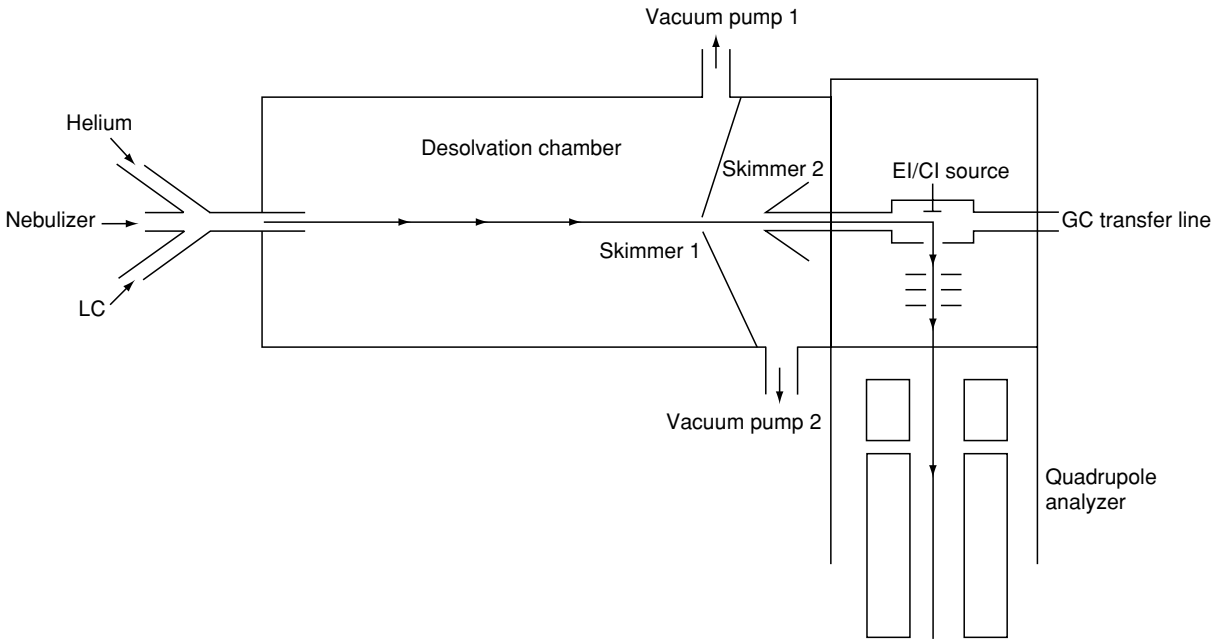

Figure 6 Schematic diagram of a particle beam liquid chromatography–mass spectrometry interface. LC, eluent exiting liquid chromatograph; EI/CI, electron impact/chemical ionization; GC, gas chromatography. and CI. APCI and ESI are effectively ionization techniques that generate anions or protonated molecules with few fragment ions under normal operating conditions. The particle beam method does not have the versatility and sensitivity of APCI and ESI but is useful for analyzing nonthermally labile molecules that are insufficiently volatile for GC-MS analysis.

Capillary Electrochromatography–Mass Spectrometry

CEC is a high-resolution separation technique that has been described as a hybrid of HPLC and CE. The high efficiency available from CEC makes it an ideal partner for coupling to mass spectrometry as the narrow chromatographic peaks result in increased mass flow per unit time into the mass spectrometer ion source, and thus greater sensitivity as well as selectivity. Many of the technical problems associated with coupling CEC to mass spectrometry (principally Joule heating and consequent bubble formation) are being tackled successfully, to the extent that automated sample introduction systems may be used with CEC-MS systems. Although the technique has not yet caught on in food science and nutrition, CEC-MS has great potential in studies requiring separation of complex mixtures and high-sensitivity/high-selectivity analysis.

Capillary Electrophoresis–Mass Spectrometry

Many of the difficulties associated with combining the ultrahigh-resolution separation technique of CE with MS have been overcome. However, a significant number of publications devoted to interfacing CE with MS still appear annually, indicating that an ideal solution is still not available. Despite this, several mass spectrometer manufacturers now supply special probes for interfacing CE with MS, indicating that the technology is now commercially viable. The ionization technique most compatible with CE is electrospray and the vast majority of CE-MS applications reported make use of this ionization technique. Recently the use of microfabricated devices ('CE on a chip') with mass spectrometers has been reported and promises significant advances in sensitivity and reproducibility. As with CEC, there are few reported applications of CE-MS in the food and nutrition sciences; nevertheless, the potential of technique in these fields is very high.

Supercritical Fluid Chromatography–Mass Spectrometry

Techniques for coupling SFC to MS were first described in the late 1970s. Although a number of different SFC-MS interfaces were developed in the

intervening years, APCI, with specially adapted SFC probes, is currently the main method of choice. The APCI source is particularly suited to SFC because it is unaffected by the increasing flow rates resulting from pressure programming of the supercritical mobile phase and because of the ease of connection with

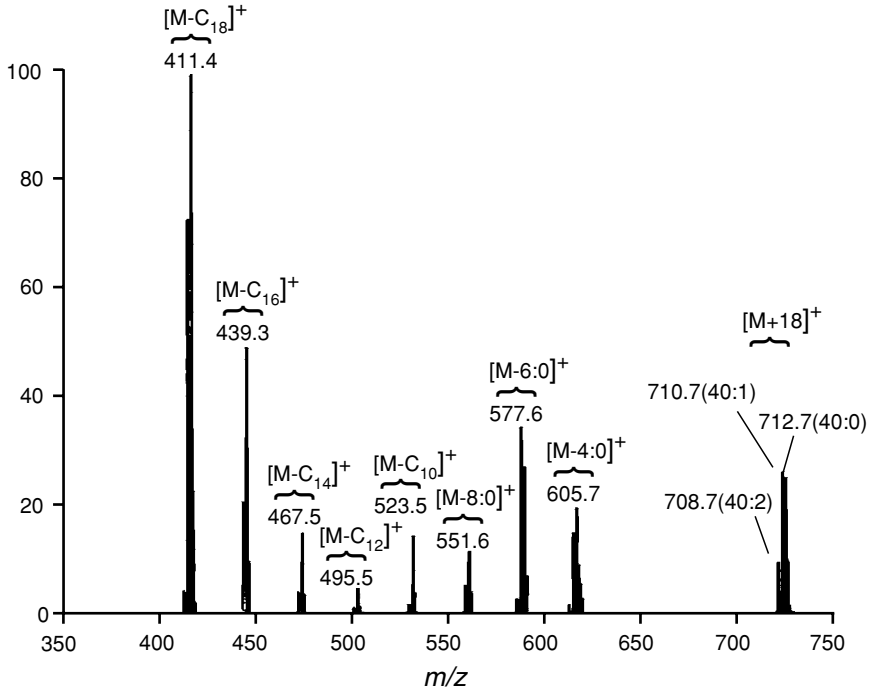

Figure 8 Mass spectrum of peak 9 in Figure 7. Samples ionized by atmospheric pressure chemical ionization with ammonia as reactant ion. Reproduced from Laakso P and Manninen P (1997) Identification of milk fat triacylglycerols by capillary supercritical fluid chromotagraphy atmosphere pressure chemical ionization mass spectrometry. *Lipids* 32: 1285–1295, with permission.

SFC systems. Although SFC-MS is much less popular than LC-MS in the food sciences, it is particularly suited to certain types of analysis. A good example is provided by the identification of milk fat triacylglycerols by capillary SFC-MS. Samples were ionized, in APCI mode, by admitting methanol or 0.5% ammonia in methanol as reagent gas. A reconstructed ion chromatogram of the milk fat triacylglycerols is shown in Figure 7.

Individual mass spectra yielded abundant $[M+18]^+$ and $[M-RCOOH]^+$ ions when ammonia was present in the reagent gas, thus defining molecular weight and the nature of the fatty acid constituents of the triacylglycerols. As can be seen in Figure 7, complete chromatographic resolution of all triacylglycerols was not achieved, However, the specificity of the mass spectrometric data allowed identification of different components of unresolved chromatographic peaks where fatty acid chain lengths yielded characteristic fragment ions. The mass spectrum of peak number 9 in Figure 7 is shown in Figure 8.

Three different chromatographically unresolved triacylglycerols, 40:0, 40:1, and 40:2, are present. This study demonstrated the value of SFC-MS in the analysis of both saturated and unsaturated triacylglycerols.

The interpretation of the mass spectrum in Figure 8 was complicated by the occurrence of several different-molecular-weight species in a single chromatographic peak. However, the $[M-RCOO]^+$ ion region contained ion clusters that indicated the presence of C_{18} and C_{16} fatty acid moieties in the triacylglycerols.

Properties and Determination

R Farré and M J Lagarda, University of Valencia, Burjassot, Spain

Physical and Chemical Properties

Chromium is a hard, brittle, white metal of the first transition series, with an atomic number of 24, a relative atomic mass of 51.996 amu, an electronic configuration $[Ar]3d^5 4s^1$, and a relative density of 7.19. The melting and boiling points are 1857 °C and 2672 °C, respectively.

The resistance of chromium to attack from a variety of chemicals at normal temperature makes it useful in protecting other more reactive metals, e.g., it is a component of stainless steel. However, at high temperatures it reacts with many chemicals.

As a typical transition metal element, chromium forms many compounds that are colored and paramagnetic. It has oxidation states from −2 to +6, but

the most common and stable oxidation states are +2, +3, and +6. Since Cr(II) is a very strong reducing agent, it is not found in biological systems. All Cr(VI) compounds, except the hexafluoride (CrF_6), are oxo compounds; chromium occurs predominantly as either chromate (CrO_4^{2-}) or dichromate ($Cr_2O_7^{2-}$). Cr(VI) compounds are strong oxidizing agents and are therefore readily reduced to Cr(III) in acidic solutions. The most stable and important oxidation state is +3.

One of the outstanding features of Cr(III) chemistry is the ability of trivalent chromium to form coordination complexes, most of which are hexacoordinated. These coordination complexes are relatively inert. In aqueous solution the hexahydrate ion $[Cr(H_2O)_6]^{3+}$ exists in an octahedral configuration. In aqueous solution the ligand and displacement reactions have half-lives of several hours.

Chromium can form bridges with hydroxyl groups (olation). Olation is enhanced by alkalis and temperatures up to 120 °C, but can be prevented and reversed by oxalate ions and other strong ligands, whereas weaker ligands can only prevent the reaction. In biological systems pyrophosphate, methionine, serine, glycine, leucine, lysine, and proline therefore inhibit the olation of Cr(III). In such systems chromium is able to react because its solubility is maintained by weaker organic and inorganic ligands.

Determination in Foods and Beverages

There are a wide range of techniques available for the analysis of chromium and other trace elements. Chromium is one of the most difficult elements to determine accurately because of the very low levels in foods.

The determination of chromium content in biological matrixes has long been a controversial problem because of the many errors that can arise and invalidate the data. Therefore, much of the earlier work should be viewed critically. Reasons for this skepticism arise from a number of problem areas:

- The low chromium content of normal (noncontaminated) biological samples. In food samples the concentration is on the order of nanograms per gram and, therefore, it is essential to apply very sensitive measurement techniques.
- Chromium losses by volatilization during sample dry ashing above 450 °C.
- Contamination at any point through sample collection and handling, before the content is measured.
- Errors inherent in the applied analytical method, such as, for instance, matrix interferences in electrothermal atomic absorption spectrometry (ETA-AAS) and spectral in inductively coupled plasma–atomic emission spectrometry (ICP-AES).

Studies should report precise data on all steps of the analytical procedure, including sample collection, homogenization, and matrix reduction. An accurate determination is a challenge because of problems that originate from the risk of chromium losses by volatilization or adsorption and/or enrichment by contamination. Interlaboratory assays therefore give rise, in the case of chromium analysis, to very variable results.

Of all of the proposed analytical methods, AAS is the one most often used for chromium determination in biological samples. When applied with a graphite furnace (ETA-AAS) it is one of the most sensitive techniques, but it is open to a wide range of interferences, which depend on the matrix and can lead to erroneous results. The advances in background correction procedures have contributed to overcome these limitations.

ICP-AES is also applied to determine chromium in foods and beverages. Although the detection limits are higher than those obtained with ETA-AAS, it offers the advantages of simpler sample preparation and the possibility of carrying out multielemental analysis.

Determination of total chromium content may not be a valid indicator of the nutritional benefit of a food because not all chromium in foods has activity as a glucose tolerance factor. Some authors point out that the alcohol-extractable fraction of chromium seems to be a more reliable index. The speciation of chromium is of great interest because of the differences in bioavailability, essentiality, and toxicity between Cr(III) and Cr(VI).

Precautions to be Taken in Chromium Determination in Foods

As mentioned above, contamination is one of the main problems encountered in chromium determination in foods. Indeed, it is the explanation why food chromium contents reported some years ago are higher than those obtained recently, as better measures have now been adopted to avoid contamination.

The possibility that small amounts of chromium can be retained by the surface of vessels makes it necessary to decontaminate the material used, whether glass or plastic. In order to decontaminate the containers, all material used has to be soaked in diluted nitric acid (10–20% v/v) for 12–24 h and then rinsed several times with deionized water. A mixture of 4 mol l^{-1} nitric acid and 4 mol l^{-1} perchloric acid

(1:1, v/v) or a solution of 2,4-pentanedione or dithizone/carbon tetrachloride has also been proposed.

To avoid losses by adsorption on to container walls, it is advisable to store digested samples and to prepare standard solutions in diluted acid (nitric or hydrochloric acid) below pH 1.5. However in acidic conditions reduction of Cr(VI) to Cr(III) is favored.

Since the acids used in chromium determination, especially nitric acid, are a source of contamination, it is advisable to use reagents of high quality or to distil them previously. Reagent blanks must be used to monitor such contamination.

Contact with materials that can give up chromium, i.e., metallic surfaces such as stainless steel, should be avoided. Therefore, knives, mixers, homogenators, or mills which are made from stainless steel should be avoided and replaced by others made from polymeric materials, quartz, or titanium. Colored polymeric materials such as screw-caps for bottles, dispensers, and pipette tips can contain chromium and should be controlled for contamination.

Chromium determinations below the $1\,\mu g\,l^{-1}$ level require strict contamination control and clean-room facilities.

Sample Digestion

The choice of the digestion method is important in trace chromium determination. The use of dry methods carries the risk of the formation of acid-insoluble Cr(III) oxide and can lead to chromium losses by adsorption on the walls of the crucible or by volatilization after formation of chromyl chloride at temperatures higher than 550 °C. These losses are minimized when the temperature is increased gradually and does not exceed 450–500 °C. Nevertheless, some authors have reported losses of chromium by volatilization at 450 °C and obtained better results at lower temperatures together with oxygen plasma. In the latter procedure, the amount of sample is limited and relatively large amounts of hydrogen peroxide are needed as an ashing aid. A dry-ashing in Pt crucibles with a temperature ramp at a rate of $50\,^{\circ}C\,h^{-1}$ up to 450 °C is the digestion method adopted by the Nordic Committee on Food Analysis as its official methodology for chromium determination in foodstuffs.

In wet digestion procedures, mixtures of acids and oxidizing agents are used, the most commonly used ones being nitric, sulfuric, and perchloric acids with hydrogen peroxide or vanadium pentoxide. When foods have a high fat content, mixtures of nitric, perchloric, and sulfuric acids, or nitric and sulfuric acids, are recommended.

The high boiling point of sulfuric acid helps the activity of oxidizing agents and, with the addition of nitric acid, the disadvantage of forming sulfate compounds of low solubility is overcome. Digestion, however, with nitric and sulfuric acids requires good refluxing to prevent losses.

Significant losses of chromium during wet ashing occur when perchloric is present and the sample is concentrated close to dryness because of chromyl chloride (CrO_2Cl_2) formation, which boils at 117 °C. Formation of chromyl chloride can be minimized by the addition of sulfuric acid.

The main risk of wet digestion is contamination through the reagents, especially when high volumes are used. Digestions in closed systems and/or in microwave systems require less time and reagents. Therefore, the risk of contamination decreases and losses by volatilization are also reduced to a minimum.

Microwave digestion is now widely used to measure chromium contents in foods, because it is faster, safer, and provides more reproducible conditions than conventional methods, resulting in better analytical precision.

In some vegetable species chromium is retained by an insoluble residue of silica. When this occurs, treatment with hydrofluoric acid is necessary to overcome the problem of low recovery values.

Extreme care must be taken in all wet ashing procedures where strong acids and strong oxidizing agents are used. The formation of explosive nitro compounds has been reported when fat-rich food samples have been digested with nitric acid.

Determination

Molecular Absorption Spectroscopy

The traditional spectrophotometric method of 520 nm, based on the violet complex formed with 1,5-diphenyl-carbazide (DPC), is still widely used for determining chromium in water, because of its high sensitivity. Chromium must be present as Cr(VI) and the diphenylcarbazide is oxidized to the diphenylcarbazone. Iron, copper, molybdenum, and vanadium can interfere. To remove interference and to increase the sensitivity of the method, both cation exchange resins (iron and copper) and cupferron (iron, copper, molybdenum, and vanadium) have been used.

This method has been applied to chromium determination in foods after destroying the organic matter and removing the interferences. Detection limits of $10\,ng\,g^{-1}$ have been reported.

The complex chromium hematoxiline, with a maximum absorbance between 360 and 390 nm, has also been applied to foods, although less often than the diphenylcarbazide method.

Flame Atomic Absorption Spectrophotometry (FAAS)

The low levels of chromium in foods and the complexity of the matrix make it difficult to measure chromium directly in digested samples by FAAS. With an air-acetylene flame and at a wavelength of 357.9 nm it is possible to obtain detection limits of 0.1 $\mu g\,g^{-1}$. It has been well established that chromium atomization is dependent on flame stoichiometry, with higher sensitivity with reducing flames (rich in acetylene). A 10-fold difference in sensitivity between fuel-lean and fuel-rich flames has been reported. However, the composition of the flame affects the behavior of the interfering compounds, and often the conditions for maximum signal-to-background are quite different from those required for minimizing interferences.

This determination is not free of interelement interferences. Iron depresses chromium absorbance in fuel-rich air-acetylene flames. It can be separated from the analyte by extraction with acetylacetone/chloroform (1:1, v/v) at pH 1–2, or by extraction, as Fe(III), from 5 $mol\,l^{-1}$ hydrochloric acid into isobutyl acetate or 4-methyl-2-pentanone (MIBK).

Direct chromium determination by FAAS in digested samples is not often applied, owing to interferences and the low concentration of chromium. For this reason it is more usual to enrich and to remove interference by chelating chromium and then extracting with an organic solvent.

Chromium can be chelated as Cr(III) with 2,4-pentanedione at pH 7.5 and heating to nearly 80 °C. The chelate is then extracted with chloroform or MIBK. With the former, a backextraction to an aqueous solution should be carried out before measuring by FAAS. To remove metal interferences the same chelating reagent or ammonium pyrrolidine dithiocarbamate (APDC) is added at a lower pH value and then extraction with chloroform is carried out.

Alternatively, chromium can be chelated with APDC as Cr(III) (pH 5 at 80–90 °C) or as Cr(VI) (pH 3–9 at room temperature). Therefore, to work under less strict conditions it is advisable to oxidize chromium to Cr(VI), and to eliminate the excess oxidizing agent. The procedure is not free of interferences, because manganese and tin are also chelated. In order to remove interfering substances and to increase the stability of the element in solution, some authors have proposed that backextraction should be carried out.

Another method that has been applied to chromium determination in foods is based on the formation of a compound by ionic association between Cr(VI) and the system hydrochloric acid/MIBK (0 °C). Prior to this, chromium is oxidized to Cr(VI) with potassium permanganate. This procedure offers the advantage that it is not necessary to remove the excess oxidizing agent.

Electrothermal Atomization Atomic Absorption Spectrophotometry

ETA-AAS is considered one of the techniques of choice for chromium determination in biological matrices and it is the technique most often used to determine chromium in foods. It is not free of interferences, but it is simpler than FAAS solvent-extraction methods. In foods, detection limits of 1 $\mu g\,kg^{-1}$ have been reported.

If organic matter is present, chromium is found mainly in the form of Cr(III), and in this oxidation state it easily forms refractory oxides during heating in graphite tubes and then reacts with graphite to form a carbide. To avoid the resulting decrease in the signal, pyrolytically or specially coated graphite tubes should be used. Pyrolytically coated tubes increase sensitivity threefold with respect to uncoated ones.

When the furnace temperature reaches 450 °C, breakdown products of chromium complexes are formed. Some of these are volatile and, therefore, there is a risk of losses of the element. Alternatively, other breakdown products can prevent complete atomization of chromium, because of the strong bonding with oxygen, nitrogen, or carbon. To achieve complete atomization of chromium, temperatures higher than 2300 °C should be used. The usual ranges of temperatures are: drying (100–200 °C), ashing (600–1600 °C), atomization (2300–2700 °C).

Diammonium hydrogen phosphate, magnesium nitrate, and palladium have been used successfully as matrix modifiers. The use of magnesium nitrate as a matrix modifier extends the possible charring temperature to 1600 °C, thus insuring a more complete remove of inorganic salts.

Since chromium is measured at a wavelength of 357.9 nm, it is better to correct background absorption with the Zeeman effect or a tungsten lamp rather than with a deuterium lamp. The emission intensity of the deuterium arc is low at the chromium resonance line of 357.9 nm. The hollow cathode lamp current has to be reduced in order to balance the source and background beams. The Zeeman effect can compensate for high absorbances, such as those produced by biological matrices.

The standard addition method is generally applied, even when prior digestion of organic matter is carried out. In the case of liquid samples, e.g., beer or wine, it is possible to determine chromium by injecting the

diluted sample directly into the graphite furnace and then applying the standard addition method. This direct procedure has also been applied to suspensions of vegetables and milk samples (whole, low-fat, skim, condensed, evaporated, and powdered). In these cases slurries of the samples were prepared with Triton X-100. Chromium contents below $0.2\,\mu g\,g^{-1}$ are measurable.

Inductively Coupled Plasma Spectrometry

The detection limits of ICP with atomic emission (ICP-AES) are lower than those obtained by direct FAAS, but not commensurate with ETA-AAS. Moreover, they can be seriously affected by spectral interferences, which are much more usual in ICP-AES than in AAS. A wavelength of 267.716 nm is usually chosen, though some overlap with emission lines of manganese and phosphorus can be observed. Other emission lines used are 283–563, 284–325, and 357–869 nm, but all are prone to spectral interference. Algorithms are generally used to correct for such interferences.

One of the main advantages of ICP is that sample preparation is simpler than in ETA-AAS, because elements can be measured when organic residues are present and several elements can be measured simultaneously. This explains why it is used in chromium determination in foods.

Online coupling mass spectrometry (MS) with ICP improves the detection limits 10–100-fold, obtaining, in optimized conditions, values below $0.1\,\mu g\,l^{-1}$ and therefore close to those of ETA-AAS. ICP-MS has the advantage of multielement capability. An ICP-MS method was proposed as the Association of Official Analytical Chemists (AOAC) official method for chromium determination in drinking, groundwater and waste waters. On the other hand, the lower background and greater sensitivity of the double-focusing instruments at low-resolution mode make it possible to obtain better detection limits than with quadrupole-based instruments.

Chromium determination in food samples by flow-injection ICP-MS has been described. The digests obtained in a wet high-pressure microwave system are delivered at a previously established flow rate to the ICP-MS instrument. FIA gives good recovery values and these are more reproducible than when a conventional method is used.

Electrochemical Methods (Polarography, Voltammetry)

Differential pulse polarography (DPP) is used to measure chromium in water and biological materials (including foods). Chromium is only detectable as Cr(VI). A reduction peak is observed at -0.80 V, when sodium citrate is used as a buffer (pH 9–10.5) and ammonia (ammonium chloride) as a support electrolyte. Detection limits as low as $0.12\,\mu g\,l^{-1}$ can be obtained.

DPP is mainly used for chromium determination in water. Preparation of the sample depends on its complexity and the expected chromium concentration.

Nitric acid should not be used to acidify the sample, since the formation of nitrous acid can partially reduce Cr(VI) to Cr(III). If water contains sulfites, these can also reduce Cr(VI) to Cr(III), so Cr(VI) must be chelated with sodium diethyldithiocarbamate (pH 4, diluted sulfuric acid/ potassium acid phthalate) and extracted with MIBK. Sulfuric acid is added and the solution is heated to remove the solvent. Hydrogen peroxide and sulfuric acid are added to insure that chromium is present entirely as Cr(VI).

In the case of samples with a high chloride or organic matter content, sodium sulfite is added to prevent the formation of chromyl chloride.

Samples having chromium levels lower than $1\,\mu g\,g^{-1}$ can be enriched by passing the solution through an ion exchange resin.

Voltammetric chromium measurements have been applied to wet digested biological samples after a controlled adsorptive preconcentration step on a hanging-mercury-drop electrode. Optimal conditions were a preconcentration potential of -1 V, a preconcentration period of 60 s, and a solution pH of 6.3. A current peak was recorded at -1.1 V.

Electrochemical determinations can also be useful to differentiate between chromium species.

Gas-Liquid Chromatography (GLC)

The great sensitivity of GLC allows the detection of extremely small amounts of chromium. GLC has been applied mainly to chromium determination in biological fluids, such as blood and urine, and to chromium determination in water, when speciation is wanted. It is applied less frequently to foods, because this method requires prior destruction of the organic matter and chromium levels are higher in foods than in biological fluids.

Since GLC can only be applied to volatile compounds, volatile chromium chelates are formed with fluorine substitutes of acetylacetone derivatives. Chromium complexes with β-diketones are volatile and stable, and trifluoroacetyllactone (TFA) is the chelating agent most frequently reported in practical applications, because of the enhanced sensitivity of halides using electron capture detection (ECD). This determination requires a purification step to remove the excess chelating reagent and other interfering

substances from the detector. An ion exchange resin can be used for this purpose. (*See* **Chromatography**: Gas Chromatography.)

ECD permits the detection of 0.1 pg of chromium injected as $Cr(TFA)_3$ chelate but, at these levels, serious complications arise in the separation of the metal chelate from interfering electron capture impurities. For this reason, several other detectors have been evaluated, among them the nitrogen-phosphorus detector, atomic absorption spectroscopy and MS. The hyphenated GLC-MS techniques provide a positive identification for the very small amounts of chromium compounds. (*See* **Mass Spectrometry**: Principles and Instrumentation.)

GLC application to foods is more difficult than in biological fluids. For instance, in liver, many of the metals present, such as iron, copper, cobalt, and nickel, tend to emerge shortly after the solvent peak in large trailing peaks. These are probably thermal decomposition products, and any chromium peak present is masked.

The introduction of the mass spectrometer as a detector in food testing meant a substantial improvement over the ECD, in particular the compatibility of monitoring a peak which can be identified with a single metal, and freedom from interferences. The detection limit is around 0.5 pg.

Neutron Activation Analysis

Neutron activation analysis (NAA) is based on the formation of radioactive isotopes, when a sample is irradiated with neutrons from a nuclear reactor or from other neutron sources. The elements of interest are identified and quantified by γ-spectroscopy.

It is generally used as a reference method to test the accuracy of other analytical methods, because it is highly specific and accurate. One of its main advantages is that it is a nondestructive method. The chief limitations to widespread use of this technique are the need for a neutron source and the very high cost of the analysis, that preclude the use of this method for routine analysis.

Moreover, in the case of chromium, the low abundance of ^{50}Cr (4.31%), a small thermal neutron section (17 barns), a low level of γ-decay and a half-life for ^{51}Cr of 27.8 days make it necessary to apply long irradiations with a high-density flux of electrons, especially when chromium concentrations are low. ^{51}Cr is separated by distillation of chromyl chloride.

NAA has also been used to investigate the behavior of chromium during drying or when the matrix is subjected to high temperatures in dry ashing, because it allows the direct determination of the sample without previous destruction of the organic matter.

Another application of NAA (radiochemical method) is to measure chromium in biological reference materials for certification purposes.

Chromium (III) and (VI) speciation

Metal speciation refers to the identification and quantification of organometallic, chelated, or free metal ion forms or their oxidation states.

As has already been mentioned, differences between the toxicity and bioavailability of Cr(III) and Cr(VI) make it necessary to ascertain not only the total chromium content but also the species present. Cr(III) plays an essential role in the maintenance of the glucose tolerance factor, while Cr(VI), because of its high oxidation potential and its relatively small size, enables it to pass through cell membranes, is toxic, and carcinogenic.

Trace metal speciation is achieved by combining two different techniques: one providing an efficient and reliable separation procedure and the other detection and quantification. Since liquid chromatogaphy is suitable for the separation of ionic, polar, and nonpolar compounds, it is recognized to be specifically efficient in the speciation of organometallics. At trace levels the chromatographed species are usually quantified by atomic absorption or emission techniques. Among the latter, most applications are based on ICP-AES or ICP-MS. When coupled with separation procedures, ICP-MS is one of the most powerful techniques for speciation analysis, and, when ICP is used as a detector for high-performance liquid chromatography (HPLC), it offers good sensitivity, a dynamic range of over five orders of magnitude and multielement detection capabilities. Moreover, in comparison with ICP-AES, ICP-MS offers the advantages of lower limits of detection (sub-ng to sub-pg levels), wide linear ranges, isotope analysis capability, and good precision values (0.1–5.0% RSD). AAS is also a sensitive detector after chromatographic separation.

A review of the literature reveals a large number of procedures for chromium speciation in water and soils. These include the Cr(VI) determination methods based on three main procedures – a selective chelation/extraction technique, coprecipitation and column separation, together with Cr speciation by hyphenated HPLC methods.

However, chromium speciation has rarely been performed in complex matrices such as foodstuffs. In these products total chromium is usually determined and then Cr(VI) or Cr(III) is separated and measured. Examples of these determinations have been reported in milk and in solid food samples.

A method has been reported for determining total chromium directly by ETA-AAS in milk after the addition of a surfactant and Pd-Mg as a chemical modifier. To extract Cr(VI) quantitatively and selectively a solid-phase extraction method using a silica column modified with NH_2 is applied to the supernatant obtained by protein precipitation.

On solid samples alkaline digestion is followed by coprecipitation with iron (III) hydroxide, redissolution with HCl and determination of Cr(III) by FAAS. This is used together with total chromium determination after a wet digestion of the sample. The amount of Cr(VI) is then calculated by substracting Cr(III) from total Cr. A positive interference was reported when the content of Cr(VI) was 10 times larger than Cr(III).

Conclusion

ETA-AAS with Zeeman background correction and matrix modification appears to be the most useful method for routine, and relatively rapid determination of the total chromium content of foods. Special precautions should be adopted to avoid sample losses and/or contamination throughout the period of analysis, i.e., from sampling to measurement. Therefore, accurate chromium determination requires the use of clean room facilities, filtered air and water, and ultrapure reagents to control environmental pollution. The daily use of appropriate reference materials is essential to check analytical accuracy. At the moment NAA remains useful as a reference method.

In the future the hyphenated HPLC techniques may contribute to chromium speciation.

Physiology

R A Anderson, Beltsville Human Nutrition Research Center, Beltsville, MD, USA

Background

Chromium in the trivalent form is an essential nutrient that functions in carbohydrate, lipid, and nucleic acid metabolism. Dietary intake of Cr by humans and farm animals is often suboptimal. Insufficient dietary intake of Cr is associated with increased risk factors associated with type 2 diabetes mellitus (DM) and cardiovascular diseases. Chromium functions in glucose and insulin metabolism primarily via its role in the regulation of insulin. Adequate dietary Cr leads to a normalization of insulin leading to decreased blood glucose in subjects with elevated blood glucose, increased blood glucose in subjects with low blood sugar, and no effect on subjects with near optimal glucose tolerance. Improved insulin function is also associated with an improved lipid profile. Chromium in foods and dietary supplements is trivalent, whereas Cr often found in paints, welding fumes, and other industrial settings is hexavalent and is severalfold more toxic than the trivalent nutritional Cr.

Absorption, Transport, Storage, and Excretion

Absorbed Cr is excreted primarily in the urine, and only small amounts of Cr are lost in the hair,

perspiration, and bile. Therefore, urinary Cr excretion can be used as an accurate estimation of absorbed Cr. At normal dietary Cr intakes (10–40 μg per day), Cr absorption is inversely related to dietary intake. Chromium absorption is approximately 0.5% at a daily intake of 40 μg and increases to 2% when intake drops to 10 μg. Therefore, the amount of absorbed Cr over this range is approximately 0.2 μg and is reflected in the urinary Cr losses of approximately 0.2 μg per day. This inverse relationship of Cr intake and absorption appears to be a basal control mechanism to maintain a minimal level of absorbed Cr. Intakes above 40 μg result in corresponding increases in total Cr absorbed.

Chromium absorption in young and old normal subjects is similar, but people with type 1 DM absorb two- to fourfold more Cr than other groups of subjects tested. People with diabetes appear to have an impaired ability to convert inorganic Cr to a useable form. Diabetic mice also lose the ability to covert Cr to a useable form. People with diabetes require additional Cr, and the body responds with increased absorption, but the absorbed Cr cannot be utilized effectively and is excreted in the urine. The chromium content of tissues of people with diabetes is also lower.

Chromium absorption and incorporation into tissues are also dependent on the form of Cr ingested. An accurate estimation of Cr absorption and utilization in animal studies can be achieved by measuring Cr incorporation into tissues. The tissue with the greatest Cr concentration is the kidney, followed by the spleen, liver, lungs, heart, and skeletal muscle.

Tissue Cr is an accurate method to assess Cr absorption and utilization and is also a measure of Cr storage. The kidney, which is one of the primary sites of tissue Cr storage, is also one of the best sources of insulin potentiating forms of Cr. Chromium is transported to the tissues primarily bound to transferrin, the same protein that transports iron. There are two metal-binding sites on transferrin, one primarily for iron and a second involved in Cr transport. During conditions of high iron excess or iron overload such as in iron storage diseases (hemosiderosis; hemochromatosis), all the metal transport sites on transferrin are occupied by iron. This may explain the high incidence of diabetes in hemochromatosis patients that may be induced by Cr deficiency.

Metabolic Functions and Essentiality

The essentiality of Cr in human nutrition was documented in 1977 when diabetic signs and symptoms of a patient on total parenteral nutrition (TPN) were reversed by supplemental Cr. Diabetic symptoms, in addition to elevated blood glucose, included weight loss, impaired nerve conduction, brain disorders and abnormal respiratory quotient that were refractory to exogenous insulin. Upon daily addition of supplemental Cr to her TPN solution for 2 weeks, diabetic symptoms were alleviated, and exogenous insulin requirement dropped from 45 units per day to zero.

Table 1 Signs and symptoms of Cr deficiency

Function	*Animals*
Impaired glucose tolerance	Human, rat, mouse, squirrel monkey, guinea-pig, cattle
Elevated circulating insulin	Human, rat, pig, cattle
Glycosuria	Human, rat
Fasting hyperglycemia	Human, rat, mouse
Impaired growth	Rat, mouse, turkey
Hypoglycemia	Human
Elevated serum cholesterol and triglycerides	Human, Rat, mouse, cattle, pig
Increased incidence of aortic plaques	Rabbit, rat, mouse
Increased aortic intimal plaque area	Rabbit
Nerve disorders	Human
Brain disorders	Human
Corneal lesions	Rat, squirrel monkey
Ocular eye pressure	Human
Decreased fertility and sperm count	Rat
Decreased longevity	Rat, mouse
Decreased insulin binding	Human
Decreased insulin receptor number	Human
Decreased lean body mass	Human, pig, rat
Elevated percentage body fat	Human, pig
Impaired humoral immune response	Cattle
Increased morbidity	Cattle

Adapted from Anderson RA (1998) Chromium glucose intolerance and diabetes. *Journal of American College of Nutrition* 17: 548–555.

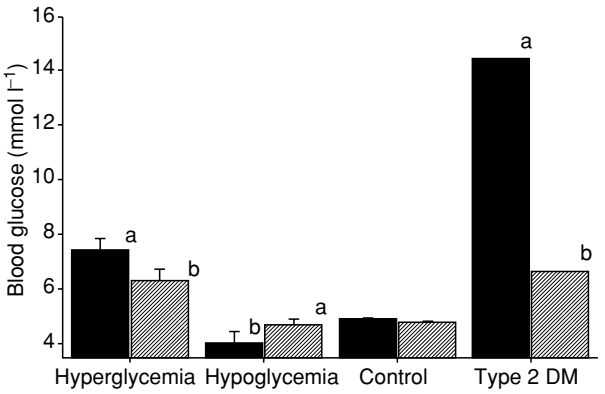

Figure 1 Response to supplemental Cr of people with hyperglycemia, hypoglycemia, optimal glycemia (control), and type 2 DM. The minimal amount of Cr usually showing beneficial effects in people with high or low blood sugar is 200 μg per day. People with diabetes require 400 to 600 μg per day or more.

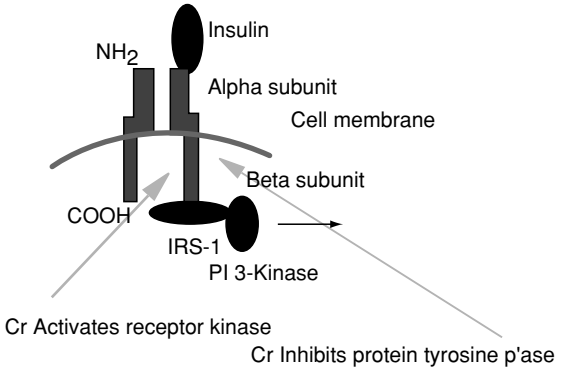

Figure 2 Postulated mechanism of action of chromium. When insulin binds to the α subunit, phosphorylation is increased, leading to increased insulin sensitivity and action. Chromium increases insulin binding to cells by increasing the insulin receptor number, which varies depending upon the type of cell, and also increases insulin sensitivity by increasing insulin receptor phosphorylation. IRS-1 denotes the insulin receptor substrate 1, and PI 3-kinase denotes phosphoinositol-3-kinase. For original references and details see Anderson RA (1998) Chromium, glucose intolerance and diabetes. *Journal of American College of Nutrition* 17: 548–555 with permission.

These findings have been repeated and documented in the scientific literature on several occasions.

Signs and symptoms of Cr deficiency listed in Table 1 are not limited to subjects on total parenteral nutrition. Improvements in glucose and/or lipid concentrations have been reported in children with protein-calorie malnutrition, the elderly, people with type 1 and type 2 DM, hypoglycemia, and marginally impaired glucose tolerance, and numerous animal species have also been shown to be improved by increased Cr intake.

The hallmark sign of marginal Cr deficiency is impaired glucose tolerance. The effects of Cr on people with high, low, and normal glucose tolerance as well as diabetes are illustrated in Figure 1. Chromium leads to a decrease in blood glucose in people with elevated blood sugar and an increase in those with low blood sugar owing to its role in normalizing insulin. In the presence of Cr in a physiologically active form, insulin is more efficient, and much lower levels of insulin are required. During periods of elevated blood glucose, more efficient insulin leads to a decrease in blood glucose. In people with low blood sugar, reactive hypoglycemia, more efficient insulin leads to a rapid rise in response to a glucose challenge and a more rapid return to baseline values. This leads to less of a drop or a raising of the hypoglycemic glucose values. Supplemental Cr also leads to increased insulin binding and increased insulin receptor number, and recent evidence suggests that Cr may be involved in the phosphorylation–dephosphorylation of the insulin receptor proteins (Figure 2). Chromium activates insulin receptor kinase, the enzyme that phosphorylates the insulin receptor leading to activation of insulin function, and appears to inhibit the phosphatase enzyme that deactivates insulin function.

Assessment of Chromium Status

There are no accurate methods for reliable a priori detection of marginal Cr deficiency. Chromium

Table 2 Daily intakes of chromium from various food groups

Food group	*Average daily intakes (μg)*	*Comments*
Cereal products	3.7	55% from wheat
Meat	5.2	55% from pork; 25% from beef
Fish and seafoods	0.6	
Fruits, vegetables, nuts, and mushrooms	6.8	70% from fruits and berries
Dairy products, eggs, and margarine	6.2	85% from milk
Beverages, confectionaries, sugar, and condiments	6.6	45% from beer, wine, and soft drinks
Total	29.1	

From Anderson RA (1988) Chromium. In: Smith K (ed.) *Trace Minerals in Foods*, pp. 231–247. New York: Marcel Dekker.

Table 3 Chromium content of selected foods

	Cr ($ng\,g^{-1}$)[a]	μg per serving
Dairy products		
Whole milk, 1 cup = 244 g	< 0.50	< 0.12
Skim milk, 1 cup = 244 g	< 0.50	< 0.12
Butter, 1 pat = 5 g	12 ± 2	0.06
Margarine, 1 pat = 5 g	3 ± 1	0.02
American cheese, 1 oz. = 28 g	20 ± 1	0.56
Eggs, 1 egg = 50 g	4 ± 1	0.20
Meats, poultry, and fish		
Beef cubes, 3 oz. = 85 g	24 ± 2	2.0
Chicken breast, 3 oz. = 85 g	6 ± 1	0.50
Turkey breast, 3 oz. = 85 g	20 ± 1	1.7
Turkey ham, 3 oz. = 85 g	122 ± 19	10.4
Ham, 3 oz. = 85 g	42 ± 4	3.6
Haddock, baked, 3 oz. = 85 g	7 ± 1	0.60
Grain products		
Waffles, 1 waffle = 75 g	89 ± 6	6.7
Whole wheat bread, 1 slice = 25 g	39 ± 1	0.98
Whole wheat roll, 1 roll = 26 g	23 ± 1	0.60
English muffin, WW, 1 muffin = 100 g	36 ± 1	3.6
Dinner roll, 1 roll = 25 g	25 ± 3	0.62
Rye bread, 1 slice = 25 g	37 ± 6	0.92
Bagel, egg, 1 bagel = 55 g	46 ± 7	2.5
Crackers, trix, 2 crackers = 14 g	9 ± 2	0.12
Spaghetti, 1 cup = 140 g	2 ± 1	0.28
Rice, white, 1 cup = 165 g	7 ± 1	1.2
Rice, brown, 1 cup = 165 g	4 ± 1	0.66
Fruits and vegetables		
Banana, peeled, 1 med = 126 g	8 ± 2	1.0
Grapes, 10 grapes = 50 g	2 ± 0	0.10
Apple, peeled, 1 med = 135 g	3 ± 1	0.40
Apple, unpeeled, 1 med = 150 g	9 ± 1	1.4
Orange, peeled, 1 med = 131 g	3 ± 1	0.39
Juice, grape, 1 cup = 250 g	30 ± 1	7.5
Juice, orange, 1 cup = 248 g	9 ± 2	2.2
Peas, 1 cup = 160 g	5 ± 1	0.80
Tomato, 1 med = 135 g	7 ± 1	0.94
Lettuce, 1 wedge = 135 g	13 ± 2	1.8
Celery, 1 stalk = 40 g	3 ± 1	0.12
Green beans, 1 cup = 135 g	16 ± 0	2.2
Carrots, raw, 1 carrot = 72 g	4 ± 1	0.29
French fries, 10 strips = 50 g	24 ± 1	1.2
Potatoes, mashed, 1 cup = 210 g	18 ± 1	2.7
Broccoli, 1 cup = 185 g	118 ± 0	22.0
Juice, tomato, 1 cup = 240 g	6 ± 1	1.5
Condiments		
Dressing, Thousand Island, 1 tbsp = 16 g	11 ± 1	0.18
Dressing, French, 1 tbsp = 15 g	12 ± 0	0.18
Pepper, 1 packet = 0.25 g	145 ± 15	0.04
Salt, 1 packet = 1 g	5 ± 1	0.01
Mayonnaise, 1 tbsp = 15 g	2 ± 1	0.03
Mustard, 1 tsp = 5 g	48 ± 6	0.24
Ketchup, 1 tbsp = 17 g	58 ± 0	0.99
Barbecue sauce, 1 tbsp = 16 g	108 ± 8	1.73
Maple syrup, 1 tbsp = 21 g	25 ± 3	0.52
Jelly, grape, 1 packet = 14 g	14 ± 1	0.20
Vinegar, 1 tbsp = 15 g	25 ± 4	0.38
Sugar, 1 packet = 6 g	3 ± 1	0.03
Miscellaneous		
Fruit punch, 1 cup = 200 g	3 ± 1	0.60
Orange sherbet, 1 cup = 193 g	7 ± 1	1.4
Apple pie, 1/7 = 136 g	11 ± 1	1.5
Cookies, oatmeal raisin, 4 cookies = 52 g	18 ± 3	0.94
Cookies, vanilla sand., 4 cookies = 42 g	16 ± 4	0.64
Cookies, choc. chip, 4 cookies = 42 g	82 ± 30	3.4
Peanut butter, 1 tbsp = 16 g	38 ± 3	0.61
Soybeans, 1 tbsp = 9 g	22 ± 6	0.20

[a]Values are mean ± SD of triplicate analyses.

concentrations in hair, urine, blood, tissues, etc. can be used to assess recent Cr exposure but are not long-term measures of Cr status. The only reliable indicator of Cr status is to monitor glucose, insulin, lipid and/or related variables before and after Cr supplementation. Response in blood glucose can often be seen in 2 weeks or less, whereas effects on blood lipids may take longer. One study reported no effects of supplemental Cr on blood lipids after 3 months but significant effects after 7–16 months.

Requirements

The estimated safe and adequate daily dietary intake (ESADDI) for chromium for children 7 years to adult of 50–200 μg per day was established by committees of the US National Academy of Sciences in 1980 and affirmed in 1989. The ESADDI is similar to an RDA and is usually established prior to the RDA. The Food and Drug Administration proposed a Reference Dietary Intake for Cr effective in 1997 of 120 μg per day. However, the new committee of the National Academy of Sciences representing North America has proposed that the normal intake of Cr should serve as the adequate intake, which is 20 μg for women and 30 μg for men over 50 and 25 for women and 35 μg for men aged 19–50 years. The French Conseil National d'Etudes et de Recherche sur la nutrition et l'Alimentation has proposed daily intakes of 55 μg for adult French women 19–65 years (60 μg per day for those over 65 years) and 65 and 70 μg, respectively, for the men.

Chromium requirement is related to the degree of glucose intolerance and diabetes. Glucose tolerance of subjects with mild glucose intolerance declines when consuming diets containing less than 20 μg per day of Cr for 5 weeks, whereas glucose tolerance of subjects with near optimal glucose tolerance is not altered by these low Cr intakes. People with diabetes also have a higher requirement for Cr. Chromium supplementation with 200 μg of Cr per day to people with mild glucose intolerance results in significant improvements, whereas the blood glucose of people with diabetes often does not respond. However,

daily Cr supplementation of 400 μg or more results in significant improvements in many people with diabetes.

Dietary Sources and High Intakes

Dietary Cr content of foods varies widely, and there are no comprehensive databases to calculate dietary Cr intake. The chromium content of foods is often erroneously high owing to Cr contamination during collection and analyses. For example, stainless steel blender blades are often used in the homogenization of foods, but stainless steel is approximately 18% Cr. In the presence of acidic foods, more Cr may leach from the blender blades than is present originally in the foods. Chromium is present in several food groups but at low levels. The distribution is similar among fruits, vegetables, dairy products, beverages, and meats, with lesser amounts from cereal products and small amounts from fish and seafood (Table 2). Specific Cr contents of selected foods are listed in Table 3. The chromium content of foods is a combination of the endogenous Cr present in the foods and the Cr introduced during the various stages of growing and processing. For example, fruit juices are often high in Cr, since Cr may leach from containers during processing and storage under acidic conditions. Processed foods such as meats also often contain elevated levels of exogenous Cr (Table 3).

Trivalent Cr, the form of Cr found in foods and in nutrient supplements, is one of the least toxic nutrients. The reference dose established by an expert panel of the US Environmental Protection Agency is 350 times the upper limit of the estimated safe and adequate daily dietary intake. The reference dose is defined as "an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily exposure to the human population, including sensitive subgroups, that is likely to be without an appreciable risk of deleterious effects over a lifetime." This conservative estimate of safe intake has a much larger safety factor for trivalent Cr than almost any other nutrient. The ratio of the EPA reference dose to the ESADDI for chromium of 350 compares to roughly two to five for other trace elements such as zinc and manganese and five to seven for selenium. Chromium in the form of both Cr chloride and Cr picolinate fed to rats at several thousand times the ESADDI for humans (based on body weight) resulted in no detectable signs of toxicity.

In summary, dietary intake of Cr is suboptimal for most humans and farm animals. Increased intake of trivalent Cr leads to improved glucose and lipid metabolism. The physiological role of Cr appears to be primarily though the improved function of insulin. Increased intake of Cr leads to increased insulin binding, increased insulin receptor number, and increased phosphorylation of the insulin receptor proteins leading to increased insulin sensitivity and function. There have been no documented negative effects of supplemental Cr in any of the more than 40 Cr supplementation studies involving daily Cr intakes of 1000 μg or more.

CIDER (CYDER; HARD CIDER)

Contents

The Product and its Manufacture

B Jarvis, Ross Biosciences Ltd, Ross-on-Wye, UK

A Brief History of Cider

The fermentation of apple juice to produce an alcoholic beverage is believed to have been practiced for over 2000 years. Cider is recorded as being a common drink at the time of the Roman invasion of England in 55 BC. Celtic mythology revered the 'sacred apple,' and in his famous natural history (AD 77), Pliny the Elder refers to a drink made from the juice of the apple. Cider was drunk throughout Europe in the third century AD, and in the fourth century, St. Jerome used the term 'sicera' (whence the name cider was possibly derived) to describe drinks made from apples. Reputedly, cider was a more popular drink than beer in the eleventh and twelfth centuries in Europe. Cider is produced throughout the temperate regions of the world where apple trees flourish. Such localities include Austria, Belgium, England, France, Germany, the Northern coastal area of Spain, Switzerland, and, more recently, Argentina, Australia, Finland, New Zealand, South Africa, Sweden, and the USA.

There are many references to cider in writings from the Middle Ages. The popularity of cider in fourteenth century England was such that William of Shoreham reflected the Church's concern for the niceties of sacramental rites by stating that 'young children were not to be baptised in cider'! William Langdon in *Piers Plowman* and Shakespeare in *A Midsummers Night's Dream* make reference to the consumption of cider; Daniel Defoe observed that Hereford people 'boast the richest cider in all Britain,' and Samuel Pepys noted in his Diary that on 1 May 1666 he 'drank a cup of Syder.' From the seventeenth century onwards, cider was praised in numerous poems and other literary works as an aid to good cheer and a homely cure for almost every ailment known to man.

Prior to the twentieth century, cider was a popular rural drink, cheaper than beer and often more potent (at c. 7% alcohol by volume (abv)). Farm workers often had part of their wages paid as truck (i.e., in kind), and every farmer would make his own cider for consumption by his workers and his own family and guests – although it is recorded that the best ciders were retained for his personal use. Most farms in the West of England and the West Country had their own cider press, or used the services of a travelling cider press that was hauled by horse from farm to farm. My own cider mill and press (dated 1717) stand outside my window as I write this account!

Commercial cider production commenced during the nineteenth century in England (e.g., H Weston & Sons of Much Marcle, 1880; H P Bulmer of Hereford, 1887; Whiteways Cyder of Whimple in Devon, 1894), although a few farms produced cider commercially from as early as 1727 (e.g., Symonds Cider and English Wine Co. Ltd., Stoke Lacey, UK). Cider production in England was estimated as 250×10^6 l (55×10^6 gallons) in 1900. By 1920 the level of cider production had decreased significantly; although some 73×10^6 l (16×10^6 gallons) were still produced on farms only 23×10^6 l (5×10^6 gallons) came from factory producers. By the late 1980s, cider sales had risen to over 273×10^6 l (60×10^6 gallons) per year and, in the 12 months to September 1999, almost 500×10^6 l (109×10^6 gallons) were sold in the UK by members of the National Association of Cider Makers, a trade association formed originally in 1920; a further 23×10^6 l (5×10^6 gallons) of cider were exported from the UK. Since 1999, UK cider sales have remained constant at 500×10^6 l (109×10^6 gallons) p.a.

The significant increase in the volume of cider produced commercially each year in the UK up to 1999 followed a period when growth had been inhibited by the imposition of Excise Duty in 1976 and results both from the introduction of new cider products, linked to increased marketing activity, and from changes in drinking habits, especially of younger adults. In 2002, it is possible to obtain cider either on draught or prepackaged in glass and PET bottles and in cans. Products range in alcoholic strength from less than 0.5 to 8.5% (abv), and in sweetness from very dry to sweet. In addition, cider products now include 'white' ciders, naturally colored ciders, and blends of

cider with fruit juice or other ingredients. Some cider, made from apples of a single crop, may be sold as a defined year Vintage Cider, whilst others are made from a single apple cultivar, e.g., Kingston Black.

Because of the significant growth in cider sales in recent years, imitation ciders have appeared on the market in several countries. Such products are produced by compounding distilled alcohol with apple juice and artificial flavors. Such products are not cider. In 1998, the European Association of Cider and Fruit Wines Industries of the EU (AICV) defined the acceptable procedures for production of cider and related products. Fortification of cider or apple juice by the addition of distilled alcohol is not an approved process for a product to be sold as cider.

Cider Fruits

Traditional ciders are made from the juice of cider apples, believed to have been imported into Britain by the Normans, although it is recorded in Gaulmier's *Traite du Sidre* (1573) that a Spaniard named Dursus de l'Etre brought apple trees into France in 1486! Traditional cider apples are of four main types: bitter sweet – low in acidity but high in tannin; bitter sharp – high acidity and high tannin; sharp – high acidity but low tannin; and sweet varieties – low acidity and low tannin. Examples of some cider fruit cultivars are listed in Table 1.

In some areas, especially Kent, Suffolk, and Norfolk in the UK, cider is made primarily from culinary fruit varieties such as the Bramley, although blends of bittersweet and culinary juices are frequently used to develop particular flavor profiles in commercial cider blends.

Table 1 Characteristics of cider apple varieties

Type	*Typical varieties*	*Typical juice composition*	
		Acidity (g per 100 ml)	*Tannin (g per 100 ml)*
Sweet	Northwood Sweet Alford Sweet Coppin	< 0.45	< 0.2
Bitter sweet	Ashton Brown Jersey Dabinett Michelin Yarlington Mill	< 0.45	> 0.2
Sharp	Brown's Apple Frederick Reinette Obry	> 0.45	< 0.2
Bitter sharp	Bulmer's Foxwhelp Brown Snout Chisel Jersey Kingston Black	> 0.45	> 0.2

Cider Orchards

The traditional farm orchard of standard trees still exists, and although generally declining in acreage, many hundreds of such orchards provide both an apple crop and grazing for livestock.

Modern cider apple orchards are largely intensive bush orchards, where the trees are frequently planted as closely as 2.4 m apart in rows some 5.5 –6 m apart. After planting, staking, and protecting against rabbits, using a wire guard, the grass under the trees is treated with a suitable herbicide to reduce competition for nutrients and water. Some growers cover the herbicide strips with a mulch of straw or other suitable material to ensure maximum retention of moisture. Although it has become standard practice to retain the herbicide strip into the productive years of an orchard, this practice is currently the subject of research to assess whether a grass sward may be better in relation to the quality of harvested fruit.

During the growing season, it may be necessary to spray the trees against pests, such as red spider mite, and diseases such as mildew, apple scab, and canker. In years of heavy potential cropping, chemical thinning (e.g., using paclobutrazol, 'Cultar') is frequently recommended, to reduce stress on the tree and thereby minimize the risk of biennialism, a condition that occurs significantly in cider fruit orchards.

Harvesting

In traditional orchards, fruits are generally allowed to fall naturally, or shaken from the trees using long poles (lugs), and then picked up either by hand or by machine. Traditionally, fruit from standard trees would be raked into piles or filled into sacks that were stored under the trees until the fruit was in a suitably ripe condition to be milled and pressed.

In intensive bush orchards, it is normal to shake the trees mechanically to cause the fruit to fall. Such shaking does not harm the tree and permits fruits to be harvested mechanically immediately after falling, so reducing the risk of rots that may occur if fruit are left for any length of time on the ground. The collected fruit is normally washed and then transported by road to the cider mill where, after weighing, the fruit is tipped into a fruit canal or on to a concrete pad for holding prior to milling and juicing.

Processing the Fruit

Milling and Pressing

The fruit is generally transferred into the mill using either a water flume, which provides additional washing, on a conveyor belt or using screw conveyors.

Detritus such as twigs, leaves, and stones is removed mechanically, and the fruit is milled using a grater, slicer, or hammer mill. The apple pulp is then conveyed to a mechanical press where the juice is extracted.

Traditionally, the presses consist of a frame containing a slatted board covered by a cloth into which a measured amount of the pulp is transferred. The corners of the cloth are folded over to form an envelope, the frame is removed, and the next slatted board is added together with the frame and another cloth. This procedure is repeated some 10 –20 times to build a 'cheese,' which is then pressed hydraulically to remove the juice, under a ram pressure of some 14 MPa (*c*. 2 MPa on the 'cheese'). This method removes up to 80% of the juice. Sometimes, the pomace residue (see below) is soaked in a small volume of water and repressed to remove further quantities of fermentable sugar.

Such processes are very labor intensive and, except for farmhouse production, have now largely been replaced by automatic presses such as the Bücher-Guyer, a horizontal cylinder press, or the Bellmer continuous belt press. Such presses are more efficient, often permit countercurrent extraction of the pomace with warm water, and have little demand for labor once properly set up. Processes such as electro-acoustic dewatering have been claimed to release a higher yield of juice by passing an electric current through the pulp prior to pressing but have not found application in the cider industry.

Pomace

Apple pomace can be used for the extraction of the natural gelling agent, pectin, used in the manufacture of jam, dairy products, and other foodstuffs, and in certain medical applications.

Pomace, either before or after depectinization, can be fed to animals either as a wet slurry or after drying; it can also be spread on to agricultural land as an organic mulch or fertilizer. Although it aids the breakdown of clay soils, its acidity often poses problems.

Apple Juice

The extracted juice is rich in malic acid, tannins, and sugar; it will also be contaminated with a variety of microorganisms derived from the fruit itself, from the orchard floor, from the harvesting equipment, and from the environment of the cider mill. Immediately after pressing, juice is treated with sulfite, either as sulfur dioxide (SO_2) or in the form of potassium metabisulfite. Sulfite acts both as an antioxidant, to prevent browning of the juice (due to polyphenol oxidase and chemical browning reactions), and as an antimicrobial that destroys 'wild' yeasts and bacteria. The sulfite-treated juice will normally be stored for some 24 h before being pumped into fermentation vessels. The level of sulfite will normally be adjusted to give 10–30 mg of free SO_2 per liter at the time of pitching with yeast.

Generally, the juice will not be clarified prior to fermentation. However, if the juice is to be concentrated by thermal evaporation, it will be treated with a mixture of enzymes (pectinases and amylases) and then clarified prior to concentration. Failure to destroy pectins and starch results in a thick viscous mass that neither concentrates effectively nor stores adequately.

Fermentation of Cider

Fermentation Vessels

Traditionally, the apple juice would have been fermented in oak vats. Although many such vats are still used, they have been largely replaced in commercial practice by vats of mild steel with a ceramic or resin lining, by lined fiber-glass resin vats and, more recently, by stainless steel vats. A few cider makers use redundant brewing vessels such as tall conico-cylindrical vats. However, there is evidence that tall conicocylindrical vats inhibit effective fermentation by creating excessive hydrostatic pressure on the yeast, although squat conicocylindrical vats are excellent. The Unitank-style vessel used frequently for the fermentation of wine is also excellent for cider fermentation. Figure 1 illustrates some of the styles of fermentation vessels used in cider making.

Fermentation Substrate

Traditional cider making fermented the whole juice, often with much of the apple solids remaining. Such solids included the pips, which contain glycosides, and so the cider would contain small quantities of cyanide derivatives.

In many countries, the practice of chaptalization has become increasingly common. Chaptalization supplements the sugar content of the apple juice with a suitable fermentation sugar (e.g., brewers' dextrose) and permits the production of strong cider with an alcohol content of 11.5–12% abv. By comparison, fresh juice fermentations, depending upon the sugar content, will rarely exceed 5.5–6.5% abv. In France, where the production of traditional cider is constrained by legislation, only the product of fermentation of fresh apple juice or fresh juice reinforced with juice from concentrate, can be called '*cidre*.' However, it is now permissible in France to produce a cider

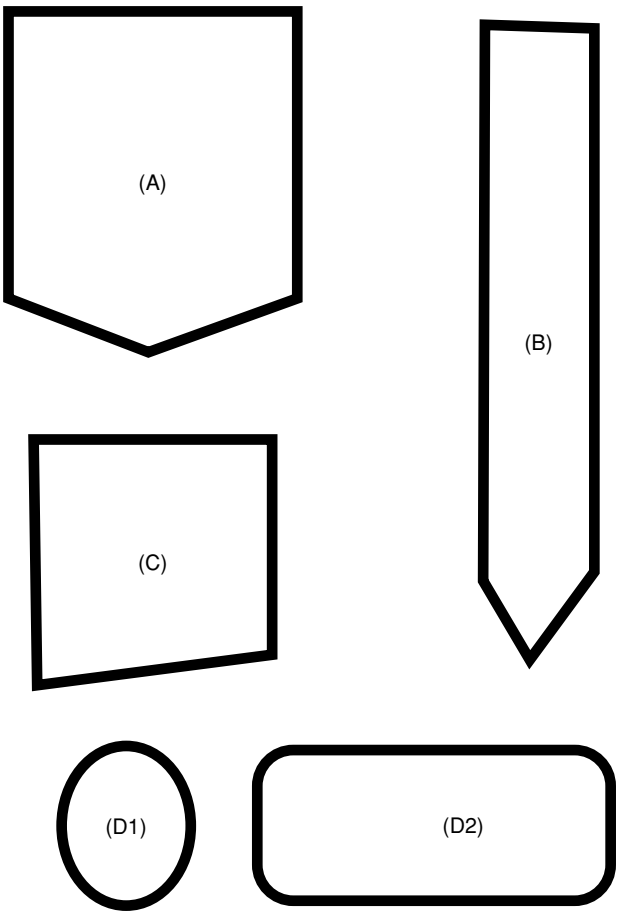

Figure 1 Schematic design of cider fermentation vessels. (A) Shallow angle conicocylindrical fermenter suitable for cider. (B) Typical steep angle, tall conicocylindrical fermenter as used for brewing beer. (C) Unitank fermentation vessel, with sloping base. (D) Oval cross-section (D1) horizontal fermentation vessel (D2).

from juice and fermentation sugar, which must be described as '*un boisson alcoolisée à base de pomme*' (*sic* an alcoholic beverage derived from apples) to differentiate it from traditional *cidre*.

In the preparation of cider, the apple juice may be fresh or reconstituted from apple juice concentrate; in many countries, pear juice (fresh or reconstituted) may be added to a maximum of 25% of the apple juice content. Other than fermentation sugars, the only other primary addition will be a suitable yeast culture. Fermentations originating wholly or largely from concentrate normally need the addition of yeast nutrients, such as ammonium phosphate, sodium pantothenate and/or thiamine.

Fermentation Process

Where a natural fermentation of the apple juice is required, the pressed and sulfite-treated juice is transferred to suitable fermentation vessels and allowed to ferment naturally. The process is monitored by measurement of the specific gravity (SG) of the juice; the fermentation is deemed to have gone to completion when the SG is 1.0000 or less.

However, most commercial cider is inoculated with a selected strain, or a mixture of strains, of a wine yeast capable of growth at elevated alcohol levels. The process consists of partially filling the vat with juice at a temperature at or below 18 °C, followed by inoculation with the specific starter culture of yeast. The use of a slightly reduced initial temperature is to prevent excessive temperature development during the initial exothermic growth of the yeast prior to onset of fermentation. The starter culture may be grown in the laboratory from a pure culture or added either as a commercial dried yeast preparation or as an aerated slurry of dried yeast – the latter is the most efficient for commercial processing. Once fermentation has started, additional substrate (i.e., apple juice and/or fermentation sugar) is added from time to time until the vat is filled. Although most cider vats are typically of $45 \times 10^3 - 9 \times 10^5$ l ($10 \times 10^3 - 2 \times 10^5$ gallons) capacity, much larger vats do exist.

At H P Bulmer's plant in Hereford, UK, the world's largest storage container for alcoholic beverages holds some 7.3×10^6 l (1.6×10^6 gallons) of product.

The fermentation typically continues with or without control of temperature, pH, or other parameters until all fermentable sugar has been metabolized into alcohol. This process can take from 10 days to 12 weeks, depending upon conditions! The modern cider fermentation plant generally has a facility to control the temperature, although ambient temperature fermentation still occurs widely (e.g., in farmhouse cider making). There is no doubt that good control of temperature can give a more rapid and more consistent fermentation. In France, cider is often fermented at temperatures below 15 °C. (*See* **Fermented Foods**: Origins and Applications.)

Maturation

When fermented to dryness, the cider is frequently left for a few days on the lees to permit the yeasts to autolyze, thereby adding cell constituents such as enzymes, amino and nucleic acids, etc. to the brew. However, if it is left for too long on the lees, there is a serious risk of development of off-flavors in the cider. The cider is separated from the lees (or tank bottoms) and transferred either directly, or after centrifugal clarification or filtration, into storage vats (traditionally made of oak). The actual process of maturation is generally uncontrolled, although, increasingly, modern commercial cider makers seek to control the storage temperature and the secondary malolactic fermentation. The maturation process is only slowly being understood: malolactic fermentation (carried out by various lactic acid bacteria) reduces the acidity by conversion of malic acid to lactic acid. Many other microbial and biochemical conversions also take place including modification of the tannins and esterification, e.g., of lactic acid to form ethyl lactate. Some of the chemical markers of maturation are now being identified, although judgment as to the extent of maturation and the suitability of the cider for use is still an art vested in the cider maker, who will have many years of experience in judging the quality of the product.

Final Processing

When required for use, different batches of cider, generally made from juices of different apple cultivars, will be blended by the cider maker to provide specific flavor attributes. The raw cider may be fined using agents such as bentonite, gelatin, or chitin and filtered to give a bright product with no haze. Modern processing refinements include the use of microfiltration systems to obviate the need for fining and to speed the process.

If the cider has a high alcohol content, it may be 'broken back' to final product strength using water or dilute apple juice. Other permitted ingredients may be added such as sugars, intense sweeteners (e.g., saccharin), color and/or additional preservative (normally limited to sulfite, although in some countries, benzoic or sorbic acids may be used). The finished blend may be treated with filter aids, such as kieselguhr (diatomaceous earth), to give an optically bright product or it may again be microfiltered. The most modern commercial plants use computer-controlled automated blending and microfiltration to convert the strong raw cider into commercial product blends.

Cider Packaging

Although a small market exists for 'live' cask-conditioned cider, i.e., cider in a wooden or plastic barrel, to which a small quantity of sugar has been added, together with a further yeast inoculum, the majority of commercial cider is carbonated and pasteurized, or sterile filtered, prior to filling into kegs, bottles, or cans. (*See* **Packaging**: Packaging of Liquids.)

Keg Cider

The cider is carbonated and pasteurized in line, through a continuous-flow plate heat exchanger. It is filled into stainless steel kegs in a plant that rinses, washes, and sterilizes the kegs prior to filling. The cider is dispensed in on-trade outlets using either carbon dioxide, or carbon dioxide and nitrogen, over-pressure through a cooling system designed to deliver the product into a glass at a temperature of 10 ± 0.5 °C. This process is similar to that used for dispensing keg beer.

Bottled Ciders

Cider to be filled into glass bottles may either be carbonated and flash pasteurized, or carbonated and then in-pack-pasteurized after filling. Since it is generally not possible to pasteurize PET bottles, the product will be flash-pasteurized prior to filling. Bottles will be sealed using either crown closures or tamper-evident metal or plastic screw caps. Glass bottles range in size from 25 cl to 1.13 l and PET bottles from 25 cl to 5 l. Carbonation pressures generally range from 2.5 to 3.5 bar, the higher initial pressures being used in PET bottles, which, due to gaseous diffusion, lose carbonation during storage. Glass bottled ciders have a shelf-life in excess of 2 years (provided that they are not opened!), whereas PET bottled ciders generally have a shelf life of 9–12 months, because of loss of carbonation.

Can Cider

The inside of cans for cider is always lacquered to prevent the product from attacking the metal. Cans are either of extruded aluminum or of mild steel, generally with a retained tag. Since sulfur dioxide is very corrosive to metal, especially if minute pinholes occur in the lacquer, cider for canning is generally prepared with little ($< 35\,mg\,l^{-1}$ total) sulfite. Such products must, of necessity, be prepared in much more controlled conditions than general blend ciders, since at these low sulfite levels, microbial contamination can lead to the formation of undesirable flavours. Cider filled into cans is always bed-pasteurized, generally at a process level of 30–40 pasteurization units (PUs). Control of dissolved oxygen levels for can ciders is also most important to prevent the development of oxidation off-flavors. Can ciders generally have a shelf-life of 9 months or less. (*See* **Canning**: Principles.)

Secondary Packaging

Bottles and cans are increasingly packaged using trays and shrink wraps, although the higher-value products (e.g., vintage and high-strength cider in glass bottles) are frequently packaged in carboard boxes with or without dividers.

Labeling of Cider Products

Throughout Europe, cider packs are required to conform to EU legislation on food labeling. At the present time, ingredient and nutritional labeling of alcoholic products is not required within the EU, although certain ingredients (e.g., intensive sweeteners) must be labeled. All alcoholic products, including cider, must display the alcohol content (as % abv) and the volume. The labeling requirements in other countries are dependent upon the national legislation.

Special Ciders

Vintage and Single Cultivar Ciders

Vintage ciders are made only from fresh juice from a named year. Some vintage and other ciders are made from the juice of a single named apple cultivar.

Sparkling Ciders

Sparkling cider is generally carbonated to a level of 3.5–4 bar pressure. Such products are filled into 'champagne-style' bottles with wired closures (generally plastic-mushroom stoppers). The product is normally sterile-filtered prior to bottling. Traditionally, sparkling cider received a secondary 'in-bottle' yeast fermentation (*méthode champanoise*), but such processing is rarely seen nowadays. A process used sometimes is that of *cuvée close*, in which a secondary yeast fermentation is done within a sealed tank, thereby developing a natural carbonation in the cider prior to bottling. Under EU legislation, it is illegal to refer to sparkling ciders as 'champagne cider.'

White cider

White cider is prepared by fermenting decolorized apple juice, or the fermented cider is itself decolorized by treatment with activated charcoal or other suitable decolorizing agent (e.g., PVPP) prior to final blending. The term '*white*' merely indicates that the product has little or no color – it is not 'white' in the sense that gin or vodka is 'water white.'

De-alcoholized and Low-Alcohol Ciders

De-alcoholized ciders are prepared by removing the alcohol from strong cider, by thermal evaporation, reverse osmosis, or other suitable technology to give a product with an alcohol content not in excess of 0.5% abv. De-alcoholized cider lacks body and flavor and is not sold commercially. Low-alcohol cider (< 1.2% abv) is prepared either using a stopped fermentation or by fortification of de-alcoholized cider with apple juice and/or other ingredients to provide a product with a flavor and aroma close to that of normal alcoholic cider.

Organic cider

Following consumer interest in organic foods, a number of cider makers now offer cider made only from fruit grown in accordance with EU Regulations governing organic horticultural practices. The fruit is pressed separately from nonorganic fruit, and at present, it can be treated only with gaseous sulfur dioxide. The other ingredients included in the product must also conform with current legislation on organic products.

Chemistry and Microbiology of Cidermaking

B Jarvis, Ross Biosciences Ltd, Ross-on-Wye, UK

Introduction

The fermentation of apple juice to cider can occur naturally through the metabolic activity of the yeasts and bacteria present on the fruit at harvest, which are then transferred into the apple juice on pressing. Other organisms, arising from the milling and pressing equipment and the general environment, can also contaminate the juice at this stage. Unless such organisms are inhibited, e.g., through the use of sulfur dioxide, the resulting mixed fermentation will yield a product that varies considerably from batch to batch, even if the composition of the apple juice for fermentation is identical.

Hence, control of the indigenous and adventitious microorganisms, followed by deliberate inoculation with a selected strain of yeast, is the preferred commercial route for the production of cider. Transfer of the fermented juice into (traditionally oak) maturation vessels will result in a secondary malolactic fermentation by microorganisms that occur naturally in these vats. Such organisms may produce beneficial or detrimental changes in the chemical and organoleptic properties of the final cider.

Microbiology of Apple Juice and Cider

Freshly pressed apple juice will contain a variety of yeasts and bacteria, many of which will be incapable of growth at the acidity of the juice. Examples of organisms often present in juice are shown in **Table 1**, together with an indication of their susceptibility to sulfur dioxide and ability to grow at the pH of the juice. (*See* **Microbiology**: Detection of Foodborne Pathogens and their Toxins.)

Role of Sulfur Dioxide in Apple Juice

The use of sulfur dioxide as a preservative in cider making is controlled by legislation, in most countries the maximum level permitted in the final product being 200 mg kg^{-1}.

The addition of sulfur dioxide to apple juice results in the formation of so-called sulfite addition compounds through the binding of sulfite to carbonyl compounds. The extent of sulfite binding is dependent upon the nature and origin of the carbonyl compounds present in the juice (see below). Similarly, if sulfur dioxide is added to an actively fermenting juice, there is a rapid combination with yeast metabolites such as acetaldehyde. Such juices will require a higher quantity of sulfite addition, if wild yeasts and other microorganisms are to be controlled effectively. Consequently, all additions of sulfur dioxide must be completed immediately after pressing the juice,

Table 1 Typical microorganisms of freshly pressed apple juice

Type	*Typical species*	*Ability to grow at the acidity of apple juice*[a]	*Sensitivity to sulfite*[b]
Yeast	*Saccharomyces cerevisiae*	++++	± or −

[b]−, insensitive; ±, relatively insensitive; ++, +++, ++++, increasingly sensitive.

[c]Only in the presence of air (e.g., on the surface of the cider).

although, provided the initial fermentation by 'wild' yeasts is inhibited, further additions to give a desired level of free sulfur dioxide can be made during the following 24h.

When dissolved in water, sulfur dioxide and its salts set up a pH-dependent equilibrium mixture of 'molecular sulfur dioxide,' bisulfite and sulfite ions (Figure 1). The antimicrobial activity of sulfur dioxide is believed to be due to the molecular sulfur dioxide moiety of that part which remains unbound (the so-called 'free' sulfur dioxide). Less sulfur dioxide is needed in juices of high acidity, for instance 15 mg l^{-1} of free sulfur dioxide at pH 3.0 has the same antimicrobial effect as 150 mg l^{-1} at pH 4.0.

Fermentation Yeasts

The fermentation process is carried out by strains of *Saccharomyces* spp., especially *S. cerevisiae* and *S. uvarum*, which are added to the sulfite-treated juice as a pure culture. The starter culture will be prepared in the laboratory from freeze-dried or liquid nitrogen frozen cultures, which are resuscitated in broth and then cultivated through increasing volumes of a suitable culture medium to give an inoculum for use in a starter propagation plant. The nature of the cultivation medium used will vary but is often based on sterile apple juice supplemented with appropriate nitrogenous substrates (e.g., yeast extract) and sometimes with vitamins such as pantothenate and thiamine. In order to insure that the starter culture has both a high viability and a high vitality, it is normal to aerate the yeast culture during the propagation stage.

Increasingly, commercial dried or frozen yeast cell preparations are used, either for direct vat inoculation or as inocula for the yeast propagation plant. The availability of such preparations enables the cider maker to use different strains of yeast for different cider fermentations without the need to maintain a wide range of cultures in the laboratory. They also reduce the risks from mutation and/or contamination of the starter culture.

The choice of culture is dependent upon many criteria, such as flocculation characteristics, ability to ferment efficiently at a range of temperatures, alcohol- and sulfur dioxide tolerance, lack of ability to produce hydrogen sulfide, etc. One desirable characteristic is the ability to produce fusel oils (e.g., higher alcohols), which affect both the flavor and aroma of the cider (Table 2).

Dependent upon temperature, the fermentation process typically takes some 10 days to 12 weeks to proceed to dryness (i.e., specific gravity (SG) 0.990–1.000) at which time all fermentable sugars will have been converted to alcohol, carbon dioxide and other metabolites (Tables 2 and 3). After inoculation, the starter yeast together with any sulfite-resistant wild yeasts from the juice will increase in numbers from an initial level of about $2–5 \times 10^5$ colony-forming units (CFU) ml^{-1} to $1–5 \times 10^7$ CFU ml^{-1}. Following an initial aerobic growth phase, the resulting oxygen limitation and high carbohydrate levels in the media trigger the onset of the anaerobic fermentation process.

In controlled fermentations, a maximum temperature of 25 °C will generally be tolerated, although fermentations controlled at 15–18 °C are not uncommon in many countries. Because of the exothermic

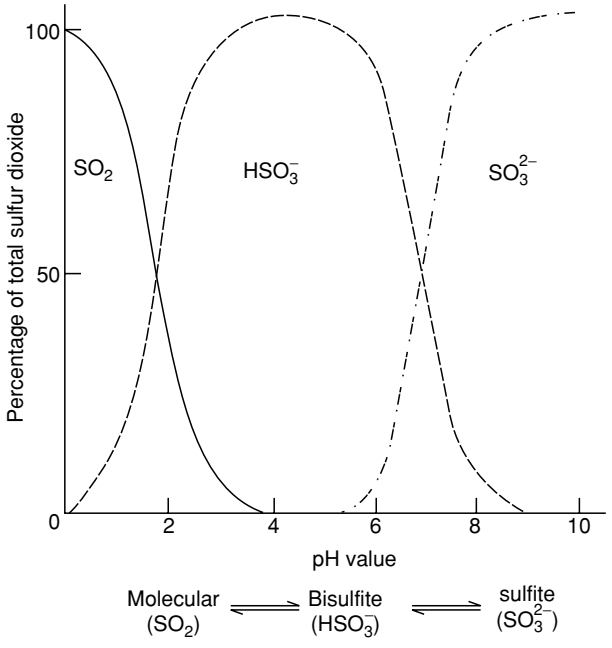

Figure 1 Percentage of sulfite, bisulfite and molecular sulfur dioxide as a function of pH in aqueous solution. Table 2 Higher alcohols in apple juices and ciders

	Concentration range (mg l^{-1})	
	Apple juices	*Ciders*
n-Propanol	0.2–2	4–200
n-Butanol	3–24	4–32
iso-Butanol		14–74
iso-Pentanol	0.1	42–196
sec-Pentanol	0.1–2	16–39
n-Hexanol	1–2	2–17
2-Phenylethanol		7–260

nature of the initial stages of fermentation, it is normal to cool the fermentation base to a temperature < 18 °C prior to inoculation, otherwise excessive temperatures (30 °C or above) can be reached. In tropical countries, it is not uncommon for temperatures as high as 35–40 °C to occur in the fermentation vat in the absence of effective temperature control.

Such high temperatures are undesirable since activity of the starter yeast strain may be inhibited – leading to 'stuck' fermentations and the growth of undesirable thermoduric yeasts and spoilage bacteria. Stuck fermentations can sometimes be restarted by 'rousing' (bubbling carbon dioxide through the vat), and/or addition of glucose, a nitrogen source (10–50 mg l^{-1}), usually diammonium phosphate, and thiamine (0.1–0.2 mg l^{-1}); yeast 'hulls' may also be added.

At the end of fermentation, the yeast cells will flocculate and settle to the bottom of the vat. During this process, a certain amount of cell autolysis occurs, which liberates cell constituents into the cider. The raw cider will be drawn (racked) off the lees as a cloudy product and transferred to storage vats for maturation. In some plants, the cider may be centrifuged or rough filtered at this time. If the cider is left too long on the lees, the extent of autolysis may become excessive leading to a build-up of nitrogenous materials that will act as substrates for subsequent undesirable microbial growth and the development of off-flavors in the product. (*See* **Yeasts**.)

Maturation and Secondary Fermentation

The maturation vats are filled with the racked-off cider and either provided with an 'over-blanket' of carbon dioxide or sealed to prevent ingress of air, which would stimulate the growth of film-forming yeasts (e.g., *Brettanomyces* spp., *Pichia membranefaciens, Candida mycoderma*) and aerobic bacteria (e.g., *Acetobacter xylinum*). Growth of such yeasts will produce precursors of an unpleasant flavor compound, believed to be 1,4,5,6-tetrahydro-2-aceto-pyridine, which is responsible for a 'mousey' flavor defect. Growth of *Acetobacter* spp. will produce acetic and other volatile acids, which impart a vinegary note. Of course, deliberate acetification of cider can be used to produce cider vinegar.

During the maturation process, growth of lactic acid bacteria (LAB) (e.g., *Lactobacillus pastorianus* var. *quinicus, L. mali, L. plantarum, Leuconostoc mesenteroides*, etc.) causes a malolactic fermentation (see below). (*See* **Lactic Acid Bacteria**.)

Spoilage and Other Microorganisms in Cider

Bacterial pathogens, such as *Salmonella* spp., *Escherichia coli*, and *Staphylococcus aureus*, may occasionally occur in apple juice, having been derived from the orchard soil, farm, and factory process equipment or human sources. Normally, the acidity of the product prevents growth, and such organisms do not survive for long in the fermenting product. In recent years, there have been several reports of food poisoning in the USA due to *E. coli* O157:H7 in 'cider'. These references to 'cider' refer not to fermented (or 'hard' cider) but to fresh pressed apple juice. It has been established that although these highly acid-tolerant strains of *E. coli*, associated with the US outbreaks, can survive for long periods, and may even grow, in apple juice, they are extremely sensitive to alcohol and die within 1–2 h in fermenting cider.

In 1994, a report of a serious outbreak of cryptosporidiosis in the USA from consumption of 'cider' was again associated with freshly pressed apple juice, *not* fermented cider. However, the report highlights a potential risk of contamination of apples, juice and cider by oocysts of *Cryptosporidium* spp. if apples are harvested from an orchard sward following grazing by animals. *Crytosporidium* oocysts are sensitive to pasteurization; furthermore, the filtration processes used in commercial cider production would remove any contaminant oocysts.

Bacterial spores from species of *Bacillus* and *Clostridium* can survive for long periods and are frequently found in cider but do not create a spoilage threat, because of the acidity, although their presence may be indicative of poor plant hygiene.

The juice from unsound fruits and juice contaminated within the process plant may show extensive contamination by microfungi, such as *Penicillium expansum, P. crustosum, Aspergillus niger, A. nidulans, A. fumigatus, Paecilomyces varioti, Byssochlamys fulva, Monascus ruber, Phialophora mustea*, and by species of *Alternaria, Cladosporium, Botrytis, Oospora*, and *Fusarium*. None are of particular direct concern in cider making, except that heat-resistant species (e.g., *Byssochlamys* spp.) can survive pasteurization and grow in cider if it is not adequately carbonated. (*See* **Microbiology**: Classification of Microorganisms; **Food Poisoning**: Classification.)

The occurrence of the mycotoxin 'patulin' in apples infected with *Penicillium expansum* may result in carry-over of patulin in the apple juice base used for cider fermentation. Although patulin initially inhibits growth of the fermentation yeasts, the organisms rapidly become tolerant to patulin, and once growth is initiated, the patulin is rapidly metabolized to form ascladiol and smaller amounts of other metabolites. Hence, if apple juice is contaminated with patulin, the fermentation may be slow to start, but the patulin will be destroyed within a few hours. Claims from France that patulin has been found in fermented cider are

believed to be associated with post-fermentation sweetening of the cider by addition of patulin-contaminated apple juice. (*See* **Mycotoxins**: Occurrence and Determination; Toxicology.)

In addition to *Brettanomyces* spp. and *Acetobacter* spp., which can cause oxidative spoilage of cider during fermentation and maturation, the yeast *Saccharomycodes ludwigii* can be a major spoilage organism. *Sacc. ludwigii*, which is often resistant to sulfite levels as high as 1000–1500 mg l^{-1}, can grow slowly during all stages of fermentation and maturation and is often an indigenous contaminant of cidermaking premises. Its presence in bulk stocks of cider does not cause overt problems. However, if it is able to contaminate 'bright' cider at bottling, its growth will result in a butyric flavor and the presence of flaky particles that spoil the appearance of the product. Although the organism is sensitive to pasteurization, it is not unknown for it to contaminate products at the packaging stage, either as a low level contaminant of clean but nonsterile bottles or from the packaging plant and its environment.

Environmental contamination of final products can occur also with wild strains of yeasts such as *S. cerevisiae, Zygosaccharomyas bailii*, and *S. uvarum*, which will metabolize any residual or added sugar to generate further alcohol and, more importantly, to increase the concentration of carbon dioxide. Process-plant strains of these organisms are frequently resistant to low levels of sulfite. In bottles of cider inoculated with such fermentative organisms, carbonation pressures of up to 9 bar have been recorded. For this reason, it is essential to maintain an adequate level of free sulfite (typically 30–50 mg l^{-1}) in the final product, particularly in multiserve containers that may be opened and then stored with a reduced volume of cider; alternatively, a second preservative such as benzoic or sorbic acid can be used, where permitted by legislation. This precaution is not necessary for products packaged in single-serve cans and small bottles that are in-pack pasteurized after filling.

Special Secondary Fermentation Processes

Conditioned draught cider Traditional 'conditioned' draught cider results from a live secondary fermentation process. After filling into barrels, a small quantity of fermentable carbohydrate is added to the cider, followed by an active inoculum of alcohol-resistant yeasts. The subsequent growth is accompanied by a low-level fermentation, during which sufficient carbon dioxide is generated to produce a 'pettilance' in the cider together with a haze of yeast cells. Such products have a relatively short shelf-life in the barrel.

Double fermented cider The cider is initially fermented to a lower than normal alcohol content (e.g., 5% abv) by restricting the total amount of sugar present. The liquor is racked off as soon as the cider has fermented to dryness and either sterile-filtered or pasteurized prior to transfer to a second sterile fermentation vat. Fermentation sugar and/or apple juice is added, and a secondary fermentation is induced following inoculation with an alcohol-tolerant strain of *Saccharomyces* spp. Such a process permits the development of very complex flavors in the cider.

Sparkling ciders Sparkling ciders are normally prepared nowadays by artificial carbonation to a pressure of 3.5–4 bar. Traditionally, sparkling ciders were prepared according to the 'methode champagnoise.' After bright filtration, the fully fermented dry cider is filled into bottles containing a small amount of sugar and an appropriate Champagne yeast culture. The bottles are corked and wired and laid on their side for the fermentation process, which will last from 1 to 2 months at 15–18 °C. Following this stage, the bottles are placed in special racks with the neck in a downwards position. The bottles are gently shaken each day to move the deposit down towards the cork, a process that can take up to 2 months. The disgorging process involves careful removal of the cork and yeast floc but without loss of any liquid (sometimes the neck of the bottle is frozen to aid this process). The disgorged product is then topped up using a syrup of alcohol, cider, and sugar prior to final corking, wiring, and labeling. It is not difficult to understand why this process is rarely used nowadays! An alternative process, known as '*cuvée close*,' involves a secondary fermentation using champagne yeast in a sealed vat. The naturally produced carbon dioxide is retained in the cider, which is filtered and bottled under a positive pressure.

Chemistry of Cider

The chemical composition of cider is dependent upon the composition of the apple juice, the nature of the fermentation yeasts, malolactic bacteria, microbial contaminants, and their metabolites, and the nature of any additives used in the final product.

Composition of Cider Apple Juice

Apple juice is a mixture of sugars (primarily fructose, glucose, and sucrose), oligosaccharides, and polysaccharides (e.g., starch) together with malic, quinic, and citromalic acids, tannins (i.e., polyphenols), amides and other nitrogenous compounds, soluble pectin, vitamin C, minerals, and a diverse range of esters

that give the juice a typical apple-like aroma (e.g., ethyl- and methyl-*iso*-valerate). The relative proportions will be dependent upon the variety of apple, the cultural conditions under which it was grown, the state of maturity of the fruit at the time of pressing, the extent of physical and biological damage (e.g., mold rots), and, to a lesser extent, the efficiency with which the juice was pressed from the fruit.

Treatment of the fresh juice and/or cider with sulfite results in the complexing of carbonyl compounds to form stable hydroxy sulfonic acids. If the apples contained a high proportion of mold rots, then appreciable amounts of carbonyls such as 2,5-dioxogluconic acid and 2,5-D-threo-hexodiulose will occur, which bind sulfite effectively. Sulfite-binding also occurs with sugars, such as glucose and xylose, and with yeast metabolites such as acetaldehyde and pyruvate. Sulfur dioxide is important also as an antioxidant that prevents enzymic and nonenzymic browning reactions of the polyphenols.

Products of the Fermentation Process

The primary objective of fermentation is the production of ethyl alcohol from fruit sugars with the associated formation of carbon dioxide. The biochemical pathways that govern this process are well recognized (Embden–Meyerhof–Parnass pathway).

The various intermediates in this metabolic pathway can also be converted to form a diverse range of other metabolites, including glycerol (up to 0.5%). Diacetyl and acetaldehyde may also occur, particularly if the conversion of pyruvate to ethanol is inhibited by excess sulfite and/or if uncontrolled lactic fermentation occurs. Other metabolic pathways operate simultaneously with the formation of long- and short-chain fatty acids, esters, lactones, etc. Methanol will be produced in small quantities (10–100 mg l^{-1}) as a result of demethylation of pectin in the juice. Table 3 illustrates some of the volatile compounds found in a normal and spoiled cider blend.

If LAB are also present in the fermentation, these can convert malic and quinic acids to lactic and dihydroshikimic acids, respectively, thereby reducing the acidity of the cider. These reactions are accompanied by further diverse, but not widely understood, chemical and biochemical changes that result in subtle, yet important, flavor changes in the final product. Lactic and acetic acids can also be formed by metabolism of residual sugars and ethanol; great care needs to be taken to avoid excessive production of volatile acids in cider.

It has long been believed that most tannins in cider do not change significantly during fermentation, other than the reduction of the chlorogenic, caffeic and *p*-coumaryl quinic acids to dihydroshikimic acid and ethyl catechol, respectively. However, recent work has shown that several other very important quantitative and qualitative changes occur, especially during the malolactic fermentation. Such changes modify the organoleptic perception of bitterness and astringency in cider.

The nitrogen content of cider juice includes a range of amino acids, the most important of which are asparagine, aspartic acid, glutamine, and glutamic acid; small amounts of proline and 4-hydroxy-methyl-proline also occur. Aromatic amino acids are virtually absent from apple juices. With the exception of proline and 4-hydroxy-methyl-proline, the amino acids are largely assimilated by the yeasts

Table 3 Volatile compounds in a normal and a diacetyl-spoiled cider

Compound	*Normalized peak area*[a]	
	Normal cider	*Spoiled cider*
Ethyl acetate	86.1	89.2
Diacetyl	0	3.4
Ethyl-2-methylbutyrate	10.3	12.9
2-Methylpropanol	35.4	97.3
iso-Amyl alcohol	305	213
2- and 3-Methyl-butan-1-ol	503	456
Ethyl hexanoate	233	179
Hexyl acetate	2	6.3
Octanol	0.7	1.2
Ethyl lactate	45.9	37.9
Hexan-1-ol	35.7	29.5
Nonanol	0.8	0.9
Unknown ester or acetal (relative molecular mass 172)	25.6	77.7
Ethyl octanoate	280	226
Heptan-1-ol	1.3	0.8
Ethyl octanoate	3.4	11.5
Decan-2-one	3.6	0.9
Benzalaldehyde	1.4	1.4
Ethyl-2-hydroxy-4-methyl pentanoate	4.2	7
Ethyl decanoate	57.6	53.4
Decanal	7.5	0.4
Ethyl benzoate	4.7	5.7
Diethyl succinate	5.2	2.9
Unknown ester	3.2	4.9
Methionol	1.3	0.6
Undecanal	2.2	1.2
2-Phenylethyl acetate	11.4	6.4
Hexanoic acid	12.6	12.6
Ethyl dodecanate	2.1	1
2-Phenylethanol	69	61.6
Heptanoic acid	0	3.4
d-Decalactone	4.4	3.4
Ethyl guaiacol	2.5	4.5
Octanoic acid	34.6	29.4
Nonanoic acid	1	1.2

[a]Based on gas chromatography–mass spectroscopy analysis of headspace volatiles.

during fermentation. However, leaving the cider on the lees for an appreciable length of time will significantly increase the amino nitrogen content as a consequence of the release of cell constituents during autolysis.

Inorganic compounds in cider are derived largely from the fruit and will depend upon the conditions prevailing in the orchard. These levels do not change significantly during fermentation. Small amounts of iron and copper may occur naturally, but the presence of more than a few milligrams per liter will result in significant black or green discolorations and flavor deterioration. The discolorations are due to the formation of iron or copper tannates from traces of metal ions derived from equipment and/or from the use of rotten fruit.

Cider Maturation

The aroma and flavor of freshly fermented cider are quite harsh. During maturation, significant changes occur in the composition of the cider that are due to microbial and biochemical activity, producing diverse compositional changes. More than 200 metabolites have been identified in mature cider; some produce desirable aroma and flavor characteristics, whereas others may be responsible for undesirable characteristics, especially if present in excessive amounts. The 'malolactic fermentation' causes a reduction in the acidity of the cider and imparts subtle flavor changes that generally improve the flavor. Much of the lactic acid, produced by decarboxylation of malic acid, is esterified with the formation of ethyl-lactate and other esters, which impart a smooth 'creamy' flavor to the product. Malolactic fermentation also results in the production of important volatile metabolites such as 1-hexanol, 2- and 3-methyl-butanol, and 2-phenyl-ethanol. The occurrence in mature cider of a compound with molecular mass 172 has been attributed variously to the occurrence of 1-ethoxyoct-5-en-1-ol, ethenylthio-octane, 5-chloro-salicylic, and other metabolites. It has been suggested that this compound may be responsible for the typical 'cider' flavor and aroma. Changes to the polyphenols (tannins) result in subtle changes to the perception of astringency and bitter characteristics.

However, in certain circumstances, metabolites of the lactic acid bacteria may damage the flavor and result in spoilage, e.g., excessive production of diacetyl (and its vicinyl-diketone precursors), the 'butterscotch-like' taste of which can be detected in cider at a threshold level of about 0.6 mg l^{-1}.

Commercial Ciders

A final blending of ciders is made to attain specific characteristics of sweetness, dryness, alcohol content, flavor, and aroma. Sugars or intense sweeteners, such as saccharin (which increases the perception of asringency), may be added. Artificial colors, ascorbic acid (as an antioxidant), and additional chemical preservatives (e.g., sulfur dioxide or sorbic acid) may also be added. Prior to final packaging, the cider is carbonated to give the product a petillance or sparkle.

CIRRHOSIS AND DISORDERS OF HIGH ALCOHOL CONSUMPTION

I Bitsch, Institut für Ernährungswissenschaft der Justus-Liebig Universit, Giessen, Germany

Introduction

It is well documented that heavy drinking of alcoholic beverages carries an increased risk of morbidity and mortality from diseases affecting many organs and may lead to psychic and physical dependence on alcohol. The risks depend on the amount of alcohol consumed, the drinking pattern, and the individual sensitivity. For these reasons, no generally valid threshold value for safe alcohol consumption can be given. Most authors agree that an upper limit of 80 g of ethanol per day should not be exceeded. A moderate drinker is considered as one who consumes 5–25 g of ethanol per day and a light drinker as one who consumes 0.2–5 g per day. Definitions of moderate drinking vary among studies. The US Department of Agriculture and the US Department of Health and Human Services define moderate drinking as not more than 24 g pure alcohol per day for men and not more than 12 g per day for women. Women appear to be more vulnerable than men to many adverse consequences of alcohol use. Women achieve higher concentrations of alcohol in the blood and become more impaired than men after drinking equivalent amounts of alcohol. Research also suggests that women are more susceptible than men to alcohol-related organ damage. Compared with men, women develop alcohol-induced liver disease over a shorter period of time and after consuming less alcohol. In addition women are more likely than men to develop alcoholic hepatitis and to die from cirrhosis.

Alcoholism

Three main patterns of chronic alcohol abuse are described in the *Diagnostic and Statistical Manual of Mental Disorders* of the American Psychiatric Association (1994):

- regular drinking of large amounts
- regular heavy drinking but limited to weekends
- episodic binges of heavy daily drinking lasting weeks or months, interrupted by long periods of sobriety

These criteria for the diagnosis of alcoholism also include an impairment in social or occupational functioning. Alcoholism is further distinguished from alcohol abuse by tolerance and physical dependence. Tolerance is defined as the 'need for markedly increased amounts of alcohol to achieve the desired effect, or a markedly diminished effect with regular use of the same amount.' Dependence is defined as 'the development of alcohol withdrawal syndrome after cessation of or reduction in drinking.' (*See* **Alcohol**: Metabolism, Beneficial Effects, and Toxicology; **Alcohol**: Alcohol Consumption.)

Excessive alcohol intake is often associated with malnutrition. This results from the limited intake of nutritionally adequate foods and from the impairment of digestion, absorption, transport, storage, metabolism, and excretion of many nutrients by direct or indirect action of ethanol. The role of nutrient deficiencies in the initiation and progression of the medical complications of alcoholism is still controversial.

Protein malnutrition (kwashiorkor-like) and protein-energy malnutrition (marasmus-like) are frequent in alcoholic patients with liver disease and, in some studies, the prevalence of the malnutrition correlates closely with the severity of organ failure. On the other hand, many patients who drink to excess are clearly not protein-energy-malnourished. Ethanol has appreciable effects on amino acid metabolism. Intestinal absorption and transport of isoleucine, arginine, and methionine are impaired by high concentrations of ethanol. Branched-chain amino acids and α-amino-*N*-butyric acid are increased in the plasma of alcoholics. (*See* **Protein**: Deficiency.)

Vitamin deficiencies are frequent in alcoholics and especially in those with liver disease. Most common is an insufficient folate supply, characterized by megaloblastic anemia and macrocytosis of the intestinal epithelium. Many factors contribute to folate deficiency in alcoholics. These include dietary deficiency, intestinal malabsorption, impairment of uptake and/or storage in the liver, and increased urinary excretion. Also ethanol metabolism perturbs folate metabolism through inhibition of methionine synthase, resulting in dysregulation of nucleotides and enhanced cancer risk. Also, the acetaldehyde product of ethanol metabolism was shown *in vitro* to trigger oxidative catabolism of the folic acid molecule. Poor dietary intake is undoubtedly the major cause, with the exception of heavy beer drinkers: 2 l of beer contain nearly 50% of the recommended daily allowance of folate for an adult man. The combined effect of low folate concentration in the diet and heavy alcohol

drinking leads to damage of intestinal mucosal epithelial structures, often associated with diarrhea, and results in malabsorption of folates and other nutrients. Symptoms of vitamin B_{12} deficiency are much less common than those of folate deficiency in alcoholics. This is probably attributable to the large stores of vitamin B_{12} in the body and the reserve capacity for absorption. In most studies the circulating levels of vitamin B_{12} in alcoholics are not different from normal controls. (*See* **Cobalamins**: Physiology; **Folic Acid**: Physiology.)

As with folate, poor dietary intake and an impairment of absorption are the main causes for insufficient thiamin supply in alcoholics. Alcohol inhibits active transport of thiamin across the intestinal mucosa, due to inhibition of Na,K-ATPase at the basolateral membrane of enterocyte, whereas the passive transport remains unimpaired. In addition, hepatic storage of thiamin may be reduced owing to fatty infiltration of the liver, hepatocellular damage, or cirrhosis in chronic alcoholic patients. Extreme thiamin deficiency is responsible for the Wernicke–Korsakoff syndrome, beriberi, and polyneuropathy in alcoholics. (*See* **Thiamin**: Physiology.)

The incidence of pyridoxine deficiency in alcoholic patients, as defined by low plasma levels of its circulating form, pyridoxal-5-phosphate (PLP), is more than 50% in different studies. Clinical data indicate that malnutrition, rather than the amount and duration of alcohol abuse, is the major determinant of pyridoxine deficiency. Pyridoxine absorption is primarily passive and is affected only by very high concentrations of ethanol. PLP in erythrocytes and liver is more rapidly destroyed in the presence of acetaldehyde, the first metabolite of ethanol oxidation, perhaps by displacement of PLP from protein and its exposure to phosphatases. This results in high pyridoxic acid excretion in the urine. Clinical signs of pyridoxine deficiency in alcoholics are infrequent. Sideroblastic bone marrow changes often occur in alcoholics with low plasma PLP values, but most of these patients also suffer from liver disease and folate deficiency. (*See* **Vitamin B_6**: Properties and Determination.)

Studies of vitamin A deficiency in alcoholism have mainly concerned patients with established cirrhosis, who may have impaired storage or transport of vitamin A because of an inadequate synthesis of retinol-binding protein. Most of them also have inadequate dietary intake. Other complications of alcoholism, e.g., pancreatic and biliary insufficiency, lead to malabsorption of vitamin A because this fat-soluble vitamin requires for its absorption adequate quantities of pancreatic lipases and bile salts in the small intestine. Another possible mechanism for low hepatic vitamin A level is increased hepatic metabolism of retinoic acid to polar metabolites through the action of microsomal enzymes, which are inducible by ethanol consumption. The clinical consequences of insufficient vitamin A supply in alcoholics are increased incidence of night blindness, follicular keratosis, and corneal ulcerations. Vitamin A deficiency may compromise immune function and may be procarcinogenic through effects on epithelial cell metaplasia in the oropharynx. Alcoholics with these complications often require both vitamin A and zinc treatment to correct visual dysfunction, because of an association between zinc and vitamin A metabolism. Zinc is an essential cofactor in the conversion of retinol to retinaldehyde in the retina. Alcohol appears to stimulate the release of zinc from hepatic stores, and its urinary excretion. Zinc levels in plasma and red blood cells are often reduced in humans after chronic alcohol ingestion. Also zinc pools are redistributed with greater tissue binding in response to various cytokine mediators of alcoholic liver injury. The potential consequences of zinc deficiency include acrodermatitis, altered taste and smell, and night blindness. (*See* **Retinol**: Physiology; **Zinc**: Physiology.)

Vitamin D intake, absorption, and metabolism seem to be impaired in alcoholics, and there are abnormalities of phosphorus, calcium, and magnesium homeostasis. Alcoholic patients often suffer from decreased bone mass and an increased incidence of fractures. (*See* **Calcium**: Physiology; **Cholecalciferol**: Physiology; **Magnesium**.)

Alcoholic Cirrhosis

Alcohol is the most common cause of cirrhosis in western countries. The incidence of this disease in alcoholics depends upon the mean daily intake of alcohol and the mean duration of alcohol consumption. However, only about 20% of heavy drinkers develop cirrhosis, and liver disease may progress to cirrhosis after cessation of ethanol ingestion. This fact suggests that other factors superimposed on alcohol drinking are involved in the pathogenesis of this severe form of liver injury. These include gender, genetic or immunological variables, other hepatotoxins, nutrition, viral hepatitis, and others. Individual predisposition is an important physiological factor in the development of this disease. Understanding the mechanism of the differences in susceptibility to cirrhosis may help clinicians to identify and treat patients at increased risk. (*See* **Liver**: Nutritional Management of Liver and Biliary Disorders.)

Morphologically, cirrhosis of the liver is a diffuse process, characterized by an excessive proliferation of connective tissue and the deposition of structurally

abnormal nodules. Alcoholic cirrhosis is mostly micronodular in type, with a size of nodules from 1 to 5 mm. Macronodules with a size ranging from 5 to 50 mm may occur, especially in the late phases of the disease. The loss of normal liver architecture, with separation of the portal tracts and the central zones of the liver by septa of fibrotic tissue, results in alterations of the vascular supply and a disturbance of the intrahepatic blood circulation.

Morbidity and mortality resulting from alcoholic cirrhosis are related principally to the loss of liver cell function, to derangements in the vascular system of the liver, or to both. The onset of cirrhosis is often insidious and associated with nonspecific symptoms such as fatigue, anorexia, weight loss, nausea, and abdominal discomfort. As the disease progresses, signs of hepatocellular failure became prominent. The most severe complications are iron overload, hepatic encephalopathy, and portal hypertension with ascites and bleeding from esophageal varices.

In association with cirrhosis of the liver, hepatocellular carcinoma may develop. The pathogenesis of the carcinomatous transformation is still unclear, especially because these tumor forms may also occur in noncirrhotic livers.

Ethanol leads to a number of metabolic and structural alterations in the liver that predispose this organ to derangements in its functional integrity. These are as follows: an increase in the ratio of NADH (the reduced form of nicotinamide adenine dinucleotide, or NAD) to NAD; interactions of ethanol with lipid and protein metabolism; stimulation of fibrosis with deposition of collagen; inhibition of liver cell regeneration; humoral and cellular immunological alterations; and excessive production of free radicals and cytokines. Alcohol induces cell death and inflammation, which can result in scarring that distorts the liver's internal structure and impairs its function. Acetaldehyde, the first oxidation product of ethanol metabolism, may exert some toxic effects of its own in liver tissue; it activates stellate cells directly and promotes liver scarring in the absence of inflammation.

All stages of liver injury can be produced in the baboon fed high-protein and vitamin-supplemented diets. This evidence suggests that toxic effects of alcohol, and not malnutrition, are the principal causes for the development of cirrhosis in chronic alcoholics. But alcohol abuse establishes only the conditions for the generation of cirrhotic lesions, which require the addition of some independent factors emerging over time.

Abstinence from alcohol is the essential factor for prevention and treatment of alcoholic cirrhosis. If irreversible liver damage is already established, some complications of cirrhosis can be alleviated by nutritional treatment. Portal-systemic encephalopathy, for example, often responds to an application of amino acid mixtures, enriched with branched-chain amino acids, whereas ascites responds favorably to sodium restriction.

Wernicke's Encephalopathy and Korsakoff's Syndrome

Wernicke's encephalopathy and Korsakoff's psychosis are diseases of the central nervous system (CNS) secondary to alcoholism. They represent a continuum of the same neuropathological process and develop in about 2–3% of alcoholics. Wernicke's disease is often followed by Korsakoff's syndrome. Severe alcoholics may have both diseases, but some of them show Korsakoff's psychosis without preceding Wernicke's encephalopathy. Wernicke's disease is an acute or chronic encephalopathy with a triad of clinical abnormalities: ophthalmoplegia, ataxia, and mental confusion. Korsakoff's syndrome is a psychosis with marked abnormalities in cognitive function: the cardinal symptoms are anterograde amnesia, disorientation, learning deficits, and confabulations. The relationship between the two diseases is not entirely clear. The neuropathological changes seen in autopsy materials of Wernicke–Korsakoff patients consist of circumscribed, symmetrical lesions in the diencephalon and brainstem. Most affected are the mammillary bodies and the dorsomedial nuclei of the thalamus. In acute cases the lesions are widespread and severe. In chronic cases the lesions are more restricted and show great variations in extent and severity within the affected area. There are corresponding variations of the clinical symptoms.

Extreme deficiency of thiamin, induced by malnutrition and interaction of ethanol with thiamin absorption and metabolism, is regarded as the primary cause of this syndrome. Patients with Wernicke's disease often have a high energy intake, consisting mainly of ethanol and/or carbohydrates, without sufficient protein and vitamins. Beyond that a direct toxic effect of alcohol on the brain has also been implicated. The Wernicke–Korsakoff's disease is not confined to alcoholism, but is also present in other conditions associated with thiamin malnutrition, e.g., hyperemesis gravidarum, Hodgkin's lymphoma, carcinoma of the stomach, and anorexia nervosa. Thiamin application can reverse Wernicke's syndrome in many but not all patients, at least when administered early in the course of the disease. In contrast, Korsakoff's patients often show poor response to thiamin therapy. Additional factors, of as yet unknown origin, seem to be necessary for the full development of

Korsakoff's psychosis. There is evidence to suggest that a genetic predisposition is involved in the etiology of the Wernicke–Korsakoff syndrome.

In some patients a variant form of transketolase with a low affinity for its coenzyme thiamin pyrophosphate has been diagnosed. This isoenzyme requires much larger amounts of thiamin to function than the normal enzyme. Some authors suggest that a variant transketolase and thiamin deficiency together contribute to the pathogenesis of the brain damage of the Wernicke–Korsakoff syndrome. In other studies this hypothesis has not been confirmed. (*See* **Anorexia Nervosa**.)

Alcoholic Polyneuropathy, and Beriberi in Alcoholics

Symmetric and predominantly distal polyneuropathy is probably the most common sequela of chronic alcohol abuse. It occurs in about 20% of all alcoholics. First symptoms include paresthesia, dysesthesia and pain sensations affecting primarily the lower extremities, accompanied by reduced or absent reflex activity. These symptoms are usually followed in the more advanced stages of the disease by marked motor impairments, such as weakness and atrophy of the anterior tibial muscles. Electrophysiological slowdown of the sensory and motor conduction velocities of the peripheral nerves, as well as myopathic changes, are usually observed. The predominant pathological abnormalities are distal pronounced axonal degenerations, mainly of the large fibers with a gradient of changes toward the extremities ('dying-back degeneration'). Segmental demyelination appears as a secondary phenomenon. Alcoholic polyneuropathy is clinically indistinguishable from beriberi ('dry beriberi') neuropathy. As in the Wernicke–Korsakoff syndrome, thiamin deficiency is regarded as the primary cause. Besides that, a long-lasting low protein-energy supply seems to be one of the main pathogenic factors for the development of the typical lesions of peripheric nerves. In addition, insufficient intake or absorption of pyridoxine, folates, B_{12} and other B vitamins contributes to the development of the disease, and direct toxic effects of ethanol and its metabolites are involved in the destruction of nerve ultrastructure and function. Recovery from alcoholic peripheral neuropathy is slow and often incomplete. The most important therapeutic factors are abstinence from alcohol and improvement of the overall nutritional status. Additional supplementation with high doses of B-complex vitamins is necessary. With this therapeutic schedule a slow diminution of symptoms may be expected in many but not all cases.

Pancreatitis

The association between alcohol consumption and pancreatitis is well recognized. In general, about 60–90% of all cases of chronic pancreatitis are alcohol-related. As with alcoholic cirrhosis, there has been an increasing prevalence of alcoholic pancreatitis in industrialized countries in the last 30 years. This disease often develops without obvious clinical symptoms. However, in autopsies of patients with a history of alcoholism, marked pancreatic lesions are frequently observed. Patients with severe or complicated forms of this disease may rapidly develop marked generalized malnutrition. (*See* **Gallbladder**.)

A favored hypothesis regarding the mechanism of action of chronic alcohol consumption on the pancreas is the observation that ethanol increases the protein content of pancreatic juice, with a concomitant decrease in water and electrolytes. This induces a precipitation of protein plugs within the pancreatic ducts, followed by retraction and calcification, resulting in pancreatic stones, atrophy of the duct epithelium, and proliferation of the connective tissue. The consequences are stenosis or dilatations of the ducts, cysts and pseudocysts, and progressive disappearance of the pancreatic exocrine tissue which is replaced by fibrosis. Pathologically, the gland is edematous and hemorrhagic. Besides chronic overconsumption of alcohol, both a high-fat, high-protein diet and, paradoxically, malnutrition have been implicated in the pathogenesis of the disorder.

Alcoholic pancreatitis tends to be recurrent and progressive and to result in pancreatic exocrine insufficiency. Some 1–2% of alcoholics suffer from an acute form. This complication can be quite severe, with violent epigastric pain, nausea, and vomiting. Cases of sudden death from acute attacks have been reported.

Even heavy drinking does not modify the risk for pancreatic cancer. Several epidemiologic studies do not support an association between alcohol consumption and incidence of pancreatic cancer.

Effect of Chronic Alcohol Consumption on the Brain

Ethanol – in common with other centrally acting agents – rapidly diffuses across the blood–brain barrier and equilibrates in brain tissue. Its concentration depends upon the plasma concentration, vascularization, local blood flow, and water content of the concerned brain area. Chronic ethanol consumption is associated with a variety of deficits in brain function over a wide range of doses and is often followed by clinically obvious brain damage.

Alcoholic Dementia

Alcoholics often suffer from disorders in cognitive processes, varying from a relatively slight memory reduction to deep dementia. The deficits in cognitive function are similar to those seen in patients with Alzheimer's disease or multiinfarct dementia. Histopathologically, the brain structures that are possibly involved do not show any lesion or atrophy, but there is considerable evidence that alcoholic dementia may potentially result from progressive loss of some neurons, synapses, and/or their associated receptors. Prolonged abstinence has a considerable reducing effect on dementia symptoms, but in most subjects the reversibility is only partial. Alcoholic dementia seems to be a severe form of Korsakoff's syndrome.

Alcohol Tolerance and Dependence

Functional tolerance and physical dependence are inexorably linked phenomena reflecting adaptive changes in the brain which compensate for the inhibition of functions by ethanol. Functional tolerance means a decrease in the sensitivity of the CNS produced by chronic alcohol intake. Physical dependence means hyperexcitability of the CNS following alcohol withdrawal after adaptation. The molecular mechanisms underlying both phenomena are as yet unknown. Possibly the effects are primarily related to changes in the microorganization and physical state of brain membranes.

Brain Shrinkage

Cerebral shrinkage seems to be one of the most frequent brain lesions induced by chronic alcohol consumption. It can be demonstrated by computerized tomography (CT) scanning in patients with alcoholism and even in 'social drinkers.' Cerebral shrinkage relates to a loss of white matter rather than of gray matter. In alcoholics the shrinking results in a lower brain weight compared to age- and sex-matched controls. After cessation of alcohol drinking cerebral shrinkage is often partially reversed.

Cerebellar Atrophy

Many alcoholics show cerebellar atrophy with progressive ataxia of stance and gait and, occasionally, an impairment of speech and ocular motility. This cerebellar degeneration is characterized by great uniformity of the clinical and pathological manifestations. In the majority of cases the disorder develops over several weeks or months, followed by years of stability. The pathological changes consist of degeneration of neuronal elements of the cerebellar cortex, particularly of the Purkinje cells. The dendritic networks of these cells show alterations in length parameters under the influence of ethanol in rats. Topographically, the lesions of the cerebellum are restricted to the anterior and superior vermis and to the hemispheres.

Although cerebellar atrophy is most frequently encountered in chronic alcoholic patients, it has also been reported in old people and in malnourished individuals, who allegedly did not drink. It has been postulated that alcohol and the aging process superimposed upon malnutrition may be responsible for the damage caused to the cerebellum.

Fetal Alcohol Syndrome

Prenatal exposure to alcohol produces various morphological, physiological, and behavioral abnormalities in the newborn, termed fetal alcohol syndrome (FAS). It has been observed in 1 in every 1000 children born to alcoholic mothers, and is the most common known cause of mental retardation. The Fetal Alcohol Study Group of the Research Society on Alcoholism has defined three criteria for the diagnosis of FAS:

- growth retardation
- abnormalities of the CNS
- abnormal facial features

The mechanisms by which alcohol produces these effects are not yet fully elucidated. Possibly ethanol affects NMDA and γ-aminobutyric acid receptors in the developing brain, leading to neuron death. The minimum level of alcohol consumed during pregnancy that causes FAS has not been established. Animal models have demonstrated conclusively that ethanol can cross the placenta and is teratogenic in several species. The effect is dose-dependent and the type of malformation observed depends upon the stage of development when the exposure occurred. Besides the toxic effects of ethanol, another potential cause of FAS is maternal and/or fetal malnutrition induced by impaired placental transfer of essential nutrients.

Among the neuroanatomical alterations observed in humans and animal models with FAS are decreased brain weight, delays in dendritic development, decreased numbers of pyramidal neurons in the hippocampus, and sprouting in the dentate gyrus. The clinical symptoms of the CNS dysfunction are mental retardation, hyperactivity, and learning disabilities. Despite nutritional rehabilitation, the physical and mental development of the children remains impaired. To date, a safe intake of alcohol for pregnant women has not been established. CITRUS FRUITS

Contents

Types on the Market

J Forsyth, Formerly of New South Wales Agriculture, Orange, NSW, Australia
J Damiani, Australian Citrus Growers Inc., Mildura, Victoria, Australia

Background

Citrus is the main fruit tree crop grown throughout the world. It is made up of many species that vary in importance due to different uses, markets, growing conditions, and climatic zones. The large production has significance in local and world trade for both fresh and processed products. Brief details on the classification of the species, growing regions and conditions, production statistics, with the utilization of the main and also lesser known types are discussed.

Classification

The taxonomic classification of the *Citrus* species is complex and diverse, and not universally agreed upon, but those used by Swingle and Reece will be followed in this article. Citrus, as a social and cultural

fruit crop, also has countless local names and identities throughout the world, often for an identical cultivar.

Citrus trees belong to the plant family Rutaceae, subfamily Aurantioideae, which comprises 33 well-known and described genera and 203 species. In addition, many natural and man-made hybrids also exist that have resulted in new edible cultivars. Many genera contain unusual or remote relatives of citrus with nonedible fruit, but of ornamental value like *Merrillia* and *Murraya*, or have genetic importance in breeding programs like *Poncirus* and *Severinia*.

True citrus fruit trees, which have a berry fruit called a hesperidium, belong to six genera: *Citrus, Fortunella, Poncirus, Microcitrus, Eremocitrus*, and *Clymenia*. Only the *Citrus* and *Fortunella* genera have fresh fruit cultivars of commercial importance. Both these genera are evergreen and unifoliate, and the genus *Citrus* provides nearly all of the commercial cultivars grown throughout the world.

Main Types on the Market

Citrus fruits are principally marketed according to how they are consumed:

1. As fresh or dessert fruits – sweet oranges, mandarins (eaten out of hand), grapefruit, or pummelo (spooned). Juice, slices, segments, rind, and leaves are also used to garnish food.
2. As processed products – juice (fresh, chilled, frozen, canned, blended, or concentrated), syrups and cordials, segments and rind oil, or essence. After the juice is extracted, there remain residues that can be a source material from which over 300 valuable byproducts can be produced. Some specialized types are also candied, dried, or used for marmalade manufacture. (*See* **Citrus Fruits**: Composition and Characterization; Processed and Derived Products of Oranges.)

The main types of fresh citrus fruits on the export or main local markets, and also used for processing, are normally broadly grouped as oranges, mandarins, lemons and limes, and grapefruit. There is also a wide range of other minor or lesser known species and types that may have regional or local significance. Some of these are mentioned in a later section. The following brief comments are made on the main citrus types, as listed in available statistics and found on world markets.

Sweet Oranges

The sweet orange types (*Citrus sinensis* [L.] Osbeck) are the most widely grown citrus fruits throughout the world and provide the greatest fruit marketing production. The many known cultivars can be subdivided into three main groups as the acidless or sugar oranges do not contribute to world trade:

- Common oranges (also known as blond or white oranges). The Valencia is the main cultivar grown, with harvesting from spring to autumn, depending on local climates. The fruit is dual purpose and suitable for both eating as fresh fruit or processing, while seedless types are also grown, e.g., Delta and Midknight. Other common oranges are often seedy and mainly suitable for processing, e.g., Pera, Hamlin, and Pineapple.
- Navel oranges are also widely grown as winter seedless eating fruit (**Figure 1**). The Washington navel with numerous clones or selections is the most important cultivar, while there are many others navels (over 50 distinct varieties or clones) available that spread the maturity period from early (like Fukumoto, Navelina, Leng, and Newhall) to late (Lane and Navelate), and to what are now being called 'summer navels,' following the location of many new very late maturing cultivars in Australia, e.g., Powell, Chislett, and Barnfield. A new pink/red fleshed navel – Cara Cara – is also creating marketing interest.
- Blood or pigmented oranges have been popular in Mediterranean countries for their distinctive flavor and both rind, flesh, and juice pigments, e.g., Tarocco, Sanguinello, and Moro.

Figure 1 (see color plate 25) Navels are the most important sweet, juicy, and seedless orange marketed for fresh fruit consumption.

Mandarins

Mandarins are also referred to as 'tangerines' in some countries. The mandarin group and related hybrids is very diverse (with over 100 cultivars), but can be classified into a number of main groups, some of which contain a large number of subgroups. This fruit is more seasonal, with each cultivar maturing and suitable for harvesting only over a short period of time, e.g., 6–8 weeks. Some are now available for the main types that can supply fresh fruit from very early to very late maturity. Mandarins production is increasing with a consumer trend towards easier to peel, segment, and seedless lunch/eaten out of hand fruit, while limited quantities are processed into juice or canned segments.

- Satsuma mandarins (*C. unshiu* Marcovitch) are also known as 'Unshiu mikan' in Japan and China. This is an important expanding seedless group that includes Clausellina, Miho, Miyagawa and Okitsu.
- Common mandarins (*C. reticulata* Blanco) are a very extensive group of different cultivars widely grown and available in world markets, e.g., Imperial, Nova, Ponkan, Sunburst, and Fortune. The group also includes the seedless clementines (like Marisol, Clemenules, and Hernandina), and two hybrid groups, e.g., tangors, which are hybrids of the mandarin and orange (like Murcott and Ellendale), and tangelos, hybrids of the mandarin and grapefruit or pummelo (Minneola and Seminole).
- Mediterranean mandarin (*C. deliciosa* Tenore) is also known as 'Willowleaf' and includes Avana clones.

Lemons

The lemon (*C. limon* [L.] Burm. f.) is an important fresh fruit group in world markets. Even though they are not eaten fresh, they are widely used for their acid juice content and slices, and for processing. The main cultivars are dual purpose and include Eureka, Lisbon, Meyer (a hybrid), Fino, and Verna. A minor related group of sweet or acidless cultivars and hybrids also exists.

Limes

Limes are also a varied group with a distinctive flavor and aroma, consisting mainly of two broad subgroups:

- Acid limes are small fruited (*C. aurantifolia* Swing) with West Indian, Mexican, or Key lime as the main cultivar, and often also processed into cordial; the large fruited (*C. latifolia* Tan) with Persian, Tahiti, or Bearss the main cultivar, is normally marketed as a fresh seedless fruit (Figure 2).
- Sweet limes (*C. limettioides* Tan), also known as the Palestine or Indian sweet lime, are insipid and not normally attractive to Western palates.

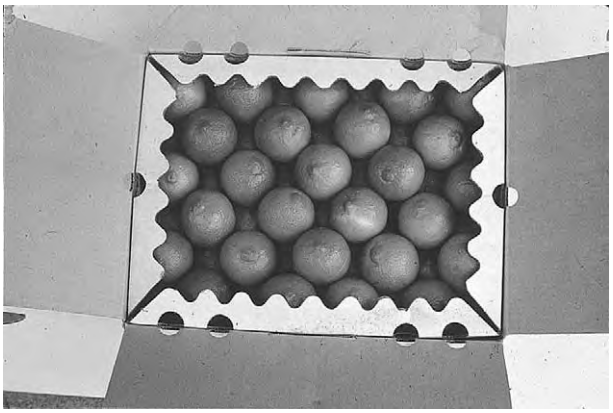

Figure 2 (see color plate 26) Limes are normally harvested for fresh marketing when mature but with green or light green to silver-colored rinds.

Grapefruit

Grapefruit is one of the newer types (*C. paradisi* Macfadyen) of citrus. It contains several distinct groups according to the rind or flesh-colored pigments:

- Common or white fleshed, with Marsh (seedless) the main cultivar.
- Pigmented, where the older cultivars were considered 'pink'-fleshed (with Thompson and Ruby the main cultivars), while newer selections, mutations or cultivars bred in the USA are now classified as 'red'-fleshed, due to the deeper pigmentation in both the rind and flesh while also being seedless. From this group, Star Ruby, Flame, and Rio Red are becoming important in world markets (Figure 3).

A recent breeding program in California, where an acidless pummelo was crossed with a white seedy grapefruit, has resulted in the selection and release of two new low-acid seedless grapefruit type cultivars – Melogold and Oroblanco (also called 'Sweetie' in Israel and some other countries).

Growing Regions and Conditions

Production regions are located in a wide range of climatic conditions, including the humid tropics, arid subtropics and intermediate climates. Commercial production tends to be located in two narrow belts in the subtropics and between 20 and 40° latitude north and south of the equator.

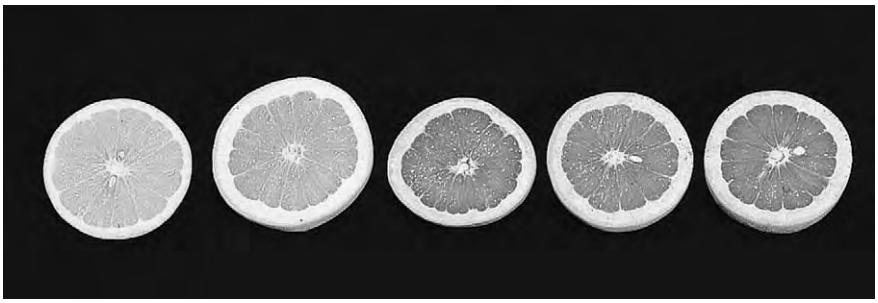

Figure 3 (see color plate 28) A range of internal pigments are now available in grapefruit, with consumer interest in the newer red fleshed cultivars (left to right: Marsh, Thompson, Rio Red, Flame, and Star Ruby).

Table 1 Fresh citrus crop production and utilization (with respective percentages), and the main producing countries of each for the major types produced throughout the world in 1998–1999

Citrus type	*Total production ($\times 10^3$ t) %*	*Exports ($\times 10^3$ t) %*	*Processed ($\times 10^3$ t) %*	*Main producing countries*
Oranges	53 644 65	4 327 48	22 784 82	Brazil, USA, Mexico, Spain, China
Mandarins	14 463 18	2 191 24	1 206 5	China, Spain, Japan, Brazil, Korea
Lemons and limes	9 446 11	1 362 15	1 991 7	Argentina, Mexico, Brazil, Spain, Egypt
Grapefruit	4 614 6	1 135 13	1 682 6	USA, Israel, Cuba, China, Argentina
Total world	82 166	9 015 11	27 664 34	Brazil, USA, China, Spain, Mexico

Citrus grows best in cooler, frost-free, Mediterranean-type climates, provided that the soils are suitable and rainfall is at least 1200 mm, distributed evenly throughout the year, or supplemented by irrigation. Climate can significantly affect yield, fruit quality, and tree health. In particular, minimum temperatures and degrees of frost restrict commercial production within many countries of the world.

Some cultivars have been bred or selected that extend production into marginally cooler climates, e.g., satsuma mandarins in Japan and China. Limes and pummelos grow well in tropical areas, where the normal rind color of oranges does not develop. High-quality grapefruit tend to be grown in hot desert areas.

Production Statistics

Commercial citrus production has been recorded by the FAO in over 100 different countries and through out six regions – Africa, North America, South America, Asia, Europe (Mediterranean), and Oceania. The world's citrus production has been gradually increasing through a 3-year average of $87\,980 \times 10^3$ t in 1995–1998, to a slightly smaller total crop of $82\,166 \times 10^3$ t in 1998–1999, as shown in Table 1. The production for the main types for 1998–1999 is shown in Figure 4. 'Other' citrus types totaled only 5124×10^3 t, with the majority recorded in Asia. The 4-year 1995–1999 production trends and percentage of the main citrus types grown are shown in Figure 5.

The largest growing areas are located in the northern hemisphere, where 68% of world production occurs, and include the important Mediterranean region with 20%, e.g., Spain, Egypt, Italy and the USA, China, and Mexico, whereas the southern hemisphere (32%) includes the largest producer in the world – Brazil, together with Argentina and South Africa. Nonspecified areas of citrus production with just over $16\,000 \times 10^3$ t in 1998–1999 would mainly occur in the subcontinent (especially India) and Asia.

Some regions like Japan, China, India, Mexico, and Asia have important local or domestic markets for their fresh citrus fruits, whereas others like Spain, USA, South Africa, Morocco, Turkey, and Argentina depend on exports as a major outlet for much of their production. Table 1 indicates total world fresh fruit exports of 11% in 1998–1999 for the main citrus types and with FAO recording 92 countries exporting some citrus.

In the two largest producing countries (Brazil and the USA), there has been an increasing trend for a large percentage of the production to be processed into frozen concentrated orange juice for storage and/or export throughout the world. The processing of some citrus production in Spain, Argentina, and Italy is also an important fresh juice market (Figure 6). Overall, in 1998–1999, $27\,664 \times 10^3$ t were processed, or 34% of total citrus production

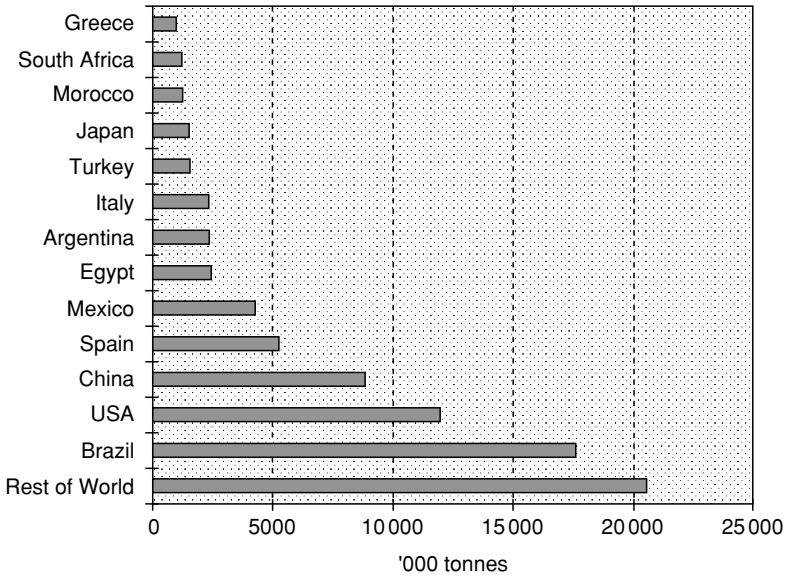

Figure 4 World citrus production, 1998–1999 for major producers and the rest of the world (which includes Cuba, Israel, Australia, Venezuela, South Korea, Lebanon, Uruguay and Cyprus).

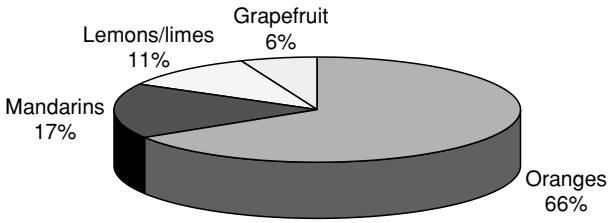

Figure 5 (see color plate 27) Average production percentages for the main citrus types grown in the world between 1995 and 1996 and between 1998 and 1999.

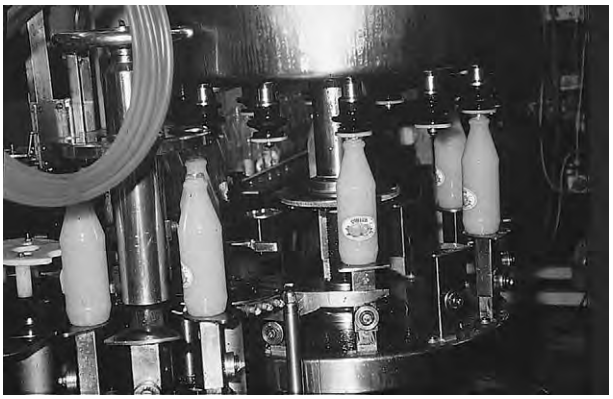

Figure 6 Juicing of oranges into various products is an important market in many countries. Fresh juice and citrus drinks are normally sold in consumer convenience packs.

(Table 1), whereas Brazil is reported to have processed 73% of their total orange production in 1989–1999, and the USA 88%.

Utilization of Lesser-Known Citrus Types

Some minor and lesser-known citrus fruit types that have fresh or processing uses and have some market importance in different countries or regions of the world are listed in alphabetical order. In many situations, local names exist for some of these types.

Bergamot (*C. bergamia* Risso)

This appears to be a variant of the sour orange and is mainly grown for its unique aromatic rind oil or essence in the coastal region of Calabria, a province of Italy. This essence is widely used in the food trade and in confectionery, and as an aroma for liqueurs, teas, sweets, and candied fruit.

Calamondin (*C. madurensis* Loureiro)

This resembles the mandarin and is grown extensively in the Orient, China, Taiwan, Japan, and the Philippines (where it is known as the 'Calamonding' or 'Kalamansi'). The fresh fruit is sour but is widely used for processing and as an ornamental tree.

Citrons (*C. medica* L.)

Like the other members of the acid group of lemons and limes, these also have two classes, the acid and the sweet, each with several cultivars. Citron are principally used for candied peel, but the etrog citron is also used in Jewish religious ceremonies. The Fingered Citron or Buddha's Hand, has an unusual appearance, with a distinctive and pervasive aroma,

Figure 7 Fresh or dried Kaffir lime leaves are an important garnish in many Asian recipes. (Market packaged dried leaves (L) and freshly picked leaves showing their distinctive shape (R)).

and is also used in religious ceremonies, perfuming rooms, and clothing for its medicinal values, and serves to highlight fruit-bowl arrangements.

Kaffir Lime (*C. hystrix* DC)

This belongs to the subgenus *Papeda* and is not a true 'lime,' but as the Kaffir lime is widely grown in Thailand, Philippines, Malaysia, Indonesia, and generally throughout Asia. It has unusual looking leaves (having a large winged petiole, see Figure 7) that are used (fresh or dried) with the fruit rind (as the fruit is normally not eaten) as a seasoning, flavoring, and garnishing in Asian food or recipes.

Kumquats (*Fortunella* spp.)

Also known as 'cumquats,' these are the smallest of the true citrus fruits. They can be eaten as fresh fruit or marmalade, or can be brandied. Several distinct cultivars that bear edible fruits are known:

- Nagami or oval kumquat (*F. margarita* [Lour.] Swing)
- Marumi or round kumquat (*F. japonica* [Thumb.] Swing)
- Meiwa or large round kumquat (*F. crassifolia* Swing).

Several minor kumquats are also grown mainly for ornamental purposes, e.g., Hong Kong (*F. hindsii* Swing) and Malayan (*F. polyandra* Tan).

Pummelo (*C. grandis* [L.] Osbeck)

This is also known as 'shaddock' or 'pomelo' and is the largest of the citrus fruits. Because pummelo hybridizes very readily, this has resulted in acid, acidless or sweet, pigmented or nonpigmented flesh, seedy or seedless cultivars being grown. This citrus type is common in some Asian countries, e.g., Thailand, China, and Indonesia, but is not common in Western countries or in world markets. It is usually eaten as a spooned desert fruit.

Sour oranges (*C. aurantium* L.)

Also known as bitter oranges, sour oranges are normally used for processing (marmalade or rind oil to flavor soft drinks and liqueurs). Most cultivars can be classified into three groups:

- Common, bitter, or sour oranges, of which the Seville (rough or smoothed skinned) is the most important.
- The bittersweet orange is a subgroup of the above common sour orange but has a lower acidity and better flavor.
- Variant bitter oranges or Bouquetiers are an important perfumery cultivar.

Conclusion

Many types of citrus fruits and processed products are now widely available throughout the world from local production or importation to supplement local supplies or in non-producing countries. Citrus is mainly consumed as fresh fruit, with their distinctive refreshing appeal and flavor, while also being a healthy, enjoyable, convenient and nutritious food. The fruit is also an excellent source of vitamins, minerals, dietary fiber and still low in kilojoules. Some fruit are used extensively to garnish food, while many processed products especially juices, cordials and marmalades are also widely available and consumed.

Composition and Characterization

L Izquierdo, Formerly of Consejo Superior de Investigaciones Científicas, Valencia, Spain

J M Sendra, Instituto de Agroquímica y Technología de Alimentos, Valencia, Spain

Introduction

Citrus fruits are one of the largest fruit crops in the world. About 30% of citrus fruits is processed to obtain various products, mainly juice. Similarly, the citrus industry is also the second largest fruit-processing industry, surpassed again by the grape industry, which mainly produces wine. Neither orange juice nor wine can be considered essential foods but they do have an important role in our lives.

Although citrus fruits have been consumed since ancient times, citrus processing, as it is known today, was not possible until thermal treatment (to inactivate enzymes and microorganisms) and concentration processes were commercially available. Since then, the citrus industry has developed rapidly, becoming prominent among food industries.

Although consumption of fresh citrus fruits is popular in all producing countries, processed products must still be considered almost as luxury products. Breakfast with orange juice is only common in developed countries. Thus, citrus industries process value-added products whose quality, nutritional characteristics, and purity are appreciated. Since these three aspects are closely related to composition, the analysis of citrus constituents is a frequent subject of research work, supported by governments and industries.

This article covers the most important aspects of citrus fruit composition, its relationship to nutritional value, and its importance for product authentication. Several books have been published on these subjects and the Further reading section lists some of them as well as published composition tables.

Constituents

The genus *Citrus* has many species and the differences among them are of great interest to specialists. However, from a general point of view, the similarities are greater than the differences, which is not surprising when considering species of the same genus. The economic importance also differs among species and compositional studies of the main species are more frequent. Thus, data from *Citrus sinensis* (sweet orange) are more extensive than from *C. reticulata* (tangerine), *C. limon* (lemon), or *C. paradisi* (grapefruit), and data from these species are more comprehensive than from other *Citrus* species. Within each species some varieties are better known than others. Valencia orange is the best-studied sweet orange, since it is the most important variety for juice extraction, the main citrus product. Thus, most information given here will refer to the juice rather than to the fruit, since juice, accounting for about half of the total weight of an orange, is the most important part of the fruit, and is the part of the fruit mainly consumed by humans.

Orange peel constitutes most of the other half of the fruit, but peel is of much less importance than juice. Although some byproducts (cattle feed, molasses) are obtained from peel, it is more a question of removing residues and avoiding pollution than of economic interest. Only peel oil (obtained before or during juice obtention) and pectins (obtained only from suitable species and varieties) are important peel products for human consumption, perfumery, and cosmetics.

Our knowledge of the chemical composition of juice and fruits is being continuously improved. The efficiency of instrumental methods of analysis allows the rapid identification of more and more minor constituents. But the basic major constituents have been well known since the application to citrus research of classical methods of analysis, which are still of interest for some rapid determinations. Both types of methods will be considered in this article, but it must be pointed out that analysis is a dynamic discipline and methods (mainly instrumental) are continuously being improved. Many of those which seem almost perfect today will look old-fashioned tomorrow.

Citrus fruit parts are represented schematically in **Figure 1**, and the approximate constitution of oranges is shown in **Table 1**. Juice vesicles, located in the endocarp, contain the juice, which constitutes about 50% of the total weight of a typical orange fruit. The peel is formed by the flavedo (epicarp and outer mesocarp) and the albedo (inner mesocarp). Flavedo and albedo account, respectively, for about 10 and

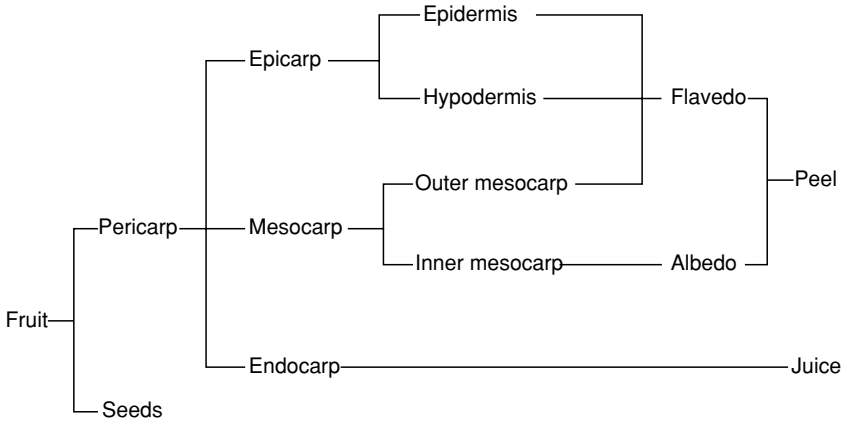

Figure 1 Structure of citrus fruits. Reproduced from Citrus Fruits: Composition and characterization, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Table 1 Approximate composition of oranges

Overall composition (%)	
Juice	40–50
Flavedo	8–10
Albedo	15–25
Rag, pulp, and seeds	Rest
Main constituents (%)	
Water	85–90
Sugars	6–9
Acids	0.5–1.5
Pectins	0.5–1.5
Minerals	0.5–0.8
Essential oils	0.2–0.5
Fiber	0.5–1.0
Protein	0.5–0.8
Fat	0.1–0.2

25% of the whole fruit. The flavedo contains peel oil in the oil sacs and the albedo most of the pectins. After juice extraction, rag, pulp, and seeds account for the rest of the total fruit weight. Most of the fruit (almost 90%), is water. The rest is mainly formed by sugars and acids. Minerals, amino acids, aroma compounds, and pectins are present in smaller proportions. These percentages vary greatly in other citrus fruits, but they also vary within orange fruits, depending on variety, ripeness, area, and culture practices. Concentrations, distribution, and methods of analysis of these constituents will be discussed in more detail in the following sections.

Sugars and Acids

Soluble solids of citrus juices consist mainly of sugars and acids. Sugars are more abundant (70–80% of total solids) in oranges, tangerines, and grapefruits, whereas citric acid is predominant in ripe lemons and limes. Soluble solids are usually expressed in degrees Brix (for easy and rapid evaluation with refractometers), referring to all juice solids as sucrose. Total acidity is expressed in grams of citric acid per 100 ml of juice, approximately equivalent to percentage.

The total solids increase with ripeness in all citrus species. In most cases, this is due to the increase in sugar content but, in lemons, citric acid increases with ripeness. Ranges from 9 to 14°Brix and from 1.5 to 0.5% acidity can be considered usual in orange juices processed in citrus plants. Commercial juices, prepared by blending juices of different varieties at different degrees of ripeness, show less variations: from 11 to 12°Brix and from 0.8 to 0.9% acidity are normal ranges. (*See* **Ripening of Fruit**.)

The degrees Brix-to-acidity ratio, also called the maturity index, is a fundamental measure of quality of citrus juices. In commercial orange juice it usually has values from 12 to 14 and no orange juice is considered of high quality if it shows a ratio lower than 11. The importance of the degrees Brix-to-acidity ratio as a quality index lies in its relationship with the equilibrium between sweetness and sourness, one of the most appreciated sensory characteristics of citrus fruits. As discussed above, degree Brix value depends mainly on sugars.

Only three sugars are important in citrus fruits, sucrose, glucose, and fructose, which produce juice (or fruit) sweetness. Other sugars, such as galactose, heptulose, mannose, rhamnose, xylose, or trehalose, have only been detected as traces. (*See* **Carbohydrates**: Classification and Properties; **Fructose**; **Sucrose**: Properties and Determination.)

The analysis of citrus sugars has been approached by many different methods. A classical standard method is the determination of reducing sugars (fructose and glucose) by copper reduction, followed by

the inversion of sucrose to fructose and glucose, which can then also be determined as reducing sugars. By this method, the concentrations of the main citrus sugars (reducing and nonreducing) are determined. When the sugar composition must be known in more detail, separative (chromatographic) methods are used. Numerous analyses of citrus sugars have been performed by paper chromatography, gas chromatography, and high-performance liquid chromatography. Traces of the different minor sugars mentioned above have been detected by these techniques. The analyses of citrus sugars have shown that the typical ratios of sucrose to glucose to fructose are 2:1:1 in orange juice, 1:4:4 in lemons and 1:3:3 in limes. Typical contents of total sugars are 8% of total weight in orange and grapefruit juices, and 2% in lemon juice, although these percentages can vary greatly with variety and ripeness. (*See* **Chromatography**: Principles; High-performance Liquid Chromatography; Gas Chromatography.)

The major acid in citrus fruits is citric acid. Total acidity, which is determined by titration, is expressed as grams of citric acid per 100 ml of juice. Malic acid is the second most important acid, present in variable but much lower amounts than citric acid. Other organic acids, such as succinic, malonic, lactic, oxalic, phosphoric, tartaric, adipic, isocitric, etc., are present in even smaller amounts and have been detected by separative methods, such as gas chromatography of methyl ester derivatives. (*See* **Acids**: Properties and Determination.)

Acid content, like total solids, varies greatly with ripeness. Ranges from 0.5 to 1.5% in orange juice, from 0.8 to 2.5% in grapefruits, and from 4 to 8% in lemons and limes are usual.

Polysaccharides

Citrus fruits contain cellulose, hemicelluloses, and pectic substances, mainly in the peel. The juice contains only small amounts of these compounds, although they play an important role. From the nutritional point of view, they provide dietary fiber. Concerning quality, pectin acts as a colloidal stabilizer, protecting juice cloud. Pectins are polymers of galacturonic acid and exist in juices at levels of about 0.5%. In the form of the methyl ester, polygalacturonic acid maintains juice turbidity. If deesterification occurs, the colloid degrades and the juice clarifies. The main reason for thermal treatment of commercial juices is not only to destroy microorganisms, but to inactivate the enzyme pectinesterase, which produces pectin degradation. Citrus peel, mainly from lemon, is an important source of commercial pectins, which is of great interest in the food industry because of their gelling power. (*See* **Dietary Fiber**: Properties and Sources.)

Nitrogenous Compounds

About 0.7% of citrus juices consists of nitrogenous compounds. Free amino acids are the most important part of the nitrogenous fraction (70%); the rest consists of vitamins, proteins (mainly enzymes), and inorganic compounds. Although not important as nutrients due to their low concentration, amino acids are extensively used for characterization purposes and to detect adulteration in fruit juices. Total nitrogen determination (closely related to total amino acid content) is a standard method of purity control. Nevertheless, the nitrogen content can be easily manipulated by adding inorganic salts. For this reason, separative techniques allowing the determination of individual amino acids are of considerable interest. Gas chromatography of volatile derivatives has often been used for this purpose, as has ion exchange chromatography. Reversed-phase liquid chromatography is an increasingly accepted technique. Figure 2 shows chromatograms obtained by this method from the dansyl derivatives of orange juice amino acids. (*See*

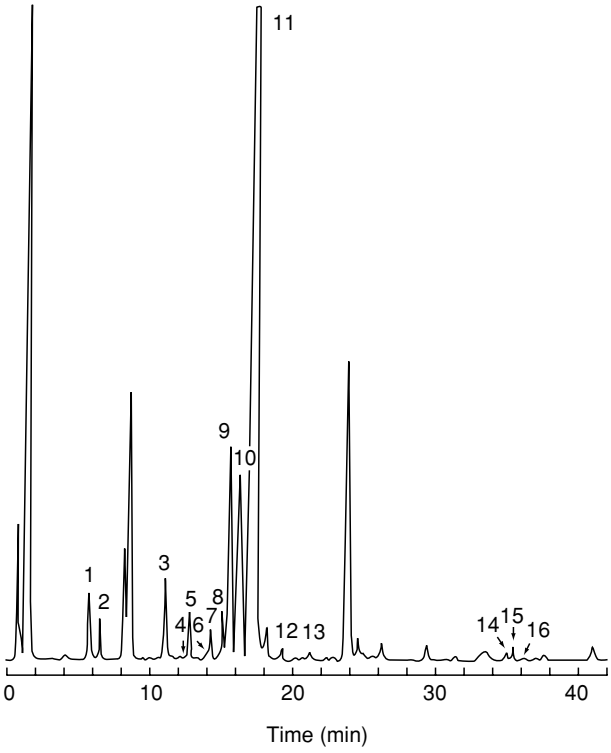

Figure 2 Liquid chromatogram of orange juice amino acids: 1, aspartic acid; 2, glutamic acid; 3, asparagine; 4, glutamine; 5, serine; 6, threonine; 7, glycine; 8, alanine; 9, arginine; 10, γ-aminobutyric acid; 11, proline; 12, valine; 13, methionine; 14, ornithine; 15, lysine; 16, histidine. Amino Acids: Determination; **Chromatography**: Thin-layer Chromatography.)

Bitter Compounds

Two main types of bitterness, caused by two different types of compounds, occur in citrus fruits. Flavanone neohesperidosides, as naringin in grapefruit and neohesperidin in sour oranges, produce the typical bitterness of fruits and juices from these species. The other type of bitterness, which constitutes an extremely negative quality factor in some orange juices, is produced by limonin, a triterpene derivative of the limonoid group. Limonin bitterness is known as 'delayed bitterness' since it is not detected in fresh fruits or freshly extracted juices, but develops during juice storage or with heat treatment. The reason is that fresh fruits do not contain limonin, but a nonbitter precursor which converts into limonin after juice preparation. Limonin is detected by taste at concentrations of about 6–8 mg l^{-1} in orange juice. Citrus industries avoid exceeding these concentrations in commercial juices by using only proper fruits or by blending different raw materials to obtain the desired final products. The limonin content of orange juice depends on variety and ripeness. It is extremely high in Navel varieties (still about 15 mg l^{-1} at a degrees Brix-to-acidity ratio of 12), which makes them very unsuitable for juice processing. Generally, early varieties produce more bitter juices than late varieties but country/region of origin can also affect limonin contents. Problems of bitterness are worse in temperate areas (California, Australia, Spain) than in tropical or subtropical regions (Brazil, Florida). (*See* **Flavor (Flavour) Compounds**: Structures and Characteristics.)

Reduction of bitterness has been attempted by many means, involving changes in cultivation practices (rootstock, fertilization) and juice treatments. Debittering of processed juices seems to be the most promising approach and some citrus industries are already equipped with debittering devices.

Limonin analysis is essential in quality control. Thin-layer chromatography or immunoassay methods as well as liquid chromatography techniques are used in its determination.

Minerals

Amounts and proportions of minerals contained in citrus juices are interesting for nutrition. Total mineral content, referred to as 'ash,' is about 0.4% of juice weight. Ash composition varies in relation to the species, ripeness, growth area, and methods of cultivation. Generally, the major inorganic components of citrus juices are potassium and nitrogen, each accounting for about 40% of the total. Calcium, magnesium, and phosphorus are less abundant (about 5% each). Sodium, iron, sulfur, and chlorine are also important. About 20 more minerals have been detected in smaller proportions or only as traces. Some of these minor constituents have been proposed for ascertaining the geographic origin of orange juice. Minerals are very satisfactorily determined by atomic absorption spectrometry or plasma emission techniques, where available. Refer to individual minerals.

Aromas

The typical citrus aroma depends on many minor constituents. Their individual contribution and relative proportions, as well as interactions among them, give the characteristic odor to each species. These constituents are present in juice vesicles of the endocarp and, in larger amounts and different proportions, in the oil sacs of the flavedo. When extracting the juice, oil sacs break and part of the oil joins the juice. Peel oil is also obtained as an independent product in citrus plants. One of its principal uses is as a flavoring ingredient for soft drinks.

Odor compounds constitute a part of the volatile fraction of citrus juices, which also contain nonodorous compounds. The distinction between both types of constituents and the evaluation of their relative importance in juice aromas are important research objectives in this field. Table 2 shows the main types of compounds forming the volatile fraction of orange juice. Several examples of individual constituents, including some which cause off-flavors, are listed in the table. Major constituents of the volatile fraction are ethanol (about 0.5 ml l^{-1} in juice) and limonene (0.15 ml l^{-1}). None of these are important for aroma, since their concentrations are lower than detection thresholds. Chromatography, preferably gas chromatography using capillary columns of high resolution coupled to a mass spectrometer, is the most suitable method for determining either individual compounds or quite large groups of volatile compounds in a single analysis. Due to the low concentrations in the juice of most volatiles, a concentration step may be necessary for detailed studies. This step can be performed by solvent extraction of the juice or of a juice distillate, followed by solvent removal.

For rapid determinations, necessary in routine quality control, the total analysis of recoverable oil or the specific analysis of some groups of constituents, such as alcohols, aldehydes, and ketones, or unsaturated constituents, is also used. (*See* **Alcohol**: Properties and Determination; **Essential Oils**: Properties and Uses.)

Other Minor Constituents

Juice color in all citrus fruits is due to carotenoids, with the exception of blood oranges in which

anthocyanins, types of flavonoid compounds, are responsible for their typical color. β-Carotene is present in orange juice in concentrations of about 0.5 mg l^{-1}, representing a small but significant source of vitamin A. Color is one of the principal quality attributes of citrus juices and several methods, either visual or instrumental, have been used for its evaluation. The Hunter colorimeter must be mentioned since it was specifically developed for citrus fruits. Basically it determines three parameters: *L*, *a*, and *b*, respectively related to lightness, green-to-red, and blue-to-yellow preponderance. (*See* **Colorants (Colourants)**: Properties and Determination of Natural Pigments.)

Lipids constitute about 0.07% of orange juice and consist mainly of fatty acids, 90% of them being palmitic, palmitoleic, oleic, linoleic, and linolenic acids. The rest of the lipid fraction includes a range of both polar and nonpolar compounds. Lipids can be partially responsible for off-flavor development since, even though they contribute little to flavor, they are precursors of malodorous compounds. Independently, lipids are important for taxonomy because each different species has its own profile of lipid components. (*See* **Fatty Acids**: Analysis.)

Fully methoxylated flavones, belonging to the flavonoid group, are considerably more abundant in the peel than in the juice, where their concentration increases with extracting pressure. Consequently, these compounds can be considered as a potential index of extractor performance. Figure 3 shows chromatograms obtained by liquid chromatography of fully methoxylated flavones of orange and tangerine juices.

Vitamins are very important minor constituents of citrus fruits, and will be discussed in the following section.

Nutritional Value

Although citrus fruits cannot be considered as basic foods, they are excellent complementary foods to appropriate diets. During the eighteenth century, citrus fruits were the only known source of vitamin C able to prevent scurvy on long sea journeys, but this was a long time ago. Nevertheless, the contribution to the diet of vitamins, minerals, and dietary fiber from citrus fruits is still significant. (*See* **Scurvy**.)

Orange juice is an important source of vitamins. Composition tables show that it contains (per 100 ml) about 100 μg thiamin, 30 μg riboflavin, 40 μg vitamin B_6, 20 μg vitamin E, 300 μg niacin, 200 μg pantothenic acid, 300 μg folacin and 50 mg vitamin C. Thus, a glass of orange juice covers the daily requirements of vitamin C, about 25% of those for folacin, and 5% for vitamin B_6. This contribution to dietary needs increases in interest if the low energy content of orange juice (about 50 cal per 100 ml) is considered as this allows higher consumption of orange juice than of other foods richer in vitamins (but also in energy). On the other hand, commercial orange juice needs less heat treatment for microorganism inactivation than other less acid foods, so vitamin losses are lower. Refer to individual vitamins.

Lemon juice contains similar amounts of vitamins C and B_6, but less folacin (100 μg per 100 ml), whereas tangerine juice is poorer in vitamin C (30 mg per 100 ml), and grapefruit juice has a lower content of all these three vitamins.

Concerning minerals, citrus juices are rich in potassium (150–200 mg l^{-1}) but low in sodium (1–2 mg l^{-1}), which makes them very suitable for people receiving treatment with diuretics.

Finally, cellulose, hemicelluloses, and pectins contained in citrus fruits are a source of dietary fiber, but which will make only a small contribution to daily intake for most people. (*See* **Dietary Fiber**: Properties and Sources.)

Authentication

Citrus processing is an important world industry and some products reach high prices, which may make the idea of adulteration attractive. Although typical adulteration of citrus juices (by dilution, addition of sugar, blends of juices from different species without declaration) is not harmful to health, the consumer is paying for a substandard product, and unfair competition against honest producers is always involved. (*See* **Adulteration of Foods**: Detection.)

The methods for detecting adulteration generally consist of comparing the values of some selected characteristics (i.e., constituent concentrations) of suspicious samples with the known ranges of values in pure products. The effectiveness of the method will depend mainly on the success in selecting those characteristics which are specific to the pure product, easy to determine accurately, and difficult to mask. For a sound knowledge of the characteristics of pure products, sufficient data, representative of the possible raw materials, must be collected. Data variability is usually high due to ripeness, area, or fruit variety. Consequently, values show wide ranges, which complicates the detection of adulteration. Mean values and ranges of several characteristics of Spanish orange juices are presented in Table 3.

Table 3 Mean values and ranges of some characteristics of Spanish orange juices (values in mg l^{-1}, except for absorbances)

	Mean	*Minimum*	*Maximum*

Detection methods may be based on the determination of one, few, or many characteristics. Instrumental analysis, computers, and statistics are useful in all cases but essential where multiple data must be obtained and processed from each sample.

Several types of adulteration are possible in citrus products. The most important will be mentioned and the methods developed for their detection discussed.

Since water, sucrose, and citric acid are the main constituents of juices and can be obtained from cheaper sources, an easy type of adulteration consists of their addition to the juice in proportions that keep the solid content and acidity at normal juice levels. In this simple method, the adulteration should be easy to detect, since concentrations of the remaining con-

stituents decrease with dilution level. However, these concentrations can also be manipulated. Detection methods have increased in complexity by successively determining minerals, individual sugars, total nitrogen, nitrogen from amino acids, specific amino acids, and so on. Masking procedures also increased in their complexity by successively adding inorganic salts, blends of sugars, ammonium salts, glycine, amino acid blends, and so on. The ideal final situation to prevent adulteration will be achieved when masking procedures are either more difficult or more expensive than producing pure products.

The methods mentioned above work on the basis that all artificially added constituents, even from external sources, are normal constituents of juices. So, only through the modification of the natural proportions between added and nonadded constituents can fraud be detected. A different approach is to consider that raw materials from extraneous sources must show some differences. For example ratios of carbon (^{13}C:^{12}C) or oxygen (^{18}O:^{16}O) isotopes can be used to determine if any sugar or water comes from sources other than the citrus fruit.

Blends of juices from different species can be detected through the knowledge of the pattern distribution of certain compounds in each species. A method of detecting the addition of grapefruit juice to orange juice consists of analyzing the profiles of flavanone glycoside concentrations.

Finally, ultraviolet absorption is useful for determining the addition of pulpwash solids to orange juice.

Oranges

S Pao, CREC, Lake Alfred, FL, USA
P J Fellers, Winter Haven, FL, USA

Background

Of all the various fruits in the world, the sweet orange (*Citrus sinensis* Osbeck) is perhaps the most cherished. The refreshing natural flavor of orange flesh or juice from mature fruit is characterized as uniquely pleasing, with just the right mix of sweetness and tartness. Furthermore, the fruit's bright sunny color is especially appealing and often complements other food items on a dining table. Much effort has been expended in the attempt to imitate orange flavor and color.

The orange is the most widely grown and popular citrus species worldwide. Its origin is believed to be the tropical and subtropical regions of Asia. The mention of oranges in Chinese literature dates to 2200 BC, long before they were introduced to Europe – about 1400 AD Continental America probably received its first oranges in the early-to-mid 1500s with the arrival of the explorers Bernal Diaz in Mexico and Ponce de Leon in Florida. Brazil probably received its first oranges with the coming of the Portuguese in the mid-1500s. Oranges entered interstate commerce in the USA in the early 1800s with the shipping of fruit, usually in barrels, from coastal Florida locals to northern cities. Today oranges and orange products are shipped all over the world from areas of production.

Production and Utilization

Oranges are cultivated in both tropical and subtropical regions around the world. The quality of a

[a]As calculated from production amount less the amount of fruit processed. From Food and Agriculture Organization of the United Nations (2000) *Citrus Fruit, Fresh and Processed. Annual Statistics*.

specific variety of fruit produced is largely influenced by rootstock, climate, types of soil, grove practice, and harvesting time. Commercial propagation of citrus is usually accomplished by bud-grafting a desired variety on to a suitable rootstock. Major rootstocks used in Florida for sweet orange varieties are Carrizo citrange, sour orange, Swingle citrumelo, Cleopatra mandarin, Volkameriana lemon, rough lemon, Milam lemon, and Palestine sweet lime. Orange varieties with different ripening periods are often cultivated to extend the availability of fruit from a particular producing region.

World production of oranges in 1998–99 amounted to 53×10^6 t, up 17×10^6 t from 1988–89. Of all the countries in the world, Brazil and the USA produce the lion's share of oranges (Table 1). Some lesser-producing countries not listed include Algeria, Cyprus, Israel, Japan, Lebanon, Tunisia, Uruguay, Former USSR, and Venezuela. About 58% of the world's orange production is consumed fresh. The USA and Brazil process the bulk of their crops, while countries like China and Egypt process very little of their crops. Spain is the world's largest exporter of fresh oranges, while Brazil is the largest exporter of processed orange juice. The leading orange fruit-importing countries in 1998–99 were Germany (467×10^3 t), The Netherlands (424×10^3 t), and France (423×10^3 t).

Anatomy and Varieties

A citrus fruit is botanically classified as a type of berry called a hesperidium that has a thick, leathery rind, with numerous oil glands, and a large flesh portion composed of several wedge-shaped sections. Unlike pome fruit, such as the apple, the citrus fruit is derived from a superior ovary, an ovary completely separate from the calyx. In general, the development of citrus fruit does not create a cavity at the blossom end of the fruit at any maturation stage.

Oranges are most often round, in contrast to the various shapes of many other citrus species. Generally, grapefruit are larger than oranges, while mandarins (especially tangerines), lemons, and limes are smaller. The major structural features of an orange from the outside to the center of an equatorial section are as follows: peel composed of the epidermis (outer layer of cells); flavedo, a layer of tissue containing plastids which are dark green when immature, and oil glands dispersed throughout; albedo, a white pulpy material surrounding the segments which in turn hold the individual juice vesicles or juice sacs; and seeds (if any) arranged around the pulpy core. Each segment is encased by a rather tough segment membrane or wall which, along with the juice vesicles, is ruptured when the fruit is extracted for the juice. Examples of seedy orange varieties are Pineapple and Parson Brown, whereas Hamlin, Washington navel, and Valencia are examples of seedless or nearly seedless varieties.

Oranges may be classified as sweet or bitter (sour), the latter having generally little commercial importance for the fruit, but great importance for the use as a rootstock. Sweet orange varieties are further classified, as follows: (1) common orange, represented by many important varieties, including Valencia (perhaps the major variety worldwide), Hamlin (important in Florida and Brazil), Pera and Natal (both of importance in Brazil), Pineapple (important in Florida), Parson Brown, Shamouti (of importance in Israel and several other Middle Eastern countries); (2) sugar or acidless orange, possessing a bland flavor; (3) blood or pigmented orange, important in the Mediterranean area of Europe, especially Spain; and (4) navel orange, especially Washington navel (of great importance in California). In addition, the Temple orange, a natural tangor, has economic significance and is being cultivated in quantity in Florida.

Composition and Nutritional Value

An orange is composed of about 88% water. The chief soluble solids in orange juice are the soluble carbohydrates or sugars (*c.* 10%), while citric acid is the main soluble solid in lemons and limes. The chief sugars in orange juice – glucose, fructose, and sucrose – occur in the approximate ratio of 1:1:2. Total sugars (especially the sucrose fraction) generally increase

with advancing maturity, and the stylar half of the fruit possesses more than the stem half.

Fresh oranges and grapefruit contain dietary fiber, being mostly soluble fibers such as pectic substances. Fiber aids in digestion and elimination, and when part of a low-fat diet rich in fruits and vegetables, the fiber therein may help reduce the risk of some cancers. Also, low-fat diets rich in fruits and vegetables containing soluble fiber may reduce the risk of heart disease. Pectin or pectic substances, made up of complex carbohydrate derivatives or polysaccharides, are important in terms of juice quality for imparting body or viscosity and the cloudy appearance. Pectic substances are a major component of primary cell wall and middle lamella in all fruit. In the orange, up to 30% of the albedo, on a dry-weight basis, may be pectin, but only 0.01–0.13% occurs in the juice. Without heat stabilization to inactivate pectinesterase enzyme, clarification or loss of cloud may occur in single-strength orange juice due to the settling out of pectins and other solids, while in concentrate a pectin gel may form, resulting in a nonpourable product. The pectinesterase in orange fruit is mainly associated with fruit peel, rag, and juice sac tissue (pulp). It is introduced to the juice from the ruptured cell membrane or wall tissue during the extraction process. In addition to pectinesterase, numerous other enzymes have been identified, including 18 oxidoreductases, nine lyases, nine transferases, seven hydrolases, three isomerases, and three ligases.

The acidity of orange juice is due primarily to the organic acid, citric acid and, to a much lesser extent, malic and succinic acids. Orange juice with about 0.5–1.0% acid (pH of about 3.5) is less acidic than that of grapefruit, and much less acidic than lemon and lime. Perhaps more so than any other quality factor, it is the favorable ratio of sugar to acid (sweetness to tartness), along with the unique orange flavor, that gives orange juice its universal high consumer acceptance. Orange flesh and orange juice are excellent sources of ascorbic acid (vitamin C). One medium-sized orange (about 154 g) may provide 120% of required daily vitamin C value. Vitamin C is an important antioxidant and scientists now believe that antioxidants may counteract harmful free radicals, which may contribute to the onset of several major diseases. Folate (folate acid), a B-vitamin commonly found in orange juice and green leafy vegetables, has been shown to help in the production of mature red blood cells. Recent research shows that women of child-bearing age can reduce the risk of having babies with birth defects of the brain and spine by consuming ample quantities of fruits and vegetables to maintain adequate levels of folate.

About 70% of the nitrogen in citrus juices occurs in free amino acids which constitute about 0.1% (w/w) in oranges. Proline is the major amino acid with less quantities of asparagine, aspartic acid, arginine, and gamma-aminobutyric acid.

The most abundant mineral in orange juice is potassium, with other minerals of significant quantity being calcium, iron, magnesium, phosphorus, and sulfur. Other elements of note are chlorine and nitrogen. Orange flesh and orange juice are considered to be excellent sources of potassium which is necessary to maintain fluid balance in the body, maintain cell strength and structure, and aid in nerve transmission.

Limonin, a triterpene derivative, because of its bitter nature, is an important constituent in certain citrus fruits, such as navel orange and grapefruit. When the juice of navel oranges is extracted, an undesirable bitter taste develops in the juice after a period of time. This is a problem of great significance in several large citrus-producing areas around the world, unless a debittering treatment is used. Limonin exists in the major sweet orange varieties (Hamlin, Pineapple, and Valencia) but generally in low enough levels not to produce significant bitterness problems.

Most of the lipid content of oranges occurs as fatty acids, with most being in the seeds. The five major fatty acids are palmitic, palmitoleic, oleic, linoleic, and linolenic. Phosphatidylcholine and phosphatidylethanolamine comprise the bulk of the phospholipid fraction of Florida and Calfornia orange juice. Orange essential oils are found primarily in the peel, with significantly less in the juice vesicles. One study shows that the amount of oil in fruit ranged from a low 0.29% in Hamlins to a high of 0.94% in Valencias. Orange oil contains at least 150 volatile essential oil components. Of these, *d*-limonene is most abundant, comprising about 95% by weight of orange oil, but it is the oxygenated aldehydes and esters that are considered the most important contributors to orange flavor. Many oxygenated alcohols are present in orange oil but not ketones. Coumarins and flavonoids comprise most of the 1% of the nonvolatile constituents in orange oil. Generall, total yield of orange oil decreases with increasing maturity.

An unusually large number and quantity of flavonoids, C_{15} compounds, occur in citrus. Compounds have been identified in oranges representing the three major flavonoid types: (1) flavanones (including flavanonols) generally occurring as glycosides in oranges, (2) flavones (including flavonols), and (3) anthocyanins, of importance in citrus only as red pigments in blood oranges.

The orange color in peel generally associated with mature fruit is due primarily to carotenoids, chiefly β-citraurin, while the green peel color generally

associated with immature oranges is due to chlorophyl. The main pigment in orange juice producing the orange color is the carotenoid, β-crytoxanthin.

Harvesting and Packinghouse Procedures

Oranges, like most other nonclimacteric fruits, do not continue to ripen after separation from the trees. Therefore, the fruit are picked only after they have reached maturity. In most citrus-producing areas, maturity standards must be met prior to the fruit being utilized in the fresh or processed markets. In the USA, the US Department of Agriculture and various state agencies develop and oversee the maturity standards. Internal standards generally consider a minimum ratio of Brix to percentage of acid (below which the juice will taste too acidic or tart), total soluble solids, total acid, and juice content. External grade standards include skin color, texture, discoloration and blemishes, fruit form, and firmness.

Harvesting is accomplished primarily by hand, and the fruit is placed in a picking bag or other container. A considerable effort has been expended on developing mechanical harvesting methods, especially with fruit that is destined for processing. In the 1999–2000 season, an estimated 6500 acres of oranges were mechanically harvested in Florida. The harvesting systems varied from those which could shake fruit to the ground from the oldest and tallest trees ($\sim$10 trees per hour) to those which could be continuously shaken with fruit caught on smaller uniformly spaced and skirted trees ($\sim$500 trees per hour). In most of the heavy citrus-producing areas, oranges harvested for fresh market are placed in pallet boxes (a standard pallet box in Florida holds 408.2 kg or 900 lb of oranges) for transport to the packinghouses. Otherwise, fruit may be loaded on to semitrailer trucks for bulk transport to the processing plants.

Most fresh oranges are marketed in the USA in fiberboard boxes holding 14.5–19.0 kg (32.0–41.9 lb) net weight of fruit. Preparation of oranges for market may include degreening, washing, applying fungicides, grading, waxing, and sizing. These procedures are usually performed in a citrus packinghouse near the groves. Figure 1 is a common process flowchart for a citrus packinghouse.

Some early-season oranges such as Hamlins and Washington navels are mature internally but may still be greenish or patchy green externally. Consumers generally believe greenish fruit to be immature, thus it is desirable to degreen the fruit. Degreening may be accomplished through use of either ethylene, or color enhancement utilizing a dye or a combination of the two treatments. In Florida, degreening with ethylene gas, a natural plant hormone, is generally at

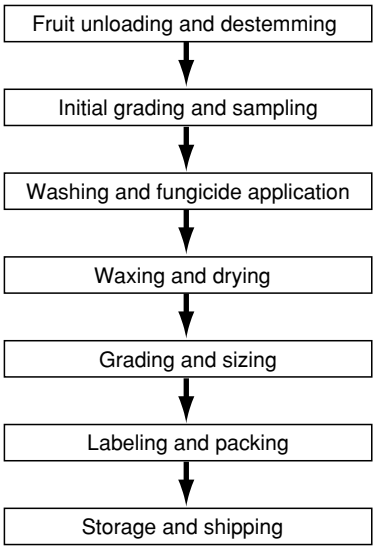

Figure 1 Common process flowchart for a citrus packinghouse.

1–5 p.p.m. in a room maintained for 36 h or less between 29 and 30 °C, 90–96% relative humidity, and having at least one change of air per hour. Use of much longer holding periods such as 72 or 96 h is not uncommon at times. Degreening procedures vary with citrus growing area, cultivar, fruit condition, etc. Color enhancement of the peel may be used in certain cases. In Florida, for example, for degreened (or naturally pale) oranges, temples and tangelos having a final yellow appearance, these fruit, under government supervision, may be flooded in a tank containing Citrus Red no. 2 for orange color enhancement, with 2 p.p.m. residue being allowed following rinsing. California and many other countries do not allow coloring of citrus.

Fruit may be treated with fungicides to control postharvest decay. Important postharvest fungal diseases are stem-end rot caused by *Diplodia natalensis* or *Phomopsis citri*, green mold caused by *Penicillium digitatum*, and sour rot caused by *Geotrichum candidum*. Fungicides, each with its own mode of application, used to control decay include sodium *ortho*-phenlyphenate (SOPP), thiabendazole (TBZ), and imazalil. Oranges to be exported from the USA to other citrus-producing areas are either fumigated with methyl bromide or subjected to cold treatment at 1.1 °C for 17 days to rid the fruit of potentially harmful fruit fly larvae and eggs.

In the washing operation, natural waxes are lost and rind permeability is increased, allowing moisture loss, and a decrease in sugar content, flavor, texture, quality, and ascorbic acid. Waxing of fruit tends to minimize the negative side-effects of washing plus enhancing the appearance of the rind and, in some

cases, provides a vehicle for antimicrobial agents. There are numerous formulations of waxes and wax-like materials available for application on oranges, but the most commonly used are water waxes, either emulsion-based or as a resin solution. During storage, waxes on fruit may cause the reduction of fruit internal oxygen levels, and increase internal carbon dioxide and ethanol levels. Recent studies show that the shellac-based waxes which give high surface shine are not the optimal choice for extended cold storage of oranges due to their relatively poor control of water loss and their low gas permeability that lead to off-flavor development within 5–10 weeks of storage. Polyethylene- and carnauba-based waxes, on the other hand, may provide better weight loss control, allow sufficient gas exchange, and maintain good internal quality under the extended storage conditions.

Storing citrus in the refrigerator keeps it better-tasting, better-looking, and firmer than citrus stored at room temperature. Cold storage of oranges at 0–1 °C for Florida fruit, and 3–9 °C for California fruit, will generally provide several weeks of marketability; otherwise, fruit held at room temperature has a significantly shorter shelf-life. Controlled-atmosphere storage, using increased carbon dioxide and decreased oxygen at cool temperature, does not work for extending the shelf-life of citrus fruit.

Fresh and Minimally Processed Citrus Products

'Fresh' or 'fresh-squeezed' citrus juice is pure juice obtained from mature citrus fruit and has not been further pasteurized, frozen, or concentrated after extraction. It is valued by many consumers for its superior natural taste and fresh quality. Although less processing is involved within its production, it is generally marketed at higher prices than pasteurized juice. Commercially, fresh orange juice is mechanically extracted from graded and washed fruit, and is commonly distributed for the retail market once packaged and refrigerated. Both chemical and thermal antimicrobial treatments may be applied to fruit surfaces prior to juice extraction to achieve a desired decontamination. In the USA, federal regulations also mandate the application of Hazard Analysis and Critical Control Point (HACCP) principles for the safe and sanitary processing of juices. Mechanical juice extractors that are designed to separate the juice from the fruit peel, seeds, and large pieces of pulp simultaneously are commonly utilized in the fresh juice industry. Small-scale extractors squeeze one fruit at a time and are often favored by local retailers. They are portable, simple to clean, and specially designed to attract the attention of shoppers in store or roadside operations. At juice-processing plants, largescale extractors are used. These machines have the capacity to extract hundreds of fruit per minute. Many of these extractors are adjustable with different types of cutters and strainer tubes to accommodate fruit of various sizes, and allow desired amounts of oil and pulp to pass into the juice. Good mechanical extraction of oranges yields about 45–55% juice by weight. Juice-blending programs are used by some processors following extraction. The program often extends the season by mixing juice from two or more varieties of available fruit to enhance nonblended juice color and/or taste. After processing, juice is packed and marketed at 0–4 °C. Freshly squeezed orange juice packed in plastic containers and held at −1 to 4 °C loses somewhat less than 1% ascorbic acid per day. The loss of ascorbic acid in the juice of whole oranges during the normal marketing life is expected to be less than 10%. (*See* **Hazard Analysis Critical Control Point**.)

'Fresh-cut produce' is an established food category that incorporates old and new processing techniques to prepare fresh, convenient, ready-to-eat products. Although the laborious task of removing citrus peel for personal consumption has been reduced by peelers such as modified knives and scoops, a growing segment of consumers desire no preparation. Thus, preparing citrus fruit to ready-to-eat forms would encourage fruit consumption at more dining occasions and by greater numbers of consumers. Both hand and mechanical peeling methods have been used in commercial preparation of citrus products for retail and food service outlets. The traditional peeling processes are often facilitated by steam treatment to loosen the peel and/or chemical digestion to remove peel remnants. High-temperature treatments and caustic chemicals damage the fruit and render it unsuitable for the fresh market. The resulting product is one that is chemically preserved, canned, or frozen before consumption. Citrus fruit may also be mechanically peeled with knives without steam or chemical treatment, but wastage is typically high and juice vesicle damage is often excessive. Recent efforts have been focused on minimizing damage due to peeling to maintain the integrity of fruit during storage. It has been found that the removal of citrus peel may be facilitated by vacuum or pressure infusion of an enzyme mixture (consisting of pectinase and/or pectinase and cellulase) or water into the peel. The fluids digest or solubilize the pectin-rich albedo tissue of the peel, and thus, the peel is loosened from the flesh. The peel may then be manually or mechanically removed, and the flesh may be packaged intact or cut into sections for marketing and consumption.

Processed and Derived Products of Oranges

C M Lanza, University of Catania, Catania, Italy

It seems that the sky had scattered gold dust and the earth had moulded this into shining spheres. (Abù l-Hasan Ahmad – Arabian poet in Sicily)

Background

Wine and the olive in the west, and the mango and litchi in the east, have played a determining role in the culture in which they have flourished, whereas citrus fruits, with their high quality and high content of vitamin C, have become well established across all continents, societies, and cultures, from man's first interests in agriculture through to the most sophisticated technology to date. At the beginning of the last century, countries dedicated to citrus fruit cultivation processed one or two products per species, discarding the rest (for example, lemon growing in Sicily was mainly used for essential oil and citric acid production). Today, such countries must concentrate their efforts on an industrial system providing the best utilization of the fruit to minimize costs and to offer a wide range of products on the basis of the consumer's economic status. High-value products are aimed at wealthy markets, whereas a large proportion of the less expensive byproducts can be added to the diets of consumers in economically weak countries. This new perspective is not really a technological problem, because equipment for the citrus industry is being continually developed. Rather, the problem concerns the political decisions to organize the citrus agricultural sector for production for industrial utilization. This is, perhaps, more difficult for those countries that have a citrus fruit-growing history. Traditionally, there has often been a lack of flexibility and holistic management in dealing with production problems.

Sweet orange constitutes by far the most important class of commercial citrus fruits grown in tropical and subtropical regions around the world. Approximately 55 million tonnes of orange are produced per year worldwide. About 40% of the total tonnage is processed, the rest being consumed as fresh fruit. Their quality, and the quality of the extracted juice, is greatly influenced by grove practices and pedoclimatic conditions (**Table 1**).

As a whole fruit, the orange is widely recognized for its nutritional (**Figure 1**) and sensorial characteris-

Table 1 Quality parameters of orange juices

tics of freshness, juiciness, crispness and sugar/acid content.

To extend the availability of orange fruit during the year and utilize better processing equipment, varieties with different ripening periods are grown. Together, Brazil and the USA grow 50% of the world's oranges and produce around 90% of the world's orange juice. Some Mediterranean regions, such as Italy, are oriented to the fresh fruit market, because of more profit. Italian orange production, concentrated primarily in the south of Italy, comprises 70% of pigmented orange ('Tarocco,' 'Sanguinello,' and 'Moro'), and the remainder blonde ('Navel' and 'Valencia late').

Blonde oranges contain relatively large amounts of a mixture of carotenoids, whereas the red color of blood oranges is due to (besides carotenoids) anthocyanins, water-soluble pigments such as cyanidin-3-glucoside and delphinidin-3-glucoside in Moro oranges. Many of the biological properties of these compounds have been correlated with their ability to scavenge oxygen-generated free radicals and to

inhibit lipid peroxidation. With regard to therapeutic properties, anthocyanins are largely used in the pharmaceutical industry because of their ability to prevent capillary fragility. The most important objective at the moment in Italy is the qualitative improvement of pigmented oranges and their juice, which has created a niche market for export in Northern Europe (Denmark, Germany, Holland, Sweden, Switzerland) (Figure 2).

Juice

Orange juice, the predominant product of the citrus industry, has the sensory and nutritional properties of the fresh fruit (Table 2), but, being a complex beverage sensitive to treatments, it is very difficult to preserve the same level of quality of orange juice squeezed directly from fresh oranges. The maximum juice yield from an orange is 40–60% by weight, depending on the fruit variety and local climate.

Even if orange fruit is not climacteric, its quality begins to deteriorate after picking, and so it must be processed into juice and other products as quickly as possible to insure that the microbiological, nutritional and sensorial qualities are maintained (Figure 3).

Oranges unloaded by hydraulic lifts from storage silos on the waiting conveyors undergo a first washing to remove dirt, leaves, and stems, and then, in the first grading process, damaged or substandard fruit is removed. The oranges are then conveyed to the final washing and grading area, where they are inspected and automatically sorted by size for entry to the extractor.

Two extraction systems are used: (1) squeezing and (2) reaming, either whole or halved, under mechanical pressure. In the first system as shown in Figure 4 the fruit are often lined up (up to 15 per line). The cups (upper and lower) are brought together as the corresponding cutters cut two holes in the fruit (Step 1). As the cups continue to come together, the peel is separated from the fruit, which is forced into the prefinisher tube (Step 2). The peeled fruit moves into the orifice tube through the holes of the prefinisher tube, forcing the juice to flow into the manifold (Step 3). The juice is instantaneously separated from the seeds, and the rest of the fruit, including the oil emulsion, is sent to the centrifugal processing part.

In the reamer type of extractor, the fruit is cut in half, and the halves are penetrated and rotated by a series of nylon reamers mounted on a rotating turntable. The juice, pulp, rag, and seeds are separated from the peel by a strainer, and the juice and pulp are separated from the rag and seeds and passed to the

finishers. In this system, peel oil can be recovered in a separate step by puncturing the oil sacs of the flavedo and washing the oil out.

Another extraction system is the rotary press, popular in the Mediterranean area since the turn of the twentieth century. This machine consists of a combination of two units arranged in a cascade, one to extract essential oil by rasping the outer surface of the whole fruits and the other to extract juice. Fruits introduced into the machine are pushed forward by paddles along couples of rotating rasping cylinders. The essential oil is then gathered by sprays of water, the mixture flows into a finisher to eliminate any solid particles, and essential oil is recovered by centrifugal separators. After oil extraction, the fruits are cut into two halves and squeezed against a stainless steel screen, and then seeds, pulp, and peels are removed from the juice. Juice obtained by the different extraction processes has a high content of pulp derived from juice vesicles and membrane material. These represent the principal part of the segments, which, during processing, are destroyed by enzymes and microorganisms in the peel. *Lactobacillus* and *Leuconostoc* are the most common genera of lactic acid bacteria that cause spoilage of orange juice, producing diacetyl and, consequently, off-flavors. The yeasts *Saccharomyces cerevisiae*, *Rhodotorula*, and *Zygosaccharomyces* can impart a fermented taste, transforming the delicate aroma of orange juice into an unpleasant smell. Only rarely are molds responsible for juice spoilage, because, even if they grow in juice, they are generally sensitive to heat treatment. (*See* **Yeasts**.)

The pulpy juice therefore must be finished and clarified by centrifugation to remove the oil, if necessary, before undergoing further treatments. A recent improvement of clarification has been introduced, using ultrafiltration to separate the serum from the pulp. The latter is then subjected to thermal treatment before being remixed with the serum to obtain a product with a better flavor and nutritional value. After this step, the juice takes different paths, leading to different products:

- Freshly squeezed juice: This has a shelf-life of 5–6-day and is a product that is not thermally processed, thus satisfying increasing demands for natural products. The raw materials are selected with great care, and washed, squeezed, aseptically packaged, and distributed for retail.
- Not-from-concentrate juice: Minimal thermal treatment is used for this juice. It is processed and stored frozen, or quickly pasteurized and stored in aseptic form. Most of these juices also consist of a blend, differing in quality in terms of color, sugar content, etc., being extracted throughout the picking season and/or in different producing countries.
- Frozen concentrate orange juice: This form is very advantageous for storage and freight, requiring less than five to six times volume than fresh juice. It provides a year-round supply to consumers and consists of a concentrate of a blend of specified quality from different orange varieties. Analytical control of blends uses the following characteristics: °Brix, per cent acid, Brix/acid ratio, per cent oil, per

Figure 5 (see color plate 31) Model thermally accelerated short-time evaporator. Courtesy of FMC Food Tech Citrus System, Catania (Sicily) Italy.

cent pulp and color. Today, a 'thermally accelerated short-time evaporator' is often used (Figure 5), which yields a concentration of up to 65/75 °Brix in a very short time, thus insuring a high product quality. (*See* **Heat Treatment:** Chemical and Microbiological Changes.)

During a preheating cycle, juice is pasteurized to deactive pectinase enzymes (which cause cloudiness) and prevent spoilage, thus prolonging the shelf-life. It then undergoes a variable number of stages under vacuum until the required concentration is obtained. The disadvantage is that the heat treatment reduces the oxidative balance and removes some of the flavor components. Particularly in blood-orange juice, a considerable change in color is ascribed to the degradation of anthocyanins and the different distribution of carotenoids between the serum and pulp structure in juices reconstituted from concentrate. There is also a remarkable loss of aroma components and generation of off-flavors such as *p*-vinylguaiacol, *p*-vinylphenol, and decarboxylation products of hydroxycinnamic acids in red juices processed and stored for up to 4 months.

Byproducts

The use of whole fruit in citrus processing is necessary to reduce costs and justify new investments in equipment, providing a correct solution for the pollution problem connected with the process. Any improvement in the recovery process would be of great interest, especially if this were obtained using technologies respectful of product quality such as the use of enzymes, peeling of the fruit, reduction of bitterness juices, reduction in the viscosity of pulp wash, and hydrolysis of peel solids to produce fermentable sugars.

Comminuted juice

Originally developed in the UK, this byproduct is made by milling the whole fresh fruit or by mixing juice concentrate with milled peel. The comminuted citrus base has a stronger flavor and provides more cloud than pure orange juice, thus imparting a good orange flavor in fruit drinks of low fruit content.

Peel Oil

Valuable oil recovered (about 0.3% of the fruit intake) from peel is used to produce various flavor compounds in the beverage, chemical and cosmetic industries. 'Cold-pressed peel oil' is obtained by mechanical pressure of oil glands (using different methods), whereas a less valuable oil can be recovered by distillation of waste peel residue. Among the numerous compounds, the major component is D-limonene, which is also used in the electronics industry and in the manufacture of synthetic resins and adhesives. Other hydrocarbons produced include myrcene, α-pinene, sabinene, and valencene. Important aromatic compounds include aldehydes, esters, alcohols, ketones, and phenols, and the nonvolatile residues include waxes, coumarins, flavonoids, fatty acids, and sterols. To avoid the problem of dissolved wax from peel, the oil is stored at 1 °C (winterization) to allow successive sedimentation of wax.

Colored essential oils rich in carotenoids can be obtained from orange peels, for use as colorants in the drink industry. The increased use of citrus essential oil to aromatize baking products promotes the technology of encapsulation by drying spray obtaining powders capable of maintaining the aroma intensity during cooking. Another interesting technology is the extraction of essential oil using supercritical fluid,

especially CO_2. Among the citrus peels, the most important essential oil is extracted from bergamot (*C. bergamia*, Risso) hybrid, a close relative of the sour orange cultivated only in the narrow strip of land of Southern Italy (Calabria). It is indispensable to the international perfume industry and is also used in the pharmaceutical industry as an antiseptic and as an aroma for liqueurs, tea, sweets, and candied fruits.

Essence

The recovery of volatile components (essence) from the evaporation process constitutes an interesting use of this component. Two phases are separated: the first containing the water-soluble compounds (essence aroma) and the second (essence oil), containing fruit flavor. The latter is more desirable than peel derivatives in the manufacture of flavor mixtures for the beverage and other food industries.

Hesperidin

In sweet orange, the predominant flavonoid is the tasteless and odorless hesperidin, located in the membrane and peel, which is not soluble in neutral solutions but slightly soluble in acidic solution as citrus juice. After extraction of the juice, the hesperidin forms crystals that appear as white flakes; these are more evident during evaporation and concentration of juice. The recovery of this product is a profitable investment for its therapeutic properties in the treatment of capillary fragility. The traditional extraction method, with a very low recovery, treats triturated peel with alkaline compounds to dissolve the flavonoids, which, after separation of solid residue, are precipitated by acidification. An innovative method to recover hesperidin from orange peel and waste water utilizes (at a pH of around 7) styrene-divinylbenzene as the absorbing phase and removing the flavonoid with alcoholic NaOH. The results may be a useful starting point for industrial applications.

Pectin

Pectin is a product found mainly in the albedo and juice sac, and has a high molecular weight (100 000–200 000 Da). Very important for the stability of juice cloud, pectin consists of long chains of polygalacturonic acid units linked together by α (1–4) glycosidic bonds with side chains of rhamnose, arabinans, galactans, and xylose. Many of the carboxyl groups are esterified with methanol to form methoxy groups; these determine the gelling ability of the pectin used in jam, marmalade, jelly, and preserve production. Lemon peel is the most common source for extraction of commercial pectin. After oil extraction, the peel is shredded and washed with water to remove sugars and other soluble material. The peel is heated to deactivate the pectinase enzymes and then treated with hot mineral acid to extract pectin. To the concentrated solution (containing a low content of pectin) alcohol is then added to 50–70% by weight, resulting in a precipitate of pectin in a gelatinous mass, which can be washed and dried as a powder. (*See* **Pectin**: Food Use.)

Peel in Brine and Candies

The peel in this case must be processed by a soft system, as 'sfumatura,' or peeling to extract the oil. First, the peel is hardened using lime, dried, and dipped for 24 h in tanks containing 3% sodium chloride. Then, the peel is dripped, stored in containers, and transferred to candy factories. Immersion in hot water for a few minutes softens the peel. The peel is cut by machine to undergo a cold or warm liquid sweetening process, depending on the technology chosen. The former process requires more time, because the diffusion of sugar into peel is slow, but the sensory characteristics of these candies are more valuable than those obtained by the latter process.

Fruit Sections

Very popular in the USA and Israel, fruit sections have good nutritional characteristics and a long shelf-life. Prior to processing, orange should be held in storage bins to allow the fruit to soften. Hot-water treatment at 100 °C for a few minutes facilitates peeling by hand or machine. The fruit is then subjected to a hot caustic spray (about 2.0% NaOH) for a few seconds and water sprays to remove the basic solutions. The peeled fruit is then chilled in water to facilitate sectioning of the fruit. A sweetener solution containing water, juice, and sugar is finally added to the fruit sections.

Pulp

Pulp recovered after the extraction process usually can be added back to juice and juice drinks to improve the mouth feel and give a natural appearance to the product. After the different components are separated by an in-line extractor, it is possible to recover whole juice sacs (premium pulp) by the premium pulp recovery system (Figure 6) (FMC Food Tech Citrus System).

Specially designed extractor components separate the juice, pulp, core, and seeds into a single stream. The core material is gently separated from the seeds, juice, and pulp and sent to the core wash system or

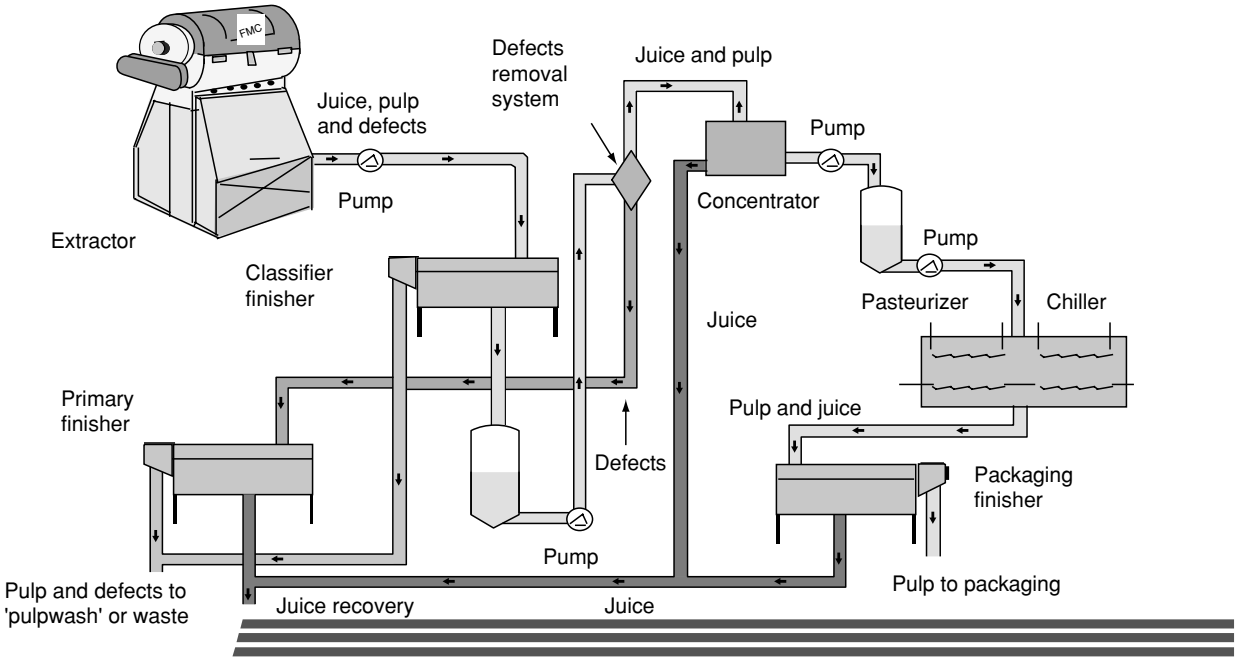

Figure 6 (see color plate 30) Premium pulp recovery process. Courtesy of FMC Food Tech Citrus System, Catania (Sicily) Italy.

waste. The core stream is finished to separate and recover any remaining juice. The remaining juice, seeds, and pulp are sent to a classifying finisher, which separates the seeds from the pulpy juice stream. Minor impurities are then removed, and the premium pulp, finally separated from the juice, is ready for pasteurization and packaging.

Pulp Wash

Product referred to as 'water-extracted soluble orange solids' is reclaimed from the pulp stream and is often used in fruit drinks as a source of sugars. It is also added, where the law permits, as a clouding agent to provide body and mouth feel because of its pectin content. The diffusion techniques currently in use for the preparation of pulp wash are optimized using a citrus finisher (Figure 7).

The unfinished juice feeds into the finishing cavity, a space created by a spiral with specially designed flights inside 360° cylindrical screens, resulting in a finishing action. Once inside the finisher cavity, the product is immediately carried outward on to the screw's helical spirals, thus making full use of the entire screen area, which results in high-capacity finishing. As the screw rotates, air restriction at the discharge end places pressure on the product causing the liquid to move toward the lower-pressure area outside the screen. Once through the screens, the liquid flows into a fully enclosed pan and discharges. The pulp discharges through the plug valve assembly.

Animal Feed

Unprocessed citrus peel, rag, pulp, and seed constitute waste products, but they can provide substantial profits if they are processed as feed. As the product is susceptible to spoilage (owing to its 78–90% moisture content), it must be consumed quickly and presents expensive transportation costs. The principal qualitative parameters are the amounts of protein, crude fiber, fat, ash, and nitrogen-free extract, primarily carbohydrates, which varies somewhat. The total quality of the feed is generally estimated from the total digestible nutrients: nitrogen-free extract, protein, crude fiber, and fat. The type of animal, effect of these products on food, economics involved, and storage capabilities must all be considered before using these waste products.

The high acidity of orange peel requires blending with lemon peel, usually by ensilage with straw and/or other material. Research carried out in 1960 showed, in mixtures of orange pulp and straw (10%) ensiled for 2 months, good fermentation and digestibility characteristics without any effluent being released.

Pressed Peel

To reduce transportation costs, the peel is limed, shredded, and pressed to improve the texture and composition. The reaction between lime and peel removes (by pressing) about 10% of the peel moisture. After this

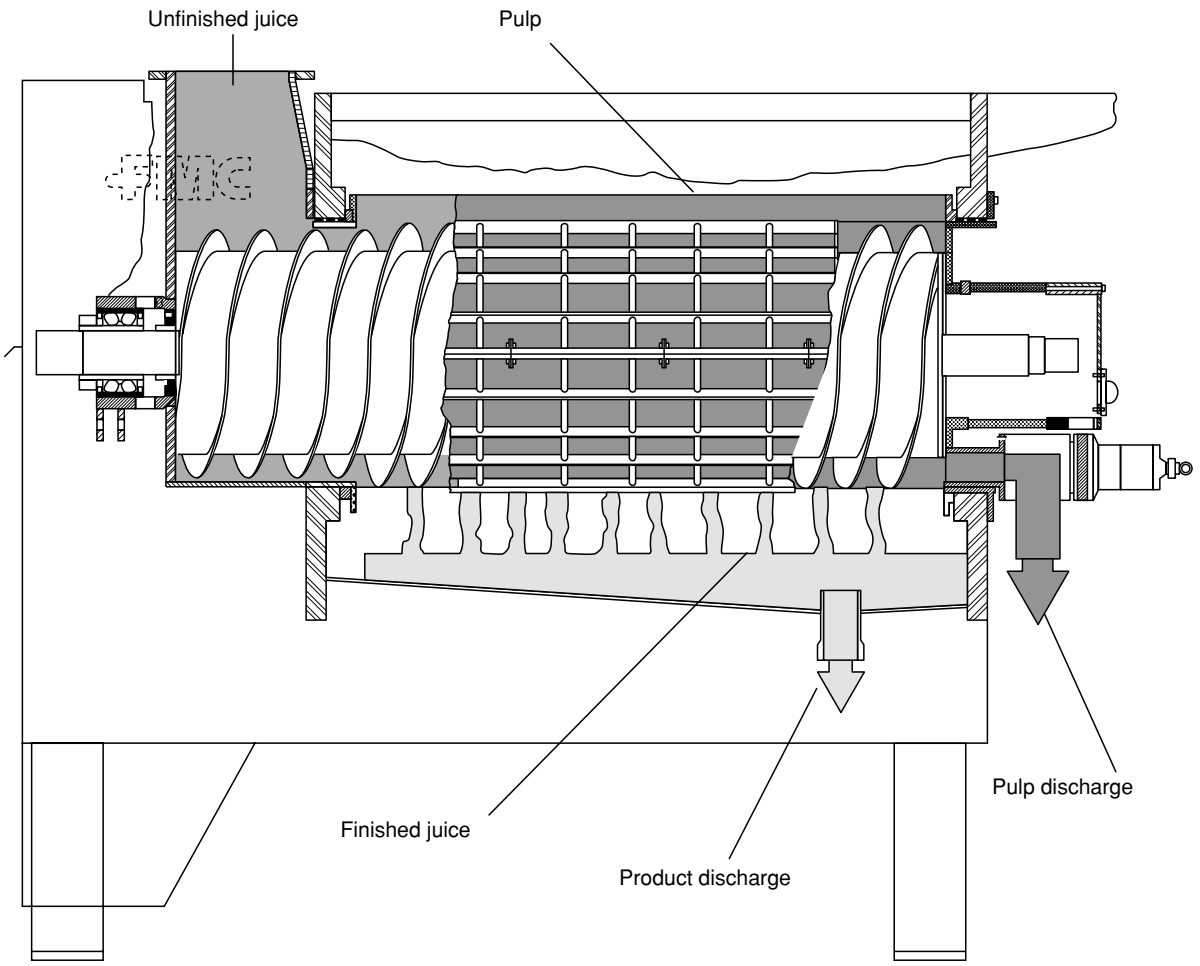

Figure 7 Citrus finisher. Courtesy of FMC Food Tech Citrus System, Catania (Sicily) Italy.

treatment, the peel is shredded and then conveyed to the peel press. Warm molasses is added to the peel (1:3), along with some press liquor, and the slurry is pumped to the feed mill ('pumped peel'). Using a supercharger and a sealed screw air pockets are removed, thus allowing the peel to feed into the press under pressure and to leave the press at a moisture content as low as 60%.

Dried Peel and Pulp

Dried citrus peel is one of the most common feeds. It is manufactured by pressing peel through a rotary dryer and adding citrus molasses to help the drying process and help prevent the peel from burning. The moisture content of dried peel must be below 10%. Many experiments published in the 1970s have shown that dried orange pulp, partially or completely replacing cereals in concentrate mixtures, are particularly useful in reducing feeding costs in dairy cows, have no influence on production, and have a good palatability. Dried pulp has also been used in swine, which have been shown to utilize it at a ratio of up to 20–25%. Besides its use as a substitute for maize, up to 20% in diet has no influence on the growth and production of laying hens. The dried pulp can be pelletized and is consumed more easily by ruminants with advantages of storage, shipping, and microbial spoilage. Pellets made from dried pulp have different dimensions, and several factors affect their characteristics, such as the energy used in pelletizing and the proportions of citrus molasses (about 5–15% of the total weight gives excellent results) used as binding agents.

Citric Molasses

The solution obtained from shredded and limed peel (press liquor) containing 10% sugar is principally concentrated to citric molasses. It is used as an additive to animal feed and for the production of citrus alcohol by fermentation, and also can be mixed with

pressed peel to facilitate drying. In the manufacture of citric molasses, antifoaming agents are used, or the suspended solids are removed by centrifugation, to prevent foaming from microbial spoilage and alkaline processing. The advantages of citric molasses in terms of press liquor are a reduction in cost during storage and a better microbial protection owing to the sugar content.

Alcohol Production

Citrus press liquor and citric molasses can be used as a feedstock for commercial alcoholic fermentations carried out by yeasts in continuous fermentators. The presence of peel oil, which is toxic to most microorganisms, must be at levels of no more than 0.08%. Press liquor contains at least 0.2% oil (based on 11.8 °Brix), whereas citric molasses usually contain much less oil stripped out during evaporation. Liquor is removed from the citrus press before fermentation, often using direct steam injection. Also, the oil removed in this way (steam-distilled oil) can be sold as a fuel, herbicide, or feedstock in chemical manufacture.

Final Consideration

In industrialized countries, the citrus industry cannot be static, but must apply scientific and technological know-how to increase the value added to the market prices of products. It is necessary to develop new mild technology to limit the damage during processing, to re-evaluate minor products, and to obtain a new ingredient better suited to consumer requirements: fresher products that retain their nutritional characteristics, especially the active components (vitamins, antioxidants, fermentation agents), have a longer shelf-life, and are more convenient for ecologically compatible cultivation and animal rearing systems.

Lemons

R Goodrich, University of Florida, Lake Alfred, FL, USA

Background

Lemon (*Citrus limon* (L.) Burm.) a yellow or pale yellow prolate fruit with five to 10 seeds, botanically a berry, is known throughout the world, and is used in numerous foodways and cuisines. The juice of the fruit is commonly used as a food ingredient in both commercial and home recipes, and is valued for its tart, tangy, and fresh character. The exceptionally fragrant rind is used as a garnish and flavoring and is a major source of commercial essential oil and aroma compounds. The lemon flower is sweetly scented, with an aroma similar to other citrus flowers. The essential oils from the flowers, twigs, and fruit can be distilled or otherwise extracted to obtain materials suitable for use in flavors and fragrances.

The lemon tree is a small, thorny tree that grows well throughout the tropical and subtropical regions of the world. Lemons are cultivated in modest amounts for home use almost everywhere that citrus trees can survive, but large-scale commercial production is limited to the subtropical regions since more humid tropical environments enhance pest and

disease problems for both fruit and tree. Lemon trees grow to about 3–6 m and are sparsely foliaged. Compared to orange and grapefruit, the trees are rather cold-sensitive. Because of the lemon's lower sugar content, the fruit can freeze at temperatures that would not affect other citrus.

The lemons has existed for so long that its true origin is not known, although experts believe it was probably a hybrid of the citron (*C. medica*). The first recorded habitat of the lemon was South-east Asia (Myanmar, and southern China); from there, it was introduced to Persia and the Middle East, were it was well established by the twelfth century. Around 1150, Arabs took the lemon to Spain and North Africa. The lemon traveled from the Mediterranean to the New World with Columbus on his second voyage in 1493. Lemon culture spread from Haiti through the West Indies and then to South and North America. Plantings existed in Florida by the 1500s and were established in the mission gardens of California and Baja California by the mid-eighteenth century.

Table 1 Lemon production (tonnes) by selected countries for crop years 1995–96 and 1999–2000

	1995–96	*1999–2000*
Argentina	720	1050
Spain	457	899
USA	900	797
Italy	699	590
Turkey	418	500
Greece	133	155
South Africa	71	110

Table 2 Leading lemon (*Citrus limon*) varieties

Variety	*Primary growing location(s)*
Bearss (Sicilian)	Florida (USA)
Eureka	California (USA), Australia, Argentina, Israel
Lamas	Turkey (early season)
Lisbon	California, Arizona (USA), Australia
Meyer Lemon (not a true lemon)	USA, New Zealand
Verna (Berna)	Spain

Worldwide Production

Leading producers are Argentina, Spain, California (USA), and Italy. Table 1 summarizes lemon fruit production for the 1995–96 and 1999–2000 seasons. Production from the top four countries accounted for about 75% of the world's total output. Argentina and Spain in particular have experienced significant growth in lemon production in the past few decades; in 1965, the USA and Italy alone accounted for about 75% of the world's lemons. From a global perspective, understanding the system of coordination of production, harvesting, and marketing of lemon fruit is complicated due to factors such as multiple harvesting seasons, the numerous commercial varieties, and the substantial regional differences in practices and markets throughout the world. The following discussion summarizes the commercially important lemon varieties and harvesting periods in the major lemon producing regions.

The principle varieties of lemon are listed in Table 2, along with their associated growing regions. Different varieties of lemons can be difficult to identify by the fruit alone, especially as the everbearing trait results in the presence of fruits of various size, color, and appearance on a single tree at the same time. Most lemon fruits are oval to elliptical in shape, with characteristic necks (stem end) and nipples (blossom end). The peel is yellow at maturity (generally) but can vary substantially in thickness and smoothness. The flesh is pale yellow (straw-colored) and very acidic, and can have a variable number of seeds. As a further complication, the same variety can present visually different fruit under different climate conditions and horticultural practices. Lemons are often identified by tree characteristics, which are less variable.

Most of the US production is from California, although there is some from Arizona. In coastal California, the primary growing region, the lemon tree blooms and sets fruit essentially year round, but there is a heavier set in the spring and fall season. This multiple flowering and fruiting phenomenon can be utilized to provide a steady stream of fruit with pickings occurring every 6–8 weeks throughout the year. In south-central California and Arizona, the other major lemon-producing areas in the USA, harvesting is usually limited to late fall to early winter (October through January).

One of the oldest commercial varieties is the Eureka lemon, and it is also one of the most widely grown varieties outside the Mediterranean area. It is a major part of the crop in California, Australia, South Africa, and Israel. It is also a significant part of Argentina's crop. The Eureka has achieved predominance due to its quality and productivity, and because a large proportion of fruit matures during late spring and summer when demand and prices are greatest. New plantings of the Lisbon lemon have replaced Eureka in central California due to the former's dense foliage, making the fruit less susceptible to

sunburn and possibly freeze damage. The Eureka tree, however, is less thorny than the Lisbon and thus easier to pick. The Eureka tree also appears to be more susceptible to cold damage, making it most suitable for the coastal areas of California and Australia, where freezes seldom occur. The two fruits, however, are very similar, and processors in particular have difficulty in differentiating the two.

The Mesero lemon, of Spanish origin but grown more commonly in Italy, is considered one of the best processing lemons; it has a smooth, thin, somewhat pale rind, but contains a large amount of juice. Conversely, the Interdonato is primarily a fresh cultivar, with a lower juice content and a smooth, thin rind. The fruit itself is large, and the flesh contains few seeds.

Winter is the main harvest for Verna fruit grown in Spain, Algeria, and Morocco. However, in Spain, where Verna is the primary cultivar, a significant supply of fruit is kept available for harvest throughout much of the summer, a peak season for lemon demand. The Femminello, a name for an everbearing group of cultivars grown in the Mediterranean countries, has its main crop reaching maturing in the late winter and early spring but is also marketed throughout the year. Interestingly, in Italy, each particular lemon crop has its own name, and is marketed according to season instead of by the varietal name. Thus, the *Primofiore* is from the September through November harvest, the *Limoni* is from December to May, the *Bianchetti* is from the April to June harvest, and the *Verdelli* is from the June to September harvest. Collectively, this group accounts for about 75% of the lemons grown in Italy. Most (over 90%) of the lemons grown in Italy are produced in the coastal area of Sicily, a warm, dry climate that is highly favorable for lemon production The Interdonoto, another Mediterranean cultivar, is harvested in the fall and early winter. This cultivar is a significant portion of Turkey's lemon crop.

The Genova is grown principally in South America and is the leading variety in Chile. The fruit has a good internal quality (high acid, flavor, and juice yield), similar to Eureka, and a characteristic spherical shape. The origin of Genova is Italy, and it is actually considered a strain of Eureka in California, where it was first imported from Italy in the late nineteenth century.

Compared to other citrus, the projected production growth of lemons is forecast to be only modest, with an estimated rate of 1.5% per annum into 2005. This is about half the growth of the previous decade. The geographic production will also shift, with the strongest production growth forecast for Italy and Argentina, and with possible crop reductions in California.

Fruit Structure and Chemistry

The structure of the lemon fruit is similar to other citrus and consists of the peel and the interior edible portion (endocarp or pulp). The peel is composed of two distinct layers; the outside layer is termed the flavedo (epicarp), and the interior of the peel (the white spongy part) is the albedo (mesocarp). The many chemical constituents of the lemon fruit are distributed among the various tissues, usually in differing concentrations. The flavedo is composed of mainly carotenoid pigments, vitamins, and essential oils. The green appearance of immature lemon flavedo is due to the predominance of chlorophyl over the carotenoid pigments prior to complete ripening. The albedo contains celluloses and soluble carbohydrates, pectin and protopectin, flavonoids, amino acids, and vitamins. The oil glands, containing the valuable essential oil, are embedded primarily in the flavedo, although larger oil glands may also extend through to the upper part of the albedo.

The pulp of the lemon fruit, like other citrus, is divided into segments called carpels. Each segment is composed of up to several hundred units called juice sacs or vesicles. These vesicles are the compartments, which contain the actual lemon juice. The walls of the vesicles are composed of celluloses, hemicelluloses, pectin, protopectin, sugars, flavonoids, and other minor components such as amino acids and vitamin C. When intact, the vesicles effectively contain the juice and limit microbial and enzymatic degradation of the juice.

Comparisons of California fruit (navel and Valencia oranges, and lemons) show that, in relation to the oranges, lemons have a somewhat lower protein content, a substantially lower sugar content, and a much higher acid content. These biochemical measurements of the fruit, confirmed by obvious taste characteristics, lead to the categorization of citrus by horticulturalists as either low-acid (oranges, mandarins and grapefruit) or high-acid (lemons and limes) fruit. Lemon juice contains about 4.3–4.8 g citric acid per 100 ml, as compared to around 0.8–1.0 g per 100 ml for mandarin, orange, or grapefruit juices.

Fresh lemon juice has approximately the following vitamin levels per 100 g: β-carotene, 12 μg; thiamin, 0.3 mg; riboflavin, 0.01 mg; vitamin B_6, 0.05 mg; folate, 13 μg; and vitamin C, 36 mg. These figures vary depending on the source of the fruit and processing and storage conditions.

The peel and seeds of all citrus are relatively rich in phenolic compounds such as flavonoids and phenolic acids. Phenolic compounds are known, potent antioxidants. Citrus flavonoids include polymethoxylated flavones and glycosylated flavanones; both are

Table 3 Volatile compounds identified in lemon oils and essences

Acetone	Myrcene
3-Buten-2-ol	Neral
Ethanol	Octanal
Geranial	Octanol
Geranyl acetate	β-Pinene
Limonene	Terpinene-4-ol
Linalool	α-Terpineol
Methanol	

unique to citrus and are thought to have bioactive properties such as anticancer, antiinflammatory, and antiviral effects, among others. Methanol extracts of lemon seeds are rich in eriocitrin and hesperidin, while peel extracts contain significant amounts of neoeriocitrin, naringin, and neohesperidin. There are many ongoing research programs investigating the functional properties of these flavonoids, and other bioactive compounds in all citrus, including lemon.

All fruits and fruit products contain a range of volatile, low-molecular-weight (< 250) compounds that are important in producing the characteristic flavor and aroma of the specific fruit. The predominant compounds responsible for lemon aroma number are relatively few (two to five) compared to other citrus. The most important component is citral, an aldehyde that is a *cis–trans* mixture of the isomers neral and geranial. Table 3 summarizes some volatile compounds found in commercial lemon oils and essences.

Postharvest Handling and Fruit for the Fresh Market

In the past, the USA, Italy, and Spain dominated total lemon production, and, as noted in Table 1, Argentina has become a major producer. For fresh fruit markets, Spain has the major and profitable role in supplying fresh lemon fruit to Western Europe and other markets; the USA, Argentina, and Italy continue to process about half of their fruit and market the other half as fresh fruit.

Two terms must be understood in order to discuss citrus fruit quality, markets, and economics: grade and maturity. The grade refers to external characteristics such as size, presence of blemishes, and appearance, while maturity refers to mostly internal characteristics such as juice content, taste, total soluble solids (TSS), acid content (titratable acidity; TA) and the ratio of TSS to TA. As with most produce destined for the fresh market, appearance is the primary attribute of quality for fresh market lemons, and grading is critical and standardized in a given country or region. Consumers may make repurchasing decisions based upon internal quality, but generally will not choose a fruit initially if it presents exterior faults. Areas with hot, dry summers and cool, wet winters (Mediterranean climate) typically produce citrus fruit with brighter, thicker peel than areas with more humid growing seasons and warmer winter nights. The Mediterranean climate is also associated with generally better exterior fruit appearance (at the same level of inputs such as fertilizer and pesticides) than fruit grown in a humid climate and is yet another reason for the predominance of fresh market lemon production in the Mediterranean-type climate. Quality indices include color intensity and uniformity; size (larger lemons are preferred), visually pleasing shape and smoothness; freedom from obvious decay and damage; and freedom from exterior blemishes, splotches, and rind discoloration. Fresh-fruit pricing in most lemon-producing countries is based on these factors, along with market supply and demand.

Lemons for both the fresh and processed markets are harvested manually. Pickers use bags, ladders, clippers, and gauges to judge the size of the fruit. Fruit picked early in each variety's particular growing season may be quite green, even though they may be deemed physiologically mature. Lemons picked while still green will generally have a longer postharvest shelf-life than the fully yellow lemons that need to be handled gently and marketed more rapidly. Young lemons can be degreened at the packing house, if necessary. Degreening is accomplished by exposing the lemons to 1–10 p.p.m. ethylene for 1–3 days at relatively high temperatures (20–25 °C). Ethylene is a natural product of plant metabolism and acts as a plant hormone by regulating many aspects of growth, development, and senescence of the fruit.

At the packing house, the lemons are unloaded, washed, and graded, degreened as described above, if necessary, sized, waxed, and packed in cartons or other shipping containers. Each packing house may be set up slightly differently, but the major unit operations in packing fresh lemons are the same as for other citrus fruit.

Citrus fruits, lemons included, are nonclimacteric, and their respiration and ethylene production rates are low. Postharvest changes are therefore low in relation to commodities that are climacteric, such as avocados, bananas, and berries. Most lemon cultivars can be, and are, stored for a moderate amount of time; this requires no special controlled atmosphere (as with apples) if the environmental conditions of humidity and temperature are carefully controlled, and the fruit has been properly handled. The

optimum temperature range for lemon storage is 12–14 °C, depending on cultivar, maturity stage at harvest, and intended distribution and transport time. The relative optimum humidity for storage is 90–95%.

An interesting and specific example of long-term lemon storage is the traditional practice of harvesting lemons (primarily in the coastal California area) in mid- to late winter, and storing them until the summer marketing season. These lemons, when picked, are green, thick-skinned, and not very juicy but after storage (termed curing) are yellow, juicy, and thin-skinned. The thinning of the peel is due to water transpiration loss, while the increase in juice yield is probably due to physiological changes in which the water in the juice vesicles is released into the vesicles from its gel-bound form at the membrane.

As noted, lemon fruit for fresh markets must be attractive and wholesome in appearance; physiological disorders, defined as the breakdown of fruit tissue not caused by microbes or mechanical damage, must be prevented or minimized. Adverse preharvest or postharvest conditions, or nutritional deficiencies during growth and development, can cause physiological disorders in lemons. Fresh citrus fruit are more prone than pome fruits (apples, pears) to a particular type of physiological disorder, termed chilling disorder. In lemons, storage at suboptimal temperatures can lead to symptoms such as pitting of the flavedo, membrane browning, and red blotches. Lemons should not be stored at temperatures below 10 °C.

Major Processed Products and Byproducts

Lemon juice is a commonly used ingredient in both commercial and home kitchens, as well as a component of many processed food and beverage formulas. The following discussion focuses on the commercial production of lemon juice and concentrate.

After the fruit has been delivered to the processing plant, it is unloaded, washed, and graded. The juice is extracted in the same manner as other citrus fruit; Brown and FMC extractors are the most commonly used in the western hemisphere, although there are other citrus juice extractors available. Either prior to (Brown system) or during (FMC system) extraction, the lemon oil in the peel is recovered by washing with water to form an emulsion that is used to produce cold-pressed (CP) lemon oil (see below). After extraction, the juice is separated from the rag, seeds, and ruptured juice sacs in a process known as finishing. The juice sacs, along with a small amount of juice, may be stabilized and packaged to produce a product termed pulpy juice, which can be added to juices, beverages, and other food products. Juice that requires even more depulping can be centrifuged to reduce the insoluble solids level even further.

Most lemon juice is then heat-stabilized and concentrated in special evaporators developed for the citrus industry. These evaporators operate under a moderate vacuum and thus lower temperatures to minimize undesirable thermal effects. While all citrus juices are particularly susceptible to thermal abuse during processing, lemon juice is especially prone to reactions such as browning and acid hydrolysis, which are accelerated by the very high TA of the juice. Most fruit and vegetable juices are concentrated to a standard °Brix level (°Brix is a measure of soluble solids, which is correlated to sugar content or sucrose equivalent). Since the major soluble solid in high-acid fruit (lemons and limes) is citric acid, not sugar, lemon and lime concentrates are produced and sold on the basis of grams of equivalent citric acid per liter of solution (GPL). Lemon concentrate of 400 ± 5 GPL is most commonly produced. The concentrate is then either stored at low temperature in large stainless steel tanks or packed in drums or pails and frozen.

Single-strength lemon juice can be bottled or otherwise packaged for consumer, food service, or industrial use. Most often, the juice is reconstituted to a standardized GPL from lemon concentrate and purified water. Approved preservatives, such as sodium benzoate at very specific levels, are often added. Some not-from-concentrate (NFC) lemon juice is produced and packaged, but its initially higher quality suffers unless the product is quickly pasteurized, packaged, and then frozen (-10 to -20°C) throughout warehousing, distribution, and marketing.

Lemon juice and concentrate are most often used throughout the world not as pure juice but as an ingredient in juice beverages. In many parts of the world, a sweetened, diluted lemon drink, known as lemonade, is the most popular citrus drink. Lemonade is specifically defined in the USA under the Code of Federal Regulations and must have the requisite GPL of citric acid from the lemon juice (not added) to be marketed under that name. Elsewhere, standards may differ, although almost all lemonade is composed of lemon concentrate, water, and sweetener(s), and possibly added flavors and colors, in slightly differing proportions.

Lemon oil is a valuable byproduct and, along with lime oil, has the greatest economic value of all of the CP citrus oils. It has been made for centuries in Sicily by traditional processes, and the methods and oil characterization have been described in the classical essential oil literature. This discussion focuses on

current recovery methods in commercial use in lemon processing facilities.

As the water–oil emulsion is produced just before or during the juice extraction step, it enters the oil-recovery process. The emulsion may contain small particles of peel and other insoluble solids, and may be sent to a finisher for their removal. In both the Brown and FMC systems, the emulsion, containing about 0.5–3.0% oil goes through a two-step centrifugation process. The first centrifuge, known as the desludger, concentrates the mixture to about 50–60% oil, removing water and insoluble solids. The second step, known as polishing, removes the remainder of the water, along with any remaining solids. Depending on the specifications of the oil that is being produced, the lemon oil may be dewaxed. This process is known as winterization and refers to the removal of natural waxes from the peel, by exposing the oil to low temperatures and letting the wax solidify and settle out. The oil is then packaged in containers that are inert and that exclude air.

The typical yield of oil from lemon peel is somewhat less than the total amount available (60–70%) and is dependent on the efficiencies of the operations, fruit condition, and even economic incentives. Lemon oil recovery processes usually try to recover as much oil as possible, due to the value of CP lemon oil. Recovery of lemon oil from Californian lemons ranges from about 4 to 10 kg of oil per tonne of fruit.

Lemon oil quality is related to the aldehyde content, specifically citral, which ranges from about 2.0 to 5.5%, depending on horticultural factors. D-Limonene, the major constituent (> 95%) of orange and grapefruit CP oils, is significantly less in lemon oil but still the major volatile component of CP lemon oil. The largely flavorless, but oxidatively unstable, D-limonene may be removed through various concentration techniques to produce a folded lemon oil that is more stable and more highly concentrated in desirable flavor compounds.

The albedo portion of spent lemon peel is an important source of raw material for commercial pectin production and contains about 35–40% pectin on a dry-weight basis. Pectin is a functional ingredient in many processed food products, where it is used extensively as a gelling agent and mouth-feel enhancer. Pectin exists primarily a polymer of galacturonic acid units, some of which are esterified with methanol, and has a molecular weight of between 100 000 and 300 000. As most pectin is sold as a dry powder, there is a complex recovery scheme to obtain the pectin from the spent peel and process it into a commercially useful product. Figure 1 is a flow diagram outlining the major processing steps in refining citrus pectin, which is extracted from the peel through an acid treatment, then recovered by precipitation with alcohol. Lemon, grapefruit, and lime albedo have a higher level of pectins than that of orange or tangerine, neither of which is typically used for commercial pectin production.

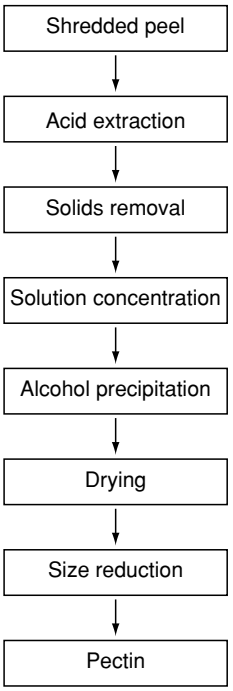

Figure 1 Commercial citrus pectin production.

Grapefruits

J Forsyth, Citrus Consultant, Sydney, NSW, Australia

Background

Grapefruits, with 6% of world production, are the fourth most important commercial group within the edible *Citrus* species. They consist of a small number of cultivars that vary in importance due to market requirements, growing conditions, and climatic zones. Stable production over the last 20 years is now being influenced by new cultivars with lower acid levels and red-pigmented flesh. These factors are creating renewed interest by growers, marketers, and consumers for fruit or processed products.

They are mainly consumed as fresh fruit because of their refreshing, but distinctive, flavor, and they are desirable as a chilled breakfast fruit served in halves or as a juice. The 1970s 'grapefruit diet' created considerable interest in this fruit. There are several health benefits associated with fresh citrus consumption, such as the low levels of energy (calories), fat, and sodium and good sources of vitamin C, dietary fiber, folate, and potassium.

Origin

As with other *Citrus* species, the origin and significance of the grapefruit name remain obscure. It is considered unique as it is the only citrus species known to have originated in the New World and not Asia. Almost certainly, the grapefruit originated in the West Indies/Caribbean region during the seventeenth and eighteenth centuries, before being introduced to Florida in the USA early in the nineteenth century (Figure 1).

Classification

The taxonomic classification of the *Citrus* species is complex and diverse, and not universally agreed upon, in this article grapefruit will be classified by *C. paradisi* (Macfadyen). Citrus as a social and cultural fruit crop, also has local names throughout the world, often for an identical group, e.g., Pamplemousse in French, Pompelmo in Italian, or Pomelo in Spanish. Note that Pomelo (*C. grandis* (L). Osbeck) is also known as shaddock or pomelo/pummelo and, while similar in many characteristics (like shape and rind color, but larger fruits), horticulturally, the pummelos and grapefruit comprise separate classes.

Grapefruit Groups

The grapefruit group and related hybrids group of cultivars is limited, with important commercial but very diverse cultivars that are classified into two groups: common (or white fleshed) and pigmented. The fruit is medium to large in size and more seasonal, with each cultivar maturing and suitable for harvesting over a relatively short period of time. Different cultivars are available that can supply fresh fruit from very early to very late maturity.

Figure 1 (see color plate 34) Grapefruit are often borne in clusters, like a small bunch of grapes and this has been suggested as the origin of the fruits name.

Common or White-fleshed

Marsh is the main cultivar with a number of other, now minor, seedy types including Duncan, Davis, and Wheeny.

Marsh (seedless) This originated as a chance seedling in Florida, selected and commercially propagated in 1886, as the first seedless grapefruit. The cultivar spread throughout the world to become the most important grapefruit grown. In more recent times, planting has declined in favor of the new red-fleshed cultivars.

The fruit is medium in size with few or no seeds. The rind color is pale to light yellow at marurity, medium thin, and very smooth. The flesh is buff-colored, tender, and juicy, with a good flavor. Because of the high heat requirements, successful Marsh production is restricted commercially to very hot climates (Figure 2).

White hybrids A breeding program by the University of California in 1958 crossed an acidless pummelo with a white seedy grapefruit, resulting in the selection and release of two new patented low-acid seedless grapefruit hybrids: Oroblanco and Melogold. The classification is as for grapefruit *C. paradisi*. They have many similar characteristics (thick rinds) but some differences.

Oroblanco This was released in 1980, with major plantings limited to California and Israel. The fruit shape is similar to that of Marsh, but it is larger and slightly flatter. The rind remains greener far longer (even when internally mature) and is thicker. The flesh is paler with an open core. Oroblanco matures about 6 weeks before Marsh, and the flavor is sweeter due to higher total soluble solids (TSS) and lower acid. This internal quality, together with the lack of bitterness, when Marsh is grown in cooler areas, created early interest when it was first released to industry. Initial plantings on vigorous rootstocks like rough lemon and *C. volkamerianna* adversely affected the fruit quality – thick rinds, reduced juice content, and poorer flavor. Oroblanco is considered by growers to be slightly better than Melogold, partly because of the better TSS: acid ratio and smaller fruit (Figure 3).

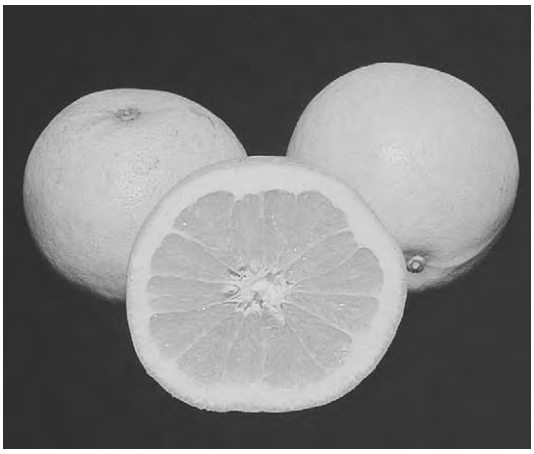

Figure 2 Marsh is one of the oldest, most important and widely grown cultivars.

Melogold This was released in 1985. The fruit shape is similar to that of other grapefruit except for a slightly tapering neck (sheepnose), and the fruit often initially produces significantly larger fruit, but as the trees become older, the average fruit size is reduced. The rind color is more normal than the greener Oroblanco and the taste inferior, although Melogold has a thinner skin and smoother texture, and matures slightly later in the season. The fruit does not peel easily, and the segments do not separate as with traditional breakfast grapefruit or pummelo. Initially, growers in California preferred Melogold, but this is now being replaced.

Pigmented

While the older cultivars were considered 'pink'-fleshed with Thompson and Redblush the main cultivars; newer selections are classified as 'red'-fleshed, due to the deeper pigmentation in the rind and flesh while also being seedless. From this group, Star Ruby, Flame, and Rio Red are becoming more important on world markets, with a consumer trend away from the older white-fleshed cultivars.

Pink-fleshed Foster originated as a limb sport and the first recognized pink-fleshed cultivar located in Florida (1907). The pink or red rind and flesh pigments in grapefruit are lycopene and carotene, and are not due to anthocyanins, as in blood oranges. Thompson (Pink Marsh) was found as a limb sport on a Marsh tree in 1913 and replaced Foster as a commercial cultivar.

Redblush (Ruby, Ruby Red) This originated as a limb sport of Thompson in Texas in 1931, while Ruby is thought to have originated from the same source but in a different locality in 1929. Both are so similar as to be indistinguishable for all practical purposes and are considered identical. The fruit is similar to Thompson (which it generally replaced), except for a much deeper pigmentation in the flesh and albedo (but not the juice) and a crimson blush on the rind, especially at the points of contact between

Figure 3 (see color plate 35) Oroblanco is a new low acid white-fleshed hybrid grapefruit.

fruits. This was the first pink grapefruit that could be recognized externally without having to cut the fruit, due to a rind blush. Having been replaced in some localities by the newer red-fleshed cultivars, Redblush remains an important cultivar in Florida, California, and South Africa (Figure 4).

Red-fleshed The following cultivars are relative new to the industry, originating from more recent natural mutations or seedlings, breeding, or irradiation programs in the USA from the 1970s:

Star Ruby This was selected as a seedling from a Texas seed irradiation program in 1959 and released to industry in 1970. The fruit has a yellow, smooth, fine, and thin rind, with red blushes. The flesh is redder than that of Redblush, with a later maturity, higher TSS and acid but few seeds (rarely more than two). The juice content is high and as sweet as, or sweeter than, Marsh and other new pigmented cultivars.

The tree shows herbicide, nematicide, heat, and cold sensitivity. These deleterious effects have been widely recorded, as Star Ruby appears the most difficult of the new grapefruits to grow successfully. It is also more susceptible to *Phytophthora* diseases and to *Alternaria* brown spot. These problems lead to erratic bearing, small fruit size, low tree vigour, and short longevity.

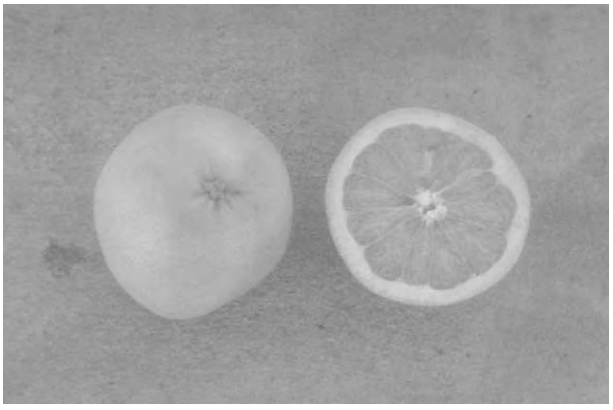

Figure 4 Redblush was the first cultivar to have a deeper red flesh and some rind pigmentation.

Subsequent nucellar clones from the original Star Ruby, now available in Israel, Southern Africa, and Australia, produce high-quality fruit with less of the above-mentioned cultural problems (Figure 5).

Flame This is now thought to have originated from a natural mutation of Ruby Red grapefruit seed collected in Texas (1973) and, after selection and evaluation, was released in 1987. During the last decade, more has become known about Flame's performance, especially from Florida and Argentina.

Trees are vigorous and not as cold- or herbicide-sensitive as Star Ruby. The larger round fruit has an attractive appearance with a very smooth thin rind; an external blush is slightly less than Rio Red or Star Ruby. The background rind color tends to be light bronze (similar to Star Ruby) rather than yellow like Rio Red. Internally, the color is of a uniform intensity, similar to Rio Red, and uniform across the segments. Fruit hangs on the tree, with a maturity similar to that of Star Ruby, but earlier than Rio Red. Flame is now widely planted in Florida and is expected to perform well in similar climates.

Figure 5 (see color plate 36) Star Ruby is a newer grapefruit cultivar with a deep red pigmented flesh.

Rio Red This originated in Texas from irradiated budwood sourced from a Ruby Red tree, which, in 1976, produced a natural bud mutation that was then evaluated before release in 1988. The fruit shape is generally good but tends to be slightly sheepnose when grown under semiarid and drier conditions.

The Rio Red fruit is the latest maturing of the new cultivars, and a deep blush develops where adjacent fruits touch. The flesh color may be patchy, especially early and late in the season, but for much of the marketing period is only slightly lighter than Star Ruby. The thicker rind is compensated for by a softer flesh and higher juice content.

Henderson and Ray Ruby These are two other new red-fleshed varieties from Texas that have attracted only a minor growing or marketing interest. All these new red cultivars have been available for a relatively short period. Little comparative information is available for the red-fleshed cultivars, on the effect of different climatic growing conditions in many citrus-growing regions of the world, i.e. the effect on tree longevity, yield, fruit quality and pigmentation. Table 1 summarizes several important fruit quality parameters.

Growing Regions and Conditions

Grapefruit, with a range of total heat requirements, is grown in varying climatic conditions and regions, including the humid tropics, arid subtropics, and intermediate climates. Commercial production tends to be located in two narrow belts of the subtropics and between 20 and 40° latitude north and south of the equator.

Resistance to heat is outstanding and in cold tolerance is similar to that of sweet oranges. Their very high heat requirement for the production of good-quality fruit restricts successful commercial culture to hotter climates. The sweetest, juiciest, and most bitter-free fruit is grown in semitropical summer rainfall areas such as Florida, Texas, and areas of Southern Africa. This makes grapefruit almost equally well adapted to hot desert and humid semitropical or tropical climates. In the cooler drier Mediterranean climates, there is a tendency for the fruit to have a thicker rind, lower sugar, high acid levels, and some bitterness.

Under desert growing conditions, the color is brighter and deeper with a rich flavor more pronounced than in humid climates, where smaller fruit sizes, a less oblate shape, and a lower juice content

Table 1 Some internal and external grapefruit quality parameters

Variety	*Percentage juice*[a]	*Percentage acid*[a]	*TSS:acid ratio*[a]	*Number of seeds*[a]	*Rind*	*Flesh*

Table 2 World grapefruit production trends

Year	*Total production* ($\times 10^3$ t)	*Exported* ($\times 10^3$ t)	*Processed* ($\times 10^3$ t)
1980/81 to 1988/89 average	4640	920	1815
1995/96	5007	1175	1986
1996/97	5056	1177	1919
1997/98	4726	1082	1733
1998/99	4614	1135	1682
Four-year average	4851 (38%)	1142 (24%)	1830 (38%)

From FAO (1999) *Citrus Fruit Fresh and Processed, Annual Statistics, Tables 1–10 and 16–20*. Rome: Food and Agriculture Organization; USDA (1999) World fresh citrus situation. In: *World Horticultural Trade and US Export Opportunities, Circular Series FHORTH*. Foreign Agricultural Service.

may occur. For example, Florida leads the world in grapefruit production, with a warm to hot and humid climate, resulting in a grapefruit of excellent internal quality, with a thin peel and attractive shape.

For the newer red-fleshed cultivars, the trees are resistant to heat but sensitive to cold. They can be grown under a range of climatic conditions, but very hot and warm night temperatures are necessary to produce high-quality fruit. The newer low acid cultivars like Oroblanco may be harvested and marketed before the full yellow rind color develops, with green or only pale colored rinds, although the fruit is mature to eat with a TSS: acid ratio of 8:1 and less than 1% acid.

Site selection and soil management will be influenced by climate, while some cultural practices may modify harmful effects, including cold protection, irrigation, and windbreaks. However, they cannot completely overcome major unfavorable climatic effects on tree growth or fruit quality. Some of these effects include regular severe frosts, poor rind color/pigment development, variable maturity, high acidity or naringin levels, poor fruit form, or pest and disease incidence.

Although susceptible to the normal range of citrus pests and diseases, they are particularly susceptible to grapefruit stem pitting caused by certain strains of Citrus Tristeza Virus (CTV). The disease will cause sudden or 'quick tree decline,' pits in the tree and small, lopsided or malformed fruits. CTV is spread in infected budwood and the brown citrus aphid *Toxoptera citricida*. This disease is endemic in many countries, but the planting of tolerant rootstocks like Troyer and Carrizo citrange, together with only propagating nursery trees with budwood that has been preimmunized and carries a mild strain cross-protection, will limit losses.

Production Statistics

Although grapefruit is a relatively new citrus fruit, having been marketed for just over 100 years, grapefruit is now the fourth most important citrus with 6% of total production in 1998–99, after oranges (with 66%), mandarins (17%), lemons, and limes (11%).

The world's grapefruit production has been almost stable from the 10-year average of 4640×10^3 t in 1980/81 to 1988/89, to only slightly larger average total crops (allowing for annual variations) in the four 1995/96–1998/99 seasons of 4851×10^3 t, as shown in Table 2. About 20% of this production is estimated to be pummelo fruit.

Although production is forecast to increase slightly to 4930×10^3 t by 2005, this is still below the slightly

higher production recorded in 1995–97 (Table 2). The latest increases will mostly be in pummelo production, especially in Asia, China, the Philippines, Indonesia, and India. Only small increases in are grapefruit production are expected in Mexico, Argentina, Cuba, Brazil, and South Africa.

The largest growing regions are in the northern hemisphere, with 86% (Table 3) of world production, and include countries like the USA, Israel, Cuba, and China, while the southern hemisphere, with only 14%, is relatively minor but expanding, mainly in Argentina and South Africa.

Unlike other citrus types, the Mediterranean region (apart from Israel) produces only minor quantities of grapefruit (14% of the world production, Table 3), mainly due to local climatic conditions. There is, however, interest in producing new red grapefruit cultivars, especially in Spain, Cyprus, and Turkey.

In the two largest citrus-producing countries (Brazil and the USA), grapefruit are relatively minor with only 4% in Brazil, but due to a wider range of climatic regions especially in Florida and Texas, a more significant 19% of USA total production. The relative importance of grapefruit producing in some countries is outlined below.

Table 3 Fresh grapefruit crop production and utilization (with respective percentages), and the main producing countries throughout the world in 1998–99

Region/country	*Total production* $\times 10^3$ *t (%)*	*Exports* $\times 10^3$ *t (%)*	*Processed* $\times 10^3$ *t (%)*

USA

Florida is the principal state with about 17% (or 56 630 ha) of citrus plantings devoted to grapefruit, with Marsh the main cultivar (50% of planting) because of its use in both fresh and processing markets. Older, pink-fleshed varieties like Thompson and Redblush make up 37% and were the industry standards. Recent development has revolved around the new 'seedless' red-fleshed cultivars. Since 1982, many new plantings were Flame and Ray Ruby and, more recently, Rio Red. Some Star Ruby has been planted, but cultural problems have limited grower acceptance, despite prices usually being higher than for other red cultivars.

Interest in the newer cultivars is based on current consumer preference for red-fleshed grapefruit. Because of the long marketing season, retaining flesh color is critical. Flame and other deep red-fleshed fruit begin and end the season with a better color than that of Redblush. A rind blush also enhances consumer appeal, and despite perceptions, there are no substantial quality differences between white and red-fleshed grapefruit.

White grapefruit are easily processed (in the early 1990s, about 70% of the crop), but a relatively high TSS:acid ratio juice is required while a smaller part of the red types are processed (30–40%). Fresh fruit exports are important, e.g., for white seedless cultivars to Japan, but the French market favors the red-fleshed seedless.

In Texas, before the freezes in the late 1980s, nearly 66% of all citrus plantings were devoted to grapefruit, mainly the red-fleshed varieties – Redblush, Rio Red, Star Ruby, Ray Ruby, and Henderson. Extensive replanting in the early 1990s indicated that 61% were grapefruit, with 87% Rio Red (replacing the inconsistent bearing and cultural problems of Star Ruby) and 5% Henderson and Ray.

In California and Arizona, grapefruit are less important (9% of plantings), but Marsh and Redblush are grown in selected areas. Oroblanco was being grown (1000 ha planted by 1999) for the Japanese export market and was preferred by growers over Melogold, but in recent years, returns have been reduced markedly. Problems with low production, small fruit sizes, and thick rinds are now reported, and only limited plantings are expected.

Israel

In the 1980s, Israel's grapefruit declined from a 60% dominance of the European import market to 30%,

with shelves left available for red grapefruits from Florida. Following restructuring of the industry's marketing activities, success has been achieved in the export of 'Sweetie' (Oroblanco) grapefruit. This grew successfully in Israel and was found to be highly suited to the Japanese palate. In recent times, most of the 'Sweetie' grapefruit produced has been exported to Japan and sold as green-skinned, early grapefruit or later in the season with yellow skin as 'Golden Sweetie.'

Grapefruits have expanded rapidly, resulting in the planting of 27 000 ha, with a low 13%, nonbearing. About half are red-fleshed cultivars, like 'Sunrise' (Star Ruby) and 'Sweetie' (Oroblanco).

Cuba

Given its climate, citrus are widely grown in Cuba, with grapefruit production increasing to 270 000 t in 1998/99. Following the loss of some European export markets in the 1990s, the markets declined from a 10-year average of 134 900 t to only 43 750 t during the four years of 1995/96 to 1998/99. An increased percentage of the crop is processed, up from the 10-year average in 1980/81 to 1988/99 of 32 800 t to an average of 158 000 t during the 4 years of 1995/96 to 1998/99. The main cultivar grown has been the traditional white Marsh.

China

Although listed as the fourth largest producer of 'grapefruit' in the world, most production is pummelo. Owing to favorable climatic conditions and the very large domestic market, production will increase generally in tropical Asian countries.

Southern Africa

Although only the sixth largest grapefruit producer, Southern Africa's production has increased significantly from the 10-year average of only 76 900 t in 1970/71 to 1978/79 to 189 000 t in 1998/99. In the southern hemisphere, this production is only slightly smaller than the fifth producing country, Argentina (210 000 t, Table 3). Grapefruit makes up 17% of plantings with 5% red-fleshed cultivars, 10% white, and 2% rose or pink, with greatest expansion for Star Ruby. Of all the other red-fleshed cultivars, their degree of pigmentation is far less than that of Star Ruby. Total exports have increased rapidly since 1984 from 24 000 to 548 000 cartons.

Harvesting and Marketing

The growing, harvesting, and marketing of grapefruit can present unique problems, which are best overcome by specialist growers in selected climatically suitable localities. Present-day production focuses on careful cultivar selection to best suit conditions and cultural practices, in order to achieve a successful marketing outcome.

Maturity

Early in the marketing season, grapefruit are especially prone to poor palatability and low consumer acceptance due to the high acidity and bitterness from the glucoside naringin and/or limonin. This problem is worse where fruits are harvested from marginal growing climates and poorly chosen rootstocks. Most regions now have maturity standards to insure that all marketed grapefruits are palatable and acceptable to consumers, e.g., in Southern Africa, export standards have been set at 50% minimum juice, 90° TSS, 1.75 maximum acidity and 6:1 minimum TSS:acid ratio. As grapefruit mature on the tree, the TSS increases, and the acidity decreases, but once harvested, these do not change.

The estimated maturity and main marketing periods for some grapefruit in Southern Africa (southern hemisphere) are:

- Marsh: end of April to end of August
- Ray Ruby, Flame, Star Ruby: all maturing mid-May to end of August
- Rio Red: early June to end of September.

Only a limited number of cultivars may be grown in any locality, but there is a small difference in optimum maturity (see above) that can be taken into account when selecting those cultivars to be grown and helping to insure a continuous supply of fresh fruit for the available markets. In Florida, all commercial cultivars reach their legal maturity in September or October (northern hemisphere), but can be stored on the tree (as described below) for several months and up to the end of May, when they begin to fall, and seeds start germinating within the fruits.

Degreening

Early in the season, mature grapefruit may not be fully colored. Fruit may be degreened by exposure to ethylene gas for short periods in special chambers.

Preharvest Drop

Grapefruit are prone to preharvest drop and severe crop losses (Figure 6). A common cultural practice is to apply a registered growth regulator (like 2,4-D amine salts) at color change. This spray has the beneficial effect of delaying the formation of the abscission cell layer at the junction of the fruit stem and button. It greatly reduces fruit drop over a period of

Figure 6 Preharvest fruit drop off near mature grapefruit.

several months and helps retain green buttons after harvest. Fruit can be 'stored on the tree' for up to 7 months past normal maturity and fruit drop, enabling more orderly harvesting and marketing over much longer periods of time than would be normal without treatment.

Rind Aging

Another cultural practice is the application of a registered growth regulator, gibberellic acid, to slow down the rind aging process without affecting fruit quality, by reducing the rind thickness and puffiness in late-hanging fruit.

Cold Storage

Apart from the normal marketing periods, grapefruit are not held for long-term cold storage. Fruit may be stored for 5–8 weeks at 15.5–10.0 °C but are very susceptible to common storage breakdown problems and chilling injury, like peel pitting and oil-gland darkening.

Crop Utilization

Grapefruits are principally marketed according to how they are consumed, with local fresh fruit and exports totaling 62% and 38% processed (compared with 34% of oranges) as summarized in Table 2. All major producing countries process a significant proportion of their crops; the USA is the largest processor with 53%, followed by Israel and Cuba (both 57%). See Tables 2 and 3.

In the world fresh grapefruit export fruit trade in 1998/99, the following regions/countries were the major importers: Japan, the Mediterranean region, the Netherlands, France, and Belgium.

Fresh Fruit

Grapefruit cannot be considered a 'sweet dessert' fruit, but because of its refreshing flavor and mild bitterness, fresh grapefruit is desirable as a healthy breakfast fruit. Chilled halves with the sections loosened from the peel, flavored with sugar or honey to taste and the pulp spooned out make a refreshing start to the day.

As an appetizer before dinner, grapefruit halves may be similarly sweetened, lightly boiled, and served hot, often topped with a maraschino cherry. Sections are commonly used in fruit cups or fruit salads, in gelatins, puddings, or tarts. Fresh (chilled) juice makes a refreshing healthy drink any time of the day. Segments are suitable for garnishing and decorating salads or topping desserts. The fruit and juice can be used in dishes such as grapefruit and ginger chicken.

Grapefruit and other edible citrus fruits derive their unique qualities from about 20 principal factors, which can mainly be conveniently grouped as internal and external. The internal or chemical ones can also be measured like sugars or carbohydrates (sucrose, glucose and fructose as total soluble solids – TSS), organic acids (citric and malic measured as titratable acidity – TA), sugar:acid ratio – TSS; TA, juice content and color, are of vital concern for consumer acceptance and preference. All of these factors change

Table 4 Selected food values per 100 g of some edible grapefruit portions[a]

Chemical composition	*Pulp (raw)*	*Juice (raw)*
Calories	34.4–46.4	37–42
Moisture	87.5–91.3 g	89.2–90.4 g
protein	0.5–1.0 g	0.4–0.5 g

as fruit matures and with grapefruit can be extended for over six or seven months on the tree, before becoming overmature and unacceptable.

See Table 4 for some food values of normal edible grapefruit portions – pulp and juice. The bitterness factors of limonin are normally found in the peel oil, while glycoside naringin occurs in the pulp segments.

Processed Products

Processed grapefruit products include white, pink, or red segments in syrup or natural juice, juice products (fresh or frozen, canned, dehydrated as a powder, or concentrated), and rind oil or essence as often used in aromatherapy, for massage, or in baths. After the juice is extracted, there remain residues that can be a source material for other valuable byproducts. Some specialized types are also candied, dried, or used for marmalade, jelly, and pectin manufacture.

White-fleshed varieties are mainly processed into higher-priced juice products. A smaller percentage of red-fleshed varieties are juiced, one reason being because if the processing fruits and therefore the juices are mixed the red lycopene pigment turns the white juice an undesirable brown or muddy color, and juice prices are lower for normal red juice. With the trend towards increased red-fleshed varieties, this has resulted in problems of disposing of processing or non-fresh marketable fruit. Whether significant volumes of red juice and other processed products can be successfully marketed will depend on innovative companies with new products like red grapefruit juice cocktails and aggressive promotion and marketing.

Limes

R E Berry, Citrus/Tropical Fruit Products, Winter Haven, FL, USA

Introduction

Limes constitute one of the general types of citrus fruits long known and consumed throughout the world. Relative values of parts of the fruit are closely related to relative amounts of acid and sugars, and to the amount and composition of the peel oil. Several main cultivars and fruit types of limes are quite different in appearance as well as physical and chemical composition. Lime juices and oils are prepared by several different processes, and their economic value is directly related to the method of preparation, as well as the fruit source.

History and General Characteristics

Limes are known world-wide for their tart, tangy-flavored juice and especially for their unique flowery, characteristic aromas. They were introduced to many parts of the world through the explorations of the British navy, where they were probably first used for clinical and nutritional purposes. Their extensive use on-board ship to prevent or treat attacks of 'scurvy' (caused by vitamin C deficiency) earned British sailors the distinctive name 'Limeys.' Most evidence indicates that limes probably originated in northeastern India and migrated via the trade routes into the Middle East and on to the Western world through sailing vessel trade markets.

The juice of most types of limes is too acidic to be consumed undiluted. However, limes are popular for use in juice mixtures, -ades (mixes with sugar, water and/or other juices) and carbonated beverages, and as a component of alcoholic drinks and mixes. In some countries, they are used in pickling, culinary, and medical applications. A main economical value of limes comes from the highly valued lime oil, used in products as diverse as cosmetics (shave lotions, perfumes, and colognes) and household cleaning products (washing powders, soaps, furniture polish, and bathroom deodorants). Lime trees are extremely cold-sensitive and will be productive only in subtropical to tropical climates where temperatures seldom go below the freezing point.

Limes are the most acidic of all citrus fruits and lower in vitamin C content than lemons. Like lemons, they are highly valued for their juice and acid content. Most limes consist of 40% or more juice by weight or volume. The remainder consists of seeds, vascular bundles, parts of albedo (white inner part) adhering to the skin or flavedo (outer, colored part), and parts of fruit segments, collectively referred to as 'rag.' The juice of most cultivars consists of about 90–91% water, 0.2–0.3% protein, 0.7% (in acid types) to 9.0% (in sweet types) sugars, 0.1% fat, and 0.3% minerals (ash). The juice (100 ml) supplies 110–140 kJ (26 kcal) of energy, 50 mg of ascorbic acid (vitamin C) and a trace of dietary fiber. A wide range of vitamin C levels has been reported, and, as with most citrus fruits, the level is higher in the peel or rind (63–121 mg%) than in the fruit or juice (30–70 mg%).

Quite different from the basis of value for other types of citrus, the value of limes (and lemons) is based primarily on the weight of acid (as citric, although there are traces of many others) per unit volume of juice. This is in contrast to the ratio of sugar to acid used for oranges, grapefruits, tangerines, etc. Computer programs and automatic titrator instruments provide such data at a high rate in citrus processing plant quality-control and inspection laboratories. The values reported for lime juice acid content (as citric) range from about 6.0 to 8.5% (average 7.20%).

Cultivars and Fruit Types

The small-fruited, acid lime (*Citrus aurantifolia* Swingle) is the predominant type in the world. It is widely grown in India, Mexico, Egypt, the West Indies, China, California, the southern tip of the Florida Peninsula, and the Florida Keys (USA), where it is known as the 'Mexican' or 'Key' lime. Although found in Brazil as the 'Gallego' lime, it is not as well known there. The fruit is small, round, somewhat short-elliptical, and bright to greenish yellow when mature. Moderately seedy, it has a thin rind (smooth and leathery), and the flesh is very juicy, highly acid, and has a unique, distinctive flowery aroma.

The large-fruited, acid limes (main cultivar *Citrus latifolia* Tan.) are more oblong in shape, light to dark green at maturity, and two to five times larger, on average, than the small-fruited limes. These limes, often called Tahitian or Persian, were brought to California from Tahiti, but do not seem to have any connection with Persia. About the size and shape of the common Bearss lemon, they may be a hybrid of the citron and/or the lemon, but the parentage and true source are not definite. This lime is grown mostly in South Florida (and, to some extent, in Australia and California) because of its better tolerance of cold and its lower requirement for heat to reach maturity. Other types of lime – the Bearss, from California, as well as the Sahesli of Tunisia and the Pond of Hawaii – seem certain, from horticultural evidence, to be the same as the Persian. The juice has a high-quality characteristic lime flavor, and the aroma is typical of that commonly described as 'lime-like' throughout most of the world.

The sweet lime (*Citrus limettioides* Tan.) is widely consumed in India, the Middle East, and Latin America. It is known as the Palestine or Indian sweet lime, and is used in those countries for medicinal purposes. The fruit, medium in size and round to slightly oblong, is greenish yellow to orange-yellow at maturity. The flesh is yellowish; the rind has a distinctive, slightly medicine- or turpentine-like aroma, and the juice is so nonacid as to be insipid to most tastes. These limes are seldom processed except in very small-scale, simple home-type juicing and bottling operations. (*See* **Atherosclerosis**.)

Lime Juice

Lime juice can be prepared and concentrated in large amounts at high rates in the same general manner as

for orange and grapefruit juices, using similar equipment. For juice extraction, however, smaller (than usual for oranges) cups are used on one type of extractor, which individually cuts and presses each fruit. Another type of extractor presses and disrupts the entire fruit between rotating converging disks, and the fruit, pulp, and rag mixture is then separated from the juice in a screw press/screen finisher. Single-strength lime juice may be blended with sugars, syrups, water, or carbonated water and bottled in glass or sealed in metal cans. These types of juice products are usually preserved with a small amount of added sulfite or bisulfite. They may remain stable without refrigeration up to a year or longer.

The juice can be concentrated on a thermal accelerated short time evaporator (TASTE), widely used throughout the world citrus processing industries. However, since lime juice contains a higher percentage of organic acids than of carbohydrates, the degree of concentration is determined as grams per liter of acid rather than the degrees Brix (approximate percentage of sugars) commonly used for other citrus concentrates. However, Brix measurements with a commonly available Brixometer remain necessary, to determine the bulk density from which the GPL can be calculated. Computer programs and automated instrumentation provide dependable determinations at a high rate. Most lime concentrates are evaporated to about 400–500 $g\,l^{-1}$. The uncorrected, observed, desired Brix value (roughly analogous to the acid concentration desired) must be known since evaporation control is based on in-line Brixometers. The approximate desired Brix value must be determined based on the acid and Brix of the incoming single strength juice, using standard methods.

Lime Oil

Lime oil, a major commercial product in world markets is, in most processes, more valuable than the juice, which may be considered a byproduct of the lime oil process. It may be prepared by allowing the liquid, separated from the pressed mixture of fruit parts described above, to stand until the oil 'layers' off at the top, and then decanting or distilling off the layer. The character and composition of the decanted oil vary considerably from those of the distilled oil. As a byproduct of this process, the bottom juice layer is a clarified, sparkling clear, light green-colored juice. Special clarifying additives are often used in this process to enhance the clarity of the resultant juice. This product is distributed widely around the world, especially in the UK and the Caribbean area, as a mixer base for alcoholic and soft drinks.

Lime oil may also be prepared by a long-used conventional 'cold-pressing' process, whereby the flavedo and adhering fruit parts are passed into a conical pressure filtration press. The 'peel juice' is pressed through a steel screen, and the oil is separated in a high-speed centrifuge. This process produces a clear, green-colored oil with a fine aromatic quality and stability of aroma and flavor. The juice or concentrate resulting from this type of process has a stable, well-suspended 'cloud' and is used in bases for juice drinks, -ades, and soft drinks. (*See* **Soft Drinks**: Production.)

The oil is located in oval-shaped oil sacs situated rather evenly throughout the flavedo or outer layer of the peel. The oil sacs function as a natural toxic barrier to microorganisms and insects that might otherwise attack the fruit. The oil is composed of a base sesquiterpene hydrocarbon (D-limonene, more than 50%) and a mixture of other mono- and sesquiterpenes. From lime oil analyses many organic components have been identified, including 12 alcohols, seven aldehydes, four esters, one ketone, and 22 hydrocarbons, with 7% nonvolatiles (mainly coumarins).

To control and classify the quality and value of citrus oils, the National Research Council, officially recognized by the US Food and Drug Administration, has published and regularly updates the 'Food Chemicals Codex' (FCC). A current summary of lime oil specifications and standards can be readily obtained from that source.

Storage

Because of their extremely high acidity and low pH, limes are more stable than many other citrus fruits. However, problems may be encountered at certain temperatures and humidities with growth of acid-tolerant surface fungi. Control has been accomplished using biological growth regulators. In Persian limes, 2,4-dichlorophenolindophenol (24D) and gibberellic acid (GA) have been successful in reducing the growth of '*Penicillium*'-type molds, yellowing, mottling and discoloration of the rinds during storage. Such problems have not been solved through the use of controlled-atmosphere storage, but can be greatly controlled through the use of optimum storage conditions for fresh fruit, i.e., 10 °C and 90–95% relative humidity where a storage life of up to 4 weeks or longer has been reported without any notable injury, pitting, or discoloration of fruit.

Value

The great majority of limes in the world are produced in India, Indonesia, and Mexico, predominantly for

local fresh fruit markets, and thus statistical data on value and extent of the crop and the fresh market are unavoidably biased and not highly accurate. Few dependable agricultural statistics are available for local fresh markets in most geographic areas. Although the USA is a notable and important producer of limes and lime products, it is not the major world producer of the fresh fruit, but the most dependable statistics on production and value of products are those for the USA. The total annual production of all types of limes in the USA ranges around 70 000–80 000 t. In general, the amount of those processed has been about 50–60% of the total crop. The annual value varies considerably and is highly influenced by climate, local weather, outbreaks of plant diseases, and insect-control measures. The USA imports five to 10 times more limes than it exports, and the total USA annual crop has been equal to about 25% of the world crop during the past decade. Data on US production of limes, lime juice products and lime oil are available from the US Department of Agriculture statistics department, and Florida fruit data are available from the Florida Department of Citrus, Lakeland, FL.

Mandarins

J Forsyth, Citrus Consultant, Sydney, NSW, Australia

Background

Mandarins, which are also known as tangerines[1] in some parts of the world, and their related hybrids, are the largest and most variable group within the edible *Citrus* species. They consist of many cultivars that vary in importance according to local and export market needs, growing conditions, and climatic zones. The large and increasing production has significance in local and world trade, especially for fresh fruit. Some brief details on mandarin classification and origin of the species, growing regions and conditions, production statistics, harvesting marketing, and crop utilization are discussed.

Fruits range from oblate to globose to subglobose in shape, and small to medium in average size. The rind varies from thin to medium in thickness, with a smooth to rough or pebbled surface texture that may be easy or tight to peel. The color of both the rind and flesh may be yellow, or light to dark orange. Maturity ranges from very early to late, depending on the cultivar and growing conditions.

Mandarins are mainly consumed as fresh fruit. There are several health benefits associated with fresh citrus consumption: citrus fruits are a source of many essential nutrients and compounds, and a low-energy (low calories), fat-free source of vitamin C, dietary fiber, folate, potassium, and several phytochemicals. These multiple nutritional benefits from citrus, and especially the very convenient mandarins group, are only possible through the consumption of fresh fruit and juices and currently cannot be obtained from supplements.

Classification

The taxonomic classification of the *Citrus* species is complex and diverse, and not universally agreed upon, but those used by Swingle and Reece will be followed in this article. Citrus, as a social and cultural fruit crop, also has countless local or regional names and identities[2] throughout the world, often for an

[1]Tangerine was initially adopted in the USA, to better describe those mandarin cultivars that had a deep reddish orange rind like the Dancy cultivar.

[2]Ortanique originated in Jamaica but is also known as Topaz (in Israel), Tambor (Southern Africa), Mandore (Cyprus), Ortaline (Morocco), and Ormanda (Honduras).

identical cultivar. (*See* **Citrus Fruits**: Types on the Market.)

The mandarin group and related hybrids are very diverse (with over 100 cultivars), but can be classified into a number of main groups, some of which contain a large number of subgroups. This fruits is more seasonal, with each cultivar maturing and suitable for harvesting only over a relatively short period of time, e.g., 6–8 weeks on average. Several cultivars are now available for the main types that can supply fresh fruit from very early to very late maturity. Mandarin production is increasing, with a consumer trend towards fruit that is easier to peel and segment and is seedless. Only limited quantities are processed into juice or canned segments.

- Common mandarins (*Citrus reticulata* Blanco) are a very extensive group of different cultivars now widely grown and available in world markets; e.g., Imperial, Kara, Emperor, Ponkan, Dancy, Kinnow, Sunburst, and Fortune are all old cultivars, with some examples of newer common mandarins including Michal, Nova, Fallglo, Encore, and Daisy. This large group also includes several other commercially important subclasses.

  The clementine may have originated in Algeria, as a natural hybrid located and growing there in the 1890s.
  Two hybrid groups exist, e.g., tangors, which are hybrids of the mandarin and orange *C. reticulata* × *C. sinensis* [L] Osbeck like Murcott, Afourer, Mor, Ortanique, Temple, Tankan, and Ellendale. Tangelos are hybrids of the mandarin and grapefruit or pummelo *C. reticulata* × *C. paradisi* Macfadyen with Minneola, Orlando, Page, and Seminole as cultivar examples.
- Satsuma mandarins (*C. unshiu* Marcovitch) are also known as *Unshiu mikan* in Japan and China. They were initially mainly grown in Japan and Spain up to the 1980s but are now an important expanding seedless group throughout the world, because of their cold hardiness. This Satsuma group now includes many newer selections, like Hashimoto, Clausellina, Miho, Owari, Miyagawa, and Okitsu.
- The Mediterranean mandarin (*C. deliciosa* Tenore) is also known as Willowleaf (because of its drooping branches and small narrow leaf characteristics) and includes Avana clones Apireno and Tardivo.
- King mandarins (*C. nobilis* Loureiro) are a small and relatively minor group like the King/King of Siam and the Kunenbo. They are mainly grown in South-east Asia and are extremely late maturing. There is only minor world interest in King hybrids like Encore, Kinnow, and Wilking cultivars.
- Small-fruited mandarins remain old cultivars mainly in China and Asia, where they are sold on local markets, e.g., Bendizau, Nanfengmiju, and Hungchien. Some are also used as specialist citrus rootstocks, i.e., Cleopatra mandarin (*C. reshni*) from India and Sunki mandarin (*C. sunki*) from China.

Origin

The main common mandarins are thought to be native to northeastern India and southern China and were grown there in very early times (twelfth century BC). The clementine may have originated in Algeria, as one of the first cultivars grown in the 1890s bore this name. Other distinctive groups (satsuma types) are believed to have originated in Japan or China, the Mediterranean mandarins are thought to have been introduced mainly to Italy from China in 1805 (via England and Malta) and the minor King group appears to have originated in Indo-China.

Some current cultivars are very old and originated in ancient cultures or growing regions. However, a large number of current commercially important mandarin are of much more recent origin, especially in the 1900s through natural mutations or sports, chance seedlings, or the result of specific breeding programs and irradiation treatment of seeds or budwood, e.g.:

- Ellendale originated as a seedling in about 1878 in Queensland, Australia.
- Kara is a hybrid of Owari satsuma and King mandarin in 1915, but not released to the USA industry until 1935.
- Marisol is a bud mutation found in 1970 on a Oroval clementine tree in Spain.
- Miho and Okitsu are nucellar selections derived from Miyagawa satsuma by controlled pollination in 1940 in Japan and released in 1953.
- Fallglo is a complex hybrid of Bower (clementine × Orlando) and Temple in 1962, but not released in the USA until 1987.

For the remainder of this article, the term 'mandarin' is used without qualification and should be taken to cover and include the whole mandarin group and related hybrids mentioned above.

With recent improvements in virus or other transmissible disease elimination like shoot–tip grafting *in vitro*, heat therapy, and postentry plant quarantine procedures, many more recent and modern cultivars

are now available for evaluation and local culture throughout many countries of the world.

There is also a trend for new cultivars to be protected and patented, so that the breeder can help offset the high cost of breeding, evaluating and multiplying new releases by receiving royalty payments. For example Gold Nugget in the USA, Loretina in Spain, Sunset in Australia, Robyn in South Africa, Afourer in Morocco, Cami in Italy, and Mor in Israel have all become available and patented only in the last 10 years.

Many countries throughout the world have major citrus germplasm collections – for cultivar evaluation, breeding programs and/or sources of propagation material. One of these major germplasm collections by the Institute National de Recherche Agronomique in Corsica has 716 scion cultivars recorded in 1997. These included a total of 271 (varieties, hybrids, selections, or clones) or 38% as mandarins, collected from around the world (mainly common mandarins 78 cultivars, clementine 83, satsuma 31, and tangelo 31).

Growing Regions and Conditions

Growing regions for mandarins, with a range of total heat requirements are like all citrus in general, being produced in a wide range of climatic conditions, including the humid tropics, arid subtropics, and intermediate climates. Commercial production also tends to be located in two narrow belts in the subtropics and between 20 and 40° latitude north and south of the equator.

Citrus grows best in cooler, frost-free, Mediterranean-type climates, provided that the soils are suitable, and rainfall is at least 1200 mm, distributed evenly throughout the year or supplemented by irrigation. Climate can have a significant effect on yield, fruit quality, and tree health. In particular, minimum temperatures and degrees of frost restrict commercial mandarin production within specific areas of many growing countries of the world.

However, mandarin trees are generally the most cold-resistant of all the citrus species of commercial importance, but the fruit is more susceptible to cold damage than oranges or grapefruit, owing to its small size and thin soft rind. Many cultivars are still very specific to their individual climatic requirements.

Some cultivars have been bred or selected that extend production into marginally colder subtropical climates; e.g., satsuma mandarins in Japan, China, Korea, and New Zealand are the hardiest. Clementines have a low heat requirement, and many current cultivars mature early to mid-season, but the King group is the most tender, with a high heat requirement, and tends to mature late.

At the other extreme, mandarins are amongst the most heat-resistant of citrus fruits, comparing favorably with grapefruit. For the development of good flavor, some hotter weather at the end of the growing season seems essential. However, exposed fruit can become sunburnt.

As with other yellow/orange rind citrus, mandarins grown in tropical climates are less successful commercially than other types and will not develop a normal full rind color but are usually harvested and marketed with green or only pale-colored rinds, although the fruit may be sufficiently mature to harvest and eat.

While site selection and soil management are influenced by local climate, some cultural practices also may modify harmful effects, including cold protection, soil drainage, irrigation, and windbreaks. However, these practices cannot completely overcome major differences and unfavorable climatic effects. Some of these effects include regular severe frosts, poor rind color development, variable maturity, fruit form, and pest and disease incidence, when production is under extreme or regular unfavorable production conditions.

Production Statistics

Commercial citrus production has been recorded by the FAO in over 100 different countries and throughout six regions – Africa, North America, South America, Asia, Europe (Mediterranean), and Oceania. The world's mandarin production has been gradually increasing from a 10-year average of 8745×10^3 tonnes in 1980–81 to 1988–89, to a significantly larger average total crop (allowing for annual seasonal variations, especially the common alternate cropping) in the four 1995/96–1998/99 seasons of $14\,865 \times 10^3$ tonnes, as shown in Table 1.

The largest mandarin growing areas are located in the northern hemisphere, where 90% of recorded world production occurs, and include the important growing countries like China, the Mediterranean region, with 26% (e.g., Spain, Italy, Morocco, Egypt, and Turkey), Japan, and Korea. The southern hemisphere, with only 10%, is a relatively minor growing region, as in Brazil and Argentina, with smaller plantings in Australia and South Africa. Omitted from the FAO statistics is the known and projected mandarin production in Pakistan of 547×10^3 tonnes in 2005.

Many countries like Japan, China, India, Mexico, and Asia have important local or domestic markets for their fresh mandarin fruits, overall in 1998–99

with 77% of total world production, with only 15% exported and 8% processed. However current and future export marketing will be important markets for Spain (currently the largest exporter), Morocco, Turkey, and China (Tables 1 and 2).

It is interesting to note that in the two largest citrus-producing countries (Brazil and the USA), mandarins are a relatively minor type produced with only 4 and 3%, respectively, of their total production. In other countries, mandarins are significantly more important, and these are discussed below.

Table 1 World mandarin production trends

Year	*Total production* $\times 10^3$ *tonnes*	*Exported* $\times 10^3$ *tonnes*	*Processed* $\times 10^3$ *tonnes*
1980–81 to 1988–89 average	8745	1236	1055
1995–96	14350	2052	876
1996–97	14133	2205	1256
1997–98	16516	2406	1508
1998–99	14463	2191	1206
Four-year average	14865 (82%)	2214 (12%)	1212 (6%)

China

Plantings have expanded rapidly in China (Figure 1) over the past three decades, and current nonbearing planting will increase production further. China is now the largest producer of mandarins in the world (totaling 68% of its total citrus production). Newer plantings are mainly satsuma cultivars (with over 40% including Wenzhou mikan), replacing older and previously more popular Tankan, Ponkan, Hongju, Zhuju, and small fruit local cultivars Nanfengmiju and Bendizau. Over 90% of mandarin production is consumed in the huge domestic market as fresh fruit (sometime ex-local storage), but with an increasing 4% processed (canned segments) and 3% exported. These exports are expected to increase in the long term, especially to Pacific Rim countries.

Spain

Spain is the largest citrus producer in the Mediterranean region, and the fourth largest in the world, and for mandarins, it is the second largest producer (after

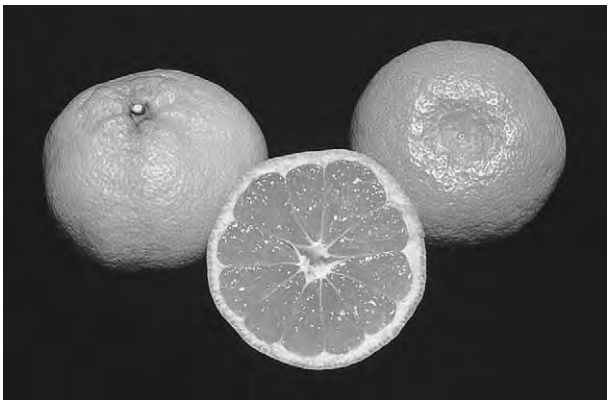

Figure 2 Okitsu satsuma has become an important new cultivar in many countries.

China), but the largest exporter of fresh fruit. Plantings in Spain continue to expand (totaling 270 000 ha in 1995). Main citrus types are oranges 55%, mandarins 31%, and lemons 13% of these plantings. Of the 21.7 million trees planted between 1990 and 1995, the main mandarin cultivar demand trends (in thousands of trees planted) were:

Satsuma	Okitsu	1575
	Owari	219
	Clausellina	131
Clementine	Marisol	1925
	Clemenules	1900
	Hernandina	991
Mandarins	Nova	1391
	Fortune	1122
	Ellendale	443.

See Figures 2 and 3.

Japan

Japan is currently third in world mandarin production, although it has experienced a significant decline in recent decades. Mandarins total 92% of Japanese citrus production, with only minor plantings of other citrus types. Most of this production is now in the form of satsuma cultivars (unshiu or mikan) and has generally replaced other older cultivars like Natsumikan, Hassaku, and Iyokan. As the satsuma group has evolved, a large number of distinct new cultivars have emerged and become important initially locally, but more recently also throughout the world. A large range of different satsuma cultivars are now available, varying from very early (Goko Wase) to midseason and late-maturity periods, i.e., Hashimoto, Miyagawa, Okitsu (Figure 2) and Miho (Wase); Hayashi, Owari, Nankan No. 20, Seto (mid); Aoshim, Juman and Otsu No. 4 (late). This enables satsuma fruit to be harvested over about 3 months, although culture in plastic/heated tunnels will advance the season by up to 4 months. Coupled with

Figure 3 (see color plate 32) Harvesting Fortune mandarins for export in Spain.

specialized storage procedures, this means that local satsuma fruit can be available for up to 8 months of the year.

Harvesting and Marketing

The growing, harvesting, and marketing of mandarins as soft fruit present many problems, which can be best overcome by specialist growers and carefully selected growing localities. They are comparatively higher in all these costs, when compared with other types of citrus production. Present day mandarin production focuses on careful type and cultivar selection to best suit local climatic conditions and cultural practices, in order to achieve a successful product and outcome.

Mandarins are mature and are ready for harvesting for a much shorter period of time than most other citrus types. Fruit left on the tree for more than a few weeks quickly pass the stage of optimum maturity and marketability, usually becoming insipid (reduced juice acidity), puffy, soft, and dry.

Early in the season, some cultivars may be internally mature before the rind color has fully developed, like Marisol clementine. Most respond to selective initial harvesting for larger fruit sizes or the required rind color development. All mandarins require careful harvesting, transport, and grading for size in order to reduce rind blemish and damage. Some cultivars are more difficult to harvest and require clipping to reduce plugging, where a small piece of rind is left attached to the stalk that remains on the tree.

Unlike many other citrus fruits, which may be available the whole year, mandarins are normally available as fresh fruit only in late autumn, winter, and spring. Within this period, a range of modern cultivars are now available for the main commercial types (common, clementine, and satsuma) that permit the production and marketing of fresh fruit from very early, early, mid (season), late, and very late maturity periods. See **Figure 4** for an example of the maturity range and sequence for some important cultivars in the Mediterranean region. All selection and breeding programs have a basic need to develop new cultivars that fit into a particular maturity period, when no cultivar is currently available or some major problem exists with the current cultivar (alternate cropper, poor fruit size, pest- or disease-susceptible).

Apart from the normal marketing periods, all mandarins are unsuitable for long-term cold storage. They are more perishable than sweet oranges or grapefruit and very susceptible to common storage breakdown problems and chilling injury. In normal export trade, careful storage is often necessary for several weeks depending on the shipping distance between producing countries, such as southern hemisphere producers like Argentina, Southern Africa, and Australia, exporting to the northern hemisphere's major markets in Europe, South-east Asia, Japan, and North America.

Crop Utilization

Mandarins are the second most important citrus type grown through the world with 17% of total production in 1998–99, after oranges (with 66%) but ahead of lemons and limes (11%), and grapefruit (6%).

As with all citrus fruits, mandarins are principally marketed according to how they are consumed, with domestic or local fresh fruit and exports totaling 92% of world production, with only a minor 8% processed – compared with 34% of oranges processed in 1998–99 (**Figure 5**).

In the world mandarin fresh export fruit trade in 1997–89, the following regions/countries (as generally noncitrus-producing) were the major importers – Mediterranean, Germany, France, UK, the former USSR, and The Netherlands.

As fresh or dessert fruits, mandarins are usually eaten out of hand, as they are generally easier to peel and separate into segments (than other citrus types) and have a distinctive, pleasant flavor. This is why mandarins are also known and promoted by a range of other descriptive terms, i.e., easy peelers, zipper-skin, TV fruit, soft fruit, kid glove citrus, picnic, or lunch box fruit. In some cultures, the presentation and eating of citrus, for example during the Chinese New Year, are considered important. Fresh mandarin segments are also suitable for garnishing and decorating salads or topping desserts.

In the home, mandarins can be widely used for juicing; cooking (as with mandarin bran muffins or mandarin-glazed spare ribs), sweets (like mandarin trifle and chocolate coating), marmalade, drying, glace, or crystallizing.

Mandarins are used as commercial processed products, mainly as segments in syrup or natural juice, with only limited production of juice products (often because of the limonene bitterness factors) and rind oil or essence, as often used in aromatherapy. After the juice has been extracted, there remain residues that can be a source material from which over 300 valuable byproducts can be produced. Some specialized types are also candied (the peel), dried, or used for marmalade and pectin manufacture.

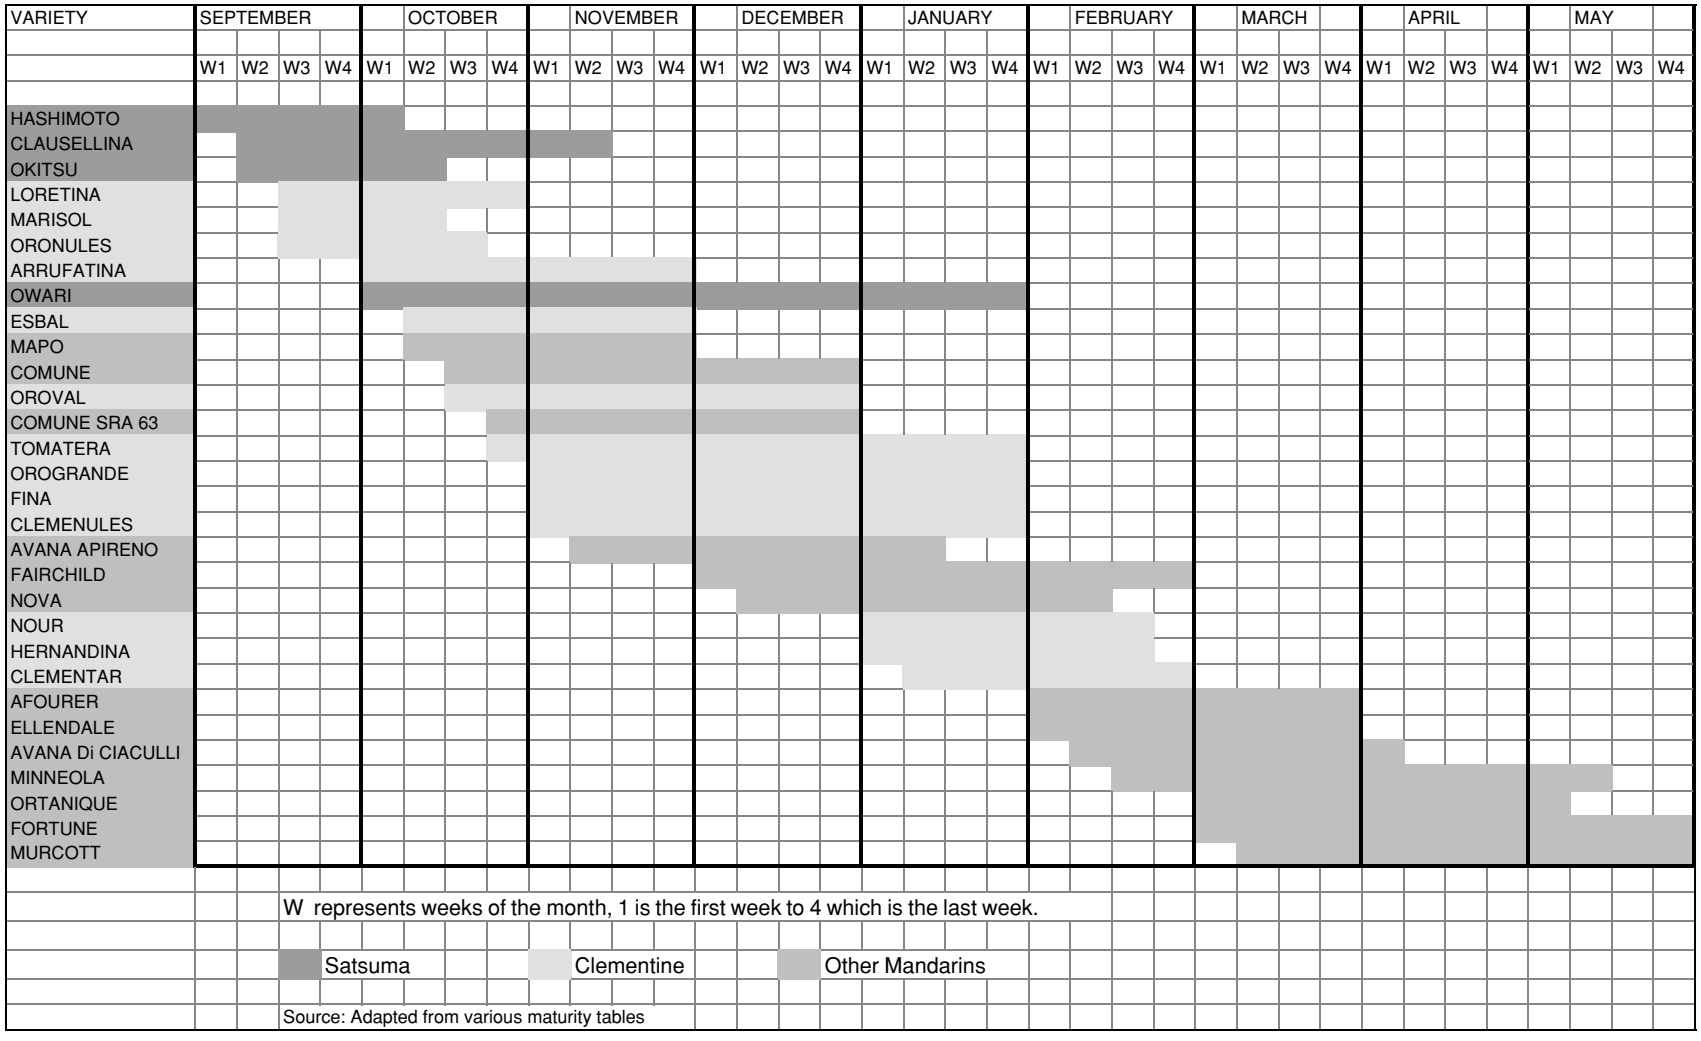

Figure 4 Some typical mandarin maturity periods in the Mediterranean region.

Figure 5 (see color plate 33) Moroccan clementine exports in open 10-kg packages.

(*See* **Citrus Fruits**; Composition and Characterization; Processed and Derived Products of Oranges.)

Over 400 different constituents have been isolated from fruit of different citrus species including mandarins. The principal components of non-acid fruits (like lemons and limes) are carbohydrates, which include mainly sucrose, glucose and fructose. These constitute about 75% of the total soluble solids (TSS) in juice. Organic acids, mainly citric and malic constitute less than 10% of the TSS and free amino acids, nitrogenous bases and glutathione about 6%. The remaining components include inorganic ions (about 3%), vitamins (2.5%), flavonoids and volatiles (1.2%) and lipids (1.2%).

CLEANING PROCEDURES IN THE FACTORY

Contents

Types of Detergent

H M J van Eijk and F A Majoor, Unilever Research Vlaardingen, Vlaardingen, The Netherlands

Background

A wide variety of chemicals can be used in the cleaning process, and these are generally classified as:

- water, which acts as the transport medium for chemicals and soil as well as delivering thermal and mechanical energy;
- cleaning agents, chemicals whose function is to remove soil.

Water

Water in general makes up the great majority of the cleaning solution (> 90%), and must therefore be given careful consideration. In most cases, the water used for making up the cleaning solution is also used for intermediate and final rinses and must therefore be of suitable microbiological quality. Particular attention should be also given to the content of inorganic material. If the hardness of the water is high (> 60 mg of Ca^{2+} per liter), it might be less suitable for cleaning purposes, and partial softening should be considered.

Cleaning Agents

Although water is important during cleaning, it cannot always remove all soils, particularly those encountered in the food industry, and therefore, detergents are required. Since no one detergent or combination of detergents possesses all the properties required for the removal of all types of soil at minimum cost, a selection must be made of the most appropriate for the application being considered. Materials used must be acceptable to regulatory agencies, especially with regard to biodegradability and the effect on the environment when discharged into surface waters. Typical components of a detergent formulation will include some of the following:

- alkalinity;
- surfactant/antifoam;
- sequestrant;
- threshold agents;
- hydrotropes;
- specialties;
- acids.

Many cleaning formulations are currently being reviewed in light of environmental concerns. It is probable that there will be an increasing use of low-phosphate, completely biodegradable products and a reduced use of sequestrants such as ethylene diaminetetraacetic acid (EDTA). Such changes in cleaning chemicals may well affect the other cleaning parameters such as the time and temperatures used.

Alkalis

Alkaline compounds are effective for the dissolution of proteins and removal of fats. Strong alkalis result in hydrolysis of the protein, forming water-soluble compounds. Examples of alkalis are sodium hydroxide (caustic soda) and potassium hydroxide (caustic potash). These compounds, being hazardous to personnel, are more widely used in cleaning in-place than in open-plant cleaners and, where used, should be in combination with automatic dosing equipment.

Further strong alkalis are:

- sodium orthosilicate;
- sodium metasilicate.

Milder alkalis include:

- sodium triphosphate;
- triethanol amine;
- sodium carbonate.

The milder alkalis possess some degree of protein hydrolysis and fat-removing capabilities but mainly

act as builders or sequestrants to soften water. In this respect, alkalis act to suspend and disperse the soil deposit in solution.

Surfactants/Wetting Agents

Surfactants are chemicals that lower the surface tension of water, and thus aid the 'wetting' of surfaces. For this reason, they are commonly called wetting agents. They also aid the penetration of the cleaning solution into the deposit.

Surfactant molecules consist of a hydrophobic (water hating) tail and a hydrophillic (water loving) head, as shown in Figure 1. The hydrophobic part of the molecule has an affinity for fats and oils, whereas the hydrophilic part of the molecule has an affinity for water. These molecules therefore emulsify and disperse oils, fats, waxes, and pigments. Some will precipitate at high pHs (> 12) and are unsuitable for use in combination with strong alkalis.

The polar nature of water molecules creates a high surface tension, and as a result, water forms droplets on a surface (Figure 2a). When a surfactant is added, the hydrophillic heads are attached by the water at a water/air or water/substrate interface (Figure 2b). The orientation of the surfactant molecules at the interface lowers the surface tension and results in spreading of the water droplet (Figure 2c). In a formulated detergent, these effects of the surfactant result in better penetration of that detergent into the soil deposit.

At a water/substrate interface, the same orientation of the surfactant molecules also occurs. This allows surfactants to solubilize or emulsify fats. On contact with a fatty soil, the hydrophobic ends of the surfactant enter the fat. As more such hydrophobic ends enter the fatty soil, the soil comes to occupy the center of a micelle molecular array, resulting in solubilization of the fat (Figure 3).

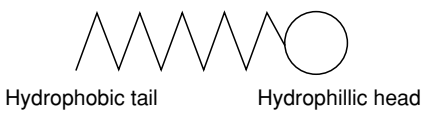

Figure 1 Surfactant molecule.

Surfactants are classified into three groups based on the charge of the active part of the molecule (in solution).

Anionic Surfactants

The active part of an anionic surfactant molecule carries a negative charge. Included in this group are the fatty acid salts and the sulfated and sulfonated derivatives of fatty acids. Anionic surfactants act in the same way as soaps, except that they are less affected by hard water ions and are generally high foaming.

Cationic Surfactants

The active part of a cationic surfactant molecule carries a positive charge. Included in the cationic surfactants are the quaternary ammonium compounds (quats). These compounds have limited detergent characteristics but have found an effective use as disinfectants.

Nonionic Surfactants

The nonionic surfactants do not ionize, and therefore, no charged species are formed. A wide range of nonionics exist, and consequently, these surfactants have a wide range of chemical properties. Nonionics can be low foaming and very penetrative wetting agents, making them particularly effective at removing oils.

Sequestrants

Sequestrants serve to enhance the effectiveness of the detergent by forming chelate complexes with metal ions in the deposit, or in the water itself. The metal ions mostly encountered are calcium and magnesium. If these ions are not complexed, they will readily form deposits on surfaces and will make the removal of fats more difficult.

Sequestrants commonly used are:

- phosphates;
- EDTA;
- nitrilotriacetic acid (NTA);
- gluconate.

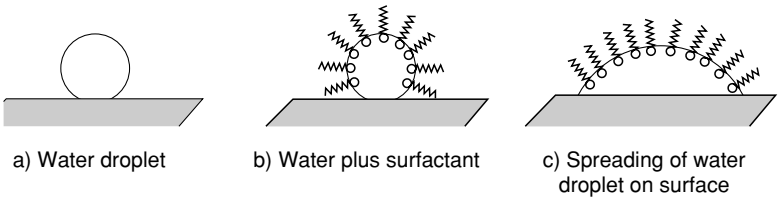

Figure 2 Wetting effect of surfactants.

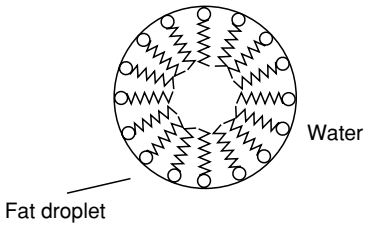

Figure 3 Solubilization of fat in water.

The sequestering power of EDTA is sufficiently high that even calcium salts can be redissolved.

Threshold Agents

Threshold agents prevent the deposition of hard water salts by disrupting the (calcium carbonate) crystal growth. These agents are added to detergents, not to prevent the deposition of hard water salts during cleaning (this is done by the sequestrant) but during the rinse stage. Threshold agents are used at very low concentrations (5–20 mg l^{-1}), which is sufficient to prevent deposition of hard water salts.

Hydrotropes

Hydrotropes are used to stabilize the neat product to ensure an adequate storage life. Liquid detergents generally contain a significant number of chemically active species, and special chemicals are necessary to prevent separation or sedimentation during storage.

Specialties

Further additions to detergents consist of corrosion inhibitors, tracers, and dyes.

Acids

Acids, both organic and inorganic, are commonly used for the removal of mineral deposits such as hard water scale or milkstone. Examples of inorganic acids are phosphoric, nitric, and sulfamic acid, and examples of organic acids are gluconic, hydroxyacetic, citric, and formic acid.

Whilst extremely effective at solubilizing mineral salts, acids are potentially corrosive to construction materials and must be used with care. Hydrochloric acid and fluoric acid are too corrosive (even to stainless steel), and they should not be used for cleaning in the food industry. A summary of the main functions of the chemicals is given in Table 1.

Table 1 Main functions of chemicals in detergents

Type	*Chemical*	*Function*
Strong alkalis	Sodium hydroxide	Removal of fat and protein
	Potassium hydroxide	Removal of fat and protein
	Orthosilicate	Emulsification
	Metasilicate	Corrosion inhibition
Mild alkalis	Sodium triphosphate	Dispersion
	Sodium carbonate	Alkalinity
Surfactants	Anionics	Wetting and foam
	Cationics	Corrosion inhibition
	Nonionics	Wetting and antifoam
Sequestrants	Polyphosphate	Prevention of Ca deposits
	Gluconate	Prevention of Ca deposits
	Na.NTA	Prevention of Ca deposits
	Na.EDTA	Dissolution of Ca deposits
Threshold agents	Phosphonates	Prevention of Ca deposits during rinse
	Polyacrylates	
Inorganic acids	Phosphoric acid	Removal of inorganic scale
	Nitric acid	
	Sulfamic acid	
Organic acids	Hydroxyacetic acid	Removal of inorganic scale
	Gluconic acid	
	Citric acid	
	Formic acid

Types of Disinfectant

J Fisher, Diversey Ltd, Riddings, UK

Background

In food factories, the detergent stage is normally followed by a disinfecting stage. The detergent stage is required to remove all the soil, leaving a chemically clean surface. The disinfectant stage is used as an extra guarantee of cleanliness and to prevent recontamination in some cases. It does not compensate for a bad detergent stage or badly designed process or cleaning equipment.

Disinfection

The definition of disinfection taken from BS5283 (1986) states 'The destruction of microorganisms, but not usually bacterial spores. It does not necessarily kill all microorganisms but reduces them to a level acceptable for a defined purpose, for example a level which is harmful neither to health nor to the quality of perishable goods.' The acceptable level of microbial contamination on a surface or piece of equipment has to be determined; obviously, no pathogens should be found. (*See* **Spoilage:** Bacterial Spoilage; Molds in Spoilage; Yeasts in Spoilage.)

The state of sterility is defined as free from all living microorganisms. This is not achievable in the food factory by using acceptable chemicals ('acceptable' meaning safe for humans, plant materials and products).

Disinfectants are used after the detergent application in cleaning-in-place (CIP) operations where the term 'terminal sterilant' may be used. They are also used after hand cleaning. Equipment should be left in a soak bath until it is ready to be used, thus ensuring that it remains free from recontamination.

There are a wide range of disinfectants available. The choice of disinfectant depends on the user's requirements, the type of processing and cleaning equipment, the method of use, and, to some extent, the personal preference of the user.

Types of Disinfectant

Disinfectants can be split into two broad groups, oxidizing and nonoxidizing. Oxidizing disinfectants include the halogens, chlorine, iodine, bromine, and chlorine dioxide, and oxygen-releasing materials such as peracetic acid and hydrogen peroxide. Nonoxidizing disinfectants are as follows: quaternary ammonium compounds, amphoterics, biguanides, and acid anionics.

Physical and Chemical Properties

Oxidizing Disinfectants

Halogens Chlorine and iodine have been used as terminal disinfectants for many years. More recently, bromine and chlorine dioxide have been introduced.

Chlorine Chlorine was first used as a gas for fumigation in hospitals in 1791, but this application has one obvious drawback – chlorine gas is toxic. Active chlorine is available from two types of material:

1. Inorganic compounds containing hypochlorite ions either as a liquid, e.g., sodium hypochlorite (NaOCl), or as a powder, e.g., chlorinated trisodium phosphate
$$((Na_3PO_4.11H_2O)_4NaOCl, NaCl).$$
2. Powdered organic chlorine release agents, e.g., trichloroisocyanurate (Figure 1).

In solution, both types hydrolyze to produce hypochlorous acid and/or hypochlorite ions, depending on the pH.

Acid				Alkaline
Cl_2	$\rightleftharpoons$	HOCl	$\rightleftharpoons$	OCl^-
Chlorine gas		Hypochlorous acid		Hypochlorite ion

In the food industry, sodium hypochlorite is used as a general-purpose disinfectant. It is most stable in a slightly alkaline solution, and it is for this reason that the concentrate is supplied stabilized with sodium hydrocide at a pH of up to 12. An in-use solution of between 50 and 300 p.p.m. will have a pH between 7 and 9. The optimum pH for disinfection is pH 5.0, but

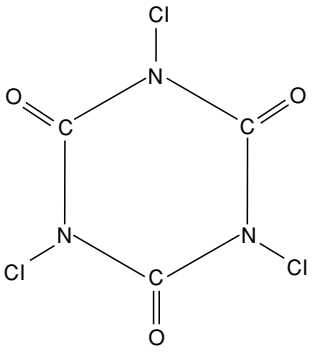

Figure 1 Trichloroisocyanuric acid. Reproduced from Cleaning Procedures in the Factory: Types of Disinfectant, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

the solution is less stable. Below pH 5.0, chlorine gas will be produced.

Applications for sodium hypochlorite in the food industries are CIP, soak, and spray. Sodium hypochlorite has many advantages: it is nonfoaming; it is not affected by water hardness; it does not leave an active residue, and it has a wide antimicrobial spectrum, which includes activity against bacterial spores and viruses. It is also fast-acting and cheap.

However, it also has numerous disadvantages: it can be corrosive to a wide range of components, including stainless steel; it is irritating to the skin and eyes; the in-use solution is unstable; it is inactivated by organic materials, and it may give rise to taint problems.

Chlorine dioxide Chlorine dioxide (ClO_2) is an unstable and toxic gas that is soluble in water. When chlorine dioxide is generated in solution, as shown below, it is a very effective water disinfectant at point of use.

$$5NaClO_2 + 4HCl \rightleftharpoons 4ClO_2 + 5NaCl + 2H_2O.$$

Chlorine dioxide at use concentrations (0.5–1 p.p.m.) overcomes some of the disadvantages of hypochlorite in that it is nontainting, noncorrosive, and nontoxic. Its sole use at present is in water disinfection.

Iodine Iodine itself is not very soluble in water, and the vapor is irritating to the eyes, making it difficult to handle. Iodine is a very reactive element, and it is this reactivity that makes it a good disinfectant.

Iodine compounds used in the food industry contain iodine complexed with polyvinylpyrrolidone and other surface active agents, usually in an acid solution. These are known as iodophors and were first introduced in 1949.

The complexes formed between iodine and carrier molecule are water-soluble and overcome the handling difficulties of iodine whilst retaining the disinfecting power. On dilution, the iodophors release iodine gradually, and it is the free iodine that acts as the disinfecting agent. The optimum pH for microbial activity is pH 5.0.

$$\underset{\substack{\text{Greatest}\\\text{activity}}}{\overset{\text{Acid}}{I_2}} \rightleftharpoons \underset{\substack{\text{Some}\\\text{activity}}}{HOI} \rightleftharpoons \underset{\text{Inactive}}{OI^-} \rightleftharpoons \underset{\text{Inactive}}{\overset{\text{Alkaline}}{IO^-}}.$$

The surface-active agents provide better wetting and organic soil penetration, thus making iodophors less affected by soil than hypochlorite. The choice of surface-active agent may lead to foam generation in applications such as CIP.

Iodophors have a broad antimicrobial spectrum that is similar to hypochlorite, although they are less active against bacterial spores. In common with sodium hypochlorite, they are fast-acting but are more expensive. Iodophors are used in soak baths and spray application at up to 10 p.p.m. available iodine. In solution, iodophors are yellow-brown in color. This color can be an advantage: in a soak bath application, the color indicates the presence of iodine; the in-use solutions are unstable, so that as the iodine dissipates, the solution will become colorless.

Staining may be a problem, especially with some plastics, and this may also result in taint problems. Iodophors can be corrosive; it is therefore necessary to ensure that the correct dilution is used; otherwise, damage to plant and personnel may occur.

Bromine Bromine itself is not used as a disinfectant, mainly because of its handling difficulties. Bromochlorodimethylhydantoin is supplied as a powder or a solid. In solution, it releases hypobromous and hypochlorous acids.

Oxygen-releasing compounds

Peracetic acid Peracetic acid was introduced in 1955. The material is supplied as an equilibrium mixture:

$$\underset{\text{Peracetic acid}}{CH_3C(=O)OOH} + \underset{\text{Water}}{H_2O} \rightleftharpoons \underset{\text{Acetic acid}}{CH_3C(=O)OH} + \underset{\text{Hydrogen peroxide}}{H_2O_2}.$$

It is soluble in water and is completely biodegradable, breaking down to harmless products:

$$2CH_3C(=O)OOH \rightarrow 2CH_3C(=O)OH + O_2$$

As supplied, peracetic acid is corrosive and has a very irritating smell, similar to vinegar; because of these properties, it is unpleasant to handle, and manual use is not recommended. It is suitable for CIP, as it is nonfoaming.

Peracetic acid is a highly reactive material. As an in-use solution, it is not very stable and will react with organic materials. Peracetic acid may attack plant materials, such as rubber gaskets, and at higher concentrations, corrosion may be a problem.

Peracetic acid has a wide antimicrobial spectrum, which includes bacterial spores and viruses. This activity is fast and is maintained at temperatures lower than ambient.

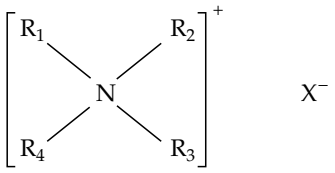
Hydrogen peroxide Hydrogen peroxide (H_2O_2) was introduced as a disinfectant in 1887. It is supplied in solution, which has a tendency to decompose:

$$2H_2O_2 \rightarrow 2H_2O + O_2.$$

Manual use of hydrogen peroxide is not recommended, but it is used in spray applications such as aseptic packaging. Hydrogen peroxide is both bactericidal and fungicidal. Some bacteria and fungi are less sensitive because of catalase activity, which destroys H_2O_2. Hydrogen peroxide is slow-acting, so that a long contact time or elevated temperature is required for effective disinfection.

Nonoxidizing Disinfectants

Quaternary ammonium compounds Quaternary ammonium compounds (QACs) were first introduced in 1917 and are probably the best known cationic surface-active agents. Their general formula is as follows:



X is usually a halide but sometimes a sulfate ion. R_1, R_2, R_3, and R_4 may be a variety of alkyl or aryl groups.

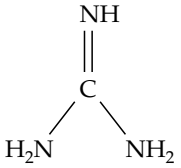
QACs are generally poor detergents but good wetting agents. In solution, they ionize to produce a cation, the substituted nitrogen part of the molecule, which provides the surface-active property. The length of the carbon chain in the R groups affects the disinfectant ability; usually, C_8 to C_{18} are the most effective.

The surface-active nature of these molecules tends to make them too high-foaming for CIP use, but they can be used for soak and manual cleaning at 200–400 p.p.m. active. The optimum activity is around neutral pH, but QACs are active between pH 3.0 and 10.0. Activity may be inhibited by water hardness.

QACs are noncorrosive and are stable at in-use dilution. Their major disadvantages are that they are affected by organic soil and that they tend to cling to surfaces, so that they may be difficult to rinse off, resulting in possible taint problems.

The antimicrobial range of QACs is less than that of the oxidizing disinfectants. They are less effective against Gram-negative bacteria than against Gram-positive bacteria. They also have limited activity against bacterial spores and very little activity against viruses. To be effective against yeasts and molds, a higher concentration is required.

Biguanides Biguanides with antimicrobial activity were first reported in 1933. The biguanides are derivatives of guanidine, a naturally occurring substance found in vegetables such as turnips and cereals:



Biguanides are usually supplied as polymers in the salt form, mostly as the hydrochloride. Optimum activity lies between pH 3.0 and pH 9.0. Below pH 3.0, activity is suppressed, whilst above pH 9.0, they are precipitated.

They are cationic in nature but are not regarded as surface-active. Biguanides do not foam and are, therefore, suitable for CIP; they may also be used for soak and manual cleaning. They are noncorrosive but taint may be a problem if not properly rinsed. The in-use solution is stable but is affected by organic soil and, to some extent, by hard water.

Most biguanides have equal antibacterial activity against Gram-positive and Gram-negative microorganisms. They are less effective against molds and yeasts, and are ineffective against bacterial spores and viruses.

Amphoterics Amphoterics have been in use as disinfectants since the early 1950s. They are based on a substituted amino acid, usually glycerine. The term ampholyte is often used to describe them because in solution they ionize to produce cations, anions, or zwitterions, depending on the pH:

$$R-\overset{+}{N}H_2-CH_2-CH_2-C(=O)OH$$
Acid cation

$$R-\overset{+}{N}H_2-CH_2-CH_2-C(=O)O^-$$
Zwitterion

$$R-NH-CH_2-CH_2-C(=O)O^-$$
Alkaline anion.

Only certain amphoterics have a disinfecting ability and surface activity. The disinfecting ability appears to increase with the increase of basic groups.

Amphoterics tend to be viscous liquids that are freely soluble in water. They are generally too high-foaming for use in CIP, but are suitable for soak, spray, and hand use. Amphoterics are equally effective against Gram-negative and Gram-positive bacteria; they are less effective against yeasts and molds, and have very little effect against bacterial spores and viruses. The optimum activity lies between pH 3.0 and 9.0.

Properties such as soil tolerance and corrosion vary with the amphoteric concerned. Corrosion is not usually a problem. The in-use solution, usually 1000 p.p.m. active, is stable.

Acid anionics The active molecule in acid anionics varies considerably. There are two main types: those based on carboxylic acids, which include fatty acids and derivatives, and those based on anionic surfactants combined with mineral acid.

Acid anionics tend to be formulated products with additions to aid activity or solubility. Properties will vary with product, but they tend to have some detergent and wetting ability. The higher-foaming products are unsuitable for CIP, so that their general use is for spray. They are not suitable for hand use, since a pH of 2 is required for optimum antimicrobial activity.

The antimicrobial activity is against Gram-negative and Gram-positive bacteria, but they are less effective against bacterial spores and viruses. Certain carboxylic acid types are active against yeasts and molds. Both types are affected by organic soil and water hardness, but again, both properties will vary with the product. The in-use solutions are stable.

Effluent Problems

The oxidizing disinfectants are degraded very easily by organic soil to ineffective products. Peracetic acid and hydrogen peroxide break down to the products that have been described earlier.

The breakdown products from the halogens vary with pH of the effluent, but in general, halide ions will be produced. The halogens should not be mixed with acid products, as chlorine will react with organic chemicals to produce organo-chloro compounds, which may be carcinogenic. The nonoxidizing disinfectants in modern products tend to consist of biodegradable compounds. The cationic products will adsorb on to organic material. The biguanides are incompatible with alkaline chemicals and will form a precipitate. (*See* **Effluents from Food Processing**: On-Site Processing of Waste; Disposal of Waste Water; Composition and Analysis.)

Analysis of Disinfectants in Waste Water

Obviously, detection will tend to depend on the concentration of disinfectant present. The oxidizing disinfectants are unlikely to be detected. Halide ions can be detected but cannot be identified as coming from the disinfectant.

Using an available chlorine probe, chlorine may be detected up to 200 p.p.m., but because of the presence of organic material and other chemicals, the presence of available chlorine may not be detected. As with chlorine, available iodine can be detected using a probe, but iodine is converted very quickly to iodide. The breakdown products of peracetic acid and hydrogen peroxide are unlikely to be detected.

For the quaternary ammonium compounds, the biguanides and the amphoterics, it would be necessary to know the specific active molecule to be able to quantify these activities in effluent. The active content could then be determined by HPLC.

Acid anionics can be detected in the effluent by determining the anionic content.

Comparison with Steam

There is no chemical suitable for use as a disinfectant in the food factory that can compete with steam. It is effective against bacteria, molds, yeasts, bacterial spores, and viruses. It is not affected by soil and hard water. There are no corrosion or stability problems, and it leaves no residues. The drawbacks are that it cannot be used with heat-sensitive plant materials, and it needs careful use to avoid human contact.

Overall Approach

H M J van Eijk and F A Majoor, Unilever Research Vlaardingen, Vlaardingen, The Netherlands

Background

Plant and equipment is generally cleaned for one of two reasons.

1. Microbiological
   - defined by required final product microbiological quality.
2. Process

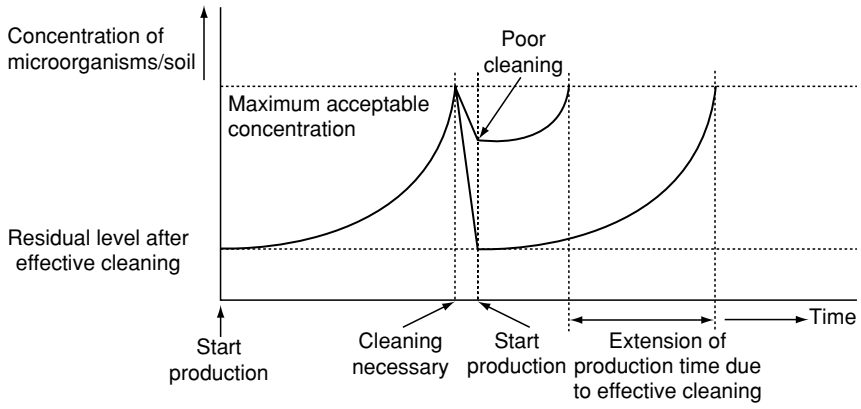

Figure 1 Influence of cleaning efficiency on available production time.

- formation of deposits that may adversely affect the operation of equipment.
- changeover to a different product;
- production shutdown over an extended period.

An example of a *microbiological requirement* for cleaning would be a food process line where the microbiological quality of the final product decreases during production until the point where shutdown and cleaning is required.

An example of a *process-related* requirement for *open* plant cleaning would be a freezer in which ice build-up on the evaporator surfaces takes place, eventually resulting in a failure to maintain the desired air temperature and flow velocity. The effect of this would be to reduce the capacity of the freezer and eventually reach a point at which the products are not cooled to the required temperature, thus requiring production to be terminated. A *process-related* requirement for cleaning of a *closed* system would be a pasteurizer, in which fouling of the heat transfer surfaces takes place, eventually resulting in both physical blockage of the heat exchanger and failure to maintain the desired pasteurizing temperature. The microbiological effect of the pasteurization process would therefore be reduced below that required for product safety, thus requiring production to be terminated.

There are a variety of mechanisms by which surfaces may become fouled, as shown in Table 1, and the nature and composition of the resultant soil can therefore also vary widely. Failure to clean effectively may have serious implications in terms of product quality and storage characteristics as well as process operation and control. Figure 1 shows how a properly cleaned process line can operate for a much longer period of time before the microbiological quality of the product becomes unacceptable, and the line must be shut down and cleaned.

Table 1 Major fouling mechanisms

1. Chemical reaction	Deposits formed at the surface by chemical reactions in which the construction material itself is not a reactant
2. Crystallization	Deposition/formation of crystals on a surface
3. Particulate	Accumulation of solid particles from the fluid stream on the surface
4. Biological	Deposition and growth of microorganisms on a surface
5. Corrosion	Corrosion of the surface itself which may in turn promote the attachment of other soil
6. Solidification	Solidification of fluid components on a surface

Clean equipment leaves microorganisms exposed to disinfection agents such as hot water, steam, and chemical disinfectants. Microbiological methods of evaluation may be used to validate the condition of the system after cleaning, and several countries have recommended hygiene standards based on colony counts per unit surface area. In addition to standard microbiological techniques (contact plates, swabs) a variety of more direct methods may be used to assess the cleanliness and/or hygienic status of surfaces.

Scope and Philosophy of Cleaning Operations

Cleaning operations within any manufacturing environment are likely to involve a variety of surfaces, materials of construction, and cleanliness requirements. Patterns of cleaning will also vary considerably according to the environment, equipment, and products. An initial classification is used to differentiate between the types of surface that are to be cleaned, product contact and nonproduct contact, which may be defined as:

Product contact surfaces These include all equipment surfaces that intentionally or unintentionally (e.g., resulting from splashing) come into contact with the product, or from which product or condensate may drain, drop, or be drawn into the main product or product container. This includes surfaces that may indirectly cross-contaminate product contact surfaces or containers.

Nonproduct contact surfaces These include all other exposed surfaces. These may include surfaces associated with equipment such as support structures, control panels, and external surfaces. They also include surfaces related to the manufacturing environment.

It is important to appreciate the importance of the manufacturing environment as a potential source of pathogens and/or spoilage organisms. Drains, drain channels, walls, floors, and roofs near air intakes have all been implicated as significant sources of microorganisms.

In certain situations, environmental cleaning can only be carried out during a production shut-down period and therefore can be difficult and costly. Because of this and the trend towards extended production runs within the food industry, intermediate cleaning is being considered more frequently. An example of this is cleaning a line, while production continues on an adjacent line in the same area.

A further subdivision of cleaning operations is whether the process is carried out dry or wet.

Dry cleaning

Dry cleaning methods are primarily used where the products are hygroscopic or where water can react to form hard deposits that are difficult to remove. The principal safety risk is that failure to control moisture can permit the growth of pathogens, e.g., *Salmonella* spp., in the food processing environment. Environments typically dry-cleaned include plants producing flour, cocoa, dry milk products, dry soup and snack mixes, and dry infant formulae.

Dry cleaning is essentially the mechanical removal of soils using sweeping, brushing, wiping, and vacuuming. Vacuuming is in principle a desirable system for removing dust and dirt. Disinfection following dry cleaning may pose difficulties, although alcohol-based disinfectants can be applied and allowed to dry off before equipment is reassembled.

Additional wet cleaning in a dry area needs great care, and it is usually best to remove equipment or parts requiring wet cleaning to a separate area. The wet-cleaned parts must be throughly dried before returning to the dry area for reassembly.

Wet Cleaning

Wet cleaning, as its name implies, involves the application of fluids, usually water based, to achieve the desired cleaning result. This can be carried out in place (CIP), where the plant remains assembled as for production.

The other alternative is to clean using open plant cleaning (OPC). In this case, the surfaces to be cleaned have to be made accessible to the cleaning fluids, which may involve the use of delivery systems to enable the operator to deliver the necessary cleaning fluids, e.g., lances, sprays, or dismantling of the equipment to allow the necessary access. In addition, some plant components may be physically removed from the production area and cleaned separately in a designated cleaning area. This is termed cleaning out of place (COP).

More complex process equipment may involve a combination of OPC and CIP; for example, a pump may be cleaned in place along with the rest of the line, but if it is known that CIP is not fully effective, it may be stripped down and cleaned manually before production restarts.

Manufacturing environments may require a combination of dry and wet cleaning. Dry cleaning using scrapers, shovels, or brushes may be more appropriate, particularly immediately after production, to remove quantities of gross soil and thus reduce the challenge to the wet cleaning process.

Factors Affecting Cleaning of Equipment

The equipment to be cleaned may be considered as a set of unit components that may vary widely in terms of volume, configuration, and geometry. There are several interrelated factors that have a direct bearing on the effectiveness and ease of cleaning process plant (Figure 2). A key point to appreciate is that a system of poor mechanical or process design may be uncleanable, irrespective of the cleaning process imposed on it. It is therefore essential that consideration of cleaning should be integrated into the mechanical and process design at an early stage rather than a final process to be incorporated into an already fully specified plant.

The factors that can contribute to the efficiency of a cleaning process are mechanical, thermal and chemical activity – and the time for these to work. The cleaning process is invariably a combination of these factors, and different cleaning processes involve a different balance of these factors, which has implications for the type of detergent to be used. For example, a cleaning process carried out at a low temperature with little mechanical activity would require a more powerful detergent than one carried

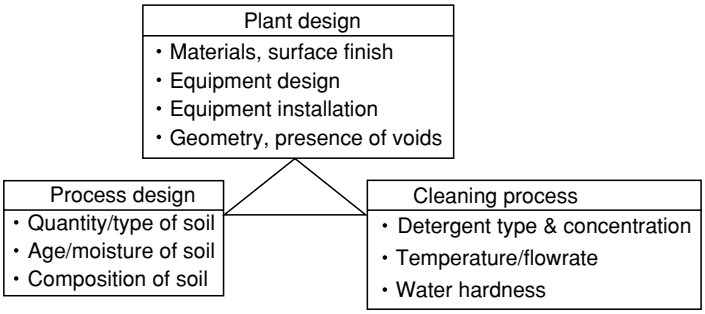

Figure 2 Factors affecting process plant cleaning.

out at a high temperature with a large amount of agitation.

Plant-cleaning Options

Open Plant Cleaning (OPC)

The function of OPC process is to clean and, where necessary, disinfect all surfaces to an acceptably high and consistently reproducible standard. A process plant cleaned in this way is disassembled and/or moved from its normal location for cleaning. This also applies to plant that is opened up to make it more accessible for cleaning manually or using some form of delivery system such as a hose.

The cleaning process consists of a number of stages:

Preparation for cleaning Prior to cleaning, all food and packaging material has to be removed from the area, including pallets, crates, bins, etc. All food material that can be reused further should be stored away from the process area and packaging material returned to the packaging material store. Only if all this material is removed, will thorough and complete cleaning be possible.

Dismantle equipment Equipment should be dismantled in order to expose the surfaces to be cleaned. Small items or components may be removed at this stage for cleaning in a dedicated wash area.

Gross soil removal Before application of the detergent, the gross soil has to be removed from the surface. Detergent has little effect on soil layers several millimeters in thickness or on large lumps.

Gross soil removal can be achieved by different methods as scraping, brushing, or spraying, but it is not necessary for the line to be 100% visibly clean after this step. It should be borne in mind that collecting gross soil by scraping may be more effective than flushing it to drain by pressure rinsing in terms of reducing the loading and cost of effluent treatment. Pressure rinsing could take more time and cause extra problems of drain blockage.

Detergent application Detergent is applied to the surfaces using mechanical aids to assist soil removal including brushes or high- or low-pressure water hoses as appropriate. The selection of detergent should be done in conjunction with the supplier.

Rinsing Rinsing of the detergent residues and soil can best be done under the same conditions as the prerinse. The extra demand for this rinse is that, after rinsing, the equipment should be 100% visibly clean. The rinse water should be of potable quality

Disinfection In many applications, food contact surfaces have to be disinfected after cleaning. The choice of the correct disinfectant depends on a number of factors, including:

- type of microorganisms involved;
- construction material of the equipment;
- effluent system;
- application of final rinse after disinfection.

Final Rinse It depends on the local situation as to whether a final rinse after disinfection is necessary. In some countries, adequate draining after disinfection with approved disinfectants at approved concentrations is sufficient. If a final rinse is required, the water must be of potable quality.

Drying Liquids must be completely removed by draining and/or drying, before the next startup can be done.

Clearing Away the Cleaning Tools After cleaning, the tools must be cleaned and (optionally) disinfected

and stored in a designated area (according to local rules). It is helpful to have color coded cleaning tools for special applications/areas (for example, black-bristled brushes for drain cleaning).

Cleaning In-place (CIP)

CIP may be defined as the circulation of chemicals and/or water through the plant that remains assembled as for production, such that all product contact surfaces are cleaned and, where necessary, disinfected to an acceptably high and consistently reproducible standard.

This process consists of up to three main stages:

1. Product recovery/rinsing – removal of bulk product from the system immediately after production, or cleaning residues such as used detergents and disinfectants after cleaning.
2. Cleaning – removal of soil from product contact surfaces.
3. Disinfection – further reduction of relevant microorganisms in the plant by chemical or thermal means, to achieve the desired hygiene standards within the plant.

Hence, CIP may be taken to mean processes including some or all of the above stages.

Product recovery should be employed whenever possible to reduce product losses and decrease the effluent chemical oxygen demand (COD). Product recovery may be achieved by simple purging with water or, with a viscous product, more effectively by pigging.

For disinfection, there are several options depending on the microbiological requirements, construction materials, and plant design:

- pasteurization, a thermal process that will inactivate most vegetative organisms, including pathogens, but not heat-resistant bacterial spores;
- sterilization, a more severe thermal process that destroys all microorganisms, including heat-resistant bacterial spores;
- chemical disinfection, which, depending on the chemical and the temperature used, may kill all or only some of the microorganisms present.

It is possible to clean a plant by applying a simple 'use and dump' procedure, whether or not making use of additional equipment for preparing and pumping cleaning liquids. However, considerable savings in running costs may be achieved by installing an appropriate CIP system, which enables recovery and reuse of rinse water and detergents and a more efficient utilization of energy.

Economic and Environmental Implications of Cleaning

Economic Implications of Cleaning

Cleaning costs are often closely associated with the cost of the cleaning chemicals alone and less attention paid to the other costs of the process, namely:

- steam;
- electricity;
- water;
- effluent;
- labor;
- plant downtime.

It is difficult to be specific as regards the cost of cleaning, as this will depend on the type of plant being cleaned, the cleaning process used, and the relative cost of services, which will vary widely from site to site. It is, however, generally accepted that in open plant cleaning, the major cost factors are plant downtime and labor. Where the plant downtime cost is not included in the costing, the labor cost may be 60–85% of the total.

Although manual cleaning is widely accepted in some industries as the only way of achieving reasonable standards of cleanliness where vessel and pipeline cleaning is required, its inherent disadvantages made the eventual implementation of CIP techniques inevitable, and their use has confirmed the significant benefits anticipated. CIP may incur additional capital costs for equipment, but this can be minimized for new lines by consideration of CIP during the design stage.

1. Improved hygiene. Consistent, reproducible cleaning schedules may be carried out and monitored with a corresponding improvement in plant cleaning performance and subsequent product quality.
2. Cost savings. Optimal use of water, chemicals, and steam results in lower cleaning costs.
3. Improved plant utilization and reduced plant downtime. Tanks and pipelines can be cleaned as soon as they are empty and refilled immediately afterwards.
4. Reduced labor cost. A reduction in the need for manual disassembly of equipment, coupled with an increased use of automation leads to a dramatic reduction in labor requirements.
5. Improved occupational safety. Less opportunity for operators to come into contact with aggressive chemicals.
6. Reduced effluent, minimizing volumes of waste water. CIP systems can be used to monitor and manage the reuse of cleaning waters and chemicals.

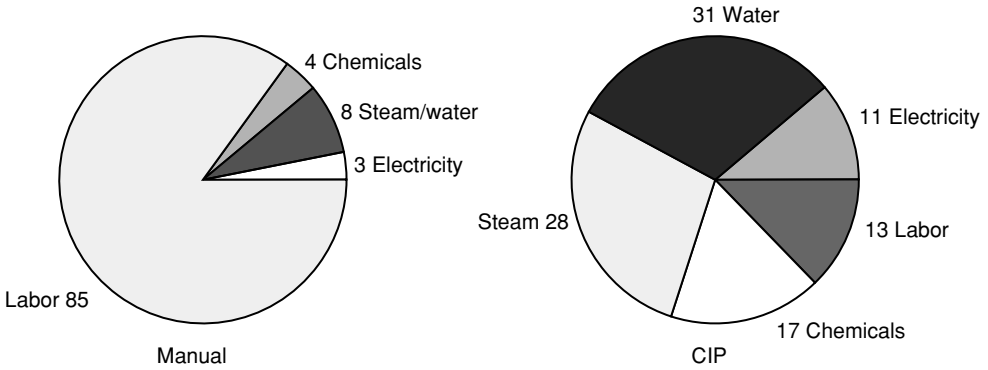

Figure 3 Typical percentage cost breakdown for manual and CIP cleaning. (Figures are percentages of total cost, excluding depreciation. Total costs of the manual and CIP operations are *not* the same.)

The cost of cleaning will depend on the plant being cleaned, the cleaning process used, and the cost of services, which will vary widely from site to site. However, the additional costs incurred with manual cleaning can be seen clearly in Figure 3, a cost breakdown of a labor-intensive manual operation and a highly automated CIP process.

The costs in Figure 3 are all shown relative to the total cost of the single stage clean, which is taken to be 1. The depreciation costs are very variable, and the total costs of manual and CIP cleaning in this figure are not the same.

With a predictive costing model, it is possible to compare the (total) cleaning costs for different cleaning procedures and thus optimize the cleaning process, which automatically results in water, effluent, and energy savings.

Environmental Implications of Cleaning

Cleaning in the food industry will inevitably bring a high amount of organic material into the effluent system. In general, more than 95% of the organic load consists of the soil, which is removed. Scraping away gross soil and sending it to destruction, instead of rinsing it to drain, could substantially reduce the organic load that goes into the effluent system.

Any environmental assessment of cleaning should be considered in the context of the complete manufacturing operation and also include all types of cleaning operations, both OPC and CIP. These are likely to indicate that the majority of the biochemical oxygen demand/chemical oxygen demand load on the effluent plant is associated with product losses, both during production, e.g., product leakage as well as cleaning. The detergents used should contain only biodegradable surface active agents and, if possible, biodegradable sequestrants. For inorganic materials, they should not contain fillers such as chlorides and sulfates, which do not have any positive effect on the cleaning. The technical information sheet of the detergent should provide information concerning the environmental effects of the detergent. In addition, automatically preparing detergent solutions has a cost-reducing effect, and instead of manual preparation, it prevents overdosing.

The most attractive way of reducing the environmental implications for closed systems is product recovery by pigging. The so called 'pig' is sent, by means of compressed air or water as the driving force, through the pipeline and expels most of the product from the system.

Conclusions

All forms of cleaning and disinfection are known to play an increasingly important role in manufacturing in all stages of processing right up to the packaging of the final product. Because there is a trend towards improved hygiene standards in food manufacturing, cleaning/disinfection forms an essential component of such improvements.

Modern Systems

H M J van Eijk and F A Majoor, Unilever Research Vlaardingen, Vlaardingen, The Netherlands

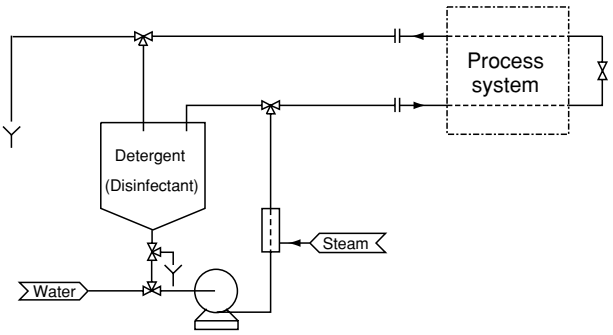

Figure 1 Flow diagram of a 'single-use' CIP system (types of valves depending on specific local requirements).

Introduction

In the design stage of a process line, the cleaning requirements should already be taken into account. A CIP-able plant should be designed in such a way that cleaning and disinfection can take place in the same line configuration as that during processing. Unfortunately, in practice, this target cannot always be reached; it is possible that some parts are not cleanable in-place and thus require dismantling and manual cleaning. Those parts have to be physically separated from the system, and it should be realized that reinstalling may result in contamination of the cleaned process line. Implementation of a CIP system depends on the type of process and whether the equipment is suitable to be cleaned in-place.

Resulting from this discussion, normally more options can be defined. If some of those solutions are equivalent, a detailed cost comparison should follow, taking into account investment in equipment, running costs, and, increasingly importantly, plant down time.

Options for central CIP systems

In some cases, CIP of a plant can be done without the addition of extra equipment. This could be appropriate for small plants with only a few tanks and short pipe runs. Cleaning liquids can be prepared in the production equipment itself, e.g., in balance tanks of pasteurizers. Possible disadvantages are that running costs may be high because of losses of cleaning chemicals and process down time. Therefore, it should be investigated in all cases whether possible savings in running costs can justify the investments in additional CIP equipment, normally consisting of extra tanks, pumps and pipe runs.

'Single-use' CIP system

Such a system (**Figure 1**) consists of one tank that is used to prepare a certain cleaning solution at the desired temperature. This can already be done when the line is still in production, provided that there is a good physical separation between the cleaning system and the production system. After connection to the process line, a centrifugal pump circulates the cleaning solution through the part of the process plant that has to be cleaned. The pipe system between tank and pump contains a manifold through which optionally cold or hot water or steam can be introduced into the circuit. Prerinsing and postrinsing are once-through operations; after passing the process equipment, the rinse is discharged directly to drain. The cleaning liquid may be circulated over the tank for a certain period of time, but is also discharged to drain at the end of the cleaning procedure.

The automation level of such systems can be kept low; because of their simplicity they can be easily operated manually. The advantage of these systems is that time is gained during preparation of the cleaning solution(s). The disadvantage of possibly high running costs is still the same.

Single-use System with Partial Recovery

This system can be used under the same conditions as above, but now the option of recovering fluids has been added by the use of two buffer tanks (**Figure 2**). Also, here, the detergent solution is normally dumped after use, but when, after the prerinse, the residual soiling is light, recovery of the cleaning solution in one of the tanks may be considered. This may be used one or more times for subsequent cleaning procedures. When a disinfection step is required, there might also be recovery of disinfectant in one of the buffers. If detergent cannot be recovered, there is still the possibility of recovering postrinse water, which can be used for the next prerinse.

Optimal Reuse System with Maximum Recovery (Centralized System)

This system contains sufficient tanks that several fluids and solutions used in cleaning have their own

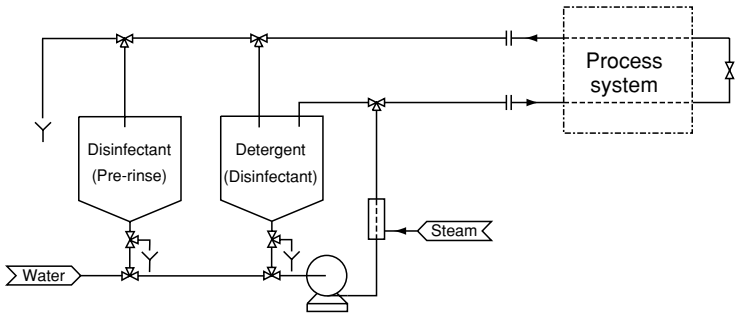

Figure 2 Flow diagram of a 'single-use' CIP system with partial recovery (types of valves depending on specific local requirements).

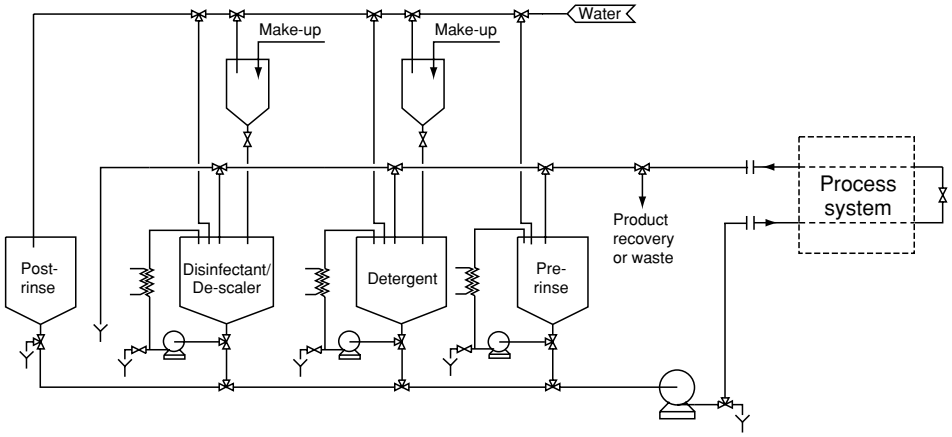

Figure 3 Flow diagram of an optimal, centralized reuse CIP system with the possibility of maximum recovery (types of valves depending on specific local requirements).

dedicated buffer (Figure 3). In the simplest form, there are at least two tanks; one for prerinse water and one for detergent solution. Postrinse may be recovered in the prerinse tank, and the detergent can be recovered (after a certain waiting time to prevent dilution) in its own buffer. Extra tanks might be necessary for buffering, e.g., a disinfectant, descaling solution or postrinse water.

The benefits are clear; cleaning can start immediately after production stops, and the cleaning procedure can be executed without any interruptions. Preparation of cleaning fluids of the right strength and temperature can be done with separate circuits to avoid any delay between cleaning stages. Moreover, there is a cost saving from the recovery of water, chemicals, and energy, and, in some cases, by the possibility to recover product (if this can be reworked).

An additional advantage is a better control over the effluent costs. To run such systems in a safe and efficient way, a higher level of automation is highly preferred. This implies higher investment costs.

Partially Decentralized System

When, in a factory, a centralized CIP system (as described before) is situated a long distance from the various process systems, the efficiency of such a system might be affected by the following factors:

- large volume of liquid in long pipe runs, thus requiring larger tanks and more energy input;
- long time needed to purge out a liquid/replace it by another (resulting in chemical loss);
- when more cleaning loops are necessary, the costs of pipe work increase dramatically.

To overcome this, a central CIP system can be extended with satellites, which only serve one distinct part of a process system (Figure 4). These satellites can be rather simple, but should be able to receive the required cleaning liquids from the central plant within a reasonably short time, e.g., by means of a main loop system with relatively small pipe diameters.

Depending on the situation, a decision can be made on whether or not to recover liquids to be sent back to

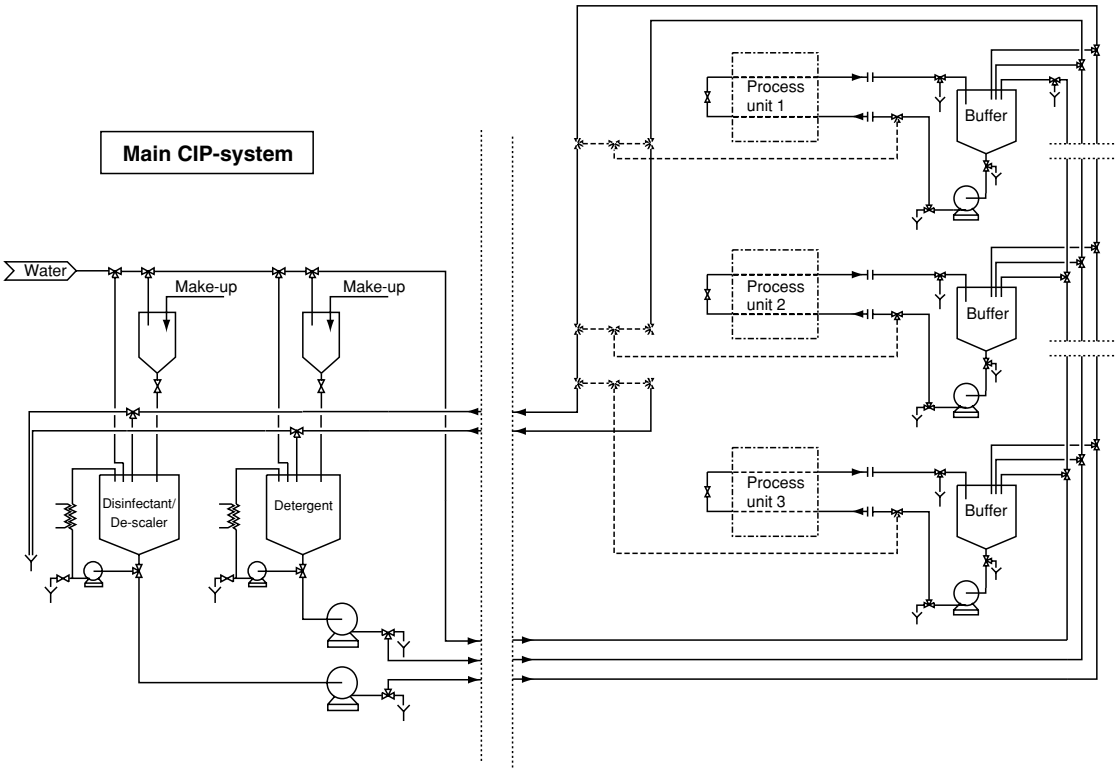

Figure 4 Flow diagram of a partially decentralized system with satellites (types of valves depending on specific local requirements).

the central system. Such a system may offer particular advantages, e.g., when preparation stages of a process can be cleaned while, downstream, other process equipment and filling machines are still in use. In such cases, a centralized CIP system will require far more safety measures (e.g., leak protected valves) or should make partial cleaning unacceptable. Also, parts that require more frequent cleaning could be cleaned by satellite systems.

Logistic Aspects Affecting the Layout of the CIP System

Normally, a process plant will be cleaned at the end of a (series of) production run(s). A logical sequence is to start with complete removal of all loose product from the process line by purging (optionally for recovery) and prerinsing (to waste and/or to drain). This means that the complete prerinse of the whole plant is done before cleaning liquid is introduced. Usually, such a rinsing procedure follows the same routing as the process; starting from the introduction point of raw materials, the process line is followed down stream to the filling machine. Later on, the same sequence is repeated with subsequent cleaning fluids. From a control point of view, this is a good and simple option, and moreover, only a few safety measures are required. The only safety precaution necessary is to physically separate the central CIP system immediately after the feed pump from the process system during actual production. Another advantage is that switching over from one stage to the next (e.g., prerinse to detergent cleaning), has to take place only once, so that any losses by mixing of liquids in the CIP circuit are minimized. A typical example of such a 'sequential' system is presented in Figure 5.

A disadvantage of such a system is that, because of this sequential procedure, the cleaning time might be rather long. It can be regarded as a waste of time that a prerinsed preparation vessel has to wait for the next cleaning cycle because the finished product buffer still has to be rinsed. Moreover, it is common practice to start cleaning of an ingredient preparation department directly after preparing the last batch. Frequently, at that moment, processing and especially filling of the product will still continue for a considerable time.

For these reasons, a process system might be split up in individual smaller units. As mentioned previously such units should all be able to be physically separated from the CIP system and from each other. By doing this, the parts that are already out of production can be immediately cleaned, resulting in a considerable gain of time. An example of such a 'unit cleaning' system is presented in Figure 6. This

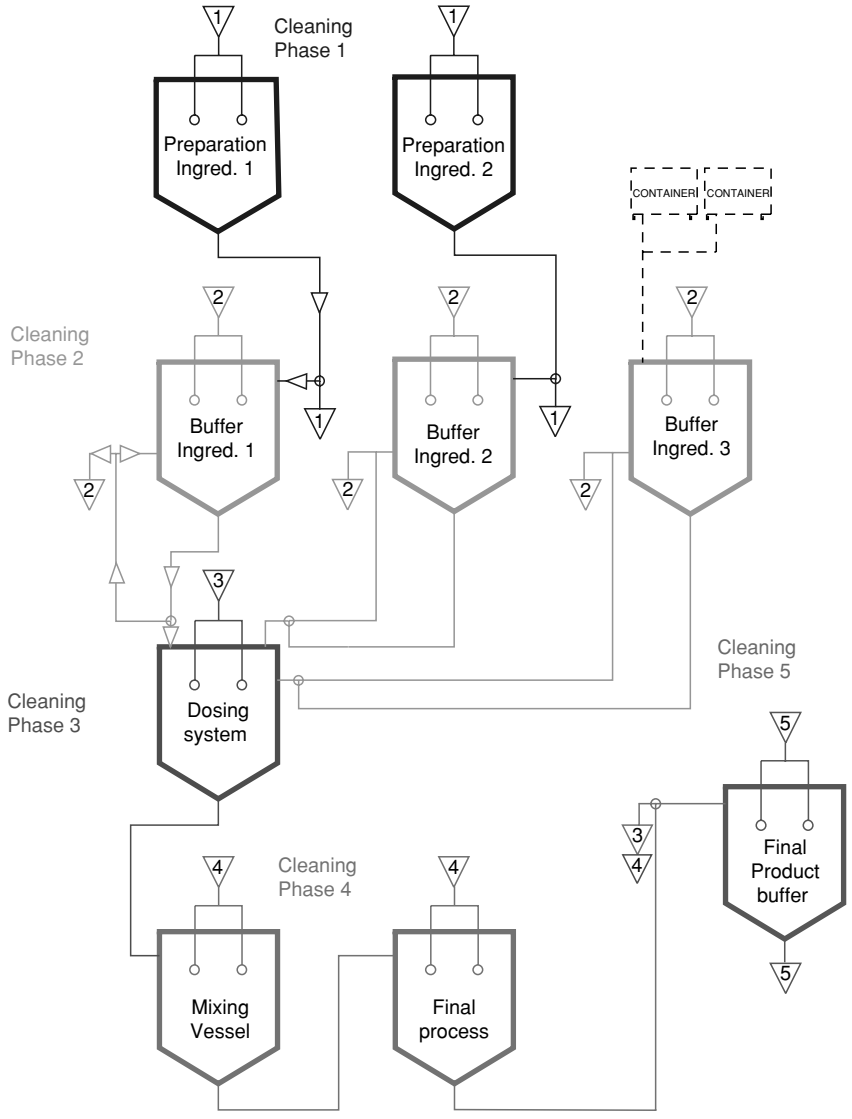

Figure 5 Typical example of a process line that is cleaned 'sequentially'. All CIP inlets and outlets (triangles) are connected to the same CIP circuit.

may result in overlapping of cleaning cycles of various parts of the plant, which are not compatible with each other (e.g., one part requires detergent, another post-rinse water). Again, this may give rise to undesired waiting times. A solution is then to install more cleaning circuits with feed and return pumps connected to the same buffer tanks. Each of these circuits is connected to a defined and separated part of the process. This latter option is also the optimal practice when parts of the process require a much higher cleaning frequency than the total plant. To avoid an extensive, complete safeguarding of the total plant, such parts can be provided with their own dedicated cleaning loop, connected to the same central CIP-buffer tanks, with only one physical separation in supply and return.

Systems for Open Plant Cleaning (OPC)

A wide range of systems are available for the delivery of pressurized water and the application of detergents in open plant cleaning. These systems vary in terms of sophistication and investment. The selection will be based on a number of factors, which can be broadly classified on the basis of whether the operation being carried out is a cleaning, disinfection, or rinsing step.

Hosing is one of the most usual ways of delivering water, which is used as a cleaning agent. Pressure systems are generally characterized as being either low pressure–high volume or high pressure–low volume.

Normally, for (warm) rinsing water, a ring main system is available with tap points through the

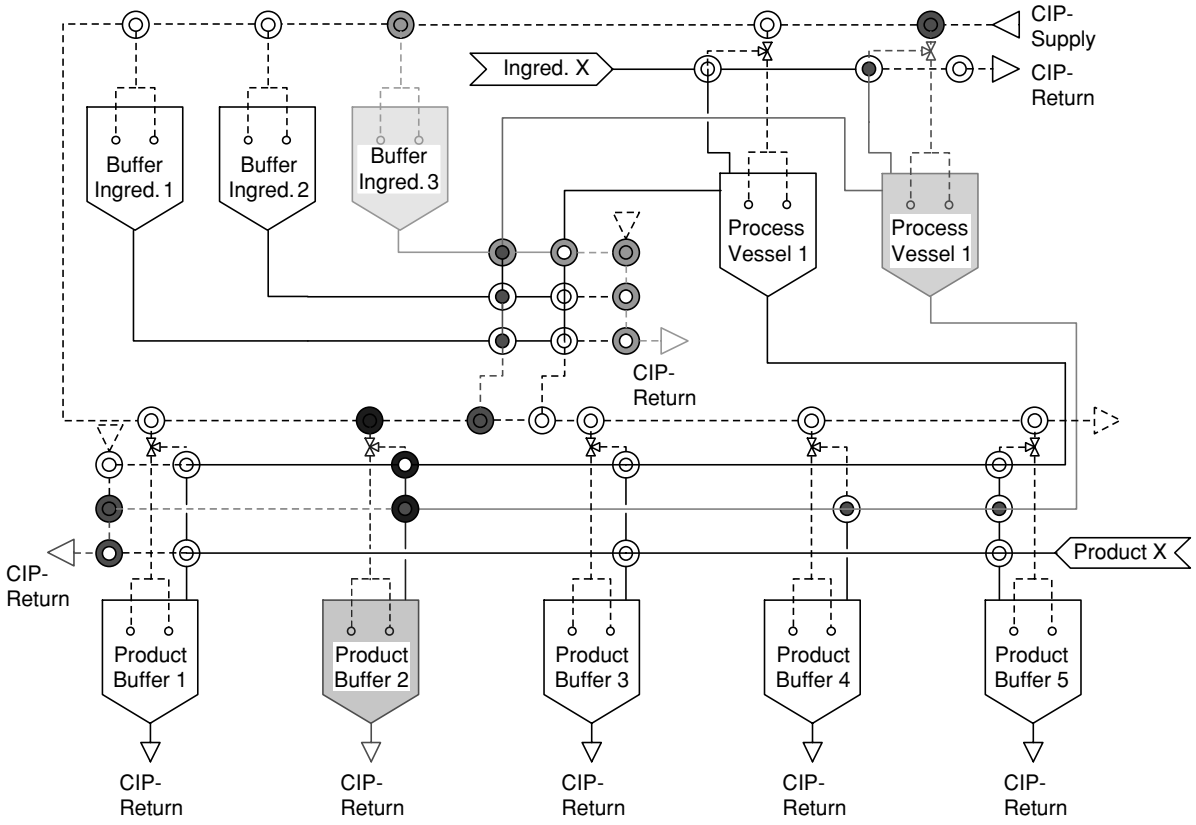

Figure 6 Example of a 'unit cleaning' system. The various degrees of shading indicate some of the units that can be cleaned in isolation of the rest of the plant, where production may continue during the cleaning operation. The circles indicate the places where block-and-bleed systems are required. The individual units may be connected to different CIP circuits.

factory. If the gross soil removal is to be carried out by pressure rinsing, warm water (50–55 °C) at a pressure of up to 20 bar is typically used. The temperature is high enough to melt fats but not high enough to denature proteins, which could result in burn on. A pressure of 20 bar (with a flow of 20–30 l min^{-1}) is sufficiently high to remove most of the gross soil whilst minimizing risk of damage. The pressure is low enough to prevent excessive aerosol formation occurring, which could lead to microorganism-containing aerosols being created, with the risk of contaminating adjacent areas of the factory.

Foam cleaning is a process that involves applying detergent to a dirty surface as a foam. Provided that the foam is stable and not too wet, it will cling to the surface for a relatively long time (5–10 min), during which time, physical/chemical attack can soften the soil.

The foam and loosened dirt are then rinsed away from the surface. This is preferably done with a high-pressure jet, provided that there is no danger of spraying electrical switchgear or similar water-sensitive equipment. In this case, a low-pressure spray or, occasionally, a vacuum can be used to remove the foam.

Another cleaning method is *gel cleaning*. Gel cleaning detergents are chemicals that are of low viscosity as a 100% product. On dilution, however, they gelate, and by this, they will increase the contact time of the detergent on the soil (10–30 min for gels). This prolonged contact time gives a much stronger effect and therefore better cleaning results, or equal results with rinsing at reduced pressure (5–20 bar).

Mobile Equipment

Detergent and disinfection can be carried out using mobile equipment. Mobile foam or gel equipment generally consists of a pressure vessel. The vessel (50–100 l) is filled with detergent solution. The detergent solution is forced by compressed air into a mixing chamber and mixed with foam or gel. The foam is applied to the surface via a hose and foam lance provided with a vee-jet nozzle. The vee-jet nozzle allows the application of an even and thin foam layer. After the required contact time, the

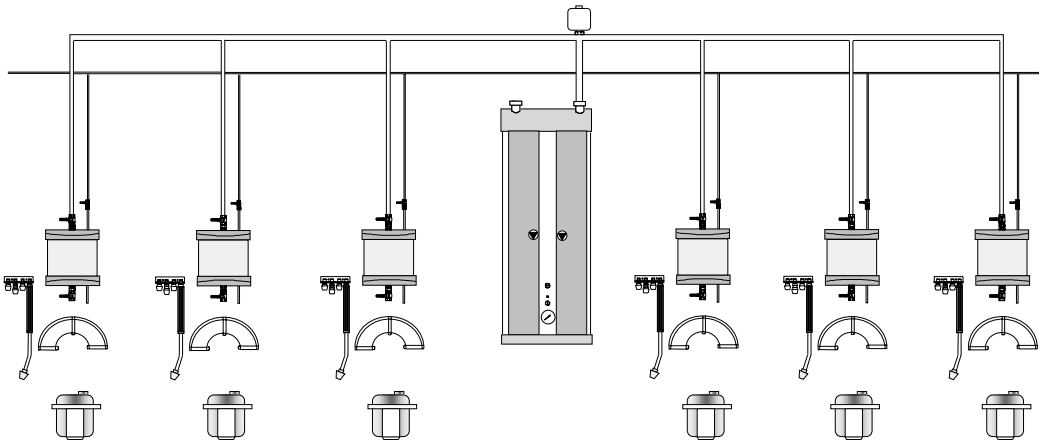

Figure 7 Decentralized OPC installation with booster pump and satellites.

foam/gel and soil are rinsed away, again using the pressurized water supply.

Foam cleaning is particularly useful for cleaning the outside of complex machinery, walls, and other large surfaces, as these surfaces can be easily and quickly covered with a foam layer.

A wide range of detergents from strongly alkaline to acidic are suitable for use with foam cleaning, so that most soiling in the food industry can be dealt with. Foam cleaning is typically not suited for surfaces covered with a thick soil layer (> 1 mm), as the foam will not be able to penetrate thick layers completely and reach the surface.

Advantages and Disadvantages

Foam cleaning is similar to the presoak approach of pressure jet cleaning, the only difference being related to the form of the detergent solution that is used for presoaking. The foam approach has important benefits:

- it is a relatively safe way of applying aggressive, e.g., caustic based detergents on to open surfaces;
- it is less likely to cause irritant aerosol problems;
- it is easy to see where the detergent has been applied;
- it strongly appeals to operators.

Against these benefits, it has the following disadvantages:

- it requires special, although not very expensive, equipment to produce the foam;
- it could give a false feeling of security because everything is covered with a white clean blanket, also if the soil cannot be attacked effectively.
- the detergent solution has to be prepared manually.

Disinfection can be done with the same equipment, except that a small tank (15 l) provided with a tube and spray-lance with a vee-jet is used. The tank is filled with 10 l of disinfectant solution and is then pressurized with 5-bar compressed air. The disinfectant is applied to the surface using the tube and the spray-pistol. The advantages of this system are its simplicity and (therefore) low cost, compared with more advanced systems.

Booster Pump with Satellites

A more advanced system consists of a booster pump (10–25 bar) that provides satellites, with pressurized (warm) water (Figure 7). The satellite is also connected to a compressed air supply. Using a venturi system, detergent or disinfectant can be diluted to suit the application concentration. Because of the connection with a compressed air supply, the detergent solution can be applied as a foam. Each satellite can be used for prerinse, detergent application, rinse, disinfectant application, and final rinse. Different satellites, connected to the same booster pump, can carry out different options (foaming, rinsing, or disinfecting). The advantages of this system are that it uses an automatic detergent solution make-up and fixed pressure and that there is no mobile equipment floating around. The disadvantage of this system is the higher capital investment compared with the previous system.

Booster Pump with Central Make-up for Detergent and Disinfectant

For large plants, with many take-off points (Figure 8), the detergent and disinfectant solution preparation can be done centrally, using dosing pumps (and flow meter measurements). Not only pressurized water,

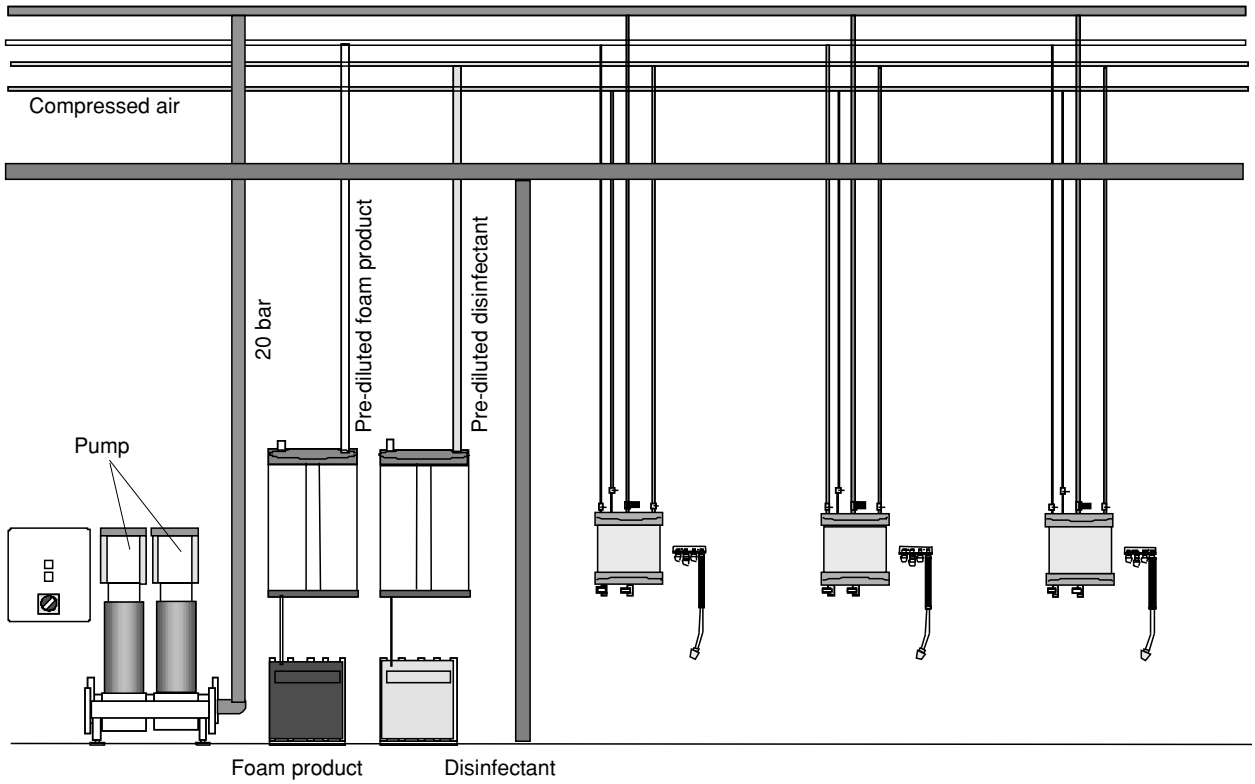

Figure 8 Central OPC installation with central booster pump, satellites, and central make-up of media.

but also detergent solution, disinfectant solution, and compressed air flow to each satellite.

The advantages of this system are that it has higher capacities and does not use concentrated chemicals in the production area. The disadvantage is that the same detergent and disinfectant have to be used on all take-off points.

CLOSTRIDIUM

Contents

Occurrence of *Clostridium perfringens*

R G Labbé, University of Massachusetts at Amherst, Amherst, MA, USA

Introduction

Clostridium perfringens is probably the most widespread of all pathogenic bacteria. There are several toxigenic types: A, B, C, D, and E. Type A is primarily associated with human illness. The other types are associated with diseases of domestic animals. In very specific situations, type C is occasionally involved in human illness. *Clostridium perfringens* is an anaerobic, spore-forming organism commonly found in fresh meat and poultry products. Spores of the organism can survive many food processing procedures. Because of its ability to grow over a wide temperature range, it is often implicated in human food poisoning. With regard to human illness in general, it should be noted that, historically, *C. perfringens* have been most closely associated with gangrene and wound infections. In this article, discussion will be limited to its role in human food poisoning.

Occurrence in Humans, Foods, and the Environment

Clostridium perfringens is part of the normal intestinal flora in humans and animals and also occurs widely in soil. It is the most commonly found *Clostridium* in clinical specimens. Because of its abundance in feces, the organism is also found in sewage-polluted water. Water authorities in certain localities use its presence as an index of water quality.

Clostridium perfringens has also been found in the intestinal tract of virtually every animal examined, with a wide variation within and between species. Although the levels of *C. perfringens* in healthy adults are relatively small compared with other strict anaerobes, *C. perfringens* can be isolated from the gut of virtually all humans. In infants, adult levels are established by 6 months of age.

Early studies on the incidence of *C. perfringens* focused on the isolation of so-called heat-resistant strains (those whose spores could survive – and be activated by – heating at 100 °C for 60 min) since it was thought that this group was more likely to survive cooking than less heat-resistant, i.e., 'heat-sensitive' spore strains. By the mid-1960s, it became apparent that heat-sensitive strains were equally capable of causing outbreaks of food poisoning. In epidemiological investigations, no distinction is now made between the two groups.

There is a wide variation in the total *C. perfringens* count in human feces. However, in healthy adults, the values are usually 10^3–10^5 per gram (Table 1). Patients in outbreaks carry 10^6–10^8 per gram. The level of spores of this organism in feces is within one log of the total count. The procedure used to obtain the spore count – heating the sample at 75–80 °C for 10–20 min – also eliminates competing microflora. The fecal spore count is one of several laboratory criteria for investigating outbreaks caused by this organism (see below).

It has become apparent that the elderly, although healthy, often carry relatively high (total or spore) numbers of *C. perfringens*, often above 10^6 per gram. This phenomenon is not attributable to ingestion of elevated levels of *C. perfringens* since surveys have been conducted in extended-care facilities where the daily intake was monitored. Such high levels in asymptomatic elderly limit the usefulness of examining stools of patients for elevated levels of *C. perfringens*. In such situations, other criteria for confirming outbreaks, discussed below, are available.

Early studies on the incidence of *C. perfringens* in raw foods focused on heat-resistant strains, thus understating true levels of the organism. Representative results of many market and slaughterhouse surveys, conducted over the years, are presented in Table 2. No distinction is made between vegetative

Table 1 Representative surveys of *C. perfringens* cells and spores in feces from various population of various countries

Population	*Country*	*Cell type*	*Levels (per gram)*

[a]Incidence of *Clostridium*; predominant species is *C. perfringens*.

cells and spores. The latter would obviously be more able to withstand subsequent cooking procedures. The data for meat and poultry were from surveys conducted in North America and the UK. Results from Japan are consistently lower. It should also be noted that such surveys have been carried out using a variety of methods for enrichment, heat selection, selective plating, and confirmation. It is clear from Table 2 that the organism is abundant in raw, protein-rich foods. The source of the organism is the intestinal contents of these animals. As noted above, the feces of all animals examined, domestic and wild, contain *C. perfringens*. In the case of fish and shellfish, there are wide fluctuations in isolation rates, presumably depending on the degree of water pollution. Such products are rarely involved in outbreaks of *C. perfringens* food poisoning.

The organism is also found in many types of processed foods, although at a low level. However, in some cases, such as soups and sauces, only short heating times are required for preparation. Other items, such as herbs and spices (well known for their high general bacterial spore levels, including *C. perfringens*) are often added to large amounts of cooked foods. Slow cooling or inadequate reheating of such foods can result in the large number of *C. perfringens* necessary to cause food poisoning. Oxygen is driven off during cooking, creating ideal conditions for growth of this organism.

Clostridium perfringens is part of the microflora of soil and is present at levels of 10^3–10^4 per gram. Even in Antarctica, moist soil samples examined contained this organism. In view of its widespread presence in soil, its presence in air and dust (including kitchen dust) is not surprising. In the case of marine sediments, there is a close relationship between the amount of fecal pollution and the number of *C. perfringens*.

Food Poisoning

Food poisoning attributable to *C. perfringens* usually occurs 8–24 h after the ingestion of temperature-abused food containing large numbers of vegetative cells. Symptoms last 1–2 days and generally include diarrhea and severe abdominal cramps. Vomiting is not common, and fever is rare. Type A cells are usually responsible. A more severe type of illness, caused by type C, occurs among young adults of the

highlands of New Guinea. It is necrotizing (necrosis: death of areas of tissue surrounded by healthy parts), hemorrhagic jejunitis (inflammation of the jejunum, the second portion of the small intestine extending from the duodenum to the ileum) which is often called 'pig-bel' (enteritis necroticans) because it follows traditional pig feasting.

It should be noted that ingestion of low levels of microbial spores, including *Clostridium botulinum* and *C. perfringens*, is a common occurrence and not a public safety issue for adults. Only when these spores have been allowed to germinate and grow in food products do they pose a health threat.

Mechanisms of Entry into the Food Chain

The vegetative cells and spores of *C. perfringens* are common surface contaminants of fresh meat and poultry carcasses. This is not surprising in view of the common occurrence of the organisms in the intestine of these animals. They can be easily disseminated during processing steps such as skinning, evisceration, and scalding. Unlike the case for *Salmonella*, the absence of this organism from fresh meat and poultry is an unreasonable expectation. Furthermore, the mere presence of *C. perfringens* (as spores) surviving cooking will not cause outbreaks of foodborne illness. For the latter to occur, gross mishandling and temperature abuse must always be involved. (*See* **Meat**: Eating Quality; Hygiene; **Poultry**: Chicken; Ducks and Geese; Turkey.)

Fate During Processing and Storage

Temperature is the single most important determinant of the survival and multiplication of *C. perfringens* subsequent to slaughter and packaging. Generation times as low as 8–10 min have been reported for this organism at its optimum growth temperature. Other considerations affecting growth include absence of oxygen, water activity, pH, and salt content. However, alterations of these usually involve further processing steps, and epidemiological investigations have consistently implicated fresh meat and poultry as sources of the organism. (*See* **Meat**: Preservation.)

The fate of *C. perfringens* during processing and storage depends on the form of the organism, i.e., vegetative cell or spore. Both are present in fresh meat and poultry, but each requires different considerations with regard to immediate or potential hazard.

Vegetative cells can grow over the temperature range of 15–50 °C, with optima between 43 and 46 °C. Even between 60 and 70 °C, viability may be maintained, but vegetative cells are rapidly inactivated at 75 °C. Considering the short generation time of the organism, the slow attainment of a safe interior temperature can actually increase the initial number of organisms and permit more cells to survive. Thus, the rate at which the interior temperature is attained may also influence the thermal survival of vegetative cells. For example, rump roast cooked to an internal temperature of 77 °C in 2.25 h has been shown to retain significant numbers of viable *C. perfringens* cells. However, experiments with chicken breast and thigh have shown complete killing of 10^8 vegetative cells when the pieces were cooked in water at 82 °C, and the internal temperature of 77 °C was attained in 20 min or less. The standard dictum that cooked meat should be kept above 62.8 °C or below 10 °C will insure safety of properly heated food.

Most *C. perfringens* spores isolated from meat and poultry are of the heat-sensitive variety. These are killed in a few minutes at 100 °C. Unfortunately, spores of the heat-resistant variety are also present in lower numbers. These have D_{100} (decimal reduction value at 100 °C) values of 6–17 min and can survive cooking procedures (which themselves drive off oxygen), germinate, and resume vegetative cell growth given the proper conditions, principally a suitable temperature.

The effect of low-temperature storage on *C. perfringens* cells is important because food safety with regard to this organism is based largely on proper refrigerated holding. *Clostridium perfringens* vegetative cells are sensitive to low temperature, e.g., refrigerated storage. Slow die-off occurs under these conditions. Similarly, long-term (several weeks) freezing slowly inactivates vegetative cells. The initial freezing step reduces the population approximately 10-fold. Surprisingly, vegetative cells die more rapidly at −5 °C than at −20 °C. As one would expect, spores are considerably more resistant. They are virtually unaffected by refrigerated storage and only somewhat inactivated by freezing. Indeed, frozen storage in the spore state is routinely used for culture carriage.

Before spores can resume vegetative cell growth, they must germinate. Proper nutrients must be available, and these are readily available in meat and poultry products. Viable bacterial spores are traditionally measured by heating a culture at an elevated temperature (75–80 °C, depending upon the strain) for 10–20 min and performance routine plating procedures. This procedure 'activates' the spore population (and inactivates any vegetative cells). In the case of raw food, this function is effectively achieved by routine cooking procedures. Optimal temperatures for germination are similar to those for vegetative cell growth, in a pH range of 5.5–7.0.

It is difficult to specify the time required for cells of *C. perfringens* to multiply in foods to attain toxic

numbers, but it has been observed that meats stored at a 'warm' temperature for at least 2 h after cooking were common factors in many outbreaks. The hazard is magnified when such food is allowed to cool slowly for several hours, e.g., overnight at room temperature, as has occurred with large turkeys or large bulk of other meats.

The multiplication of bacteria is a logarithmic function. The rate at which a product may accumulate harmful numbers of cells will depend to a large extend on the size of the inoculum. The temperature at which cooked foods is held or stored is the other highly dependent variable. As mentioned above, that is especially true with *C. perfringens* in view of its ability to grow at relatively elevated temperatures.

Detection of *Clostridium perfringens*

R G Labbé, University of Massachusetts at Amherst, Amherst, MA, USA

Laboratory Criteria for Confirming Outbreaks

Laboratory confirmation of an outbreak of *Clostridium perfringens* food poisoning is based on one of five criteria: (1) more than 10^5 of the organism per gram of food; (2) more than 10^6 spores of the organism per gram of the feces of ill person; (3) the presence of the same serotype in most of the ill patients; (4) the presence of the same serotype in the incriminated food and feces of the patients; and (5) detection of enterotoxin in feces. Detailed procedures for serotyping are available from citations in the Further Reading section at the end of the next article.

Detection in Raw and Processed Foods

Detection of *C. perfringens* in raw and processed foods is performed by similar methods. Such foods, properly handled, would not normally contain more than 100 *C. perfringens* cells or spores per gram, usually much less. In such situations, most probable number (MPN) test tube procedures can be used for enumerating low numbers in foods. Iron-containing milk (iron milk medium, or IMM, i.e., 10 ml of homogenized milk containing 0.2 g of iron powder) has been used for this purpose. When incubated at 46 °C, *C. perfringens* produces a typical 'stormy fermentation' in IMM. This is defined as the production of an acid curd (caused by lactic acid fermentation) with subsequent disruption of the curd by large volumes of gas. NonMPN enrichment media (trypticase–glucose–yeast extract broth), with incubation at 37 °C followed by selective plating on trypticase–sulfite–cycloserine (or neomycin blood agar) agar plating, can also be used for enumeration of very low numbers. Confirmation (see below) is required in either method.

Detection of Cells in Suspected Food Poisoning

Foods implicated in outbreaks of human food poisoning would normally contain large numbers of vegetative cells and relatively few spores. Such food should be chilled and processed rapidly because of the susceptible of the cells to cold shock. For delayed analyses, the highest counts are obtained when foods (finely chopped if necessary) are mixed 1:1 with 20% glycerol and kept at −20 °C or, if shipping is necessary, placed in a container of dry ice. (*See* **Food Poisoning**: Tracing Origins and Testing.)

Selective plating methods are used for enumeration of viable cells. Enrichment techniques are unnecessary for examination of food containing large numbers of cells. Most plating media depend on the ability of *C. perfringens* to reduce sulfite to sulfide, which, in the presence of an iron salt, results in the formation of black colonies owing to ferrous sulfide. Collaborative analyses have indicated that

pour-plated tryptose sulfite cycloserine (TSC) without egg yolk is the medium of choice. More consistent blackening of surface colonies can be obtained by overlaying plates with sterile media. TSC is commercially available from Unipath (Oxoid). After anaerobic incubation for 24 h at 37 °C, representative black colonies (usually 10) must be confirmed. This is achieved by inoculating a liquid medium, such as trypticase peptone glucose yeast extract broth or fluid thioglycollate medium, and incubating at 46 °C for 4 h or overnight at 37 °C. Tubes of lactose–gelatin and motility–nitrate are inoculated from each and incubated at 37 °C for 24 h. *Clostridium perfringens* is nonmotile, ferments lactose, liquefies gelatin, and reduces nitrate to nitrite. The number of *C. perfringens* per gram is determined by multiplying the presumptive plate count by the ratio of colonies confirmed as *C. perfringens*. Fecal spore levels are determined in the same manner, except that the sample is heated at 75 °C for 20 min. The elevated-temperature MPN methods mentioned above are not recommended for quantification of *C. perfringens* in outbreak stools.

Surface-plated neomycin blood agar plates are often used in the UK and can be prepared well in advance. This medium also provides information on the hemolytic activity of isolates. However, because recovery of certain heat-resistant strains may be no more than 10% on this medium, its use is limited to outbreak stools or food samples containing large numbers of *C. perfringens*. Neomycin blood agar is not recommended for examining normal food samples in which the organism is present in low numbers.

Detection of Enterotoxin in Suspected Food Poisoning

The ingestion of large numbers of vegetative cells in incriminated food is followed by multiplication of the cells in the small intestine. When they sporulate, there is an accompanying formation of enterotoxin. Lysis of the sporangia to release the mature spore also results in the release of enterotoxin.

Serum values of antienterotoxin are of little value in the diagnosis of *C. perfringens* food poisoning, and enterotoxin detection in foods is not a practical approach. However, detection of the enterotoxin in stools is of significant diagnostic importance since the toxin is not detectable in the feces of healthy adults. Of the criteria listed above, there are occasions when only detection of enterotoxin in feces is conclusive; for example, when no food is available, when the strains are not typeable, or when the incidents concern geriatric patients who may carry large numbers of the same serotype or spores without symptoms of food poisoning. Most fecal specimens from food poisonings incidents have enterotoxin concentrations exceeding 1 μg per gram of feces.

Two procedures for detection of enterotoxin in feces have found widespread use and are effective when used within 2 days of onset of symptoms. They are the enzyme-linked immunosorbent assay (ELISA) and the reversed passive latex agglutinations assay (RPLA). The latter is available as a kit from Unipath (Oxoid). Although expensive (if obtained commercially) for multiple samples, the RPLA method is the simpler of the two. In this method, latex beads that have been sanitized (treated) with enterotoxin antiserum are exposed to serial dilutions of enterotoxin-containing material. After overnight incubation, the agglutination titer is determined. Expensive equipment, such as a microplate reader (needed for ELISA), is unnecessary. However, nonspecific agglutination can occur at very low (near the detection limit) dilutions. The ELISA method is preferable when more than occasional samples are to be assayed. Some half-dozen different ELISA procedures have been proposed with sensitivities of 2–5 ng per gram of feces. (*See* **Immunoassays:** Radioimmunoassay and Enzyme Immunoassay.)

Statistics

As mentioned above, meat and poultry products are most commonly involved in cases of human food poisoning attributed to *C. perfringens*. The organism has complex nutritional requirements that are easily satisfied by such foods. However, cured meats are rarely implicated. Bacon and ham, for example, are seldom involved, presumably owing to the presence of curing salts and the lowered water activity, both of which inhibit vegetative cell growth. (*See* **Food Poisoning:** Statistics.)

Mass feeding establishments are consistently cited as the source where implicated food was eaten. Examples of these have included restaurants, cafeterias, prisons, schools, and hospitals. All such sites prepare large amounts of food well in advance of serving. Opportunities for mishandling of food in such setting are plentiful.

Detection of *Clostridium perfringens*

As with other agents of human food poisoning, the number of outbreaks of food poisoning attributable to *C. perfringens* is greatly underreported. This is particularly true with *C. perfringens* because of the relatively mild and short-lived nature of the symptoms. In addition, in some countries, e.g., the USA,

Food Poisoning by *Clostridium perfringens*

R G Labbé, University of Massachusetts at Amherst, Amherst, MA, USA

Introduction

Historically *Clostridium perfringens* is best known for its role in gas gangrene. During the 1940s and 1950s its association with foodborne illness was suggested. In the 1970s the responsible enterotoxin was isolated and its general mode of action described. In recent years work has focused on the subcellular mode of action of this toxin as well as the molecular genetics of its production.

Clinical Features and Characteristics

It is now well established that an enterotoxin is responsible for symptoms of *Clostridium perfringens* food poisoning. The symptoms are typically diarrhea and severe abdominal cramps (fever and vomiting are unusual) which occur 8–24 h after ingestion of food containing large numbers of vegetative cells. Sufficient numbers of cells survive stomach passage and sporulate in the small intestine.

The sequence of events can be duplicated in the laboratory by inoculating vegetative cells into a suitable sporulation medium. Many different types of sporulation media have been developed for this, but no single one is suitable for all strains. Figure 1 shows that about 3 h after inoculation of the sporulation medium, heat-resistant spores develop, followed closely by the intracellular accumulation of enterotoxin. Maximum numbers of spores are obtained after 7 h and free spores can be detected after 10–12 h. With the liberation of the mature spores from the sporangia, enterotoxin is released and the concentration of enterotoxin in the cell extract therefore decreases. The concentration of extracellular enterotoxin increases in parallel with the increase in free spores. In humans this corresponds to the release of enterotoxin into the lumen of the small intestine.

Site and Mode of Action

The enterotoxin of *C. perfringens* causes fluid accumulation in ligated small intestinal loops (sections), and overt diarrhea in a large number of experimental animals. The colon is not affected by the enterotoxin since, as least in rabbits, there is no change in the transport of fluid of electrolytes in this tissue. To determine the mode of action of the toxin, rabbit small intestines have been perfused with various electrolytes and nutrients after exposure to the toxin. The effects on intestinal transport and structure were determined. These procedures indicate that the enterotoxin causes a net secretion of water, sodium, and chloride. Glucose absorption is inhibited, whereas potassium and bicarbonate absorption are unaffected. The sensitivity of the rabbit's small intestine to the toxin increases from the upper duodenum downward, with the terminal ileum being the most responsive. Histological studies have shown that there is destruction of intestinal epithelial cells at the tips of

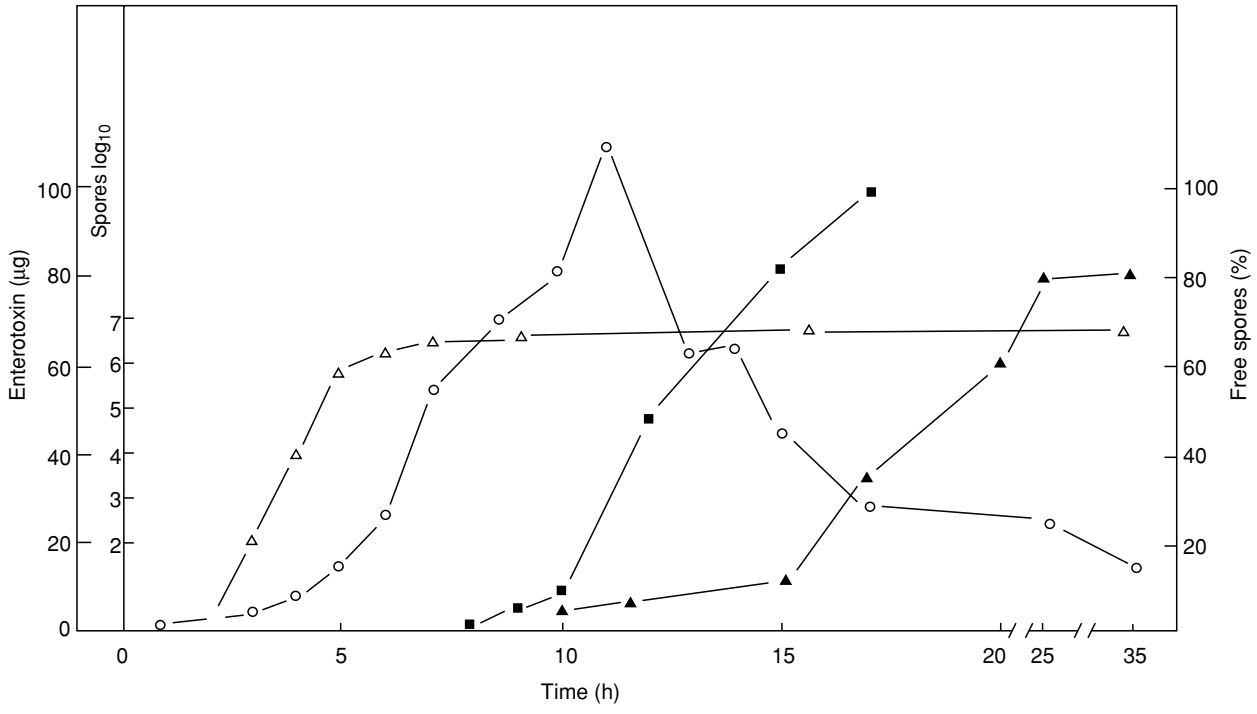

Figure 1 Time course of intracellular enterotoxin formation and release during sporulation of *Clostridium perfringens* type A. Open circles, content (μg) of biologically active enterotoxin per mg of cell protein extract; filled squares, μg of biologically active enterotoxin per ml of culture filtrate; open triangles, heat-resistant spores per ml; filled triangles, percentage of refractile spores free from sporangia. Figure 2 Effect of *Clostridium perfringens* enterotoxin on rabbit ileum. (a) Control showing typical villous morphology. (b) Ileum treated with enterotoxin for 90 min showing shortened villi denuded of epithelial cells. Reprinted from Laboratory Investigation, Baltimore, USA, with permission.

villi (Figure 2). Intestinal brush border membranes lose their characteristic folded configuration and large quantities of membrane and cytoplasm are lost to the lumen. Similar morphological changes occur after intravenous injection of the enterotoxin. The brush border (microvillous membrane) of the villus tip epithelial cells is considered to be the primary site of action of the enterotoxin.

Food Poisoning by *Clostridium perfringens*

In contrast to the effects of cholera toxin and *Escherichia coli* heat-lable enterotoxin, *C. perfringens* enterotoxin does not increase levels of cyclic adenosine monophosphate (cAMP) in intestinal mucosa that is actively secreting fluid.

Our understanding of the mode of action of the enterotoxin at the molecular level has been greatly facilitated by the use of *in vitro* model systems using various cell lines. Vero (African green monkey kidney) cells are particularly sensitive to the toxin. Rat liver, HeLa, small intestinal epithelial cells, and other cell lines have also been used as models.

The enterotoxin causes rapid membrane bleb formation in cultured Vero cells (Figure 3). Total inhibition of amino acid transport and deoxyribonucleic acid (DNA), ribonucleic acid (RNA), and protein synthesis occurs within 30 min of exposure. Within 40 min, 75% of the Vero cells detach (from the plastic culture flask) and nearly 50% are nonviable.

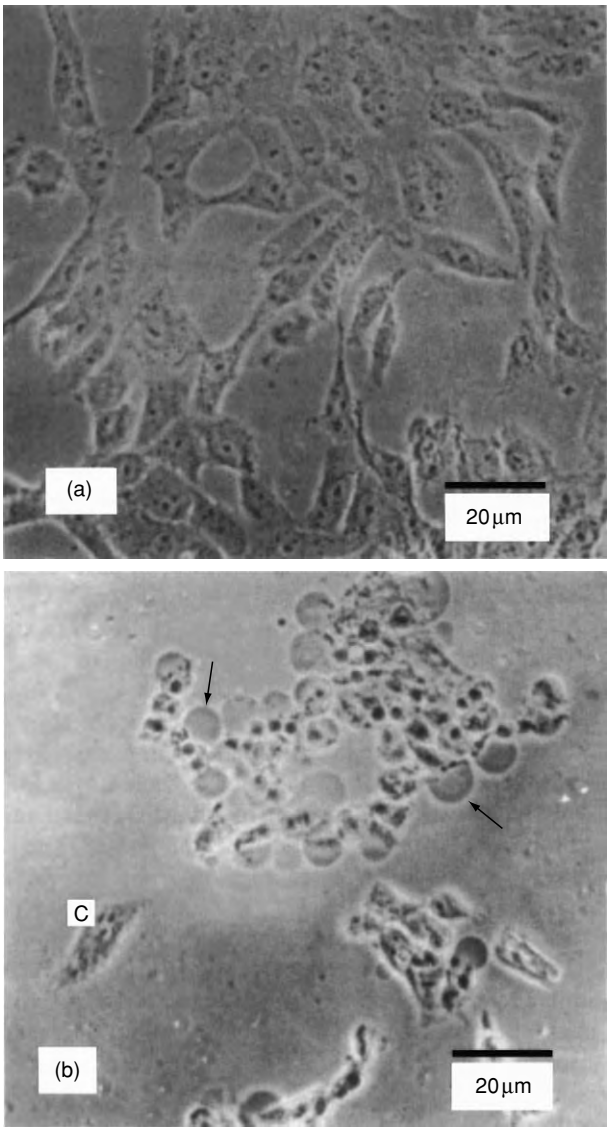

Figure 3 Effect of enterotoxin on morphology of Vero cells. (a) Control culture showing typical Vero cell morphology. (b) Vero cells after 30 min exposure to enterotoxin. Note the spherical morphology and formation of blebs (arrows). Reprinted from McClane B and McDonel J (1979) The effect of *Clostridium perfringens* enterotoxin on morphology, viability and macromolecular synthesis in Vero cells. *Journal of Cellular Physiology* 99: 193, with permission.

Disruption of the plasma membrane is the specific action of the enterotoxin in Vero cells. Binding to the cell membrane must occur and is an early event. This does not occur in naturally resistant cell lines or in cells selected for resistance to the toxin. A protein of molecular weight 50 000 has been extracted from rabbit intestinal brush border membranes. This protein inhibits biological activity of enterotoxin in Vero cells, suggesting that it has a role in enterotoxin binding. No role has been found for ganglioside GM_1 (gangliosides constitute a family of acidic glycolipids which are important membrane components) from rabbit intestinal brush border membranes in binding *C. perfringens* enterotoxin. This is in contrast to the role ganglioside GM_1 plays in binding cholera toxin.

The enterotoxin causes functional holes of defined size in Vero cell membranes. The result is an alteration of membrane permeability, causing rapid water and ion flux changes immediately after binding. Osmotic stabilizers protect against such enterotoxin-induced morphological and permeability changes, further suggesting the membrane as the site of action. With a net influx of water and ions, the membrane stretches and bleb formation results. This is followed by the loss of essential precursors through leakage. With the interruption of macromolecular synthesis the cell eventually dies. While such specific events in an *in vitro* cell model cannot be directly extrapolated to the effects of the enterotoxin in human intestinal cells, such evidence is highly suggestive that the membrane of the human small intestine is the primary site of action of *C. perfringens* enterotoxin.

Treatment of Illness

As in most cases of enterotoxin-mediated human food poisoning, symptoms are self-limiting. In the case of *C. perfringens*, symptoms subside within 1 or 2 days. Death is uncommon but has occurred in institutionalized individuals, especially the elderly. In such cases fluid and mineral replacement therapy is essential.

Prevention and Control

The factors contributing to outbreaks of foodborne illness by *C. perfringens* were identified long ago. Those most frequently cited are: (1) preparation of food too far in advance; (2) inadequate cooling; (3) storage at ambient temperature; and (4) inadequate reheating. Multiple factors are frequently cited, but

failure to refrigerate properly large portions of previously cooked foods, especially in institutional settings, invariably summarizes the events leading to an outbreak.

Spores on raw meat and poultry can survive cooking which effectively heat-activates the spores to promote germination when the product reaches a suitable temperature during cooling. Rapid, uniform cooling is therefore imperative. Gravies, broth and large pieces of meat should be cooled to 10 °C within 2–3 h. The organism can multiply rapidly in the slowly cooling masses of meat and poultry. Cooking also drives off oxygen and thereby promotes anaerobic conditions; this is especially important in liquid foods, and in rolled meats where the contaminated outside surface is rolled into the middle. Cooked, chilled foods should be reheated to a minimum internal temperature of 75 °C immediately before serving, in order to destroy vegetative cells. As noted in the preceding article, cooked meat should be kept above 62.8 °C or below 10 °C.

Human carriers are not a danger. It is impossible to prevent human carriers from handling food because most people harbor *C. perfringens* in their intestinal tract. Similarly, the organism is present in a wide variety of foods. Hence preventive measures depend largely on knowledge of proper food preparation and storage techniques, especially temperature control. Certain trade organizations related to the food service industry offer short courses dealing with proper food-handling procedures. Clearly, education of food handlers is a key aspect in the prevention of human food poisoning in general, and that caused by *C. perfringens* in particular.

Occurrence of *Clostridium botulinum*

J W Austin, Bureau of Microbial Hazards, Ottawa, Canada

Introduction

Clostridium botulinum is a Gram-positive, anaerobic, rod-shaped, spore-forming bacterium that produces the most potent biological toxin known, botulinum neurotoxin. Strains of *C. botulinum* are separated into seven types, A through G, based on the serological specificity of the neurotoxin produced. Human botulism, including foodborne, wound, and infant botulism, is associated with types A, B, E, and, very rarely, F. Types C and D cause botulism in animals. To date, there is no direct evidence linking type G to disease. Based on physiological differences and 16s rRNA gene sequencing, the species is also divided into four groups: (I) all type A and proteolytic strains of types B and F; (II) all type E and nonproteolytic strains of types B and F; (III) type C and D strains; (IV) type G strains. The emphasis here will be on groups I and II since they are involved in human illness. This article will discuss the distribution of botulinum spores in the environment and in foods, the different factors affecting growth in foods, and detection of the organism and its neurotoxin in foods.
